Social reformer, economic historian and a pioneer in America of the study of the economic position of women, Edith Abbott was born on 26 September 1876 in Nebraska, and graduated from the University of Nebraska in 1901. She enrolled in a summer session at the University of Chicago in 1902, attracting the attention of James Lawrence Laughlin and Thorstein Veblen, and on their recommendation returned to Chicago in 1903 on a fellowship in political economy, taking her PhD in 1905 with a dissertation on the wages of unskilled labour in the USA between 1850 and 1900 (Abbott, 1905). It was during this period at Chicago that she met Sophonisba Breckinridge who became her mentor and lifelong friend. In 1906, on a Carnegie Fellowship, she went to the LSE to carry out research on women in industry. In London she was influenced by the social reformers of the day, including Charles Booth and Sydney and Beatrice Webb. She returned to the USA in 1907 and taught political economy at Wellesley. In 1908 Breckinridge, now Director of Research at the newly established Chicago School of Civics and Philanthropy, invited her to become her assistant.

Abbott's work there involved her directly in action for the protection and education of juveniles and immigrants, for improvements in housing, and for the reform of correctional institutions. She also worked towards women's suffrage, the ten-hour law to protect women in employment, and the admission of women into trades unions. In the 1930s she was to become a staunch advocate of social insurance measures and the welfare state. Although sympathetic to the New Deal, she felt it to be entirely inadequate when it came to welfare policies.

Her publications ranged over a number of areas in social and public policy, and with Breckinridge, she was an influential proponent of the role of the state as the key element in any extensive programme of social welfare. The journal they jointly established in 1927, Social Science Review, was immediately recognized as a highly esteemed professional journal. Her main writings on economics were collected in her Women in Industry (1910), where a recurring theme was the distinction between the progress of 'professional' women (and the women's movements with which they were associated) and the relatively
unchanged position of working-class women. After 1920, although social work came increasingly to dominate her time, Abbott continued her role as an applied economist. She was a member of the advisory committee of the ILO on immigration, and succeeded Breckinridge as Dean of the School of Social Studies Administration at Chicago. She remained in the post until 1942, and continued editing the *Social Science Review* until 1953. She died at the age of 80 at her family home in Grand Island.

Abramovitz, Moses (1912–2000)

Richard A. Easterlin

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Abramovitz, M.; aggregate demand theory; business cycles; economic growth in the very long run; inventories; Kuznets cycles

Article

Born in Brooklyn, New York, Abramovitz was educated at Harvard (AB, 1932) and Columbia (Ph.D., 1939). He held faculty appointments at Columbia (1940–2, 1946–8) and Stanford University (1948–77) and was a member of the research staff of the National Bureau of Economic Research from 1938 to 1969. From 1942 to 1946 he worked as an economist for several organizations within the United States government. He was elected president of the American Economic Association in 1979–80.

Abramovitz’s work, which was particularly influenced by Wesley C. Mitchell and Simon Kuznets, centres on the study of long-term economic growth and fluctuations in industrialized market economies. His first major contribution was an empirical study of business inventories that demonstrated the importance of inventory change in the shorter swings of the business cycle, and showed how the classification of inventories by stage of processing aided in the explanation of their behaviour (Abramovitz, 1950). From this, Abramovitz went on to the study of longer-term fluctuations, Kuznets cycles of 15 to 20 years duration, and formulated the most widely accepted interpretation of these cycles. Using Keynesian aggregate demand theory, Abramovitz developed a model linking Kuznets cycles to long swings in building cycles and demographic variables, and to shorter-term business cycles (Abramovitz, 1959a; 1961; 1964; 1968).

Contemporaneously with his work on fluctuations, Abramovitz made important contributions to long-term economic growth. He was one of the first to demonstrate that only a small share of long-term output growth in the United States was explained by factor inputs (Abramovitz, 1956). He documented and analysed the increasing role of government during long-term economic growth (Abramovitz, 1957; 1981) and directed and coordinated a comparative study of the post-war economic growth of a number of industrialized market nations (Abramovitz, 1979b; 1986). Finally, he challenged in characteristically perceptive fashion the facile linkage made by many economists between economic growth and improving human welfare (Abramovitz, 1959b; 1979a; 1982).
Selected works

The notion of absolute (as distinct from exchangeable or relative) value arises in classical economics from the image of a given magnitude of output being distributed between the social classes. Ricardo posited that the value of the social surplus could be expressed in terms of labour regardless of how the surplus was distributed. But since changes in distribution affect exchangeable value, the value of the surplus will typically vary as distribution varies, even though its physical magnitude remains unchanged. In 1823 Ricardo concluded that ‘there is no such thing in nature as a perfect measure of value’.

Article

No one can doubt that it would be a great desideratum in political economy to have such a measure of absolute value in order to enable us to know, when commodities altered in relative value, in which the alteration in value had taken place. (David Ricardo, 1823, p. 399n)

The idea that changes in the relative or exchangeable value of a pair of commodities might usefully be attributed to alterations in the ‘absolute value’ of one or the other of them will appear rather odd to anyone accustomed to thinking of the basic problem of price theory as being the determination of sets of relative prices, with any consideration of ‘absolute’ value being confined to problems in monetary theory and the determination of the overall price level. Since in neoclassical theory it is the relative scarcity of commodities, or of the factor services which are used to produce them, which is the key to relative price formation, no conception of ‘absolute’ value, that is, a price associated with the conditions of production of a single commodity, is either relevant or necessary.

Yet the notion of absolute value arose naturally within Ricardo's analysis of value and distribution. The central problem of classical theory is to relate the physical magnitude of surplus (defined as the social
output *minus* the replacement of materials used in its production and the wage goods paid to the labourers employed) to the general rate of profit and the rents in terms of which the surplus is distributed. The key image is the distribution of a given magnitude of output between the classes of the society. ‘After all’, as Ricardo put it, ‘the great questions of Rent, Wages and Profits must be explained by the proportions in which the whole produce is divided between landlords, capitalists, and labourers, and which are not essentially connected with the doctrine of value’ (1820, p. 194). Ricardo was able to sustain this ‘material’ view of distribution only in the *Essay on Profits*, and only there by the implicit device of a sector in which all inputs and all output consist of the same commodity, corn, which is also used to pay wages in the other sectors of the economy. In the corn sector the division of the product may be expressed in physical terms, and the rate of profit expressed as a ratio of physical magnitudes. This clear and direct analysis is no longer possible once the strong assumption of a self-reproducing sector is dropped.

The need to express heterogeneous surplus (net of rent) and heterogeneous capital as homogeneous magnitudes in order to determine the rate of profit created the need for a theory of value. Ricardo's materialist approach led him to the labour theory of value. The quantity of labour embodied directly and indirectly in the production of a commodity is determined by the conditions of production of that commodity, or as Ricardo put it, by the difficulty or facility of production, and will change only when the technique changes. Hence the aggregates of social surplus and capital advanced may be expressed as quantities of labour, these quantities being invariant to changes in the distribution of social product. So the rate of profit is determined as the ratio of surplus (on the land last brought into use) to the means of production, including wages.

Once, however, the impact of changes in distribution on exchangeable value is taken into account the picture is far less clear. The value of social output, and of the surplus, measured in any given standard, will typically now vary as distribution varies, even though the physical magnitude of social output remains unchanged. The direct deductive relationship between wages, surplus, and hence, the rate of profit, is no longer self-evident, or indeed, evident at all. It was Ricardo's desire to restore clarity to his analysis which led to his search for an invariable standard of value (a standard in terms of which the size of the aggregate would not vary as distribution was changed) and for what Sraffa describes as ‘for Ricardo its necessary complement’, absolute value (Sraffa, 1951, p. xlvi).

The term ‘absolute value’ was used by Ricardo but once in the first edition of the *Principles* and occasionally in letters. It was clarified in the papers on ‘Absolute Value and Exchangeable Value’, written in 1823 in the last few years of his life. These were discovered in a locked box at the home of F. E. Cairnes, the son of the economist John Elliot Cairnes, in 1943, and published for the first time in Sraffa's edition of Ricardo's Works and Correspondence.

There are two versions of the essay. One, a rough draft, is written on odd pieces of paper, some of them the covers of letters addressed to Ricardo. The other is a scarcely corrected draft, written on uniform sheets of paper. This clean draft breaks off, unfinished.

The importance of the essay derives from the reinforcement it provides to that interpretation of Ricardo's theory of value and distribution which suggests that the problem of the determination of the relative values of commodities stemmed from Ricardo's desire to relate his image of the division of social product as a physical magnitude to the wages, rents, and rate of profit of a market economy. Ricardo was not interested for its own sake in the problem of why two commodities produced by the same quantities of labour are not of the same exchangeable value. He was, rather, concerned by the fact that as
distribution of social output changes exchangeable value changes, disrupting and obscuring an otherwise clear vision. It was this emphasis on the fact that changes in distribution lead to changes in exchangeable value, even though the quantity of social output and the method by which it is produced are unchanged, which led Ricardo into the intellectual cul-de-sac of the search for an invariable standard of value. The absolute value of a commodity is the value of that commodity measured in terms of an invariable standard. An invariable standard of value may be found

… if precisely the same length of time and neither more nor less were necessary to the production of all commodities. Commodities would then have an absolute value directly in proportion to the quantity of labour embodied in them. (Ricardo, 1823, p. 382)

Changes in the absolute values of commodities could then derive only from changes in the amount of labour embodied in them, and the value of social output would be invariate to its distribution. Yet precisely because all commodities are not produced under the same circumstances, ‘difficulty or facility of production is not absolutely the only cause of variation in value, there is one other, the rise or fall of wages’ since commodities cannot ‘be produced and brought to market in precisely the same time’ (1823, p. 368). Hence Ricardo must conclude, rather sadly, that ‘there is no such thing in nature as a perfect measure of value’ (1823, p. 404) – there is no such thing as an invariable standard of value. Marx (1883), who could not, of course, have seen the papers on Absolute and Exchangeable Value, was critical of Ricardo's absorption with the search for an invariable standard. The focus on changes in relative value obscured the fact that commodities do not exchange at rates proportional to their labour values (labour embodied). Yet Marx's attempt to restore clarity to the analysis of distribution by first determining the rate of profit as the ratio of quantities of labour, and then ‘transforming’ labour values into prices of production, encounters difficulties which derive from exactly the same source as those which bedevilled Ricardo – the difference in production conditions or ‘organic composition of capital’ of commodities.

The data of classical theory can be used to determine the rate of profit, as Sraffa (1960) has shown. But the determination cannot be ‘sequential’ – first specifying a theory of value and then evaluating the ratio of surplus to capital advanced by means of that predetermined theory of value. Rather the rate of profit and the rates at which commodities exchange must be determined simultaneously.

absorption approach to the balance of payments

David Vines
Edited by Steven N. Durlauf and Lawrence E. Blume

Article

The absorption approach to the balance of payments states that a country's balance of trade will only improve if the country's output of goods and services increases by more than its absorption, where the term 'absorption' means expenditure by domestic residents on goods and services. This approach was first put forward by Alexander (1952, 1959).

The novelty of this approach may be appreciated by considering the particular question 'will a devaluation improve a country's balance of trade?' The elasticities approach, popular when Alexander was writing, answers this question by focusing on the price elasticities of supply and demand for exports and imports. It holds that the devaluation will be successful if the price elasticities of demand for exports and imports are large enough so that the increase in exports sold to foreigners and the reduction in imports bought by domestic residents together more than offset the terms of trade loss caused by the devaluation. (A special case of this result is formalized in the Marshall–Lerner conditions.) The absorption approach argues, by contrast, that the devaluation will only be successful if it causes the gap between domestic output and domestic absorption to widen. In effect Alexander criticizes the elasticities approach for focusing on the movement along given supply and demand curves in the particular markets for exports and imports (a microeconomic approach), instead of looking at the production and spending of the nation as a whole which shift these curves (a macroeconomic approach).

Alexander's criticism of the elasticities approach is valid. But without further elaboration the absorption approach is unhelpful in rectifying the inadequacy. This is because, taken at face value, the absorption approach merely states an identity. Let the symbols, \( Y \), \( C \), \( I \), \( G \), \( X \) and \( M \) stand for output, consumption, investment, government expenditure, exports and imports respectively. Then the Keynesian income-expenditure identity states that

\[
Y = C + I + G + X - M
\]  

(1)

which may be rewritten
absorption approach to the balance of payments: The New Palgrave Dictionary of Economics

(2)

This identity states precisely that the trade balance will improve if output, \( Y \), increases by more than absorption (\( C+I+G \)).

What is needed, and what Alexander helped to provide, is an analysis of exactly how output and absorption change, in response to a devaluation, and indeed in response to other developments in the economy. Such a gap was also being filled at the time by Keynesian writers (Robinson, 1937; Harrod, 1939; Machlup, 1943; Meade, 1951; Harberger, 1950; Laursen and Metzler, 1950; see also Swan, 1956).

All of these authors grafted the Keynesian multiplier onto the elasticities approach. The resulting hybrid construct can be used to analyse the effects of a devaluation as follows. Suppose that the price elasticity effects do improve the balance of trade, \( X-M \), by ‘switching’ expenditures towards domestic goods. Then these ‘expenditure-switching’ effects provide a positive stimulus to the Keynesian multiplier process, and drive up output \( Y \) and absorption \( C+I+G \). Let \( x \) be the expenditure-switching effects on the trade balance of a devaluation of the currency by one unit, and let the overall effects of this devaluation on the trade balance be \( y \). Let the propensity to consume be \( c \), the tax rate be \( t \) and the propensity to import \( m \), so that the Keynesian multiplier is \( k=1/[1-c(1-t)+m] \). The increase in output resulting from the devaluation is \( kx \) and the increase in absorption is \( c(1-t)kx \). And so

\[
y = k[1 - t(1 - t)]x.
\]

(3)

If the propensity to consume \( c \) is less than unity and the tax rate \( t \) is positive then absorption increases by less than output, and, as equation (3) shows the trade balance is improved by the devaluation. The above sketch shows how the combination of the elasticities approach and Keynesian theory is able to provide the needed analysis of how output and absorption change following a devaluation. And instead of describing the outcomes in terms of output and absorption, as Alexander did, it is possible to give a more conventional Keynesian description, which would proceed as follows. Since the multiplier \( k=1/[1-c(1-t)+m] \) times the propensity to import \( m \) is less than unity, the increase in imports induced by the multiplier, \( mkx \), is less than the positive ‘expenditure-switching effects’, \( x \), and so the trade balance improves.

We can also show how output and absorption change after an ‘expenditure-changing’ adjustment of policy. For example, a one unit increase in government spending will cause output to increase by \( k \) whereas absorption increases by the sum of the increase in government expenditure and the induced increase in consumption \( (1-t)ck \); the trade balance thus worsens by an amount \( z \) where
Absorption approach to the balance of payments: The New Palgrave Dictionary of Economics

Again this outcome can be described in the more conventional Keynesian way: high government expenditure drives up output by the multiplier, $k$, and sucks in imports of an amount $mk$.

The combination of the elasticities approach and Keynesian multiplier theory was used to produce a theory of economic policy for an open economy, which involved the pursuit of full employment as well as a satisfactory balance of trade as policy objectives (Meade, 1951; see especially Swan 1956). This theory can be stated just as well in terms of Alexander's absorption approach. For example an improvement in the balance of trade at full employment requires a reduction in absorption, without any change in output. It is obvious from the previous two paragraphs that this, in turn, requires both expenditure-switching policies and expenditure-changing policies, since both of these policies and influence output as well as absorption. Johnson (1956) put this point masterfully, and I now express it algebraically. Let the desired increase in the trade balance be $w$, let the required devaluation of the currency be $\alpha$ units and let the required change in government expenditure be $\beta$. Then from equations (3) and (4)

$$w = [1 - c(1-t)]k\alpha - mk\beta$$

(5)

whereas, since output is not to be affected,

$$0 = k\alpha + \beta$$

(6)

Solving for $\beta$ from equation (6) and substituting into equation (5), noting that $1-c(1-t)=1/k-m$, gives

$$w = \frac{1}{k-m}k\alpha + mk\alpha = \alpha.$$

Thus the required devaluation is simply $\alpha = w/x$ and substituting in equation (6) the required change in government expenditure is simply $\beta = -w$. This states what is obvious: government absorption must be reduced enough to release resource from domestic use – the expenditure-changing component of policy...
and the devaluation must ensure that these resources are actually used to improve the trade balance, rather than leading to a fall in domestic output – the expenditure-switching component of policy. Laursen and Metzler (1950) show that what is obvious must in fact be qualified. A more careful analysis would show that the positive expenditure switching effect of a devaluation on the trade balance is slightly smaller than the positive expenditure switching stimulus which devaluation imparts to the Keynesian multiplier process (whereas we have assumed both of these effects to be equal, and have denoted them by $\beta$). See also Harberger (1950) and Svensson and Razin (1983).

Modern balance of payments theory has carried criticisms much further than this. It has shown that the hybrid of the Keynesian multiplier and elasticities approaches is inadequate in providing a full analysis of how output and absorption change. First it does not deal with the inflationary effects of devaluation. But one way in which devaluation depresses absorption relative to output is through engendering rises in costs and prices which depress the real incomes (particularly real wages) of domestic consumers (Diaz Alejandro, 1966). Furthermore, devaluation may also engender a wage-price spiral so strong as to preserve the real incomes of domestic consumers, with the end result that prices rise by the full extent of the devaluation and there is no relative price change for the price elasticities effects to work on (Ball, Burns and Laury, 1977). In that case positive effects of devaluation on the trade balance can only emerge as a result of the effects of higher prices on absorption. (Higher prices lower the real wealth of consumers and perhaps also increase the tax burden if tax rates are progressive and not indexed with inflation.) Second, the multiplier-plus-elasticities analysis is not appropriate in analysing the effects of a devaluation not accompanied by any expenditure changing policy if the economy is at full employment, for in that case output cannot be expanded through the multiplier, and the effects of the devaluation must primarily work through the influence of inflation on absorption described above. Third, the multiplier-plus-elasticities analysis does not deal with monetary conditions. A devaluation, because it raises prices, may initially also cause higher interest rates which helps to curtail absorption. But if the improvement in the trade balance caused by the devaluation is allowed to lead to an expansion of the domestic money supply, then gradually interest rates will fall, absorption will rise, and the effects of the devaluation may turn out to be temporary. This issue has been analysed by the Monetary Approach to the Balance of Payments (Frenkel and Johnson, 1976; Kyle, 1976; McCallum and Vines, 1981). Alexander made many of these points in his articles whereas the authors cited at the end of the fourth paragraph tended to skate over them. For that reason his work prefigures much subsequent balance of payments theory.

In conclusion, the absorption approach provides a useful perspective from which to view the trade balance. But it must be supplemented by a theory both of what determines absorption and of what determines output. And of course, the absorption approach only deals with the trade balance; a full theory of the balance of payments requires a theory of capital account movements (and a discussion of how the exchange rate itself is determined).

The acceleration principle holds that the demand for capital goods is a derived demand and that changes in the demand for output lead to changes in the demand for capital stock and, hence, lead to investment. The flexible accelerator, which includes both demand and supply elements, allows for lags in the adjustment of the actual capital stock towards the optimal level. The principle neglects technological change but has been used successfully in explaining investment behaviour and cyclical behaviour in a capitalist economy. Almost all macroeconomic models of the economy employ some variant of it to explain aggregate investment.

Article
The acceleration principle has been proposed as a theory of investment demand as well as a theory determining the supply of capital goods. When combined with the multiplier, it has played a very important role in models of the business cycle as well as in growth models of the Harrod–Domar type. The acceleration principle has been used to explain investment in capital equipment, the production of durable consumer goods and investment in inventories (or stocks). In general, it has been used to explain aggregate investment, although it is sometimes used to explain investment by firms (micro-investment behaviour). The main idea underlying the acceleration principle is that the demand for capital goods is a derived demand and that changes in the demand for output lead to changes in the demand for capital stock and, hence, lead to investment. Its distinctive feature, then, is its emphasis on the role of (expected) demand and its de-emphasis on relative prices of inputs or interest rates.
The acceleration principle is a relatively new concept: it is possible to find its antecedents in Marx’s *Theories of Surplus Value*, Part II (1863, p. 531). Amongst the earliest exponents of the acceleration principle is Albert Aftalion in *Les Crises périodiques de surproduction* (1913). Later contributions by J. M. Clark (1917), A.C. Pigou (1927) and R.F. Harrod (1936) discussed the acceleration principle both as a determinant of investment and in its role in explaining business cycles. Haberler (1937) provides a fairly comprehensive account of the acceleration principle up to that date. Since then the contributions by Chenery (1952) and Koyck (1954) provide important extensions and developments of the theory. In recent years work by Eisner (1960) has employed the acceleration principle in econometric work.

Almost all macroeconomic models of the economy employ some variant of the acceleration principle to explain aggregate investment.

Underlying the acceleration principle is the notion that there is some optimal relationship between output and capital stock: if output is growing, an increase in capital stock is required. In the simplest version of the acceleration principle,

\[ K_t^* = vY_t \]

where \( K_t^* \) is planned capital stock, \( Y_t \) is output and \( v \) is a positive capital–output coefficient. On the assumption that the capital stock is optimally adjusted in the initial period (that is \( K_t = K_t^* \) where \( K_t \) is the actual capital stock) an increase in output (or planned output) leads to an increase in planned capital stock,

\[ K_{t+1}^* = vY_{t+1} \]

and again on the assumption of an optimal adjustment in the unit period

\[ K_{t+1}^* - K_t^* = K_{t+1} - K_t = I_t = v(Y_{t+1} - Y_t) = v\Delta Y_t. \]

In other words, for net investment to be positive, output must be growing: \( v \) is called the accelerator. The acceleration principle can be derived from a cost-minimizing model on the assumption of either fixed (technical) coefficients and exogenous output, or variable coefficients with constant relative prices of inputs and exogenous output.
Some of the shortcomings of this simple model were well known; for example, the problem of being optimally adjusted: this was discussed in the context of whether or not the economy (or the firm) was working at full capacity. If the economy was operating with surplus capacity, an increase in aggregate demand would not lead to an increase in investment. Similarly, it was well known that the accelerator may work in an asymmetric fashion because of the limitations imposed on decreasing aggregate capital stock by the rate of depreciation: the economy as a whole could only decrease its capital stock by not replacing capital goods that were depreciating. Another important qualification to the simple accelerator model was than an increase in (expected) output would lead to an increase in investment only if it was believed that, in some way, the increase was ‘permanent’ or at least of long duration.

A generalization of the simple accelerator is provided by the flexible accelerator or the capital stock adjustment principle (also known as the distributed lag accelerator). It overcomes one of the major shortcomings of the simple accelerator, namely, the assumption that the capital stock is always optimally adjusted. The flexible accelerator also assumes that there is an optimal relationship between capital stock and output but allows for lags in the adjustment of the actual capital stock towards the optimal level. This is written as

\[ l_t = b(K_t^* - K_{t-1}) \]

where \( b \) is a positive constant between zero and one and \( K_t^* \) equals \( vY_t \). This equation implies that the adjustment path of actual capital stock towards the optimal level is asymptotic. In this version, the adjustment is not instantaneous either since, because of uncertainty, firms do not plan to make up the difference between \( K_t^* \) and \( K_{t-1} \) and/or because the supply of capital goods does not allow the adjustment to be instantaneous. A similar equation was derived by assuming increasing marginal costs of adjusting capital stock by Eisner and Strotz (1963).

In evaluating the acceleration principle it is worth stressing that, in some versions, it is used as an explanation of investment demand with the implicit assumption that the supply of capital goods will always satisfy that demand. In models where the acceleration principle is used to explain the supply of capital goods, it is assumed that they always satisfy the demand for them. The flexible accelerator is a hybrid version which includes both demand and supply elements. Although there is no formal treatment of replacement investment, it is usually postulated to be determined in the same way as net investment. A major shortcoming of the acceleration principle is its simplistic treatment of expectations of future demand as well as its neglect of expectations of the time paths of output and input prices. Although most of the work in this field treats the acceleration principle as applying to the aggregate economy, it has also been used to explain investment by firms. It is especially important that the supply of capital goods is formally modelled along with the acceleration principle determining investment demand. Aggregation over firms is usually assumed to be a simple exercise of ‘blowing up’ an individual firm's investment demand. However, it should not be forgotten that in a modern capitalist economy an individual firm may invest by simply taking over an existing firm rather than by buying new capital goods. An important shortcoming of the acceleration principle is its neglect of technological change.
The acceleration principle is an important concept and has been used successfully in explaining investment behaviour as well as cyclical behaviour in a capitalist economy. It will continue to play an important role in macroeconometric models as well as in models of business cycles.

access to land and development

Alain de Janvry and Elisabeth Sadoulet
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Access to land can be an effective policy instrument for poverty reduction. This article shows how different types of property rights can affect access and use, analyses different modes of access, especially the role of land markets, and sets out some of the policy implications. It argues that making land an effective tool for development requires more than policing access: access must be secure, combined with the use of complementary inputs, and achieved in a context of institutions, public goods, and policies that allow the sustainable competitiveness of beneficiaries.

Keywords

access to land and development; agriculture and economic development; common property resources; democracy and economic development; family farm system; Geographical information systems; human capital; Inheritance rights; land markets; land reform; land registration; land use; natural capital; open-access resources; poverty alleviation programmes; property rights; rent control; rental markets; total factor productivity; tragedy of the commons

Article

Access to land, and the conditions under which it happens, play a fundamental role in economic development. This is because the way the modes of access to land and the rules and conditions of access are set, as policy instruments, has the potential of increasing agricultural output and aggregate income growth, helping reduce poverty and inequality, improving environmental sustainability, and providing the basis for effective governance and securing peace. This potential role is, however, difficult to capture, and there are many cases of failure. History is indeed replete with serious conflicts over access to land and with instances of wasteful use of the land, both privately and socially. Governments and development agencies have for this reason had to deal with the ‘land question’ as an important item on their agendas (de Janvry et al., 2002). We explain in this article: (a) why access to land, and the conditions under which it is accessed and used, are important for economic development, (b) how
different types of property rights can affect access and use, (c) the different modes of access, and in particular the role of land markets, and (d) some of the policy implications, in order to show how access to and use of the land can contribute to economic development. We stress in this article that access to land may be a difficult policy question, but that access will translate into development only if the harder question of influencing the way it is used is effectively resolved.

Importance of access to land for development

Land is not only a factor of production, and as such a source of agricultural output and income; it is also an asset, and hence a source of wealth, prestige, and power. Because it is a natural asset, its use affects environmental sustainability or degradation. For these reasons, the link between access to land and development is quite multidimensional and complex, with many trade-offs involved.
If land is to serve as an instrument for output and income growth, investments have to be made to improve its productivity. For this to happen, incentives have to be provided. Some of these investments are short-term, but many others are tied to the land for long periods of time. As a result, security of access is a central policy issue as it is necessary for these investments to be made. Security can be guaranteed through formal means such as titles and legal enforcement, but also through informal mechanisms such as community recognition and enforcement of rights. Whichever way it is achieved, security of access must be credible if it is to induce investment (Deininger, 2003).
To result in output and income growth, access to land must not only be secure, it must also be accompanied by access to complementary inputs and occur in a context favorable to productive use of the land. Empirically well-established complementary inputs include other types of natural capital such as water, working capital, and human capital. Access to land without these complementary inputs in the agricultural production function is not useful for development. In addition, the context where land is used affects its productivity. This includes institutions (such as credit, insurance, and product and factor markets with low transactions costs), public goods (such as infrastructure, market intelligence, research and extension, land registration, and contract enforcement mechanisms), and policies (macroeconomic and agricultural policies favorable to the activities in which the land is used). If complementary inputs and a favorable context for land use are not provided, it is quite evident that access to land will achieve little for output and income. Access to land is thus necessary but not sufficient. Providing what it takes beyond access to achieve income and growth – complementary inputs and a favorable context – can be highly demanding.
Secure access to land and to complementary inputs in a context that allows productive use can be a powerful instrument for poverty reduction. The family farm, with its labour cost advantage when there are transactions costs in labour markets and incomplete incentives to hired labour, can be particularly effective for this (Bardhan, 1984). The inverse relation between farm size and total factor productivity, derived from the labour cost advantage of the family farm, has been cited as the empirical regularity justifying redistributive land reforms towards a family farm system. Access to even a small plot of land can be a source of security in the face of food market and labour market risks. Women's control over land can be a source of empowerment, helping them consolidate their decision-making status over household expenditures that will often favour children (Agarwal, 1994).
Finally, as a good in limited supply, the distribution of access to land can have a powerful influence on
social inclusion and local governance. More egalitarian access can be the basis for greater political participation, more respect for the rule of law, and the ability to raise local fiscal revenues from a land tax, and provide the basis for the consolidation of democracy (Binswanger, Deininger and Feder, 1995). While these relations are far from direct, it is impossible to ignore the role that access to land plays in affecting these outcomes.

Property rights over land

The benefits that can be derived from access to land depend on the property rights that codify access and use. Property rights become increasingly complete as they allow the following functions to accumulate: entry, extraction, management, exclusion, and sale (Ostrom, 2002). Open-access resources grant to all the rights of entry and extraction. They typically induce over-extraction, leading to the ‘tragedy of the commons’. Common property resources grant to members of a defined group, such as a community, the rights of entry, extraction, management, and exclusion of non-community members. This form of property right can result in socially optimal resource use if community members have the ability to cooperate in defining and enforcing rules for individual extraction and maintenance (Baland and Platteau, 1996). Public ownership with centralized management also gives leaders these same rights. Socially optimum resource use can be achieved if controls and incentives can be aligned between leaders and workers, which has historically proved to be difficult in agriculture, despite many attempts. Finally, individual or corporate property rights give owners the full bundle of rights, including those of rental and sale. The effectiveness of this form of property right in land use depends on the existence of efficient land rental and sales markets, as well as the ability to internalize externalities, achieve economies of scale, and access mechanisms for risk spreading. Common property resources with cooperation may be a superior form of property right when individual tenures are unable to fulfil these functions.

Whether property rights correspond to common property or to individual or corporate forms of tenure, these rights have desirable aspects that need to be realized for access to be efficient. One is duration of the rights: long-term investments require sustained access and clear specification of how rights are transferred to others. Inheritance rights are thus a fundamental aspect not only of access to land but also of land use. A second is precise demarcation of land boundaries and clear specification of rights. Geographical information systems based land demarcation, land registries and record keeping of transactions, and adjudication of rights mechanisms are thus fundamental aspects of land management. A third is availability of conflict-resolution mechanisms, where conflicts over access to land can be resolved through informal or formal procedures that are fair and expedient. Uncertain rights and unresolved conflicts over access rights are the norm rather than the exception in developing countries, requiring major investments in regularizing these situations. Finally, property rights must be evolutive, and it must be possible to individualize or consolidate rights as opportunities and needs arise.

Modes of access to land

With open-access resources, entry is granted to all. Access to common property resources is usually given by birthright in a particular community. Clear demarcation of boundaries and clear determination
of membership are important to permit the definition and enforcement of rules. Individual encroachment on public lands and establishing adverse possession rights through occupation is an important form of access where public lands remain plentiful. Finally, individual inheritance is also one of the most prevalent forms of access to land, with eventually discriminatory rights due to primogeniture and to gender and kinship privileges in inheritance.

Access to land through rental markets is often constrained by insecurity of property rights, confining transactions to narrow circles of confidence (family, friends, social peers), thus segmenting markets. While fixed-rent contracts are first-best efficient, sharecropping contracts may be the most efficient way of accessing land when there are market failures in insurance, credit, and non-traded inputs such as management and supervision (Hayami and Otsuka, 1993). In general, the role of land rental markets as a mode of access to land for the poor has been under-appreciated in land policy, and these markets have all too often been atrophied by misguided rent controls.

Finally, the land sales market should expectedly be the most effective way of providing access to land to the most efficient entrepreneurs. This may not be the case, however, because these markets suffer from serious distortions that limit the fulfilment of this role. Land tends to be overpriced relative to its value in productive use due to its function as a store of wealth, speculation on land appreciation, tax advantages, use as collateral in accessing credit, and the status and power it conveys. Overpricing implies that even full credit lines using the land as collateral will not be sufficient to allow poor people to access land without subsidies.

**Access to land and development: policy implications**

In managing their ‘land question’, most countries have experimented with some type of land reform programme (Dorner, 1992). This includes land reforms that have used the threat of expropriation to induce extensively used large farms to modernize or subdivide into smaller farms (Brazil). Other reforms have collectivized the land, either as state farms or as cooperatives. This has generally, as in Russia and eastern Europe, been based on the belief in economies of scale in farming and the superior efficiency of centralized management. In other cases, as in Latin America, collective farms have been used to facilitate transitions between large haciendas and subsequent distribution of the land as individual tenures (Mexico, Peru, Chile). Finally, the inverse relation between total factor productivity and farm size has been invoked in implementing redistributive land reforms that have established family farms out of former large farms (Taiwan, South Korea) or out of state farms or cooperatives (Albania, Bulgaria).

Because the land sales market should be the most effective way of codifying access to land, land reforms have recently taken the form of ‘market-assisted land reforms’, with examples in Brazil, Colombia, and South Africa (Deininger, 2003). In this case, transactions occur between willing sellers and willing buyers, and subsidies are granted to the poor in addition to credit so they can afford purchases at market prices that are in excess of the productive value of the land. These interesting experiments are still in progress and in much need of evaluation.

**Conclusion**
Access to and use of the land is a fundamental instrument for successful development, both economically and socially. History shows both success stories and resounding failures. In general, making land an effective tool for development requires more than policing access: access must be secure, combined with the use of complementary inputs, and achieved in a context of institutions, public goods, and policies that allow the sustainable competitiveness of beneficiaries. Many policies and programmes have been put in place to achieve this goal, but the complexity of the task explains why success requires extensive control and commitment (Warriner, 1969). A fundamental lesson derived from the history of the ‘land question’ is thus that, while reforming the pattern of access to land is difficult, it is far more difficult to make access complete in the sense of securing the competitiveness of beneficiaries so that they achieve income growth, poverty reduction, and sustainable use.

accounting and economics

Joel S. Demski

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Accounting provides an important source of economic measures, yet consistently falls short of the economist's conceptual ideal. This shortfall is fodder for economic research, is the result of economic forces, and is the key to making the best possible use of these measures.

Keywords

accounting and economics; auditing regulation; depreciation; Financial Accounting Standards Board (FASB); Generally Accepted Accounting Principles (GAAP); historical-cost accounting; information school of accounting; International Accounting Standards Board (IASB); measurement school of accounting

Article

Broadly viewed, economics is concerned with the production and allocation of resources, and accounting is concerned with measuring and reporting on the production and allocation of resources. Corporate financial reporting, income tax reporting, and product cost analysis at the firm level are familiar accounting activities. Of course, accounting itself is a production process, and the production and allocation of its output is even regulated; for example, how a firm measures and reports its financial progress and how a firm communicates with outsiders are regulated, and auditing of a firm's public financial statements is mandatory. This suggests two interrelated themes: accounting is useful in a wide variety of activities, including economics research, and accounting itself is a fascinating and important area of economics research.

Using or researching the accountant's products, however, rests on an understanding of what those products are and how they are produced. Accounting, in fact, uses the language of economics (for example, value, income and debt) and the algebra of economic valuation (as income is change in value adjusted for dividends and stock issues). But it falls far short of how an economist would approach these matters. For example, the accounting value of a firm is usually well below its market value, as measured
by the market price of its outstanding equity securities. This disparity is related to the institutional setting in which accounting products are produced, and to the economic forces operating on and within those institutions.

Institutional highlights

Accounting cannot be divorced from its institutional setting. Were firms truly single-product entities, and were markets complete and perfect, economic measurement would be well defined, the nirvana of classical income measurement (for example, Hicks, 1946) would be operational. Unfortunately, in such a setting no one would pay for the services of an accountant simply because the underlying fundamentals would be assumed to be common knowledge. But firms are multi-product entities, markets are neither perfect nor complete, and the underlying fundamentals are far from common knowledge. Here we find a demand for accounting services, such as measuring a firm's periodic income, the performance of the divisions within that firm, and the cost of each of its products. We also find considerable ambiguity over how best to perform those services.

Firms’ published financial reports are the most visible accounting product. They entail a reporting entity (the organization about which the financial reports purport to speak), a listing of resources and obligations in its balance sheet, and a listing of the flow of resources during the reporting period in its income statement. Ambiguity is omnipresent. The reporting entity is not an economically defined firm, as its economic relationships are likely to be more extensive than those identified by its formal reporting; for example, implicit economic arrangements are generally ignored in these reports. Nor is the reporting entity simply a legally defined firm, as it often includes, say, a number of wholly or partially owned though legally free-standing legal entities aggregated into its public reports. Even with an unambiguous reporting entity, that entity's control of economic resources would be incompletely and inaccurately measured. Some assets, such as proprietary knowledge or capital assets acquired through lease arrangements, would not be included. And among those included we would find a mixture of current prices (for example, cash and some financial instruments) and historical cost (for example, most real assets).

The flow measure is equally ambiguous. It is broadly based on what customers have paid minus the resources that were consumed in the process of satisfying those customers. Such wide-ranging phenomena as product warranties and potential product liabilities, uncollectible accounts, pension plans, advertising, research and development and employee training render precise identification of what customers have paid or what resources were consumed largely the product of art as opposed to science.

Regulation, to no one's surprise, now enters the picture. Public financial reports are typically required to be produced according to Generally Accepted Accounting Principles (GAAP). These reports are also typically required to be audited, where the auditor attests to the claim the reports are in compliance with GAAP. One reason for regulations is that the noted ambiguity places a premium on coordinated measurement approaches, a classic example of a network externality (Wilson, 1983). A second reason, based on investor protection concerns and again related to the ambiguity, is the potential for opportunism. Absent auditing, the public financial report is simply management's self-report of its financial results and the unverified claim that those results were measured according to GAAP. Of course the auditor's verification is statistical and judgemental; to no one's surprise, the auditor himself is also regulated.
GAAP itself is fluid, varied, contentious and political at the margin. Two major, competing boards, the Financial Accounting Standards Board (FASB) in the United States and the International Accounting Standards Board (IASB) outside the United States, are largely but not entirely responsible for the definition of GAAP. Historically, the two boards have differed (though inter-board coordination has become a priority in recent years), and have tended to lag behind innovations in transaction design. Moreover, firms design transactions with an eye towards how they will be rendered under GAAP. Leases, as noted above, are largely absent from firms’ balance sheets. This reflects careful transaction design so the acquisition and financing of capital assets can be excluded, according to GAAP, from the firm's balance sheet – in effect lowering the officially measured debt. Similarly, compensating employees with equity options was, until most recently, a form of compensation that, according to GAAP, is absent from firms’ income statements. (While GAAP is defined outside explicit governmental agencies, compliance with GAAP is legally required. The Securities and Exchange Commission in the United States has statutory authority to define GAAP, and has delegated this task, by and large, to the FASB. The European Union, in turn, has delegated this task to the IASB. Auditing regulations, in turn, are more varied, as is enforcement.)

The least visible accounting activity is what transpires inside the firm. Here we again find measures of stocks and flows of resources, aimed now at divisions, plants, departments, product lines, and so forth. The noted ambiguities remain, and extend to such arenas as tracing services from a common provider, such as human resources or cash management, to the consuming units inside a firm or dividing the accounting profit on some particular product line among the various units within the firm whose combined activities produced it. Here we also find less, but far from nil, reliance on GAAP. These measurement activities are not, literally speaking, regulated; but they do rely on the same underlying financial history. We also find a variety of non-financial measures, such as customer and employee satisfaction or student course evaluations. We also find occasional wholesale redesign of a firm’s internal accounting activity (Anderson, Hesford and Young, 2002). (Tax accounting is yet another activity, though the measurement rules are often more directly statutory in nature, and diverge from GAAP.)

Importantly, now, the question is: how are we to make sense of these patterns? Two approaches have emerged through the years, the measurement school and the information school.

The measurement school

The measurement school takes its cue from classical economics. In a fully developed general equilibrium model, with complete and perfect markets (for example, Debreu, 1959), value and income are well defined, as is the value of a firm's assets and obligations. The measurement school takes this as a desideratum and emphasizes the importance of approaching this economic ideal reasonably well. This is the source of accounting's intellectual history, its underlying definitions of asset, liability, income, revenue and expense, and the rhetoric used by its regulators. (Important contributors to this school of thought include Paton, 1922; Clark, 1923; Canning, 1929; Edwards and Bell, 1961; Solomons, 1965; and Chambers 1966.)

The advantage of the measurement approach is its (relative) clarity. Foreign currency translation at contemporaneous exchange rates, economic depreciation, and market value of complex financial instruments, for example, all take on a natural conceptual clarity at this point. Indeed, at least in the
United States, we find the national income accounts are not mere consolidations of GAAP measures, but are produced with an eye on the economic fundamentals. (See Petrick, 2002. More broadly, this leads us to the theory of measurement in general – for example, existence, uniqueness and meaningfulness of a measure – and the axiomatic characterization of additive structures; Krantz et al., 1971; and Mock, 1976. Unfortunately, adding up the value of a firm's assets views the firm as the sum of its assets, so to speak, and is inconsistent with synergies among the asset groups. In parallel fashion, marginal cost is the only meaningful product-cost statistic in a multi-product firm, absent separability. Yet accounting requires accounting product costs to sum to the total cost, which implies that the accounting product costs can be reasonably viewed as marginal-cost estimates only under conditions of separability and constant returns. This suggests theoretical limits to the measurement approach.)

Likewise, with the advent of financial engineering it is natural, from the measurement school perspective, that GAAP require fair value (that is, as if market value) estimates of these instruments. In short, with the measurement school we at least know what it is, conceptually, we are trying to measure. The disadvantage of the measurement approach is that it relies on economics to identify the conceptual ideal, but ignores economics when the time comes to worry about resources devoted to the measurement enterprise. (Audit fees alone exceed $6 billion annually in the United States.) It also raises such questions as why international differences persist, why accounting does such a poor job of tracking economic value and why, given this presumptively poor performance, it continues to survive. (Flawed as it is, from this perspective, we also know foreknowledge of firms’ annual reports would allow highly profitable speculation; Ball and Brown, 1968.) It also fails to capture the accountant's stock in trade of eschewing economic measurement and embracing historical-cost allocation. Capital assets are not measured at economic value, and no attempt is made to measure economic depreciation. Rather, the historical cost of the capital asset is allocated, is divided among multiple uses in some formula-driven manner. For example, the initial cost of a real asset is divided among periods (accounting depreciation) and from there among products, resulting in an allocated portion hitting the income statement and the net balance being the asset value on the balance sheet. Moreover, when accounting reports the cost of a firm's product, it is reporting not marginal cost but an allocated accounting cost. Morgenstern (1965, p. 79) is particularly eloquent:

> But it is clear that in the absence of a convincing and complete theory there is no unique and objective way of accounting for costs when overhead, amortization and joint costs have to be taken into consideration … ‘Cost’ is merely one aspect of a valuation process of great complexity.

The measurement school, then, focuses on economic measurement as the ideal, but ignores economic forces that impinge on the measurement process.

The information school

The information school, in contrast, focuses on these economic forces and takes its cue from the economics of uncertainty. It views the accounting product not literally as measures of resources but as information that purports to inform about these resources. Abstractly, then, accounting is a mapping
from underlying acts and events into the real numbers. In this view, accounting is one among many sources of information. Analysts, the financial press and trade associations are familiar sources of financial information, as are government statistics themselves. Moreover, firms often engage in voluntary disclosures; for example, new product announcements, major investment announcements, and even so-called earnings warnings where they reveal that a forthcoming earnings measure will be lower than originally anticipated. In addition, the typical financial report reports cash flow, an utterly reliable, unambiguous measure. (Important contributors to this school of thought include Butterworth, 1972; Feltham, 1972; Ijiri, 1975; Beaver, 1998; and Christensen and Demski, 2002.)

The advantage of this view is it forces us to think in terms of complements and substitutes when dealing with this vast array of sources, and to look for economic forces that drive the disparity that bedevils the measurement school. And it is here that the comparative advantage of the accounting channel comes into focus: it is purposely designed and managed so that it is difficult to manipulate (Ijiri, 1975). This is why it often resorts to historical-cost measurement, as this removes major elements of subjectivity and manipulation potential. It is also why, in organized financial markets, most valuation information arrives before the firm's financial reports; and in this sense the financial reports provide a veracity check on the earlier reporting sources. In addition, cost allocation now enters as a natural phenomenon, either as a simple scaling device or – to use an analogy with informationally efficient markets – as a cousin to an information-based pricing kernel in a financial market (Christensen and Demski, 2002; Ross, 2004).

Libraries are organized in coordinated fashion, as are phone books; and the same can be said about accounting. A curiosity is the political side of the regulatory apparatus. It is difficult, for example, for the incumbent government to alter a government-provided statistical series, yet it is routine for the incumbent government to intervene in the accounting regulatory process. A second curiosity is the seemingly episodic nature of financial reporting frauds (Demski, 2003), although at the micro level it is well understood that opportunistic reporting is part of the game. For example, an ability to shift income from a later to an earlier period may be an inexpensive signal or, to speak more cynically, less costly to the firm than shifting real resources.

The disadvantage of the information school is its sheer breadth. The institutional context includes a vast array of information sources and actors, and sorting out first-order effects remains problematic.

Conclusion

Accounting, then, is simultaneously an important source of economic data and a collection of institutional regularities that provide research economists with yet another venue for documentation and exploration of economic forces. Why do we see episodic regulatory interventions? Why do we see forecasts of forthcoming accounting measures? Why do we not see supplementary estimation of economic depreciation? Why do we see the mix of historical-cost and market values that characterize modern financial reporting? Questions of this sort motivate much of the current research in accounting and finance.

Adaptive estimation arises in the context of partially specified models. Partially specified models occur with some frequency in econometrics. For example, a linear regression model in which the error distribution is unknown is a partially specified model. So too are many of the diffusion models employed in empirical finance. One active research area is to understand the conditions under which the lack of full specification does not affect the asymptotic efficiency of the estimator, in which case the estimator is termed ‘adaptive’.

Keywords

adaptive estimation; kernel estimator; linearized likelihood estimation; maximum likelihood; nonparametric estimation; semiparametric estimation; spline functions

Article

An adaptive estimator is an efficient estimator for a model that is only partially specified. For example, consider estimating a parameter that describes a sample of observations drawn from a distribution $F$. One natural question is: is it possible that an estimator of the parameter constructed without knowledge of $F$ could be as efficient (asymptotically) as any well-behaved estimator that relies on knowledge of $F$? For some problems the answer is ‘yes’, and the estimator that is efficient is termed an adaptive estimator.

Consider the familiar scalar linear regression model (in which we let $t$ rather than $i$ index observations)

$$Y_t = \beta_0 + \beta_1 X_t + U_t.$$
where the regressor is exogenous and \( \{ U_t \} \) is a sequence of \( n \) independent and identically distributed random variables with distribution \( F \). The parameter vector \( \beta = (\beta_0, \beta_1)' \) is often of interest rather than the distribution of the error, \( F \). If we assume that \( F \) is described by a parameter vector \( \lambda \) (that is, we parameterize the distribution), then the resultant (maximum likelihood or ML) estimator of \( \beta \) is parametric. If we assume only that \( F \) belongs to a family of distributions, then the resultant estimator of \( \beta \) is semiparametric. Because the OLS estimator does not require that we parameterize \( F \), the OLS estimator is semiparametric. If the population error distribution is Gaussian, we know that the OLS estimator is equivalent to the ML estimator, and so is efficient. Although the OLS estimator is generally inefficient if \( F \) is not Gaussian, it may be possible to construct an alternative (semiparametric) estimator that retains asymptotic efficiency if \( F \) is not Gaussian. If we find that, for a family of distributions that includes the Gaussian, this estimator is asymptotically equivalent to the ML estimator, then this estimator is adaptive for that family.

The question then is: how can we verify that an estimator is adaptive? As there will generally be an arbitrarily large number of distributions in the family, it is not feasible to algebraically verify asymptotic equivalence for each distribution. In a creative paper, Stein (1956) first proposed a solution to this problem. Let \( \{ F_\lambda, \lambda \in \Lambda \} \) define a subset of the family of distributions, each member of which is parameterized by a value of \( \lambda \) (each member of this family must satisfy certain technical conditions, such as absolute continuity, which will not be explicitly defined). Although primary interest centers on \( \beta \), the full set of parameters includes \( \lambda \). The information matrix, evaluated at the population parameter values, is

\[
\begin{bmatrix}
\mathcal{I}_{\beta\beta} & \mathcal{I}_{\beta\lambda} \\
\mathcal{I}_{\lambda\beta} & \mathcal{I}_{\lambda\lambda}
\end{bmatrix}
\]

where \( \mathcal{I}_{\beta\beta} \) corresponds to the elements of \( \beta \). Estimators of \( \beta \) (again, the estimators must satisfy technical conditions, such as \( \sqrt{n} \) consistency, which are also not explicitly defined) will have covariance matrix that is at least as large as \( \mathcal{I}_{\beta\beta} \), which is the upper left component of \( \mathcal{I}^{-1} \). If the partial derivative of the log-likelihood with respect to \( \beta \) (the score for \( \beta \)) is orthogonal to the score for \( \lambda \), then \( \mathcal{I}_{\beta\lambda} = 0 \) and \( \mathcal{I}_{\beta\beta} = \mathcal{I}_{\beta\beta}^{-1} \). Because \( \mathcal{I}_{\beta\beta} \) corresponds only to the parameter \( \beta \), the asymptotically efficient estimator of \( \beta \) can be constructed without knowledge of \( \lambda \). Stein argued that, if the condition \( \mathcal{I}_{\beta\lambda} = 0 \) holds for all the elements of \( \{ F_\lambda \} \), then \( \beta \) is adaptively estimable.

While Stein's condition has intuitive appeal, it is not straightforward how to use the condition to define estimators that are adaptive. In an invited lecture, Bickel (1982) laid out a simpler condition that does yield a straightforward link to the construction of adaptive estimators. To understand the condition, let \( E_F \) denote expectation with respect to the population error distribution and let \( E_{\tilde{F}} \) denote expectation with respect to an arbitrary distribution \( \tilde{F} \in \mathcal{F} \). Let \( l \) be the log-likelihood for the regression model with data \( z = (y, x) \) and let \( l(z, \beta, F) \) denote the score for \( \beta \), constructed from the model in which \( F \) is the
error distribution. A familiar condition that arises in the context of likelihood estimation is that the expected population score $E_F [i(Z, \beta, F)]$ equal 0. Bickel's condition is simply that the population score must have expectation zero over the entire family $\mathcal{A}$, that is, for any $\hat{F} \in \mathcal{A}$,

$$E_{\hat{F}} [i(Z, \beta, F)] = 0.$$ 

The two conditions are linked: if $\mathcal{A}$ is a convex family, then Stein's condition is implied by Bickel's condition. In detail, if $\mathcal{A}$ is a convex family, then $F_\lambda = \lambda F + (1 - \lambda) \hat{F}$ with $\lambda$ an element of $\Lambda = (0, 1)$. Bickel's condition then arises from Stein's condition by taking the limit as $\lambda \to 0$. For the linear regression model, an adaptive estimator of $\beta$ exists for the family $\mathcal{A}$ that consists of all distributions that are symmetric about the origin (and several other technical conditions). If interest centres on the slope coefficient alone, then one need not restrict attention to distributions that are symmetric about the origin, as an adaptive estimator of $\beta_1$ can exist even if $\beta_0$ is not identified.

Bickel's score condition leads naturally to estimators that contain nonparametric estimators of the distribution, $\hat{F}$. In consequence, adaptive estimation requires a second condition: the nonparametric estimator of the score must converge in quadratic mean to the population score. The resulting estimators of $\beta$ are two-step estimators. The estimators require, as the first step, a $\sqrt{n}$-consistent estimator such as the OLS estimator. To understand the estimator's form, note that, if the distribution were known, then the two-step (linearized likelihood) estimator is

$$\hat{\beta}_{OLS} + n^{-1} \sum_{t=1}^{n} s(Z_t, \hat{\beta}_{OLS}, F),$$

with $s(Z_t, \hat{\beta}_{OLS}, F) = g^{11}(\hat{\beta}_{OLS}, F)i(Z_t, \hat{\beta}_{OLS}, F)$. The linearized likelihood estimator is asymptotically efficient. To form an adaptive estimator of $\beta$, we must replace $F$ with a nonparametric estimator $\hat{F}$. If $\hat{F}$ is constructed so that $s(Z_t, \hat{\beta}_{OLS}, \hat{F})$ converges in quadratic mean to $s(Z_t, \hat{\beta}_{OLS}, F)$, then

$$\hat{\beta}_{AD} = \hat{\beta}_{OLS} + n^{-1} \sum_{t=1}^{n} s(Z_t, \hat{\beta}_{OLS}, \hat{F}),$$

is an adaptive estimator of $\beta$ for the family $\mathcal{A}$. 

For the linear regression model, as for numerous other models, nonparametric estimation of $F$ entails nonparametric estimation of the density $f$. One popular nonparametric density estimator is the kernel estimator, which is employed by Portnoy and Koenker (1989) in their proof that semiparametric quantile estimators are also adaptive for $\beta$. If $\{\hat{U}_t\}$ denotes the OLS residuals, then a kernel density estimator is defined for all $u$ in a small neighbourhood of each value of $\hat{U}_t$ as

$$
\hat{f}_t(u) = (n - 1)^{-1} \sum_{s=1, s \neq t}^n \xi_{\sigma}(u - \hat{U}_s),
$$

where $\xi_{\sigma}$ is a weight function that depends on the smoothing parameter $\sigma$. In Steigerwald (1992), $\xi_{\sigma}$ corresponds to a Gaussian density with mean 0 and variance $\sigma^2$. The variance controls the amount of smoothing; as $\sigma^2$ declines, the weight given to residuals that lie some distance from $\hat{U}_t$ tends to zero. Of course, there are many other ways to form the nonparametric score estimator. Newey (1988) approximates the score by a series of moment conditions, which arise from exogeneity of the regressor and symmetry of $F$. Faraway (1992) uses a series of spline functions to approximate the score. Chicken and Cai (2005) use wavelets to form the basis for nonparametric estimation of $f$.

Recent results in adaptive estimation have focused on problems in which the error distribution is known, but other features are modelled nonparametrically. Some of the most intriguing results concern the type of stochastic differential equation often encountered in financial models. The price of an asset that is measured continuously over time, $P_t$, is often modelled as

$$
dP_t = m_t dt + v_t dB_t.
$$

The presence of standard Brownian motion, $B_t$, makes the model of price a stochastic differential equation. The function $m_t$ captures the deterministic movement or drift while $v_t$ is the potentially time-varying scale of the random component. Lepski and Spokoiny (1997) study the model in which $v_t$ is constant and $m_t$ is unknown. They establish that a nonparametric estimator of $m$ is pointwise adaptive. Yet an estimator that is pointwise adaptive – that is, for a given point $t_0$ the nonparametric estimator of $m(t_0)$ is asymptotically efficient – may not perform well for all values within the range of the function $m$. Such an idea is intuitive; without knowledge of the smoothness of $m$, estimators designed to be optimal for one value of $t$ may be very different from optimal estimators for another value of $t$. Cai and Low (2005) study efficient estimation of $m$ over neighbourhoods of $t_0$ and show that an estimator constructed from wavelets is adaptive. The restriction that the scale is constant is often difficult to support with
financial data. A more realistic model, which Mercurio and Spokoiny (2004) study, models the asset
return as a stochastic differential equation with drift 0 and $\nu_t$ varying over time. The time-varying scale
is assumed to be constant over (short) intervals of time, but is otherwise unspecified. They construct a
nonparametric estimator of the volatility from a kernel that performs local averaging and show that the
resultant estimator is adaptive.

The adaptive expectations hypothesis may be stated most succinctly in the form of the equation:

$$E_t x_{t+1} = \sum_{i=0}^{\infty} \lambda (1 - \lambda)^i x_{t-i}, \quad 0 < \lambda < 1$$  

(1)

where $E$ denotes an expectation, $x$ is the variable whose expectation is being calculated and $t$ indexes time. What this says is that the expectation formed at the present time, $E_t$, of some variable, $x$, at the next future date, $t+1$, may be viewed as a weighted average of all previous values of the variable, $x_{t-i}$, where the weights, $\lambda (1 - \lambda)^i$, decline geometrically. The weight attaching to the most recent, or current, observation is $\lambda$. The above equation can be manipulated readily to deliver:

$$E_t x_{t+1} = E_{t-1} x_t + \lambda (x_t - E_{t-1} x_t).$$

(2)

What this equation says is that, viewed from time $t$, the expected value of the variable, $x$ at $t+1$, is equal to the value which, at time $t-1$ was expected for $t$, plus an adjustment for the extent to which the variable turned out to be different at $t$ from the value which, viewed from date $t-1$, had been expected. The change in the expectation is simply the fraction $\lambda$ multiplied by the most recently observed forecast error. In this formulation, the adaptive expectations hypothesis is sometimes called the error learning hypothesis (see Mincer, 1969, pp. 83–90).
The adaptive expectations hypothesis was first used, though not by name, in the work of Irving Fisher (1911). The hypothesis received its major impetus, however, as a result of Phillip Cagan's (1956) work on hyperinflations. The hypothesis was used extensively in the late 1950s and 1960s in a variety of applications. L.M. Koyck (1954) used the hypothesis, though not in name, to study investment behaviour. Milton Friedman (1957), used it as a way of generating permanent income in his study of the consumption function. Marc Nerlove (1958) used it in his analysis of the dynamics of supply in the agricultural sector. Work on inflation and macro-economics in the 1960s was dominated by the use of this hypothesis. The most comprehensive survey of that work is provided by David Laidler and Michael Parkin (1975).

The adaptive expectations (or error learning) hypothesis became popular and was barely challenged from the middle-1950s through the late-1960s. It was not entirely unchallenged but it remained the only extensively-used proposition concerning the formation of expectations of inflation and a large number of other variables for something close to two decades. In the 1970s the hypothesis fell into disfavour and the rational expectations hypothesis became dominant.

The adaptive expectations hypothesis became and remained popular for so long for three reasons. First, in its error learning form it had the appearance of being an application of classical statistical inference. It looked like classical updating of an expectation based on new information. Second, the adaptive expectations hypothesis was empirically easy to employ. Koyck (1954) showed how a simple transformation of an equation with an unobservable expectation variable in it could be rendered observable by performing what became a famous transformation bearing Koyck's name. If some variable, $y_t$, is determined by the expected future value of $x_t$, that is:

$$y_t = \alpha + \beta E_t x_{t+1} + \epsilon_t$$

where $\alpha$ and $\beta$ are constants, then we can obtain an estimate of $\alpha$ and $\beta$ by using a regression model in which equation (1) [or equivalently (2)] is used to eliminate the unobservable expected future value of $x_t$. To do this, substitute (1) into (3). Then write down an equation identical to (3) but for one period earlier. Multiply that second equation by $1-\lambda$ and subtract the result from (3) (Koyck, 1954, p. 22), to give:

$$y_t = \alpha \lambda + \beta \lambda x_t + (1-\lambda) y_{t-1}$$

An equation like this may be used to estimate not only the desired values of $\alpha$ and $\beta$ but also the value of $\lambda$, the coefficient of expectations adjustment. Thus, economists seemed to have a very powerful way
of modelling situations in which unobservable expectational variables were important and of discovering speeds of response both of expectations to past events and of current events to expectations of future events.

Third, the adaptive expectations hypothesis seemed to work. That is, when equations like (4) were estimated in the wide variety of situations in which the hypothesis was applied (see above), ‘sensible’ parameter values for $\alpha$, $\beta$, $\lambda$ were obtained and, in general, a high degree of explanatory power resulted.

If the adaptive expectations hypothesis was so intuitively appealing, easy to employ, and successful, why was it eventually abandoned? There are three key reasons. First, the interpretation of the hypothesis as an application of classical inference came to be questioned, notably by John Muth (1960). Muth pointed out that the adaptive expectations hypothesis would only be optimal in the sense of delivering unbiased and minimum mean square error forecasts for a variable whose first difference was a first-order moving average process. Since this is likely to be a limited class of variables, the general validity of interpreting the adaptive expectations hypothesis as being consistent with classical inference came to be questioned. Second, in the area of macroeconomics, the adaptive expectations hypothesis was seen to be logically inconsistent with what came to be called the ‘natural rate hypothesis’ (Lucas, 1972). The latter hypothesis, that unemployment and other real variables are ultimately determined by real forces and not influenced by anticipations of inflation (at least not to a first-order) is so deeply entrenched in economics that the logical clash of the two hypotheses had to result in the modification of adaptive expectations (see Friedman, 1968, and Phelps, 1970). Third, and as almost always happens in scientific developments, a new, rational expectations alternative to adaptive expectations became available. The new theory had all the intuitive appeal of the old and, eventually, became equally tractable in empirical studies and began to show signs of success.

addiction

George Loewenstein and Scott Rick
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Research on addiction had already yielded a wide range of interesting and important findings when economists first arrived on the scene. The economic study of addiction was initiated by a seminal paper by Becker and Murphy (1988) which challenged the prevailing view of addiction as self-destructive, proposing instead a ‘rational account of addiction’. Although some empirical research has confirmed the model's critical prediction that anticipated increases in future prices will decrease current demand for a drug, more recent research by economists, stimulated by the prior work from other disciplines, has challenged some of the rational account's assumption and predictions.

Keywords

addiction, rational account of; Becker, G.; drugs; excise tax; forward price elasticity; rational behaviour; sin taxes; time consistency

Article

Economists were latecomers to the study of addiction, a concept which researchers in other disciplines usually define as including a loss of self-control, continuation of behaviour despite adverse consequences, and preoccupation or obsession with the substance or activity one is addicted to. Economists came late to the subject perhaps because the first two of these characteristics seem inconsistent with economists’ rational choice paradigm.

This may be exactly what spurred Gary Becker, along with coauthor Kevin Murphy, to propose, in 1988, a ‘rational account of addiction’, which stimulated much subsequent research and theorizing by economists. Although not the first economic account of addiction, Becker and Murphy's model (referred to henceforth as B&M) was certainly the most influential, and has spawned a very lively line of research, theorizing and debate about addiction by economists.

Contributions of disciplines other than economics
Prior to B&M, scientists in a range of disciplines had already developed a rich tradition of research on addiction. For example, early studies by psychopharmacologists identified the actions of addictive drugs in the brain, and subsequent research by neuroscientists has uncovered the neural pathways through which addictive activities derive their motivational power (see, for example, Gardner and James, 1999; Lyvers, 2000). Sociologists have also been major contributors, conducting ethnographic and life-course studies of drug users that have identified many of the social influences on drug use. Psychologists have studied the widest range of different facets of drug abuse, including biological underpinnings and social, cognitive and emotional dimensions, and have also been in the forefront when it comes to treatment. Psychologists, as well as other health professionals, have tested a great diversity of treatments for addiction, including residential treatment, counselling, psychotherapy, drug therapies such as methadone, nicotine patches and antidepressants, aversive conditioning, and hypnosis. Taken together, these diverse lines of research have yielded a number of important, and often counter-intuitive, findings.

- Historic use of different types of drugs exhibits ‘fads’, rising then falling in popularity, sometimes repeatedly for a specific drug.
- Most drug users do not just use a single drug, but many different drugs.
- Many if not most drug abusers also suffer from other psychiatric conditions, such as anxiety or mood disorders, schizophrenia or antisocial personality disorder.
- Much if not most quitting occurs outside of treatment.
- It is not short-term withdrawal from drugs (for example, for a few days) that most addicts find difficult, but long-term abstinence, which tends to be punctuated by episodes of ‘craving’ which create an almost overwhelming motivation for drug use.
- Episodes of craving are often triggered by ‘cues’ – people or other stimuli that the addict associates with drug use.
- While approximately 20 per cent of a sample of veterans reported being addicted to heroin in Vietnam, and 45 per cent reported narcotic use, only one per cent remained addicted, and two per cent reported using narcotics after returning home (Robins, 1973); this finding radically changed prevailing views of the incidence of recovery from heroin addiction.
- Humans and other mammals voluntarily self-administer most of the same chemical compounds. (Hallucinogens, which some humans seek out but most animals avoid, are a major exception.)
- Although a small number of intense users account for a large fraction of drug use, most drug users consume at moderate or low rates, and do not become addicted in the sense of losing control, suffering adverse consequences or becoming obsessed with drug-taking.
- Many of the adverse health effects of illicit drugs, such as opiates, do not stem from physical effects of the drugs themselves, but from the difficulty of financing an illegal, and hence typically expensive, habit.
- Most addictions begin when people are in their teens or early twenties, and addicts often ‘mature out’ – quitting when they reach middle age. People rarely become addicted for the first time in middle or old age.

In addition to generating a wide range of interesting and important findings, researchers in disciplines other than economics have proposed a variety of theoretical perspectives on addiction. Some
perspectives place great importance on the pleasure of drug-taking, the pain of withdrawal, or the motivational force of ‘cue-conditioned’ craving, while others view drug use as a form of self-medication for psychiatric conditions such as depression.

For better or for worse, economists’ focus on addiction has been much narrower, at both the theoretical and the empirical levels. Most empirical work has involved estimating price elasticities of demand for drugs (often using aggregate consumption data), and most theoretical work has involved some type of generalization of Becker and Murphy's perspective.

**Becker and Murphy’s model**

In Becker and Murphy’s rational model of addiction, utility from an addictive good, \( c(t) \), is assumed to depend on consumption of that good and on the degree of addiction \( S(t) \). \( S(t) \) changes according to the function \( \dot{S}(t) = c(t) - \delta S(t) \), where the first term represents the impact of engaging in the addictive good on one’s level of addiction, and the second represents the natural decline in addictedness when one desists. The individual is assumed to trade off consumption of the addictive good against consumption of other (non-addictive) goods, discounting for time delay in the conventional (exponential) fashion. The central insight of B&M is that people treat addictive goods no differently from the way they treat any good whose utility depends on consumption over time, trading them off against other goods based on current and future (anticipated) prices.

This model can accommodate a number of features of classical addiction, such as that being addicted lowers instantaneous utility \( u_S < 0 \), that it increases the instantaneous marginal utility of taking the drug \( u_{cS} > 0 \). Solving the model yields a number of implications, most importantly that it can be rational for an individual to maintain a positive rate of consumption of an addictive good.

Empirical tests of B&M have focused on the strong prediction that anticipated changes in future prices affect the current behaviour of addicts, which is counter-intuitive given that addicts are commonly seen as behaving myopically. The model is therefore typically tested by estimating what could be called the ‘forward price elasticity’ of various addictive substances. Consistent with Becker and Murphy's model, negative forward price elasticities have been found for alcohol, cigarettes, marijuana, opium, heroin and cocaine (for a review, see Pacula and Chaloupka, 2001), although the effect appears to be more consistent for adults than for youth.

**Moving beyond Becker and Murphy**

In proposing their rational account of addiction, Becker and Murphy initiated the study of addiction among economists, and made the key point that it is useful to think of addicts as solving a forward-looking optimization problem. However, the B&M model fails to incorporate a number of important features of addiction, and is either inconsistent with or fails to predict many salient features of addiction, including some of the stylized facts listed above. Responding to these limitations, economists have built upon the B&M model by relaxing some of its most extreme assumptions or incorporating more realistic assumptions that are often inspired by research in other disciplines.

One important generalization has been to examine the implications of relaxing the assumption of exponential time discounting. Gruber and Koszegi (2001; 2004), for example, propose a model in which...
time-inconsistent addicts have self-control problems: they would like to quit using but cannot force themselves to do so (see also O’Donoghue and Rabin, 1997). As in B&M, Gruber and Koszegi’s model predicts that a rise in current or anticipated excise taxes will reduce use of addictive substances. However, although the models make similar behavioural predictions, they interpret the hedonic consequences of altered usage behaviour differently. B&M predicts that taxes on addictive substances – ‘sin taxes’ – make addicts worse off since the price of a good that they enjoy has risen. Gruber and Koszegi’s model, on the other hand, predicts that the tax makes time-inconsistent addicts better off since it provides a valuable self-control device. Since behavioural data cannot distinguish between the models, Gruber and Mullainathan (2005) bypassed the standard practice of measuring the impact of policy interventions by estimating price elasticities in favour of directly examining the impact of these interventions on subjective well-being. They did so by matching cigarette excise taxation data to surveys from the United States and Canada that contain data on self-reported happiness. Consistent with Gruber and Koszegi’s model, Gruber and Mullainathan (2005) found that excise taxes on cigarettes make smokers happier.

Another implication of time inconsistency involves purchasing patterns. The B&M model predicts that addicts will behave in a time-consistent fashion and hence will buy in bulk to save time and money in satisfying their anticipated long-term habit. Wertenbroch (1998; 2003), however, found that consumers – even those who are not liquidity-constrained – often purchase ‘vice’ items, such as cigarettes, in small quantities in an attempt to control their intake of the harmful substance.

Other research has questioned the assumption that addicts begin drug taking with full knowledge of the consequences. For example, Slovic (2000a; 2000b) has argued that people take up cigarette smoking in part because they underestimate the health risks, although Viscusi (2000) counters that any error is actually in the opposite direction – that smokers overestimate the health risks of smoking. Pointing to a somewhat different type of underestimation, Loewenstein (1999) has argued, based on a wide range of evidence, that potential drug users underestimate their own proneness to addiction because they underestimate the motivational force of drug craving.

Finally, a recent line of theoretical models, while also building on the insights of Becker and Murphy, has incorporated evidence from the psychological literature on cue-conditioned craving and from neuroscience. For example, Laibson (2001) proposes a model of addiction that incorporates the role of cue-conditioned craving. In his model, environmental cues that become associated with drug use, when encountered by an ex-addict, produce surges of craving (like sudden changes in $S(t)$ in B&M). Bernheim and Rangel (2004) develop a model of addiction that is particularly closely grounded in neuroscience research and that is perhaps the most radical departure from B&M. Their model is based on the idea that repeated experience with drugs sensitizes individuals to environmental cues that trigger mistaken usage. So far, economists are still playing catch-up with researchers in other disciplines when it comes to their understanding of addiction or their influence on policy. Thus, a large fraction of empirical research on drug use by economists has focused on price elasticities. While price is one determinant of drug use, it is arguably not the most important, or even the most amenable to manipulation through the instruments of policy. Nevertheless, economic models of addiction have made great strides, building on Becker and Murphy’s seminal contribution with new models that incorporate many of the insights and findings generated by research in other disciplines.
We thank Caroline Acker, Ted O’Donoghue and Antonio Rangel for helpful suggestions.

adjustment costs

Aubhik Khan and Julia K. Thomas
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article surveys the use of adjustment frictions in macroeconomic research, exploring the consequences of convex and non-convex adjustment costs for firm-level decisions and the dynamics of macroeconomic aggregates. The mechanics of these frictions are illustrated using several prominent examples including the partial adjustment model of employment, the q-theoretic investment model, and lumpy adjustment models of investment and employment. We also review the (S,s) inventory model, where stock accumulation is explained as the result of fixed delivery costs, and briefly discuss (S,s) decision rules arising from piecewise-linear costs in the context of capital irreversibility and firing taxes.

Keywords

adjustment costs; adjustment hazards; aggregate nonlinearities; business cycles; capital irreversibility; convex cost functions; distributed lags; dynamic stochastic equilibrium analysis; Euler equations; equilibrium; frictions; intermediate goods; inventory policies; investment theory; linear quadratic inventory models; lumpy investment; market-clearing relative prices; monetary non-neutralities; neoclassical investment theory; nonlinear microeconomic adjustment; partial adjustment; piecewise-linear adjustment costs; production functions; quadratic cost functions; rational expectations; (S,s) decision rule; (S,s) policies; Tobin's q; total factor productivity

Article

Across a wide body of macroeconomic research, the interest in adjustment costs has been largely utilitarian. In designing theoretical models to organize our understanding of patterns observed in the data, we make hard choices about which of the many elements affecting the decisions of actual firms and households and the outcomes of their market interactions to include. Given their necessary simplicity, we often find that the predictions of the theoretical economies we are able to analyse are too stark relative to the behaviour observed in actual economies. Thus, in a variety of settings we have adopted adjustment costs in our economic laboratories to summarize omitted frictional elements that
reduce, delay or protract changes in the demand and supply of final goods and their factor inputs in response to changes in economic conditions. In these few pages, we describe the mechanics of commonly used adjustment costs and briefly discuss their role in several leading macroeconomic applications. Since a comprehensive survey is beyond the scope of this article, many important applications have been excluded. However, where possible we direct the reader to influential research on these topics.

1 Convex costs

Until relatively recently, most macroeconomic research involving adjustment costs emphasized the use of convex cost functions to penalize swift changes in aggregate variables and thereby induce gradual movements over time. Historically, models with convex adjustment costs were developed as a theoretical foundation to explain why the inclusion of lagged dependent variables in empirical models of factor demand led to sharp improvements in their econometric performance. While early researchers had found decision-theoretic models based on static demand theory unable to account for the serial correlation observed in aggregate employment and investment, these same models performed relatively well when they were augmented with ad hoc distributed lags of the dependent variable or its theoretical determinants (as in the flexible accelerator model of Koyck, 1954, or the flexible user-cost model of Hall and Jorgenson, 1967). These lags were broadly motivated by the idea that certain frictions prevent firms from immediately attaining their chosen employment or capital levels, instead engendering partial adjustment towards these target levels over time.

For example, by assuming that firms adjusted their workforces at constant rate \( \lambda \in (0, 1) \) towards the target implied by static demand theory, \( N_t^* \), current employment could be written as a distributed lag of previous target employments:

\[
N_t = \lambda N_t^* + (1 - \lambda) N_{t-1} = \lambda \sum_{j=0}^{\infty} (1 - \lambda)^j N_{t-j}^*.
\]

To implement such partial adjustment models, researchers replaced the distributed lag of unobservable targets with distributed lags of each observable series the theory suggested should influence them – for instance, real wages. In this way, lags of the determinants of demand were introduced into the estimation equation, thus introducing the empirically desirable serial correlation.

Without some theoretical basis to explain their empirical success, partial adjustment models might have been abandoned quickly. A partial resolution arrived in the mid- to late 1960s with the application of capital adjustment costs in models of investment (see Eisner and Strotz, 1963; Lucas, 1967; Gould, 1968; Treadway, 1971). There, gradual aggregate adjustment broadly consistent with the analogue to (1) was obtained by assuming that, beyond other costs associated with the acquisition of capital (for
example, user costs), the very act of adjusting the capital stock incurred real output costs. These costs, $\Phi(k', k)$, were strictly increasing and convex in the distance between the chosen new level of capital and the current level, $|k' - k|$, thereby implying a smoothly rising marginal adjustment cost in the size of the current adjustment. As such, they introduced dynamic elements into the firm's previously static decision problem and led it to smooth its investment activities over time. Nonetheless, so long as the treatment of expectations was incomplete, the mapping to a partial adjustment equation could not be robustly established.

The work of Sargent (1978) extended the theory in the context of employment adjustment by showing how, under rational expectations, the partial adjustment model could be derived from the profit maximization problem of a firm facing quadratic adjustment costs. To simplify the problem somewhat, consider a firm that enters any period with employment $n_{t-1}$ and incurs costs,

$$\Phi(n_t, n_{t-1}) = \frac{\phi}{2} (n_t - n_{t-1})^2,$$

in altering its workforce for production. Next, assume that the firm's production function is quadratic,

$$f(n_t, z_t) = (f_0 + z_t)n_t - \frac{f_1}{2} n_t^2,$$

where $f_0 > 0$, $f_1 > 0$, and $z$ is a serially correlated exogenous productivity process, as is the real wage, $w$. Discounting its future earnings by $\beta \in (0, 1)$ and given initial employment $n_{-1}$, the firm selects $\{n_t\}_{t=0}^{\infty}$ to maximize its expected present discounted value,

$$E \left[ \sum_{t=0}^{\infty} \beta^t (f(n_t - z_t) - w_t n_t - \Phi(n_t, n_{t-1})) | z_0, w_0 \right],$$

arriving at a sequence of Euler equations:

$$\beta E_t n_{t+1} - \left( 1 + \beta + \frac{f_1}{\phi} \right) n_t + n_{t-1} = \frac{w_t - a_t - f_0}{\phi}.$$

If we isolate the two real roots of this second-order stochastic difference equation, the solution is precisely (1) above, with target employment in each date given by

$$N_t^* = \left[ E_t \sum_{j=0}^{\infty} (\beta / \lambda) j (\chi_z z_{t+j} - \chi_w w_{t+j}) \right]$$

(2)

and the parameters $\lambda$, $\chi_z$ and $\chi_w$ determined by the adjustment cost parameter $\phi$, the discount factor $\beta$, and the parameters of the production function.

For researchers implementing equations like (1), an important contribution of Sargent's model was in illustrating how the very features that linked current employment to its lagged determinants also
necessarily divorced each date's target, $N_t^\ast$, from the statically derived optima assumed in early partial adjustment estimations. Notice that the firm's target in (2) involves expectations of each variable affecting the future value marginal product of labour, because, given adjustment costs, this current choice influences its future level of employment. Moreover, as an increase in the adjustment cost parameter, $\phi$, shifts the marginal adjustment cost schedule upward at all dates, it not only implies a slower adjustment rate (lower $\lambda$) but also increases the influence of these expectations of future variables in the determination of the current target.

Across the many models including convex adjustment costs, quadratic cost functions have been by far the most common specification, essentially for sake of tractability. Note that, given the quadratic form of $\Phi(n_t, n_{t-1})$ above, firms' decision rules described by (1) and (2) are linear. As such, they aggregate conveniently to represent economy-wide factor demand in partial adjustment models. (Hamermesh, 1989, and Hamermesh and Pfann, 1996, discuss the role of these costs in partial adjustment models of employment demand. Chirinko, 1993, Hassett and Hubbard, 1997, and Caballero, 1999, survey their use in empirical investment equations. Hall, 2004, estimates an industry-level model of production with quadratic adjustment costs applied to both labour and capital.)

A similar cost function appears in the history of $q$-theoretic investment models, unifying neoclassical investment theory with the theory of Brainard and Tobin (1968) and Tobin (1969), which holds that investment should be positively related to average $Q$, the ratio of the value of the firm relative to its capital stock. Appending the neoclassical model with a general convex adjustment cost function, Abel (1979) moved to reconcile the two theories by showing that the expected discounted marginal value of capital for a firm, marginal $q$, is sufficient to determine its investment rate. The reconciliation was complete when Hayashi (1982) showed that average $Q$ is identical to marginal $q$ if firms are perfectly competitive and both the production function and $\Phi(k', k)$ are linearly homogenous (for example, $\Phi(k', k) = \frac{\phi}{2} \frac{(k' - k)^2}{k}$).

Since the mid-1980s, macroeconomic analysis has become firmly grounded in dynamic stochastic equilibrium analysis. Nonetheless, the gradual movements implied by equilibrium relative price changes have often proven inadequate in reconciling models to data; thus, convex costs have continued to appear. A famous early application to capital adjustment is the industry equilibrium study of investment by Lucas and Prescott (1971). More recently, examples of general equilibrium models adopting these frictions may be found in almost every field of macroeconomics.

### 2 Non-convex costs

Despite their relative success in reproducing the persistence of aggregate series, empirical models based on convex adjustment costs have fared poorly along other dimensions. For example, estimations of the neoclassical investment model attribute very low explanatory power to average $Q$ and assign large coefficients to adjustment cost parameters in explaining changes in investment (Chirinko, 1993; Caballero, 1999). Large estimates of adjustment costs, which in turn imply implausibly slow adjustment speeds, are also a recurring problem for linear quadratic inventory models (Ramey and West, 1999). Elsewhere, the sharp difference between rates of employment adjustment estimated from high-frequency
adjustment costs: The New Palgrave Dictionary of Economics

firm-level data and those estimated from low-frequency aggregate data suggests spatial and temporal bias inconsistent with the common assumption of symmetric quadratic adjustment costs (Hamermesh and Pfann, 1996). Moreover, there is mounting microeconomic evidence suggesting that the predominant adjustment frictions confronting firms in actual economies may be non-convex, rather than convex, in nature.

Contrary to the smooth, continual adjustments implied by convex cost models, recent microeconomic studies reveal that firm-level factor adjustment exhibits long periods of relative inactivity punctuated by infrequent and large, or lumpy, changes in stocks. Examining capital adjustment in a 17-year sample of large, continuing US manufacturing plants, Doms and Dunne (1998) find that roughly 25 per cent of the typical plant's cumulative investment occurs in a single year, and more than half of plants exhibit capital adjustment of at least 37 per cent within one year. Using a similar dataset, Cooper, Haltiwanger and Power (1999) provide additional evidence of lumpy investment, and they show that the conditional probability of a large investment episode rises in the time since the last such episode. Microeconomic evidence of non-smooth employment adjustment is abundant (see Hamermesh and Pfann, 1996). For example, examining monthly data on employment and output across seven US manufacturing plants between 1983 and 1987, Hamermesh (1989) finds that plant-level employment remains roughly constant over long periods while production fluctuates. These long episodes of constancy are broken by infrequent but large jumps, at times roughly coinciding with the largest output fluctuations. (Interestingly, while the convex cost model is inconsistent with the lumpy employment adjustments at each plant, Hamermesh finds that it represents the aggregate of employment – and production – across plants reasonably well.) Beginning with Scarf (1960), a number of theoretical studies have shown that precisely this variety of nonlinear microeconomic adjustment can arise when firms are confronted with non-convex adjustment technologies.

2.1 \((S, s)\) stock adjustment

Scarf (1960) provided the earliest formal analysis of microeconomic adjustment behaviour in the presence of non-convex adjustment costs. There, the adjustment cost was a simple fixed cost, \(\phi > 0\), incurred at any time a firm wished to adjust its stock of inventories. (Beginning with the work of Barro, 1972, and Sheshinski and Weiss, 1977, fixed costs have also been used to develop models of \((S, s)\) firm-level price adjustment. Early studies examining the potential for monetary non-neutralities in such settings include Sheshinski and Weiss, 1983; Caplin and Spulber, 1987; and Caplin and Leahy, 1991. More recent general equilibrium analyses include Caplin and Leahy, 1997; Dotsey, King and Wolman, 1999; Gertler and Leahy, 2006; and Golosov and Lucas, forthcoming.) We briefly review the model below.

Consider a retail firm entering any period with inventories, \(Y > 0\), of a homogenous good available for sale. The firm faces stochastic demand, \(\xi\), drawn from a time-invariant distribution \(F(\xi)\), and the value of its sales is \(p \min \{y, \xi\}\). At the end of the period, it may place an order \(\chi > 0\) to increase its available stock for the next period; \(\dot{Y} = Y - \min\{Y, \xi\} + \chi\). The cost of any such order is \(\phi + c\chi\), where \(c > 0\) represents the unit cost of the good held in inventory. By proving K-concavity of the value function,
Scarf was able to establish that the firm's optimal decision rule takes the following one-sided \((S, s)\) form. (Scarf, 2005, shows this decision rule generalizes to a setting where the firm selectively sells its inventories with the option of leaving some demand unsatisfied. See Dixit, 1993, for a characterization of two-sided \((S, s)\) policies arising in continuous time settings involving fixed and piecewise linear adjustment costs.)

\[
\chi = \begin{cases} 
0 & \text{for } y \in (s, S] \\
5 - y & \text{for } y \leq s 
\end{cases}
\]

To avoid repeatedly incurring fixed costs, the firm places no orders so long as its sales do not move its stock outside the interval \((s, S]\). Only when its inventories have fallen to the lower threshold, \(s\), does it take action, resetting its stock to \(S\). Thus, the increasing returns adjustment technology implied by fixed order costs induces infrequent and relatively large, or lumpy, orders.

Just as firm-level data indicates lumpiness in microeconomic capital and employment adjustment, there are a number of studies suggesting that firms in both manufacturing and trade manage their inventories according to \((S, s)\) policies resembling that obtained in Scarf's path-breaking analysis (for example, Mosser, 1991; Hall and Rust, 2000). Nonetheless, despite the empirical difficulties associated with convex cost inventory models (Blinder and Maccini, 1991; Ramey and West, 1999), the implications of firm-level inventory policies under non-convex adjustment costs have been left relatively unexplored by macroeconomists. To reproduce the relatively smooth changes observed in the aggregate, such models necessarily involve a distribution of firms over inventory levels. As this distribution becomes part of the economy's aggregate state vector, the resulting high dimensionality makes it difficult to determine equilibrium prices, including real wages and interest rates. It is this basic problem that has generally dissuaded researchers from undertaking dynamic stochastic general equilibrium analyses of environments involving non-convexities, among them the \((S, s)\) inventory model.

One exception to this is found in Fisher and Hornstein (2000). Building on the work of Caplin (1985) and Caballero and Engel (1991), who study the aggregate implications of exogenous \((S, s)\) policies across firms, Fisher and Hornstein construct an environment that endogenously yields time-invariant one-sided \((S, s)\) adjustment rules and a constant order size per adjusting firm. This allows them to tractably study \((S, s)\) inventory policies in general equilibrium without confronting substantial heterogeneity across firms. More generally, in models involving time-varying two-sided \((S, s)\) policies, the heterogeneity becomes more cumbersome, as in Khan and Thomas' (2006a) general equilibrium business cycle study. There, at the start of any period, each firm observes the current state and then chooses whether to order intermediate goods for use in production. Given this timing, alongside positive real interest rates, inventories would never be held in the absence of some friction. However, by confronting firms with idiosyncratic order costs independent of their chosen order sizes, continual orders are deterred, and \((S, s)\) inventory adjustment adopted. Based on the results of their calibrated model, Khan and Thomas conclude that such non-convex costs can be quite successful in explaining not only the existence of aggregate inventories but also their cyclical dynamics.
2.2 Implications for aggregate investment

Non-convex adjustment costs imply distributed lags in aggregate series similar to those generated by convex costs, because they stagger the lumpy adjustments undertaken by individual firms in response to shocks (King and Thomas, 2006). However, they are distinguished by their potential for aggregate nonlinearity, which has generated particular interest within investment theory. A number of influential partial equilibrium studies (Caballero and Engel, 1999; Cooper, Haltiwanger and Power, 1999; Caballero, Engel and Haltiwanger, 1995) have argued that investment models with non-convex costs empirically outperform convex cost models because they can deliver disproportionately sharp changes in aggregate investment demand following large aggregate shocks. (Caballero and Engel, 1993, and Caballero, Engel, and Haltiwanger, 1997, arrive at similar conclusions in the context of employment adjustment.)

Caballero and Engel (1999) examine generalized \((S,\star, s)\) policies rationalized by stochastic fixed adjustment costs, \(\varphi\), distributed i.i.d. across firms and over time. In this environment, a firm's capital, \(k\), becomes part of its state vector alongside its total factor productivity, \(z\). Moreover, microeconomic adjustment becomes probabilistic; firms with the same current gap between actual and target capital do not necessarily behave identically; rather, those with relatively low \(\varphi\) draws are more likely to alter their capital than those drawing high costs. If we transform Caballero and Engel's gap-based analysis to reflect the firm-level state, \((k, z)\), the implication is an adjustment hazard, \(\Lambda(k, z)\), indicating what fraction of each group of firms sharing a common current state will choose to adjust their capital to a common target, \(k^*(z)\). The resulting generalized \((S,\star, s)\) adjustment model allows convenient aggregation and has been studied in a variety of settings. (Dotsey, King and Wolman, 1999, apply this basic framework to price adjustment, Thomas, 2002, adopts it in an equilibrium business cycle model with lumpy investment, and King and Thomas, 2006, use it to examine employment adjustment.)

To understand how this mechanism can affect the dynamics of aggregate investment, consider the following simple partial equilibrium example described by Khan and Thomas (2003). Assume that total factor productivity, \(z\), is a Markov process common to all firms. If there have been no aggregate shocks for many periods, the distribution of firms will have support at \(k^*(z)\), \((1-\delta)k^*(z)\), \((1-\delta)^2k^*(z)\), and so on. As a firm's capital stock depreciates further below the target, \(k^*(z)\), the maximum adjustment cost it will accept to reset its capital stock to that target, \(\varphi(k, z)\), rises. Thus, the adjustment hazard, \(\Lambda(k, z)\), is increasing in the distance \(\left|k^*(z) - k\right|\). Finally, the total measure of adjusting firms is \(\int \Lambda(k, z) \mu(\text{d}k)\), and aggregate investment is \(\int \Lambda(k, z) \left(k^*(z) - (1-\delta)k\right) \mu(\text{d}k)\).

Suppose that a negative aggregate shock reduces \(z\) to \(z_L\), thereby reducing expected future marginal productivity of capital. This causes a downward shift in the target stock, placing it strictly within the existing range of capital held by firms. Thus, \(\Lambda(k, z)\) falls for many firms, rising only for those with the highest levels of capital. As a result, the total adjustment rate can actually fall, thereby dampening the fall in aggregate investment demand implied by the reduced target. By contrast, when a positive technology shock raises \(z\) to \(z_H\), the target capital rises above that currently held by any firm. This increases the total adjustment rate, compounding the effect of the raised target to which firms adjust.
More generally, this example illustrates that, when there is an aggregate shock, and thus a change in the target, higher moments of the distribution of capital across firms matter in determining movements in aggregate investment, because the adjustment hazard is a non-trivial function of capital. (This is an important distinction relative to the convex cost/partial adjustment model. Rotemberg, 1987, shows its aggregate dynamics are reproduced by a model where individual firms adjust infrequently, but all face a common probability of undertaking adjustment, independent of their individual states. Given this constant hazard, only the first moment of the distribution is relevant in determining aggregate changes.) Alternatively, in the language of Caballero (1999, p. 841), microeconomic non-convexities can generate an important ‘time-varying/history-dependent aggregate elasticity’ of investment to shocks by allowing changes in the synchronization of firms’ capital adjustments.

Although findings like those above echo throughout partial equilibrium studies involving lumpy adjustments, the omission of market-clearing relative prices (for example, equilibrium interest rates) may be critical to the inferred macroeconomic importance of non-convex factor adjustment costs. Significant aggregate nonlinearities can only occur if adjustment hazards exhibit large changes in response to shocks. Clearly, from the example above, such changes depend entirely on the extent to which \( k^*(z) \) responds to changes in \( z \). However, just as the capital adopted by a representative firm facing no adjustment costs varies far less when prices adjust to clear all markets, Thomas (2002) and Khan and Thomas (2003; 2006b) show that the target capital(s) selected by firms facing non-convex costs exhibit changes an order of magnitude smaller in general equilibrium. Because large movements in target capital, and hence in aggregate investment demand, would imply intolerable consumption volatility for households (at least in the closed-economy settings examined in these studies), they do not occur in equilibrium. Instead, small changes in relative prices serve to discourage sharp changes in \( k^*(z) \), thereby preventing large synchronizations in firms’ investment timing and leaving the aggregate series largely unaffected by the microeconomic lumpiness caused by non-convex adjustment costs.

3 Piecewise-linear costs

Among the adjustment frictions commonly applied in macroeconomic research, we have thus far omitted an important type of convex costs, namely, piecewise-linear adjustment costs, which are often associated with partial irreversibilities in investment and employment. As these costs have quite different implications from those described in section 1, we briefly discuss them here. Like non-convex costs, piecewise-linear costs lead to (\( S, \cdot s \)) decision rules. However, as they yield no increasing returns in the adjustment technology, they do not in themselves cause lumpiness. Rather, when the firm’s relevant state variable reaches the lower or upper bound of its tolerated region of inaction, the firm undertakes small adjustments to maintain it at that bound. (To explore the extreme case of complete irreversibility, see Pindyck, 1988, for an analysis that emphasizes the option value of waiting to invest, or Bertola, 1998, for a characterization of firm decision rules using standard dynamic programming. Dixit and Pindyck (1994) provide a comprehensive survey of this literature.)

Partial irreversibilities have been widely examined in investment theory as an explanation for the common empirical finding that investment is insensitive to Tobin’s q. Abel and Eberly (1994) characterize firm-level investment when the purchase price of capital, \( p_K^+ \), exceeds its sale price, \( p_K^- \).
(and there are flow-fixed and convex adjustment costs). They show that this cost structure makes investment a nonlinear function of marginal $q$, implying a range of values over which the firm does not invest. (Veracierto, 2002, solves a general equilibrium business cycle model where the resale price of capital goods is a constant fraction of the purchase price. Examining a wide range of values for this irreversibility parameter, he concludes that such frictions have no quantitatively significant effects for business cycle dynamics.) Elsewhere, in the context of employment adjustment, a simple example of piecewise-linear costs is an environment where firms incur no adjustment costs in increasing their employment, but pay a tax of $\phi > 0$ per worker fired. The implications of such firing costs for aggregate employment are theoretically ambiguous. While their direct effect is to discourage firing, they also induce a reluctance to hire. Bentolila and Bertola (1990) provide an early analysis suggesting that the direct effect dominates, while Hopenhayn and Rogerson (1993) find the converse.

4 Conclusion

Throughout the history of their use, the primary purpose of adjustment costs has been to reduce the distance between model-generated and actual economic time series. Because they largely represent implicit costs of forgone output, we have little ability to directly measure adjustment frictions. Thus, when we adopt them to enhance the empirical performance of our models, the resulting improvements are, in some sense, a measure of our ignorance.

As suggested by the discussion above, the existence and size of particular adjustment frictions has typically been inferred from the extent to which they modify dynamic behaviour within a specific model to more closely resemble that in the data. This raises an obvious, but sometimes forgotten, point. Adjustment costs derived within a given class of model may be quite inappropriate in a second, distinct class of model. For example, the relative sizes of various types of adjustment frictions needed to reconcile theoretical and actual microeconomic data can differ sharply depending on the specification of equilibrium and firm-level shocks.

Abstract

A market exhibits adverse selection when the inability of buyers to distinguish among products of different quality results in a bias towards the supply of low-quality products. Typically, the average quality of a product supplied by the market depends on the price, possibly resulting in multiple Walrasian equilibria and even equilibria with rationing. Agents have an incentive to trade multidimensional contracts so that informed agents can reveal their quality by the contracts they purchase. Various mechanisms such as price floors and mandatory partial insurance may be used to reduce the market inefficiencies resulting from adverse selection.

Article

Adverse selection refers to a negative bias in the quality of goods or services offered for exchange when variations in the quality of individual goods can be observed by only one side of the market. For instance, suppose sellers of high-quality goods have a higher reservation price than sellers of low-quality goods, but that buyers cannot directly determine the quality of a specific good offered for sale. Then any mix of goods offered for sale at the market price must include the low-quality goods. That is, the market adversely selects for low-quality products.

Adverse selection may appear in any market where either the buyer or the seller has difficulties ascertaining the quality of the product to be exchanged. Examples include resale markets for durable goods where it is difficult for the buyer to identify defects known to the seller, labour markets where the seller has a better idea of his productivity than his potential employer, credit markets where the borrower knows more about her credit worthiness than the seller, and insurance markets where the insured have knowledge about their riskiness that is unavailable to the insurer.

The theoretical study of adverse selection began with the seminal paper by George Akerlof, ‘The Market for “Lemons”’ (1970). In this paper, Akerlof demonstrated how adverse selection could eliminate all trade in otherwise efficient markets. As the title suggests, he illustrated his argument in a stylized model of a market for used cars. Suppose there is a potential supply of $n^*$ cars indexed by a quality parameter $q$ that is uniformly distributed between 0 and 1. Assume that $q$ measures the reservation price of the owner, but that the reservation value of each of the potential buyers is $\frac{3}{2}q$. If both buyers and sellers can observe the quality of each car and there are enough potential buyers, efficiency requires that all cars be exchanged. However, if buyers can observe only the average quality of cars offered for sale at each price, there is no positive price at which cars will be demanded.

The argument is as follows. If buyers cannot observe the quality of individual cars and prices adjust to clear the market, then all cars must sell at the same price $p$. Since an owner offers a car of quality $q$ for sale only if $q < p$, it follows that the supply of cars is $s(p) = n_0 p$ at any price $p$ between 0 and 1 and the average quality of cars at that price is $q^a(p) = \frac{p}{2}$. But since a buyer's reservation value of a car with expected value $q$ is $\frac{3}{2}q$, he purchases at price $p$ only if $q^a(p) > \frac{2}{3}p$. Consequently, demand is $d(p) = 0$ at each price $p$ and the only market clearing price is $p = 0$ with no trade occurring at all.

Akerlof’s example of a zero-trade equilibrium illustrates the most extreme consequence of adverse selection. As demonstrated below, not all trade is necessarily eliminated. However, if goods of different quality are treated as a homogeneous good, several sources of inefficiency may persist. One problem is that the marginal value of a trade may not be equated between buyers and sellers. Since sellers offer any good for exchange that they value less than its price, the value to the sellers of the average product offered for sale is generally lower than the price. In contrast, the uninformed buyers purchase the product to the point where their value of the average car offered for sale equals the price so that their value of the marginal car offered by sellers exceeds the price.

A second source of inefficiency is that the wrong set of cars may be exchanged. In the example above, the net gain from trade of a car with quality \( q \) is \( \frac{q}{2} \) so that the highest-quality cars should be exchanged first. However, if all cars are sold at the same price, lower-quality cars will always be supplied before higher-quality cars. In general, this inefficiency depends on our assumptions regarding preferences. In a dynamic model in which the market for used cars arises endogenously, Hendel and Lizzeri (1999) argue that buyers of used cars generally value increases in quality less than sellers. Consequently, in their model the sale of the lowest-quality cars is relatively efficient and measures to increase the volume of trade may be counterproductive.

A third source of inefficiency emerges when the preferences of buyers are heterogeneous so that high-quality cars should be allocated to quality-intensive buyers. In this case, even if the efficient set of goods were exchanged, the random allocation of cars among buyers implies that buyers and sellers would not be correctly matched.

All of these sources of inefficiency can be illustrated with a slight modification to Akerlof’s example. Suppose we change the distribution of the \( n_s \) cars so that \( q \) is uniformly distributed between 1 and 5. Then, at any price \( p \) between 1 and 5, the supply of cars is \( S(p) = \frac{p-1}{4} n_s \) and average quality is \( q^*(p) = \frac{1+p}{2} \). At any price \( p > 5, S(p) = n_s \) and \( q^*(p) = 3 \). On the demand side, we suppose there are two types of buyers. For a car of quality \( q \), low-intensity buyers are willing to pay \( \frac{3}{2} q \) and high-intensity buyers are willing to pay \( 2q \). Consequently, the demand function has two steps. Low-intensity buyers are just indifferent to buying a car at price \( p = 3 \) where \( \frac{3}{2} q^*(p) = p \). For high-intensity buyers, the point of indifference is at \( p = 6 \). Consequently, if there are \( n_L \) low intensity buyers and \( n_H \) high intensity buyers, demand is

\[
D(p) = \begin{cases} 
  n_L + n_H & \text{for } p < 3 \\
  n_H & \text{for } 3 < p < 6 \\
  0 & \text{for } p > 6 
\end{cases}
\]

At prices 3 and 6, demand is a correspondence. Figure 1 illustrates two possible relations between supply and demand depending on the relative number of buyers and sellers. The supply curve labelled \( S'(p) \) corresponds to a case where \( n_s < n_H \) so that the market clears at price \( p = 6 \). At this price, all cars are sold to high-intensity buyers, and the corresponding allocation is Pareto efficient. The supply curve labelled \( S(p) \) corresponds to the case where \( n_H < \frac{n_s}{2} < n_L + n_H \) so that the market clears at price \( p = 3 \). At this price, only cars of quality \( q < 3 \) are sold and every active buyer receives a car of expected quality \( q^*(p) = 2 \). Figure 1

An inefficient Walrasian allocation

![Diagram illustrating the relationship between supply and demand]
Observe that this allocation exhibits all of the sources of inefficiency that were identified above. First, not all potential buyers purchase a car even though half of the cars remain unsold, all of which are more valuable to buyers than to owners. Second, the cars that are sold provide the least possible net benefit to buyers. If only half of the cars are to be sold, efficiency requires they be the highest-quality cars. Third, since all buyers purchase from the same pool of cars, the cars that are sold are not efficiently allocated among buyers. Since high-intensity buyers value quality more than low-intensity buyers, the efficient allocation of these cars requires that the high-intensity buyers receive the cars with the highest quality. Given the asymmetry in information, there is typically no incentive-compatible mechanism that achieves first-best efficiency. However, there may be instruments or mechanisms that may increase net surplus and in some cases even generate a Pareto improvement. For instance, for supply curve $S(p)$ a subsidy on sales would increase the volume of trade. However, the resulting allocation would not be completely efficient since low-quality cars are still sold before high-quality cars and both types of buyers still purchase from the same pool of cars. We explore below some other mechanisms that may be used to further improve efficiency.

**Multiple Walrasian equilibria**
The examples above have a unique Walrasian equilibrium. However, since average quality increases with price, it is possible that over some range of prices demand may also increase with price. As a consequence, there may be multiple market clearing prices, which can be Pareto ranked. We can illustrate this possibility in an example with one type of buyer and just two types of sellers.

Suppose half of the \( n_s \) sellers own cars of quality \( q = 1 \) and half own a car of quality \( q = 2 \). Since low-quality sellers supply cars at any price \( p \) at or above \( p = 1 \), and high-quality sellers supply cars at any price \( p \) at or above \( p = 2 \), it follows that average quality jumps from 1 to \( \frac{3}{2} \) at price \( p = 2 \). As above, suppose that each of the \( n_B \) buyers is willing to pay for a car of quality \( q \). Then \( D(p) = n_B \) for \( p < \frac{3}{2} \), but then falls to zero until the high-quality sellers enter the market at price \( p = 2 \). At this price, \( q^a(p) \) rises to \( \frac{3}{2} \) and all buyers again enter the market until \( p \) rises to \( \frac{9}{4} \), after which price exceeds the buyers’ reservation value and \( D(p) \) falls back to zero. The result is a non-monotonic demand function and consequently it is possible that there is more than one market clearing price.

In this example, multiple Walrasian equilibria arise whenever the number of buyers exceeds the total number of cars. Such a case is illustrated in Figure 2, where demand \( D(p) \), indicated by the heavy dotted line, intersects \( S(p) \) at prices \( \frac{3}{2} \), 2, and \( \frac{9}{4} \). All cars are sold at price \( p = \frac{9}{4} \), while only low-quality cars are sold at price \( p = \frac{3}{2} \). In both cases, \( p = \frac{3}{2} q^a(p) \) so that buyers are just indifferent to purchasing a car. There is also a Walrasian equilibrium at price \( p = 2 \), but to clear the market only half of the owners of high-quality cars supply their cars. As a result, average quality is reduced to \( \frac{3}{4} \) so that buyers are again just indifferent to purchasing at that price.

Figure 2

Multiple Walrasian equilibria
Observe that the allocations at these three prices may be Pareto ranked. Although buyers are indifferent to each of the prices, some or all sellers strictly benefit from selling at a higher price. In a more general model with heterogeneous buyers, Wilson (1980) shows that buyers also benefit from buying at a higher price.

**Pareto improving price floors**

Because of the dependence of average quality on price, it is sometimes possible to achieve an additional Pareto improvement by setting a price floor and rationing the excess supply of cars. Consider again the example illustrated in Figure 2. If we reduce the number of buyers to \( m_B \) where \( \frac{n_S}{2} < m_B < n_S \), then we obtain a demand curve like \( D'(p) \), illustrated by a heavy solid line. In this case, there is only one Walrasian equilibrium at price \( p = \frac{3}{2} \). At this price, only low-quality cars are offered for sale and buyers gain no net benefit.

Now suppose that we impose a floor ceiling at some price \( p^* \) between 2 and \( \frac{9}{4} \). Since high-quality cars are also supplied at this price, average quality rises to \( q^a(p^*) = \frac{3}{2} \) which provides any buyer with a positive net benefit. Since there are more sellers than buyers at this price, sales must be rationed. Nevertheless, owners of both low-quality and high-quality cars benefit from selling at this price. Owners of high-quality cars benefit because the Walrasian price is below their reservation value. And since more than half of the cars are sold at this price, the expected return to low-quality sellers is also higher at price \( p^* \). At the Walrasian price \( p = \frac{3}{2} \), their net benefit from a sale is \( \frac{1}{2} \), while at the price floor \( p^* > 2 \), their net benefit from a sale is at least 1.

**Uninformed price setters and rationing**

Our analysis so far has focused on primarily on Walrasian allocations. In a frictionless economy with perfect information and a large number of competing agents, this solution is generally robustly independent of the mechanism or conventions by which the price is set. However, once we introduce asymmetries in information, the opportunity for market participants to exploit the relation between quality and price or to indirectly identify products of different quality may lead to different market behaviour. To study these effects, we need to be more explicit in specifying the mechanism by which trade takes place.

Consider a market mechanism in which each buyer fixes a price at which he is willing to buy. To sell their cars, sellers first queue at the highest announced price. Any excess supply then spills over to successively lower-price offers until the supply of cars is exhausted or there are no more offers to buy. Buyers who announce a price below the point at which supply is exhausted do not obtain a car.
Suppose that all buyers value a car of quality \( q \) at \( \frac{3}{2} q \). Then, without regard to market conditions, each buyer prefers the price \( p \) that maximizes his or her net benefit \( \frac{3}{2} q^2 (p) - p \). However, such a price \( p \) is an equilibrium only if there is no excess demand at that price. As in a standard Bertrand game, rather than face rationing, buyers prefer a small increase in the price so that they can buy a car with certainty. Consequently, the equilibrium strategy for buyers is to set the price that maximizes net benefit \( \frac{3}{2} q - p \) subject to the constraint \( D(p) \leq S(p) \).

Figure 2 illustrate two types of solution to this problem. For the case where the number of buyers is \( n_B > n_S \), represented by the heavy dotted demand curve \( D(p) \), the equilibrium price is \( p = \frac{9}{4} \), which is the highest Walrasian price. At this price, all cars are sold to buyers who are just indifferent to purchasing a car. For the case where the number of buyers \( m_B \) satisfies \( \frac{n_S}{2} < m_B < n_S \), the equilibrium price is \( p = 2 \) (or slightly above to ensure that all owners supply their cars). All buyers demand a car and all owners supply a car. But since there are more sellers than buyers, the sellers must be rationed. With heterogeneous buyers, Wilson (1980) shows that more than one price may be announced in equilibrium. In this case, sellers are rationed at all but possibly the lowest announced price.

A mechanism in which uninformed agents set the price may not be applicable for most resale markets for durable goods. However, it may explain some pricing strategies in financial markets where the uninformed agents are large institutions such as banks. Stiglitz and Weiss (1981) implicitly use this price-setting mechanism in their study of credit rationing. In their model, banks supplying loans correspond to the uninformed buyers of the used car market, and the creditors, who know better their idiosyncratic riskiness, correspond to the car owners. Because creditors have only limited liability in the case of default, risky borrowers demand loans at higher interest rates than do less risky borrowers. So, if the demand for loans is sufficiently large, only risky borrowers are served at the Walrasian rate of interest. In such a case, it may be more profitable for banks to lower their interest rate to attract low-risk borrowers, even though they must ration their limited supply of funds among the resulting increased demand.

**Informed price setters**

In markets for products such as used cars, a mechanism in which sellers are responsible for setting the price may be of more interest. For example, consider the price-setting convention in which all sellers simultaneously announce prices for their cars, after which each buyer submits a bid at one of these prices. If demand does not equal supply at any price, the long side of the market is rationed. Since the informed agents act first, this mechanism is essentially a signalling game, first introduced by Spence (1973) and later formalized by Cho and Kreps (1987) and others.

Consider again the example above with two types of sellers, half with cars of quality \( q = 1 \) and half with cars of quality \( q = 2 \), and one type of buyer who is willing to pay \( \frac{3}{2} q \) for a car of quality \( q \). Assume also that there are more potential buyers than sellers. As in many signalling models, there is a continuum of sequential equilibria for this game. We focus here on two possible outcomes. One possibility is a pooling equilibrium in which each seller announces price \( p = \frac{9}{4} \), and exactly \( n_S \) buyers bid to purchase at that price, resulting in a Walrasian allocation. Buyer behaviour is optimal since each buyer is indifferent between buying and not buying, and seller behaviour is optimal if buyers believe that average quality will not increase at higher prices.

A second possibility is a separating equilibrium that involves rationing at some prices. In this equilibrium, low-quality sellers announce price \( p_L = \frac{3}{2} \) and high-quality sellers announce price \( p_H = 3 \). Exactly \( \frac{n_S}{2} \) buyers bid at price \( p_L \), so that demand exactly matches supply and low-quality sellers sell with probability 1. However, at price \( p_H \), only \( \frac{n_S}{3} \) (or fewer) buyers bid so that high-quality sellers sell with probability at most \( \frac{1}{4} \). Observe that at each price buyers are just indifferent between purchasing and not purchasing. Each seller is also acting optimally, since high-quality sellers would suffer a loss by selling at \( p_L \), while low-quality sellers prefer to earn a net gain of \( \frac{3}{2} \) with certainty at price \( p_L \) rather than a net gain of 2 with probability less than or equal to \( \frac{1}{4} \) at price \( p_H \). A general analysis with heterogeneous buyers is provided in Wilson (1980).

It is not obvious how expectations and prices would adjust to sustain the separating equilibrium in this example. However, the example does illustrate how market participants may use another dimension, in this case the probability of selling, to identify products of different quality, albeit at some cost. The key ingredient is that sellers of different-quality cars face a different tradeoff between price and the probability of selling. In general, there may be other dimensions in which the preferences of informed agents differ. In such a case the market may exploit multidimensional contracts to identify product quality. A market for insurance provides a good example.

**Self-selection in insurance markets**

http://www.dictionaryofeconomics.com.proxy.library.csi.cuny.edu/article?id=pde2008_A000040&goto=a&result_number=12}
In its most primitive form, an insurance policy consists of two elements, the price of coverage and the level of coverage. Although all consumers prefer a lower price to a higher price and prefer more coverage to less coverage, their tradeoff between price and quantity depends on the probability of a payout. Consequently, by offering contracts which differ in both price and the level of indemnity, sellers may be able to indirectly identify different risk classes of consumers who otherwise appear to be a homogeneous population. Some of the implications of competition in these kinds of contract can be illustrated in a simple model first studied by Rothschild and Stiglitz (1976) and Wilson (1977).

Suppose there are two types of insurance consumers. Each consumer has the same risk-averse von Neumann–Morgenstern utility $u$, the same initial wealth $W$ and the same reduction in wealth to $W - 1$ in case of an accident. Low-risk types have an accident with probability $\pi_L$ and high-risk types have an accident with probability $\pi_H$, where $\pi_L < \pi_H$. An insurance policy may be represented as pair $(p, t)$, where $t$ is the indemnity in case of an accident and $p$ is the premium. Therefore, a consumer who purchases policy $(p, t)$ is left with $W - 1 - p + t$ if he has an accident and $W - t$ if he does not. Suppose that each individual can identify his own risk type but that firms know only the proportion $\alpha$ of low-risk types. Let $\bar{\pi} = \alpha \pi_L + (1 - \alpha) \pi_H$ denote average probability of an accident among both types of consumers. To allocate the policies, we suppose that the uninformed firms are Bertrand price setters that earn zero profit for any policy that is actuarially fair.

The model is illustrated in Figure 3, where the vertical axis represents the premium and the horizontal axis represents the level of coverage. The vertical line at $t = 1$ represents the set of policies that provide full indemnity. The lines labelled $\pi_L$ and $\pi_H$ represent the set of actuarially fair policies for the low- and high-risk types respectively. The line labelled $\pi^a$ represents the set of policies that break even if both types purchase it. The curves labelled $v_L$ and $v_H$ represent typical indifference curves for the two risk types. Although both risk types prefer more coverage and a smaller premium, high-risk types have a higher marginal rate of substitution (MRS) of premium for indemnity than do low-risk types at any policy. At any full insurance policy, the MRS of each type is equal to their probability of an accident.

Figure 3

Equilibrium in an insurance market
Suppose first that firms may offer only policies that provide full coverage so that $t = 1$. In this case, the model is exactly analogous to the used-car example above when the uninformed buyers are price setters and there are more buyers than sellers. Consumers demand insurance policy $(p, 1)$ only if their expected utility from purchasing exceeds their expected utility from remaining uninsured. The policy $\beta_H = (\pi_H, 1)$ represents the full insurance policy that just breaks even for the high-risk types. For the case illustrated here, the low-risk types would also demand insurance at this price. Consequently, the unique Bertrand equilibrium is the policy $\beta^a = (\pi^a, 1)$, which just breaks even when purchased by both risk types. In effect, low-risk types are subsidizing the high-risk types.

Now suppose that firms may also compete in the indemnity dimension. To begin, we also suppose that each firm may offer only one insurance policy to its customers. Observe that the equilibrium policy under mandatory full coverage is not an equilibrium for this game. The reason is that, if some firm deviates and offers a policy near $\beta^L$ above the $\pi^L$ line and behind the $v_H$ curve, it attracts only low-risk types and earns a positive profit. But if low-risk types are attracted away from policy $\beta^L$, it earns negative profits.

The only possible equilibrium is a separating allocation in which some firms offer policy $\beta^H$, which is purchased by high-risk types, and some firms offer policy $\beta^L$, which is purchased by the low-risk types. Equilibrium requires that the policy purchased by each risk type lie on its own zero profit line. Otherwise, firms may exploit the differences in the preferences of the two risk types to offer a policy that attracts only the risk class that earns positive profits. Competition among firms must then lead to the best zero-profit policy for the high-risk types and the best zero-profit policy for the low-risk types, subject to the self-selection constraint for high-risk types to choose policy $\beta^H$.

If the aggregate zero profit line $\pi^a$ lies above the low-risk indifference curve that passes through the low-risk policy $\beta^L$, as illustrated in Figure 3, then equilibrium exists. Both policies lie on their respective zero-profit lines and each consumer selects his optimal policy from the available set. If any firm deviates with a new policy offer that attracts only the high-risk types, it must lie below the $\pi_H$ line and consequently earn negative profits. However, any new policy that attracts the low-risk types cannot earn positive profits unless it also attracts the high-risk types. But any such policy earns positive profit only if it lies above the $\pi^a$ line, which in turn attracts only the high-risk types.

If the aggregate zero-profit line intersects the low-risk indifference curve passing through $\pi^L$, as illustrated by the dotted line labelled $\pi^c$ in Figure 3, then there is no equilibrium for this game. In this case, a firm may offer a policy just above $\beta^c$ that attracts both types of consumers and still makes positive profits in the aggregate. If we permit individual firms to offer a menu of contracts as in Miyazaki (1977), then equilibrium fails to exist under an even wider range of parameters. A number of authors have suggested alternative solution
Efficient public provision of insurance

Consider the case where \((\beta_L, \beta_H)\) is an equilibrium. The low-risk types are made better off than under the equilibrium with mandatory full coverage by lowering their indemnity to segregate themselves from the high-risk types. But high-risk types are worse off since they must now pay the actuarially fair value of their coverage. Clearly, this allocation is not first-best efficient since an increase in the coverage of the low-risk types at an actuarially fair rate makes them better off. Consequently, it may be possible to increase the welfare of both types by introducing a menu of policies in which the low-risk types subsidize the high-risk types. Such an allocation is represented by policies \(\gamma_L\) and \(\gamma_H\) as illustrated in Figure 4.

Figure 4

The public provision of insurance
To see that the policies are actuarially fair in the aggregate, observe that they can be constructed by decomposing each policy into a common policy $\gamma^a$ that lies on the aggregate zero-profit line and then supplementing the coverage of each risk type with an additional policy that lies on their respective isoprofit line that passes through policy $\gamma^a$. One way to implement such an allocation is for the government to provide policy $\gamma^a$ to all consumers and then let the market supply the supplementary policies. Furthermore, by choosing the appropriate policy $\gamma^a$, this mechanism may be used to attain any constrained Pareto-optimal allocation (subject to the self-selection constraints and aggregate zero-profit condition). In this case, the supplementary pair of policies required to attain allocation $(\gamma_L, \gamma_H)$ is necessarily an equilibrium so there is no need to appeal to alternative solution concepts to ensure the existence of an equilibrium.

Abstract

Empirical studies suggest that advertising is not an important determinant of consumer behaviour and that advertising follows rather than leads cultural trends. On the core issue of whether advertising is anti- or pro-competitive, the evidence suggests that advertising is associated with lower prices.

Keywords

advertising; concentration; market structure; entry

Article

Advertising has been controversial, probably more so that its economic importance would justify, at least since the emergence of the mass media in the 19th century. In the United States, advertising spending in the second half of the 20th century was just above two per cent of GDP. This ratio grew slowly over time; it is much lower in most other countries, especially in developing nations. In the United States and elsewhere, the ratio of advertising to sales varies dramatically among industries, even if attention is limited to industries selling consumer goods and services.

Chamberlin's Theory of Monopolistic Competition (1933) was the first major work in economics to treat advertising formally, but its analysis led to few definite positive or normative conclusions. Perhaps reflecting the traditional distaste for advertising in the intellectual community, most early discussions of advertising by economists were generally critical, describing it as wasteful, manipulative, and anti-competitive. Its main redeeming feature was that it provided a source of revenue for the press (Kaldor, 1950, is a leading example). Most writers are less enthusiastic about the relation between advertising and the media, perhaps because of the rise of television.
We still know relatively little about how advertising affects consumer behaviour. Some writers distinguish between informative and persuasive advertising. Buyers are assumed to respond rationally to informative advertisements, while persuasive advertisements are somehow manipulative. But this distinction is of little value empirically: few if any advertisements present facts in a neutral fashion with no attempt to persuade, and even those with no obvious factual content signal to consumers that the seller has invested money to get their attention.

Following Nelson (1974), a number of authors have explored the possibility that advertising affects behaviour through such signals. The core of the argument is that advertising is more profitable for high-quality than low-quality producers, all else equal, since the former are more likely to enjoy repeat sales. In sharp contrast, information processing models of human behaviour, explored in the marketing literature, suggest that advertising may affect behaviour mainly by enhancing a brand's chances of being on the short list ('evoked set') from which final choices are made.

It seems likely that the role of advertising varies considerably, depending on the characteristics of products and distribution systems. In some markets advertised brands sell for substantially more than physically identical unadvertised brands; in others, restrictions on advertising serve to increase prices (Benham, 1972). Porter (1976) has argued that advertising is less powerful when retailers are an important source of consumer information. The extent to which a buyer can judge quality prior to purchase (Nelson, 1974) should also affect the role of advertising. Similarly, buyers need more information to make decisions about new products than about established products, and advertising by retailers generally provides more price information than advertising by manufacturers.

Econometric analysis of the effects of advertising on consumer spending patterns is difficult because advertising is endogenous; it reflects sellers’ decisions. This gives rise to simultaneous equations problems (Schmalensee, 1972). Survey evidence suggests that firms often follow percentage-of-sales decision rules in determining advertising budgets. If this were strictly true, the effect of advertising on sales would be impossible to identify. In fact, advertising-sales ratios are not constant over time, but it is difficult to find seller-related variables that explain the variations well. To the extent that advertising spending is based to some extent on actual or anticipated sales, but demand equations are estimated via least squares because the advertising spending decision cannot be modelled adequately, the importance of advertising as a determinant of consumer behaviour will be overstated.

Borden's (1942) massive study of the effects of advertising on demand concluded that advertising is not generally an important determinant of industry sales. Exceptions arise in new and growing sectors, where advertising can serve to accelerate growth that would occur in any case. Recent work seems generally to support these conclusions (see, for instance, Lambin, 1976). At the aggregate level, advertising tends to lag cyclical changes in total consumption slightly, not to lead those changes (Schmalensee, 1972, ch. 3). At the other extreme, while advertising is generally found to affect market shares, dollar advertising spending typically explains little of the variation in shares over time. This presumably reflects in part the fact that designing effective advertising themes and campaigns remains much more an art than a science.

Overall, advertising does not emerge from the empirical literature on consumer demand as an important determinant of consumer behaviour. Some have argued that advertising has fostered the long-run growth of materialism, but nobody has offered anything like a rigorous test of this proposition. Most practitioners contend that advertising follows rather than leads cultural trends, in part because most
advertisers are reluctant to appear out of step with society.

Seller behaviour

All else equal, one would expect sellers to spend more on advertising in markets in which demand is more responsive to advertising, and one might expect demand to be more responsive when consumers need more information to make rational decisions (see Schmalensee, 1972, ch. 2). But we observe very intensive advertising, without much obvious factual content, of some products with which consumers are generally familiar, such as beer and soft drinks.

To the extent that advertising's effects persist over time, advertising outlays are an investment, and advertising budgets must be set using dynamic optimization methods (Sethi, 1977). The greater the profit on additional sales (that is, the greater the gap between price and marginal cost), the more intensively it pays to advertise. Finally, advertising decisions by oligopolists must take into account the strategies of their rivals.

Consideration of these last two points indicates that the intensity of advertising may rise or fall with increases in market concentration (Schmalensee, 1972, ch. 2). On the one hand, reductions in the number of sellers would be expected to reduce the intensity of all forms of rivalry, and thus to reduce advertising spending. On the other hand, if sellers in concentrated markets manage to raise prices far above marginal costs, they thereby enhance incentives to advertise.

Advertising competition can serve to erode excess profits. With a fixed number of sellers, it is likely to be more effective at doing so the more sensitive market shares are to differences in advertising outlays. Greater sensitivity encourages all sellers to advertise more without necessarily increasing the size of the market for which they are competing.

The evidence on scale economies in advertising is mixed. On the one hand, there is little or no evidence that doubling the number of advertisements seen by buyers will more than double the impact on demand. On the other hand, some media offer bulk discounts. And some media, particularly network television in the United States, are such that the minimum required outlay is large in absolute terms. This may serve to disadvantage small sellers by effectively denying them the use of these media.

Economic welfare

One must distinguish between global and local welfare analysis in this context. Global analysis is concerned with questions like ‘could one ban advertising (everywhere or in some particular market) and make society better off?’ Local analysis deals with questions like ‘would society be made better off by a reduction in the level of advertising spending (everywhere or in some particular market)?’

Global questions are difficult to treat formally and thus have not been answered rigorously. Since advertising provides some information, one must specify how information would be provided if advertising were banned. In principle an omniscient bureaucrat can provide information to perfectly rational consumers optimally, so that a properly administered advertising ban can do no harm. In practice, bureaucrats are far from omniscient, and the way in which information is presented to consumers affects the extent to which they retain and use it. Advertisers have every incentive to present information effectively, though they rarely have any incentive to present all information that might
Advertising, like democracy, is terrible in principle but better than any known alternative in practice. Note also that advertising is practised, though not intensively by US standards, in socialist economies.

Local questions about the optimality of advertising are more susceptible of formal treatment. There are as many answers to these questions as there are papers that address them, however. The answers depend critically on exactly how advertising is assumed to affect behaviour. Butters (1977), for instance, assumes that advertising simply provides price information. He concludes that market-determined advertising levels are optimal if buyers cannot engage in search but are excessive if search is possible. Dixit and Norman (1978) assume that advertising simply changes tastes. If pre-advertising tastes are assumed to be socially ‘correct’, a value-laden assumption, they show that advertising is generally socially excessive.

In general the literature offers no support for a presumption that market-determined advertising levels are socially optimal. But it also fails to provide any workable scheme for regulating those levels in the public interest.

**Market structure**

Discussions of the effects of advertising spending on the evolution of market structure have been dominated by two extreme views. Advertising’s critics (for example, Kaldor, 1950) stress its persuasive nature, argue that it builds loyalties and thus reduces price elasticities of demand within markets, and contend that it is a source of barriers to entry. Beginning with Telser (1964), advertising’s defenders stress its role as a source of information, argue that it provides knowledge of alternatives and thus increases elasticities, and contend that it is a means of effecting, not deterring, entry. Since the role of advertising seems to vary considerably among markets, neither of these extreme views is likely to be universally correct.

As a theoretical matter, the impact of advertising spending on price elasticities and barriers to entry depends, once again, on exactly how advertising is assumed to affect consumer behaviour. A good deal of empirical work has attempted to choose between the two extreme views outlined above, without producing any definitive results (see Camanor and Wilson, 1979, for a survey).

Many studies have examined the cross-section correlation between advertising and seller concentration; none has provided a satisfactory interpretation of this statistic. Telser (1964) found market shares to be less stable in markets with heavy advertising than in other markets, and Lambin (1976) found price elasticities to be lower in such markets. But neither study controlled for the product characteristics that affect share stability, price elasticity, and sellers’ advertising spending decisions.

The clearest empirical regularity to emerge from this work is the strong, positive cross-section correlation between industry-level measures of advertising intensity (typically the advertising–sales ratio) and accounting measures of profitability. This stylized fact would seem to favour advertising’s critics.

But profits are high when price–cost margins are large, and large margins encourage advertising (Schmalensee, 1972, ch. 7). Since it is difficult to model advertising spending decisions empirically, it is difficult to deal adequately with this simultaneous equations problem. Moreover, accounting measures of profit treat advertising as an expense, but it should be treated as a durable investment if its effects on
demand persist over time. If those effects are assumed to be very long-lived, correcting the accounting profitability figures eliminates the correlation with advertising. Unfortunately, like so much in this area, the longevity of the impact of advertising on demand remains controversial.

New empirical developments

The core empirical question in the economics of advertising is whether its presence is anti- or pro-competitive. Beginning with Benham (1972), a number of studies have compared prices across US states that do and do not prohibit advertising (for example, Cady, 1976; Kwoka, 1984). Because of the concern that advertising prohibitions may be the result of concerted effort among firms, the effectiveness of which may be correlated with their ability to collude, other studies have considered changes in advertising regimes over time. Thus Glazer (1981) exploits a newspaper strike in New York City, which impeded advertising by supermarkets (but not small grocery stores, which do not generally advertise) in most but not all of the city, while Milyo and Waldfogel (1999) trace the pattern of prices in Rhode Island and neighbouring Massachusetts around the time the US Supreme Court struck down a law prohibiting liquor store advertising in Rhode Island. Devine and Marion (1979) published supermarket prices in Ottawa during a five-week period, and compared prices during that period to prices before and after and in Winnipeg. In none of these studies, whether cross-section or event study, are prices higher in the advertising regime. Typically they are lower, and, typically within the advertising regime, prices of advertised products are lower than those not advertised. A different approach is taken in Ackerberg (2001), where it is shown that only consumers who have not previously purchased a newly introduced yogurt are affected by advertising, and from which the author concludes that advertising in this instance is informative.

affine term structure models

Michael W. Brandt and David A. Chapman
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

An affine term structure model hypothesizes that interest rates, at any point in time, are a time-invariant linear function of a small set of common factors. This class of models has proven to be a remarkably flexible structure for examining the dynamics of default-risk free bonds, and as a result affine modelling has become the dominant framework for term structure research since the early 1980s.

Keywords

affine term structure models; arbitrage opportunities; bonds; Brownian motion; continuous-time models; expectations hypothesis; generalized method of moments; Itô integral; liquidity preference; maximum likelihood; multifactor models; Ornstein–Uhlenbeck processes; preferred habitat theory; principal components; single-factor models; state price deflators; term premiums; term structure of interest rates; zero-coupon bonds

Article

The term structure of interest rates refers to the relationship between the yields-to-maturity of a set of bonds and their times-to-maturity. It is a simple descriptive measure of the cross-section of bond prices observed at a point in time. An affine term structure model hypothesizes that the term structure of interest rates at any point in time is a time-invariant linear function of a small set of common state variables or factors. Once the dynamics of the state variables and their risk premiums are specified, the dynamics of the term structure are determined.

For the term structure of interest rates to be meaningful, the bonds being compared must have similar risk and payout characteristics. The literature we examine in this article focuses on the term structure of default-risk free nominal bonds that make a single payment at a pre-specified future date – so-called zero-coupon bonds. The models described below can be applied to other types of bonds, but zero-coupon bonds are particularly important because they represent the fundamental discount rates
embedded in all financial claims that make payments through time. The literature on term structure modelling is large and reaches back to some of the giants of early 20th century economics: Fisher, Hicks, and Keynes. The pre-eminent model of the term structure, prior to the advent of affine models, was the expectations hypothesis. While the expectation hypothesis exists in a variety of forms (see Cox, Ingersoll and Ross, 1981), most researchers today use the definition of Campbell (1986) and Campbell and Shiller (1991) that the expected returns, or so-called term premiums, on default-risk-free zero-coupon bonds are constant through time. Other commonly espoused early term structure models, namely, the liquidity preference and preferred habitat theories, can be viewed as extensions of the expectation hypothesis that make additional predictions about the size of term premiums as a function of time-to-maturity. Most empirical tests of the expectations hypothesis, including Fama and Bliss (1987) and Campbell and Shiller (1991), find strong evidence against the prediction that term premiums are constant through time. This rejection of the expectations hypothesis implies that the prices of default-risk-free zero-coupon bonds embed time-varying term premiums. Explaining the dynamics of these term premiums is an important goal of affine term structure models. Any affine term structure model starts from the assumption that there are no arbitrage opportunities in financial markets. This assumption implies the existence of a strictly positive stochastic process, \( \Lambda \), that prices all assets. (See Duffie, 2001, for a textbook treatment of the implications of absence of arbitrage for asset pricing in general and term structure modelling in particular.) This process is typically referred to as a state price deflator in continuous-time models of asset pricing or as a stochastic discount factor in discrete-time models. We follow the more common approach in the literature and develop the affine term structure models in continuous time. The existence of a state price deflator also implies that there exists a risk-neutral measure, \( \mathbb{Q} \), which is distinct from the physical measure, \( \mathbb{P} \), that generates observed variation in asset prices. Independent of any specific model of bond prices, it is always possible to express the price at time \( t \) of a zero coupon bond that matures at time \( t + \tau \) as

\[
P_t(\tau) = E^Q_t \left[ \exp \left( - \int_0^\tau r_s ds \right) \right],
\]

where \( E^Q_t [ \cdot ] \) denotes the expected value at time \( t \) under the risk-neutral measure, and \( r \) is the instantaneous rate of interest (or short rate). The short rate can be defined as

\[
r_t = \lim_{\tau \downarrow 0} \ln P_t(\tau),
\]

but it is also related to the expected value of the instantaneous rate of change of the state price deflator because

$$\frac{d\Lambda_t}{\Lambda_t} = -r_t \, dt + \sigma_{\Lambda} (\Lambda_t, t) \, dW^Q_t,$$

(3)

where $W^Q_t$ is a Brownian motion under $Q$, $\sigma_{\Lambda} (\cdot)$ is the possibly time-and state-dependent instantaneous volatility of the state price deflator, and the second term in (3) is a common shorthand notation for an Itô stochastic integral. (See Duffie, 2001, for a textbook treatment of continuous-time stochastic processes, including the definitions of Brownian motion and the Itô integral.)

As eq. (1) clearly shows, pricing zero-coupon default-risk-free bonds boils down to specifying a model for the dynamics of the short rate under the risk-neutral measure. In choosing models for $r_t$, there are two paramount considerations: (a) a flexible specification that does a reasonable job of capturing the dynamics of proxies for the short rate (since $r_t$ itself is unobservable), and (b) a specification that yields a convenient form for the bond prices that are the ultimate objects of interest.

The dynamic of the short rate, when modelled in continuous time, are completely determined by the drift function, which defines the instantaneous expected value of the short rate, and the diffusion function, which determines the instantaneous volatility of the short rate. What is not clear from eq. (1) is that, in order to move from the theoretical risk-neutral measure, $Q$, to the actual (or physical measure), $P$, that generates the observed data, a term structure model must also specify a structure for the risk premium functions controlling the transformation between the measures $Q$ and $P$. While the risk-neutral measure is sufficient for pricing, researchers wanting to fit affine term structure models to observed time-series data or wanting to use these models to forecast future interest rates require also the actual measure.

We can now turn to the basic building blocks (that is, short rate dynamics and market price of risk assumptions) and the main pricing results (that is, exponentially linear bond prices) of affine term structure models. We first present the main points in the context of single-factor models and then generalize the discussion to the multifactor case. Chapman and Pearson (2001), Dai and Singleton (2003), and Piazzesi (2005) are all recent, more detailed, and more technical examinations of the material that follows.

**Single-factor models**

In a single-factor affine model, the determinant of bond prices is the short rate itself. The model is constructed by specifying a continuous-time process for the short rate and a form of the risk premium function. As Cox, Ingersoll, and Ross (1985) note, these choices must be mutually consistent in order to avoid accidentally introducing arbitrage opportunities into a (supposedly) arbitrage-free model. The
fundamental building blocks of all affine models are the single-factor models due to Vasicek (1977) and Cox, Ingersoll, and Ross (1985) (hereafter CIR). The Vasicek model assumes that the short rate evolves as an Ornstein–Uhlenbeck process under the risk-neutral measure

$$dr_t = \kappa(\theta - r_t)dt + \sigma dW_t^Q,$$

where $\kappa > 0$ determines the speed of reversion to the constant mean, $\theta > 0$, and $\sigma$ is the unconditional instantaneous volatility of the process. The conditional and unconditional distributions of interest rate changes are Gaussian in this model. Accordingly, it is possible for the short rate to be negative. The risk premium function is a constant, $\lambda_0$, which implies that the short rate is also Gaussian under the physical measure, $\mathbb{P}$. Solving the conditional expectation in (1) under these assumptions generates an explicit expression for the price of a default-risk free zero coupon bond

$$P_t(\tau) = \exp[a(\tau) + b(\tau)r_t],$$

where

$$a(\tau) = \left(\theta - \lambda_0 \frac{\tau}{\kappa} - \frac{1}{2} \frac{\sigma^2}{\kappa} \right) \left[\frac{1}{\kappa} \left(1 - \exp(-\kappa \tau)\right) - \tau\right] - \frac{\sigma^2}{4\kappa^3} \left[1 - \exp(-\kappa \tau)\right]^2$$

and

$$b(\tau) = -\frac{1}{\kappa} \left[1 - \exp(-\kappa \tau)\right].$$

Equation (5) is the first statement of an exponential-affine pricing function. It implies a simple structure
where continuously compounded yields are Gaussian with constant volatility. The term structure of forward rates implied by this simple model can assume most (but not all) of the commonly observed shapes of the term structure. In particular, the term structure of forward rates can be upward sloping, downward sloping, or humped shaped, although the model cannot generate an inverted humped shape. Since prices at all maturities are driven by a single stochastic factor, this model implies that all yield levels are perfectly correlated. In the data, yield levels are very highly, but not perfectly, correlated. In the single-factor CIR term structure model, the short rate evolves as

\[
dr_t = \kappa(\theta - r_t)dt + \sigma \sqrt{t} dW_t^Q
\]  

where \( \kappa > 0 \) and \( \theta > 0 \) have the same interpretation as in the Vasicek case, but the short rate is no longer Gaussian. The parameter restriction \( 2\kappa\theta \geq \sigma^2 \) is imposed in order to ensure that the short rate process does not get trapped at zero. \( r_t \) has a conditional non-central chi-square distribution (and an unconditional Gamma distribution). The instantaneous conditional variance of the short rate is linear in the level of the rate. The risk premium specification that is consistent with no-arbitrage in the single-factor CIR specification is \( \lambda(r_t) = \lambda r_t \), and the no-arbitrage bond price is, again, of the form (5) with

\[
a(\tau) = \frac{2\kappa\theta}{\sigma^2} \log \left[ \frac{2\gamma \exp\left(\frac{1}{2}\tau(\kappa + \lambda_1 + \gamma)\right)}{(\kappa + \lambda_1 + \gamma)[\exp(\gamma\tau) - 1] + 2\gamma} \right]
\]

\[
b(\tau) = \frac{-2[\exp(\gamma\tau) - 1]}{(\kappa + \lambda_1 + \gamma)[\exp(\gamma\tau) - 1] + 2\gamma}
\]

where \( \gamma = \sqrt{(\kappa + \lambda_1)^2 + 2\sigma^2} \). The CIR model can generate the most common shapes of the term structure, but it still implies that all yield levels are perfectly correlated.

The Vasicek and CIR models are the most common forms of single-factor affine models, but Duffie and Kan (1996) provide the conditions on the drift, diffusion, and risk premium functions of a short rate
specification, like (4) or (8), that ensure that the bond pricing function is exponential-affine under the risk neutral measure. In particular, a pricing function of the form of (5) will follow if

\[ \mu(r_t) - \lambda(r_t) = \rho_0 + \rho_1 r_t \]  
(11)

and

\[ \sigma(r_t) = \sqrt{\beta_0 - \beta_1 r_t} \]  
(12)

hold, where \( \mu(r_t) \) is a general expression for the drift of the short rate and \( \sigma(r_t) \) is a general expression for the instantaneous volatility of the short rate. For example, in the CIR case \( \rho_0 = \kappa \theta, \rho_1 = -(\kappa + \lambda_1), \beta_0 = 0, \) and \( \beta_1 = \sigma^2. \) In this more general case, the \( a(\tau) \) and \( b(\tau) \) functions do not generally have explicit closed-form expressions. Rather, they are defined as the solutions to a pair of ordinary differential equations.

The empirical evidence clearly shows that a single-factor specification is not sufficient to describe the dynamics of the default-risk-free term structure. As such, empirical analysis of simple specifications, like (4) and (8), have shifted away from attempting to completely characterize yields on all maturities and, instead, have concentrated on explaining the dynamics of a proxy for the unobservable short rate. Chan et al. (1992) pioneered this approach, using a simple generalized method of moments estimation scheme. Durham (2003) is the natural evolution of this literature using state-of-the-art approximate maximum likelihood estimation. The conclusions of this literature are: (a) the evidence of mean reversion in the short rate is weak, at best, but (b) there is little consistent evidence of nonlinear mean reversion; and (c) there are complicated volatility dynamics that are not consistent with either constant volatility (Vasicek) or instantaneous conditional variances that are linear in the short rate (CIR).

**Multifactor models**

If single-factor models are insufficient to explain the observed term structure, then how many factors are needed and what are the dynamics of these factors? The common answer to the first question is provided by the analysis of Litterman and Scheinkman (1991). Using a simple principal components approach, they argue that three factors, extracted from bond yields or returns themselves, can explain well over 95 per cent of the variation in weekly changes of US Treasury bond prices, for maturities of up to 18 years. The answer to the second question – in the most general form consistent with an exponential-affine pricing function – is provided by Dai and Singleton (2000) and extended by Duffee (2002).
The multifactor affine term structure model consists of the following components. First, there is linear relation between the short rate and the factors:

\[ r_t = \delta_0 + \delta^t Y_t, \tag{13} \]

where \( Y_t \) denotes the \( N \)-vector of time \( t \) factor realizations. The factor dynamics conform to an affine diffusion

\[ dY_t = \kappa(\theta - Y_t) dt + \Sigma \sqrt{S_t} dW^Q_t, \tag{14} \]

where \( K \) and \( \Sigma \) are \( N \times N \) matrices (with no general restrictions) and \( S_t \) is a diagonal matrix with the \( i \)-th diagonal element equal to

\[ [S^M_t] = \alpha_i + \beta_i^t Y_t. \tag{15} \]

The \( S_t \) matrix allows for the instantaneous conditional variance of the factors to be linear functions of factor levels. If every element of \( Y_t \) can affect the conditional volatility of every other factor, then (14) is a multifactor generalization of the CIR model from the last section. Of course, the fact that volatility is linear in the level of \( Y \) requires strong restrictions on the parameters of the model in order to ensure that variances are non-negative.

If no elements of \( Y \) affect the conditional volatility, then (14) is a multifactor generalization of the Vasicek model. If \( m < N \) factors affect the conditional volatility, then the multifactor affine model is a mixture of the CIR and Vasicek forms. Dai and Singleton (2000) define different classes of affine models by the number of factors that affect the conditional factor volatilities, with \( \Lambda m(N) \) being the general notation for an \( N \)-factor model with \( m \)-factors driving conditional volatilities.

Under these assumptions, bond prices satisfy a multivariate generalization of (5) given by

\[ P_t(\tau) = \exp \{ A(\tau) + B(\tau)^t Y_t \}. \]
The functions $A(\tau)$ and $B(\tau)$ are the solutions to the ordinary differential equations

$$\frac{dA(\tau)}{d\tau} = -\theta^c B(\tau) + \frac{1}{2} \sum_{i=1}^{N} [\Sigma' B(\tau)]^2 \alpha_i - \delta_0$$

(17)

and

$$\frac{dB(\tau)}{d\tau} = -\kappa^c \beta(\tau) + \frac{1}{2} \sum_{i=1}^{N} [\Sigma' B(\tau)]^2 \beta_i - \delta.$$  

(18)

The final component of the general multifactor affine model is the specification of the market prices of risk, which connects pricing under the risk-neutral measure to pricing under the physical measure:

$$\Lambda_t = \sqrt{S_t} \lambda_0 + \sqrt{S_t^-} \lambda Y_t$$

(19)

where $\lambda_0$ is an $N$-vector of constants, $\lambda$ is an $N \times N$ matrix of constants, and $S_t^-$ is an $N$-dimensional diagonal matrix with diagonal elements equal to

$$S_t^-(ii) = \begin{cases} (\alpha_i + \beta_i' Y_t)^{-1/2}, & \text{if } \inf (\alpha_i + \beta_i' Y_t) > 0; \\ 0, & \text{otherwise} \end{cases}$$

(20)
The first term in (19) is a straightforward generalization of the single-factor risk premium specifications: risk premiums are proportional to factor volatilities. The second component is an important source of additional flexibility in multifactor affine models. It allows these models to provide a better fit to the distribution of bond excess returns, and it is also useful in rationalizing the observed violations of the expectations hypothesis discussed above.

The general multifactor affine model can be viewed as a blending of the Vasicek and CIR forms. These extreme specifications also reveal a critical trade-off in multifactor term structure modelling. The CIR form offers the greatest flexibility in specifying the volatility dynamics of bond prices. However, this flexibility comes at a cost. The parameter restrictions that are required to ensure that (15) provides a valid description of factor variances impose substantial restrictions on the permissible correlations between the factors. In the extreme case of the pure multifactor CIR model, the factors must be uncorrelated to ensure an admissible volatility specification.

Dai and Singleton (2002), Duffee (2002) and Brandt and Chapman (2005) fit multifactor affine term structure models to more than 25 years of monthly US bond data. Each paper considers the ability of different versions of $A_m$ (3) models to both explain the rejections of the expectations hypothesis and to provide accurate forecasts of future yields. Both Dai and Singleton (2002) and Brandt and Chapman (2005) find that a Gaussian version (an $A_0$ (3) model) can rationalize the risk premiums dynamics revealed by expectations hypothesis tests. Duffee (2002) demonstrates that an $A_0$ (3) model with the expanded risk premium specification of (19) can produce more accurate yield forecasts than a random walk benchmark model.

Although the ability to explain risk premiums and yield movements is an important success for multifactor affine models, their biggest failing to date is that the favoured Gaussian specifications require that conditional yield volatilities are constant. Essentially, the flexibility in factor correlations that are required to explain these features of the data require a stochastic structure that precludes the volatility dynamics that are an equally important feature of interest rate data.

**Concluding remarks**

Affine models have two important strengths compared with the earlier theories of the term structure. They explicitly rule out arbitrage opportunities in the cross-section of bond prices, and they simultaneously allow for flexible specifications of term premiums and their dynamics. Weaknesses of affine models include the fact that they are typically not easy to estimate, that model specifications which can explain the rejection of the expectations hypothesis are inconsistent with observed volatility dynamics, and that there is generally limited intuition as to the economic interpretation of the factors. Ang and Piazzesi (2003) and Ang, Dong, and Piazzesi (2005) are recent attempts to combine affine term structure modelling with elements of the macroeconomy. This line of research holds out the promise of greater intuition behind the factors as well as a greater understanding of how capital markets perceive the actions of monetary authorities.

affirmative action

Harry J. Holzer and David Neumark
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Affirmative action practices go beyond non-discrimination to enhance employment, education, and business-ownership opportunities for minorities and women. Critics argue that affirmative action does this at the expense of white males who might be more qualified, and so could be both unfair and inefficient. Supporters claim that affirmative action is necessary to overcome the many inherent disadvantages faced by minorities and women, and could enhance efficiency by expanding the pool of available talent or because diversity itself has positive impacts. This article summarizes the evidence for these arguments and claims.

Keywords

affirmative action; black–white wage differences; efficiency; labour market discrimination; labour-market institutions; National Educational Longitudinal Study (NELS); redistribution; women's work and wages

Article

‘Affirmative action’ refers to a set of practices undertaken by employers, university admissions offices, and government agencies to go beyond non-discrimination, and actively improve the economic status of minorities and women with regard to employment, education, and business ownership and growth.

Legal underpinnings and controversies

The roots of affirmative action in employment lie in a set of Executive Orders issued by US Presidents since the 1960s. Executive Order 10925 (issued in 1961) introduced the term ‘affirmative action’, encouraging employers to take action to ensure non-discrimination. Executive Order 11246 (1965) required federal contractors and subcontractors (currently, with contracts of $50,000 or more) to identify
affirmative action: The New Palgrave Dictionary of Economics

underutilized minorities, to assess availability of minorities, and if available, to set goals and timetables for reducing the underutilization. Executive Order 11375 (1967) extended this requirement to women. Federal contractors may be sued and barred from contracts if they are judged to be discriminating or not pursuing affirmative action, although this outcome is rare (Stephanopoulos and Edley, 1995). But affirmative action is not just limited to contractors; it can be imposed on non-contractor employers by courts as a remedy for past discrimination, and it can be undertaken voluntarily by employers. While universities may be bound by affirmative action in employment in their role as federal contractors, there are no explicit federal policies regarding affirmative action in university admissions. Rather, universities have voluntarily implemented affirmative action admissions policies that are widely regarded as giving preferential treatment to women and minority candidates. Court decisions have shaped (and continue to shape) what universities can and cannot do. Preferential admissions policies initially came under attack in Bakke v. University of California Regents (1978), in which the Supreme Court declared that policies that set aside a specific number of places for minority students violated the 14th Amendment of the US Constitution, which bars states from depriving citizens of equal protection of the laws. However, while this decision is viewed as declaring strict quotas illegal, it is also interpreted as ruling that race can be used as a flexible factor in university admissions.

Most recently, the Supreme Court in 2003 struck down the undergraduate admissions practices at the University of Michigan in the case of Gratz v. Bollinger et al., finding that the point system used by the university in its consideration of race (and other criteria) was too rigid. At the same time, in Grutter v. Bollinger et al., it upheld the university's law school admissions procedures, finding that the more flexible treatment of race in this case satisfied the state's compelling interest in expanding the pool of minority candidates admitted to this prestigious school. Affirmative action can also be limited by popular referenda; voters passed Proposition 209 in California in the 1990s, barring the use of racial preferences in admissions to public universities (as well as in state employment and contracting).

The third major component of affirmative action is contracting and procurement programmes. At the federal level, these have principally taken the form of preferential treatment in bidding for Small/Disadvantaged Businesses (SDBs), and Small Business Administration programmes of technical assistance. These contracting and procurement programmes focus more on minorities than on women (Stephanopoulos and Edley, 1995, Section 9). In addition to the federal government, numerous states and localities have used programmes aimed at increasing the share of contracts awarded to minority-owned businesses.

As with affirmative action in education, court rulings since the late 1980s have challenged the legal standing of such programmes. City of Richmond v. J. A. Croson Co. (1989) established that the legal standard of ‘strict scrutiny’ for compelling state interests must be met for state programmes to be legal under the 14th Amendment to the Constitution. In Adarand Constructors, Inc. v. Pena (1995), the Supreme Court ruled that strict scrutiny could apply to federal programmes as well, invoking the Fifth Amendment (which guarantees that citizens shall not ‘be deprived of life, liberty, or property, without due process of law’), instead of the 14th (which explicitly applies to states).

Affirmative action remains vastly more controversial than anti-discrimination activity, even though the distinctions between them are clearer in theory than in practice (Holzer and Neumark, 2000a). The critics of affirmative action argue that it transfers jobs, university admissions, and business contracts to minorities and women at the expense of white males who might be more qualified and therefore more deserving. If so, it might constitute a form of ‘reverse discrimination’ against white males, which could
be both inefficient and unfair. In contrast, the supporters of affirmative action claim that extra efforts beyond just the removal of explicit discrimination are necessary to overcome the many inherent disadvantages that minorities and women face in universities, the labour market, and the business sector. On this view, affirmative action is necessary for equal opportunity (or ‘fairness’), and would not necessarily reduce efficiency. Indeed, it might even raise overall efficiency by making available a wider pool of talent on which businesses and universities could draw, or because diversity itself has positive impacts.

The economic impacts of affirmative action largely centre on two issues: (a) the actual magnitudes of the redistribution of jobs, university admissions, or business contracts from white males to minorities or women attributable to affirmative action; and (b) any effects of affirmative action on efficiency, as measured (for example) by the credentials or performance of those who receive preferential treatment relative to those who do not. Evidence on these issues does not settle the ‘fairness’ question, which ultimately depends on personal values. But the evidence can and should inform the debate. A comprehensive review of the evidence is provided in Holzer and Neumark (2000a).

Redistributive effects

At this point, there seems to be little doubt that racial or gender preferences redistribute certain jobs or university admissions away from white men towards minorities and women. The question, instead, involves the magnitudes of these shifts. In terms of the labour market, a wide range of studies have demonstrated that affirmative action has shifted employment within the contractor sector from white males to minorities and women. But the magnitudes of these shifts are not necessarily large. For instance, Leonard (1990) found that employment of black males grew about five per cent faster at contractor establishments in the critical period of 1974–80 (when affirmative action requirements on contractors were rigorously enforced for the first time) than did employment of white males, while for white females and black females there were somewhat more modest effects. Looking at cross-sectional differences across establishments that did and did not use affirmative action in hiring (rather than using actual contractor status), Holzer and Neumark (1999) found that the share of total employment accounted for by white males was about 15–20 per cent lower in establishments using affirmative action than in those that did not – which is broadly consistent with the findings of Leonard and others. This does not necessarily imply that employment of white males overall is reduced by affirmative action, but only that it is redistributed to the non-affirmative action sector (where wages and benefits are likely lower).

The magnitude of the redistribution of university admissions from white males to minorities or women generated by affirmative action has been debated. On the one hand, test scores of those admitted are considerably higher among whites than minorities across the full spectrum of colleges and institutions (Datcher Loury and Garman, 1995). But at least some of these differences could be generated even with a common test score cut-off, given the racial gaps in test scores that exist in the population. And, if test scores are worse predictors of subsequent performance among blacks than whites, it might be perfectly rational for schools to put less weight on test scores in the admissions process for blacks (Dickens and Kane, 1999).

Furthermore, analyses of micro-level data on applications and admissions by Kane (1998) and by Long
affirmative action: The New Palgrave Dictionary of Economics (2004) suggest somewhat modest effects of affirmative action on overall admissions of minorities, but both studies suggest that the magnitudes rise with the overall level of scores at universities. Using data from the High School and Beyond Survey, Kane found significant racial differences in admissions (conditional on test scores and many other personal characteristics) only in the top quintile of colleges and universities by test scores. Long, using data from the National Educational Longitudinal Study (NELS), found significant effects on admissions in all quintiles. But the magnitudes of these differences were not large in absolute terms – the probability that minorities are accepted at their top choice would decline by less than two percentage points (14.7 per cent against 16.4 per cent) in the aggregate and about 2.5 percentage points in the top quintile in the absence of affirmative action. That affirmative action is more important as college quality rises is further established by Bowen and Bok (1998), who find quite large effects at a set of the most prestigious colleges and universities. Indeed, their work suggests that admissions rates among minorities at these schools would fall from 42 per cent to 13 per cent if affirmative action were abolished, a view consistent with the initial effects of Proposition 209 in California on admissions at Berkeley. The magnitudes of racial preferences in admissions in a variety of graduate programmes are also fairly large (Attiyeh and Attiyeh, 1997; Davidson and Lewis, 1997), while gender preferences are much more modest. Overall, the elimination of affirmative action in admissions to elite schools or graduate programmes would likely generate large reductions in minority student enrolments, but only modest improvements in overall grades and test scores at these institutions, as the whites who would be admitted in place of them appear to perform only marginally better in terms of these measures (Bowen and Bok, 1998). Implementing the reforms that have been recently adopted in Texas, Florida, and elsewhere, where admissions are based only on class rank rather than minority status, would likely generate major reductions as well in the presence of minorities on campus (Long, 2004). And using preferences based on family income instead of race or gender in admissions would also result in large declines in minority representation at universities. As for the redistribution of contracts from white-owned to minority- or female-owned businesses, we know of no study that has attempted to carefully measure the magnitude of this shift, though some summary studies suggest that the effects might be substantial.

Efficiency and performance effects

Regarding labour markets, it is fairly clear in theory that affirmative action could reduce efficiency in well-functioning labour markets in the short run if minorities or women were assigned to jobs for which they were not fully qualified, while it could increase efficiency if it opened up to minorities or women jobs from which they had been excluded in favour of less qualified white males. On the other hand, affirmative action might also lead minorities and women to invest in more education and training if the rewards to this investment would be increased; however, whether affirmative action would change incentives in this way is uncertain (Coate and Loury, 1993). The positive benefits on skill development across generations might be important as well. Finally, diversity per se may bring benefits, such as fostering mentoring relationships (Athey, Avery and Zemsky, 2000). To a large extent, the more important the imperfection in the labour market associated with the lower relative status of minorities – such as negative externalities generated for other members of the community, or imperfect information
driving the outcome – the greater is the chance that affirmative action will not reduce efficiency, and might even raise it.

A similar point can be made regarding university admissions. Significant market imperfections are likely to impede university admissions for some groups – such as imperfect information among university officials about individual candidates (or vice versa), and capital market problems that limit the access of lower-income groups to finance. Furthermore, important externalities might exist in the education process, at least along certain dimensions. For instance, students might learn more from one another in more diverse settings; indeed, the value of being able to interact with those of other ethnicities or nationalities might be growing over time, as product and labour markets become more diverse and more international. Alternatively, race-specific or gender-specific role models might be important for some individuals in the learning process.

What does the empirical evidence on the efficiency and performance of affirmative action beneficiaries show? One approach is to look at measures of individual employee credentials or performance, by race and/or sex, to see whether affirmative action generates major gaps in performance between white males and other groups. An earlier paper (Holzer and Neumark, 1999) compares a variety of measures of employee credentials and performance, where the former include educational attainment (absolute levels and those relative to job requirements), and the latter include wage or promotion outcomes as well as a subjective performance measure across these groups. The study inquired whether observed gaps in credentials and performance between white males and females or minorities are larger among establishments that practice affirmative action in hiring than among those that do not. The results indicated virtually no evidence of weaker credentials or performance among females in the affirmative action sector, relative to those of males within the same racial groups. In comparisons between minorities and whites, there was clear evidence of weaker educational credentials among the former group, but relatively little evidence of weaker performance.

But how could affirmative action result in minorities with weaker credentials but not weaker performance, if educational credentials generally are meaningful predictors of performance? In a separate paper, Holzer and Neumark (2000b) considered various mechanisms by which firms engaging in affirmative action might offset the productivity shortfalls among those hired from ‘protected groups’ that would otherwise be expected. The study found that firms engaging in affirmative action: (a) recruit more extensively; (b) screen more intensively and pay less attention to characteristics such as welfare recipiency or limited work experience that usually stigmatize candidates; (c) provide more training after hiring; and (d) evaluate worker performance more carefully.

Thus, these firms tend to cast a wider net with regard to job applicants, gather more information that might help uncover candidates whose productivity is not fully predicted by their educational credentials, and then invest more heavily in the productivity of those whom they have hired. This view is consistent with a variety of case studies (for example, Badgett, 1995), and other work in the literature on employee selection, suggesting that affirmative action works best if employers use a broad range of recruitment techniques and predictors of performance when hiring, and when they make a variety of efforts to enhance performance of those hired. In these studies, affirmative action need not just ‘lower the bar’ on expected performance of employees hired, and generally does not appear to do so (though some exceptions exist).

A variety of other studies have been undertaken within specific sectors of the workforce, where it is easier to define employee performance. Among the sectors that have been studied are police forces.
affirmative action: The New Palgrave Dictionary of Economics

The results of these studies again show no evidence of weaker performance among women, and generally limited evidence of weaker performance among minorities. In contrast, there is evidence of potential social benefits from affirmative action in the medical sector, as minority doctors appear more likely to locate in poor neighbourhoods and treat minority or low-income patients. Thus, the existing research finds evidence of weaker credentials but only limited evidence of weaker labour market performance among the beneficiaries of affirmative action, and evidence (at least in one important sector) consistent with positive externalities.

Regarding university admissions, there are gaps in high school grades and test scores between white and minority students admitted at universities, and the college grades of minorities lag behind as well. Black students fail to complete their college degrees at significantly higher rates, especially at institutions with higher average test scores (Datcher Loury and Garman, 1995). Similar findings have been generated for law schools (Sander, 2004). On the other hand, there is some evidence that the lower college completion rates among blacks at more selective institutions disappear once one controls for the effects of attending the historically black colleges and universities (Kane, 1998). And earnings are generally higher among blacks (as well as whites) who attend more prestigious and highly ranked schools, despite their higher rates of failure there.

The more challenging question is whether affirmative action actually hurts minority students by admitting them to colleges and universities for which some of them are unqualified, generating a poor ‘fit’ between them and the colleges or universities that they attend that may actually lead to worse outcomes. Sander (2004) claims to show evidence that affirmative action in law schools worsens outcomes for blacks, although this conclusion is disputable. Conversely, dropout rates of minorities at the most prestigious institutions are generally lower than elsewhere (Bowen and Bok, 1998). More decisive evidence on this question requires adequate comparison with counterfactuals of what would be observed absent affirmative action.

Along some other dimensions, the benefits of affirmative action in generating greater understanding and positive interactions across racial groups have been documented at these schools (Bowen and Bok, 1998). There is limited evidence of direct educational benefits of the diversity that affirmative action promotes (Antonio et al., 2004), although not yet in terms of the economic returns to education on which economists tend to rely in assessing educational outcomes. And evidence on the effects of minority or female faculty ‘mentoring’ and ‘role models’ is mixed (for example, Neumark and Gardecki, 1998).

Finally, the evidence on the performance of female- or minority-owned businesses that obtain more contracts as a result of affirmative action rules is somewhat inconclusive as well. Amendments to Section 8(a) rules on federal contracting do not allow companies to receive contracts under these provisions for longer than nine years, and apparently those who ‘graduate’ from the programme seem to perform (at least in terms of staying in business) as well as firms more generally (Stephanopoulos and Edley, 1995). On the other hand, there is some evidence of higher failure rates among firms that currently receive a high percentage of their revenues from sales to local government (Bates and Williams, 1995). The higher failure rates may be attributable to the fact that a significant fraction of the latter are ‘front’ companies that have formed or reorganized in an attempt to gain Section 8(a) contracts. There is also evidence that failure rates can be limited with the right kinds of certification and technical
assistance, especially if the reliance of the companies on governmental revenues is limited as well. In any event, this evidence suggests that failing companies are not being ‘propped up’ by government contracts, as is commonly alleged. But stronger data and analysis are needed in this area before conclusions can be drawn with a greater degree of confidence on the issue of the efficiency of minority contracting programmes.

agency problems

Luca Anderlini and Leonardo Felli
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

We illustrate agency problems with the aid of heavily stripped-down models which can be explicitly solved. Variations on a principal–agent model with both actors risk-neutral allow us to illustrate a canonical benchmark case, multi-tasking problems and informed-principal ones. We illustrate intertemporal agency problems using a two-period model with a risk-averse agent, which yields linear incentives. We conclude by briefly looking at more recent developments of the field such as present-biased preferences and motivated agents.

Keywords

Article

Within modern economic analysis, early recognition of the importance of agency problems goes back to at least Marschak (1955), Arrow (1963) and Pauly (1968). These early works are followed by the classical contributions of Mirrlees (1975), Holmström (1979), Shavell (1979) and Grossman and Hart (1983).

The canonical form of the principal–agent problem still in use crystallizes in Holmström (1979) and Grossman and Hart (1983). A risk-neutral Principal $p$ hires a risk-averse Agent $A$. Both actors are necessary to generate output, which depends stochastically on $A$'s actions. These are generally referred to as 'effort' ($e$) and, crucially are not observable by $p$ or any third party like a Court. In jargon, effort is neither observable nor verifiable, and hence no contractual arrangements can depend on $e$. (Anderlini and Felli, 1998, consider a principal–agent problem in which $e$ is in principle contractible, but where the equilibrium contract does not include it because of complexity considerations arising from the difficulties of describing it.) The interests of $p$ and $A$ are not aligned because $e$ causes disutility to $A$.

$p$ makes a take-it-or-leave-it offer of a contract to $A$ that specifies a schedule of output-contingent wages. $p$'s offer is rejected unless it meets $A$'s individual rationality constraint (henceforth IR), stating that $A$'s expected utility cannot be less than that yielded by his next-best alternative employment. In addition, the problem may or may not include an explicit limited liability constraint (henceforth LC) stating that, regardless of output, $A$'s wage cannot go below a given level. After a contract is signed, $A$ chooses $e$, then the uncertain output is realized, and finally payments are made according to the contract.

In the canonical model there is a trade-off between insurance and incentives. Optimal risk-sharing would require $p$ to insure $A$ against output uncertainty. However, doing so would leave $A$ without any incentives to exert effort; $A$ would be guaranteed a constant wage and hence would choose that $e$ which gives minimal disutility. Typically, $p$'s choice is instead to offer a contract that does not fully insure $A$, so as to give him incentives to exert effort. The contract compensates $A$ for the risk he bears in order to satisfy the IR (and possibly the LC). If $e$ is sufficiently productive in the stochastic technology, $p$'s expected profit increases as a result. The need to generate effort via incentives yields an agency problem. The equilibrium contract may be far from the ‘first-best’ world in which a social planner can choose $e$ at will. A lower than ‘socially efficient’ $e$ is selected and $A$ is not fully insured.

When both $p$ and $A$ are risk-neutral, an agency problem also arises if the LC binds (and typically the IR does not). (If the reverse is true, then giving incentives to $A$ has no cost since he does not mind risk and the IR binds on his expected payoff. In fact in this case, the ‘social optimum’ coincides with the ‘constrained social optimum’ in which a social planner can...
choose e, but only subject to giving the appropriate incentives to A. In this case in order to give A incentives \( p \) can pay him more when output indicates that effort is higher. This drives a wedge between \( p \)'s marginal cost for increased e and its social marginal cost. This in turn dictates that the equilibrium contract will differ from the first-best, and a 'second-best' constrained-inefficient outcome obtains.

Because of its tractability, the case in which both \( p \) and A are risk-neutral and the LC binds while the IR does not is a good benchmark to illustrate the mechanics of the problem and some of the more recent developments of the theory.

**A simple benchmark**

\( p \) hires A to carry out a task that requires unobservable non-contractible effort \( e \in [0, 1] \). A's effort determines the probability that the task is successful in generating output. Output equals 1 with probability \( e \) and 0 with probability \( 1 - e \). Output is observable and contractible. First, \( p \) offers a contract to A, then A accepts or rejects it. After a contract is signed, A chooses \( e \).

A contract is a pair of reals \((w_1, w_0)\), with the first being the wage (in units of output) that \( p \) pays A if output is 1, and the second being the wage if output is 0. Importantly, A has limited liability. He cannot be paid a negative wage in any state of the world. This generates the two LCs \( w_1 \geq 0 \) and \( w_0 \geq 0 \).

Both \( p \) and A are risk-neutral, and A dislikes effort which generates disutility \( e^2/2 \). Given \((w_1, w_0)\) and \( e \), \( p \)'s payoff is \( (1 - w_1) - (1 - e)w_0 \), while A's is given by \( ew_1 + (1 - e)w_0 - e^2/2 \). The outside options of both \( p \) and A are normalized to zero, so that in equilibrium both expected payoffs must be non-negative. These are the IRs.

Given \((w_1, w_0)\), A's choice of \( e \) is immediately computed as \( e = w_1 - w_0 \), this is the incentive constraint (henceforth IC) of the agent. If both \( w_0 \) and \( w_1 \) are lowered by the same amount \( e \) does not change. Hence in equilibrium \( w_0 = 0 \) and \( e = w_1 \). Taking into account IC, \( p \) maximizes \( e(1 - e) \). Therefore, in equilibrium, \( e = w_1 = 1 \). Hence \( p \)'s equilibrium payoff is \( P = 1/4 \), while A's is \( I = 1/8 \), so that the IR does not bind for either A or \( p \).

If a social planner were able to choose \( e \) at will, this would be chosen so as to maximize \( e - e^2/2 \), expected output minus cost of effort. So the first-best level of effort is \( e = 1 \). In this hypothetical world, \( P + I = 3/8 \), while in equilibrium \( P + I = 3/8 \). This gap is the result of the agency problem; A is motivated by the difference \( w_1 - w_0 \). Because of limited liability, the only way for \( p \) to motivate A is to raise \( w_0 \).

This exceeds the social marginal cost, which is \( \partial / \partial e [e^2/2] = e \), thus inducing an inefficient second-best outcome.

**Multi-tasking**

Starting with Holmström and Milgrom (1991), the theory evolved to encompass the multi-tasking case in which A has to carry out multiple tasks that affect output. (See also Holmström and Milgrom, 1994.) Some of the insights can be conveyed adapting the simple benchmark model above.

A now has two tasks; one is ‘standard’ (S) and one is ‘noisy’ (N). He chooses two effort levels: \( e_S \) and \( e_N \), both in \([0, 1]\). Choosing \((e_S, e_N)\) costs A a disutility of \((e_S^2 + e_N^2)/4 \). The two tasks are perfect complements in the stochastic technology. Given \((e_S, e_N)\), output equals 1 with probability \( \min \{e_S, e_N\} \), and 0 with probability \( 1 - \min \{e_S, e_N\} \). As in the benchmark, \( p \)'s payoff is expected output minus expected wage, while A's payoff equals his expected wage minus the disutility of effort. The LC and IR are as before.

Task N is noisier than task S in the following sense. Output is not contractible. Instead, each task yields a binary signal that can be contracted on. The signal \( \sigma_S \) for the S task is equal to 1 with probability \( e_S \), and 0 with probability \( 1 - e_S \). The signal \( \sigma_N \) for the N task is equal to 1 with probability \( e_N + (1 - e_N)(1 - p) \) and equal to 0 with the complementary probability, with \( p \in [1/2, 1] \). So, if \( p = 1/2 \) then \( \sigma_N \) contains no information about \( e_S \); while if \( p = 1 \) the signals \( \sigma_S \) and \( \sigma_N \) are equally informative about the respective tasks.

Because of the signal structure, a contract is now a quadruple of wages \((w_{S1}, w_{S0}, w_{N1}, w_{N0})\), one for each task, and for each possible value of the corresponding signal. As in the benchmark, in equilibrium we must have \( w_{S0} = w_{N0} = 0 \). Given \((w_{S1}, w_{S0}, w_{N1}, w_{N0})\), the ICs pin down \( e_S \) and \( e_N \) as satisfying \( e_S = 2w_{S1} \) and \( e_N = 2w_{N1}(2p - 1) \). Maximizing \( p \)'s profit using these restrictions gives that in equilibrium \( e_S = e_N = \max (0, 1/2 - (1 - p) / (8p - 4)) \). When \( p = 1 \) this model yields the same first best and the equilibrium payoffs as the benchmark above. When \( p = 3/5 \) or less then \( e_S = e_N = 0 \).

The literature highlights some features of the equilibrium for values of \( p \in [1/2, 1] \). As \( p \) decreases, so that task N becomes more noisy, two changes occur. In equilibrium, \( e_N \) decreases. This is not very surprising, given the increased noise. What is less straightforward is that \( e_S \) decreases as well: increased noise yields softer incentives on the standard task, as well as the noisy one. The complementarity between the tasks (extreme in the version used here, but this is not necessary) dictates that, as \( e_N \) becomes more expensive for \( p \) because of the noise, he will choose to induce lower values of \( e_S \) as well. Another way to check this is that the equilibrium values of both \( w_S \) and \( w_N \) decrease as \( p \) goes down. When \( p = 3/5 \), \( \sigma_N \)
is not informative enough. In this case \( e_s = e_M = w_{S1} = w_{N1} = 0 \). This has been interpreted as no contract being signed. The no-contract outcome obtains even though an informative contractible signal for both tasks is available.

**Informed principal**

Myerson (1983) and Maskin and Tirole (1990; 1992) examine the case in which \( p \) has private information, creating a potential signalling role for the contract offer. Despite the intricacies involved, the simple benchmark model above can be adapted again to illustrate some of the key points. (The computations below all pertain to the case of common values’ analysed in Maskin and Tirole, 1992.)

There are two types of principal, \( P_H \) and \( P_L \), \( P \) is of type \( H \) with probability \( \varphi = 18 \, / \, 29 \) and of type \( L \) with probability \( 1 - \varphi = 11 \, / \, 29 \). The principal’s type is his private information. If \( P \) is of type \( H \), \( A \)’s outside option is \( k = 9 \, / \, 32 \), while if \( P \) is of type \( L \) then \( A \)’s outside option is 0, as in the benchmark above. Hence, if \( P_H \) and \( P_L \), separate in equilibrium, there are two IRs for \( A \), while if pooling obtains \( A \)’s expected outside option is \( wH = 81 \, / \, 464 \), and he faces a single IR. \( A \)’s LCs are as in the benchmark above.

First \( p \) learns his type. Then he offers a contract to \( A \), which may take the form of a menu (wages contingent on output and \( p \)’s type). At this point \( A \) updates his beliefs about \( p \)’s type and then decides whether to accept or reject. (As in any signalling game, the issue of off-the-equilibrium-path beliefs arises. The simplest way to deal with this issue is to assume that \( A \)’s beliefs after observing an ‘unexpected’ offer are that \( p \) is of type \( H \) with probability 1. This is implicitly assumed in all computations below.) After a contract is signed \( p \) tells \( A \) which part of the menu applies in his case (if the contract is in fact a menu). Finally, \( A \) chooses effort, output is realized and payoffs are obtained.

There is a single task requiring effort which stochastically produces output as in the benchmark model. Output is contractible. \( p \)’s payoffs and IR are also as above. \( A \)’s payoff is also as in the benchmark above, except that he takes expectations using his beliefs.

In a separating equilibrium \( P_H \) and \( P_L \) offer two distinct pairs of output-contingent wages: \((w_{H1}, w_{H0})\) and \((w_{L1}, w_{L0})\) respectively. \( A \)’s ICs dictate that after being offered \((w_{H1}, w_{H0})\) effort is \( e_H = w_{H1} - w_{H0} \), while after being offered \((w_{L1}, w_{L0})\) effort is \( e_L = w_{L1} - w_{L0} \).

Separation requires that neither \( P_H \) nor \( P_L \) has an incentive to offer the other type’s wage pair. Since \( P \)’s private information does not enter directly his payoff, this can be true only if the expected profits for the two types of principals, \( \Pi_H \) and \( \Pi_L \), are the same. This is the truth telling (henceforth TC) constraint, which, using IC, since \( w_{H0} \) can be shown to be 0, reads \( \Pi_H = e_H (1 - e_H) = e_L (1 - e_L) - w_{L0} = \Pi_L \). Since \( k = 9 \, / \, 32 \), one of the two IRs for the agent does bind. Using IC this yields \( e_H = w_{H1} = 3 \, / \, 4 \). Using TC, this implies \( e_L = 1 \, / \, 2 \), \( w_{L0} = 1 \, / \, 16 \) and \( w_{L1} = 9 \, / \, 16 \). With these values \( \Pi_H = \Pi_L = 3 \, / \, 16 \).

With informed principals, the literature highlights the possibility of pooling equilibria, in which the contract is a menu. Both \( P_H \) and \( P_L \) offer a menu \((w_{H1}, w_{H0}, w_{L1}, w_{L0})\), which \( A \) has to accept or reject based on his expected IR. After a contract is signed, \( P \) tells \( A \) which pair of output-contingent wages applies. The TC constraint still applies, since both \( P_H \) and \( P_L \) have to be willing to indicate to \( A \) the appropriate wage pair. In fact, using IC and \( w_{H0} = 0 \), IC still reads \( \Pi_H = e_H M (1 - e_H) = e_L M (1 - e_L) - w_{L0} M = \Pi_L M \). Using the single binding expected IR and the ICs, which are unchanged, yields \((18 \, / \, 58)(e_H M)^2 + (11 \, / \, 29) [(e_L M)^2 + (w_{L0} M)] = 81 \, / \, 464 \). Using the TC constraint this gives \( e_H = w_{H1} = 5 \, / \, 8 \), \( e_L = 1 \, / \, 2 \), \( w_{L0} = 1 \, / \, 64 \) and \( w_{L1} = 33 \, / \, 64 \). With these values \( \Pi_H = \Pi_L = 15 \, / \, 64 \). Thus both types of \( p \) enjoy strictly higher profits than under separation. Pooling relaxes \( A \)’s IR which binds in expectation. \( P_H \) can lower \( w_{H1} \) which increases \( \Pi_H \) relative to the separation case. The increased profit for \( P_H \) affects \( P_L \) via the TC constraint. \( P_L \) lowers both output-contingent wages to satisfy the TC constraint, which in turn increases \( \Pi_L \) to keep it in line with \( \Pi_H \).

**Intertemporal incentives**

Holmström and Milgrom (1987) analyse the case of a relationship between \( p \) and \( A \) that extends over time. Some of the main insights can be gained in the following simple set-up.

There are two time periods — the first denoted \( S \) and the second denoted \( F \). \( A \) chooses an effort in \([0, 1]\) in both periods. Output can be either 1 or 0, and output draws are independent across the two periods. The first period effort is denoted \( e_F \). The second period effort if output is 1 in the first period is \( e_{IS} \), while the second period effort if output in the first period is 0 is \( e_{0S} \). The probability that output is 1 is \( \sqrt{e_F} \) in the first period, and \( \sqrt{e_{IS}} \) (with \( i \in \{ 0, 1 \} \)) in the second period.

\( A \) is paid at the end of the two periods, as a function of observed output in the two periods. The wage paid if output is \( i \in \{ 0, 1 \} \) in period \( F \) and \( j \in \{ 0, 1 \} \) in period \( S \) is denoted \( w_{ij} \).

Neither \( p \) nor \( A \) discounts the future. While \( p \) is risk-neutral, \( A \) is risk-averse with an exponential utility with a constant absolute risk-aversion coefficient equal to 1/2. His effort in the two periods is perfectly substitutable. Given a wage scheme \( w_{ij} \) and effort levels \( e_F \) and \( e_{iS} \) his expected utility is
\[
\Pi^A = -\sqrt{\epsilon F} \left[ \sqrt{e_{15}} \exp\left\{ -\frac{1}{2} (w_{11} - \epsilon F - e_{15}) \right\} + (1 - \sqrt{\epsilon F}) \exp\left\{ -\frac{1}{2} (w_{10} - \epsilon F - e_{15}) \right\} \right] - \left( 1 - \sqrt{\epsilon F} \right) \left[ \sqrt{e_{05}} \exp\left\{ -\frac{1}{2} (w_{01} - \epsilon F - e_{05}) \right\} + (1 - \sqrt{\epsilon F}) \exp\left\{ -\frac{1}{2} (w_{00} - \epsilon F - e_{05}) \right\} \right]
\]

while \( \pi^p \)'s expected payoff is

\[
\Pi^P = \sqrt{\epsilon F} \left[ \sqrt{e_{15}} (2 - w_{11}) + (1 - \sqrt{\epsilon F}) (1 - w_{10}) \right] + \left( 1 - \sqrt{\epsilon F} \right) \left[ \sqrt{\epsilon_{05}} (1 - w_{01}) + (1 - \sqrt{\epsilon}) (1 - w_{00}) \right]
\]

The optimal incentive scheme is found by maximizing \( \Pi^p \) subject to \( IR \) constraints imposing that \( \Pi^A \geq -1 \) and \( \Pi^P \geq 0 \) (these levels of reservation payoff can be taken to be a normalization for \( \pi \) and an assumption that \( A \) can earn a certain payoff of 0 elsewhere, yielding a utility level of \(-1\), and subject to the \( IC \) constraints which now impose that \( e_F, e_{0S} \) and \( e_{1S} \) should jointly maximize \( \Pi^A \) given the incentive scheme \( w_{ij} \). The \( IR \) constraint is binding for \( A \) while it is not binding for \( \pi \). The \( IC \) constraint can be subsumed in the first order conditions obtained by differentiating \( \Pi^A \) with respect to \( e_F \) and \( e_{1S} \) and setting these equal to 0 which are sufficient for a maximum. This way to proceed is known in the literature as taking the first-order approach. In the more general case considered for instance by Holmström and Milgrom (1987) this is not viable. In the simple case considered here, the first-order approach works because we are assuming that the exponent of effort variables \(-1/2\) in this case – plus \( A \)'s constant absolute risk-aversion coefficient \(-a/2\) in this case – sum to \( 0 \). Even in single-period agency models, whether the first-order approach is valid or not is an intricate question first uncovered by Mirrlees (1975). Subsequent contributions on this topic can be found in Grossman and Hart (1983), Rogerson (1985) and Jewitt (1988). To characterize the optimal incentive scheme for the two-period problem it is useful to first consider the second period (\( S \)) sub-problem after output \( i \in \{ 0, 1 \} \) has been realized in the first period (\( F \)). These problems are obtained considering (continuation) payoffs for \( A \) and \( \pi \) given by the relevant square bracket term of \( \Pi^A \) and \( \Pi^P \) above, and with an \( IR \) constraint for \( A \) given by his utility level (contingent on output in \( F \)) in the solution to the two-period problem, after factoring out the common term \exp\{e_F/2\}. If we use these binding \( IR \) constraints and the first-order \( IC \) constraints it can be seen that the difference \( (w_{i1} - w_{i0}) \geq 0 \) is independent of \( i \) – the second-period incentive premium \( \Delta i = (w_{i1} - w_{i0}) \) does not depend on first-period output. Hence, if we use the first-order \( IC \) constraints it is also the case that \( \epsilon_{0S} = \epsilon_{15} = \epsilon_S \in (0, 1) \). \( A \)'s \( IR \) constraints in each period \( S \) sub-problem determines \( w_{i0} \).

The period \( S \) sub-problems can then be plugged into the two-period problem. Viewed from period \( F \) we can think of \( \pi \) as offering \( A \) two certainty equivalent wages \( c_i \) for each period \( F \) output. Notice that we can write \( c_i = \hat{w}_i - \pi_1 \) where \( \hat{w}_i \) is the expected period \( S \) wage when the realized period \( F \) output is \( i \) and \( \pi_1 \) is the associated risk-premium. Since \( (w_{i1} - w_{i0}) = \Delta i \) is independent of \( i \), and \( A \)'s utility exhibits constant absolute risk-aversion we then get \( \pi_0 = \pi_1 = \pi. \) Hence factoring out the common term \exp\{\pi/2\} from \( A \) utility, the period \( F \) problem can be seen as having the same form as the two period \( S \) sub-problems with a different \( IR \) constraint for \( A \). Hence, as before, the difference \( \Delta F = (\hat{w}_1 - \hat{w}_0) \) does not depend on \( A \)'s reservation utility and in fact \( \Delta F = \Delta S = \Delta. \) For the same reason \( \epsilon_F = \epsilon_S = \epsilon. \)

Using \( \Delta F = \Delta S = \Delta \) and \( \epsilon_F = \epsilon_S = \epsilon \) we then get that the optimal incentive scheme is linear in output in the sense that \( w_{01} = w_{10} = w_{00} + \Delta \) and \( w_{11} = w_{00} + 2 \Delta. \) Given \( w_{00} \) the wage increases by a fixed amount \( \Delta \) for each unit of realized output over the two periods.

In the simple model we have used here output is either 1 or 0. The linearity result holds in the same model (with an arbitrary finite number of periods) when there are \( N \) possible output realizations each period. In this case the incentive scheme is linear in accounts – in essence linear in a vector of variables that count the number of realizations of each possible output level. Hellwig and Schmidt (2002) clarify that linearity in accounts need not imply linearity in aggregate output, and in fact some additional assumptions are needed for the latter to hold. They show that if \( A \) can destroy output unnoticed, and \( \pi \) only observes aggregate output at the end of the last period, then the (approximately) optimal incentive scheme is indeed linear in aggregate output.

Both Holmström and Milgrom (1987) and Hellwig and Schmidt (2002) are principally concerned with a continuous-time model in which \( A \) controls the drift of a (multi-dimensional) Brownian motion process that represents output. The continuous-time version of the problem yields elegant closed-form solutions that confirm the linearity result. Hellwig and Schmidt (2002) analyze in detail the status of the continuous-time model as the limit of discrete-time models.

The linearity of incentive schemes is of great interest in applications because of the prominence in practice of linear (or approximately linear) incentive schemes. In all known theoretical settings, linear optimal incentive schemes rely on exponential utility functions for both \( A \) and \( \pi \), whenever the latter is not risk-neutral. Stochastically independent periods also play a crucial role.
Finally, the tight linear characterizations of intertemporal incentive schemes also rely on $\tau$'s ability to commit in advance to an incentive scheme, and on $\mathcal{A}$'s ability to commit not to quit before the end. The question of whether a full-commitment long-term contract can be implemented via a sequence of short-term contracts has been analysed in a general context by Malcomson and Spinnewyn (1988), Fudenberg, Holmström and Milgrom (1990) and Rey and Salanié (1990). A common thread of this literature is that $\tau$'s ability to monitor $\mathcal{A}$'s savings decisions plays a key role in the possibility of short-term implementation of long-term contracts.

Recent developments

Since its inception the literature on agency problems and applications has grown dramatically, influencing many areas of economics ranging from development to finance. Agency theory has found a prominent place in many graduate and undergraduate programs in economics. Recent texts that provide a comprehensive treatment of the field include Salanié (2000), Laffont and Martimort (2002) and Bolton and Dewatripont (2005). Recent developments in the actual analytical framework relax some of the basic assumptions of the canonical model. Eliaz and Spiegler (2006) and O'Donoghue and Rabin (2005) focus on the underlying behavioural assumptions. The first paper tackles an environment in which agents may differ in their cognitive abilities, which generates dynamically inconsistent behaviour. The second paper is concerned with the effect of present bias in the agent’s preferences on the optimal incentive scheme. In both cases the optimal incentive scheme becomes more realistically ‘sensitive to detail’ than in the standard case.

Besley and Ghatak (2005) focus on the case of motivated agents in the provision of a public good. Motivated agents do not always regard effort as a cost. This has important effects on incentive design, which in turn sheds light on the nature of non-profit organizations.

Article
An economy consists of agents who interact in space and time and who act purposefully choosing their actions, their strategies, and their locations with some objective in mind. This purposefulness implies that they respond to incentives and information in predictable ways at the individual level, but it makes for complex aggregation. The aggregation of micro-level behaviours and interactions can create trading patterns, price bubbles and business cycles that were not built into the economy. They emerge from the bottom up. It is these patterns and regularities which economists seek to understand, explain, and predict, and which policymakers try to alter for the better.
Agent-based models of economies, like real economies, consist of computational objects that interact according to rules. Agent-based modelling allows us to consider richer environments with greater
fidelity than do existing techniques (Tesfatsion, 1997). This increased fidelity results from the inductive nature of the modelling enterprise. When constructing an agent-based model, we are constrained only by our imagination and interest. In contrast, when constructing a mathematical model, we must always be concerned with analytic tractability. This constrains our endeavours. The set of models that one believes to be tractable is small when compared with the set of models worth exploring. Thus, the flexibility and potential for realism enlarge the set of questions economists can explore (Anderson, Arrow and Pines, 1988; Arthur, Durlauf and Lane, 1997).

By freeing us from considerations of provability, agent-based models focus us on those aspects of the world that we believe most relevant. We can then encode the relevant assumptions in a computer program and allow the logical implications to iterate. Owing to the inductive nature of the enterprise, we do not know results a priori. Some agent models produce a chaotic mess and their assumptions need to be rethought. But often agent-based models produce interesting results, and these results can then be supplemented with analytic ones. We can much more easily prove a result when we know the answer. Thus, at a minimum, agent-based models can be thought of as a powerful engine for generating insights. Many mathematical theorists even admit that they use agent-based models for this purpose. But agent-based models can do far more.

The benefits of agent-based models

Proponents claim that agent-based models will advance the discipline because they can include more realistic assumptions about behaviour, structure and timing – that they have greater resonance. These claims ring true. Agent-based models look and feel more like real economies. All else equal, more realism improves models. The benefits of greater fidelity and realism in modelling behaviour can also be seen in the contributions of behavioural economics (Camerer, 2003). Agent-based models go further than behavioural models by also taking a realistic approach to modelling interaction structures and the timing of events (Kirman, 1997).

The four primary features of agent-based models – learning, networks, externalities and heterogeneity – which once lied outside of the mainstream have all received growing interest from economists over the past two decades. That said, despite what their advocates claim, agent-based models are not likely to lead to a complete rethinking of economics or of social science. No matter how they are implemented, be it mathematically or computationally, economic models will always have consumers and producers. Consumers will still choose bundles of goods with an eye towards getting high utility. Producers will still try to buy low and sell high. And markets, most of the time, will come close to efficiently allocating goods and services.

As Holland and Miller (1991) stated early on, agent-based models occupy a middle ground between stark, dry rigorous mathematics and loose, possibly inconsistent, descriptive accounts. We should not expect that middle ground to differ in kind from the two end points. We might, though, expect a better, more comprehensive economics. Thus, the real contribution of agent-based models will more likely be to push theory into places it has heretofore ignored or avoided. Thus, we should not expect a revolution based on this new methodology, but we should expect absorption. Like experimental economics, agent-based modelling should become one more row of street lights for economists to stand underneath (de Marchi, 2005).
When first introduced, agent-based models were somewhat controversial. This was caused by claims that they combined the precision of Samuelson with the scope and breadth of Keynes. Critics responded by dismissing agent-based models as simulations, as mere examples or sets of examples, to be contrasted with the general truths revealed by mathematics-based theory. Both sides were partly correct. Agent-based models are logically consistent. Agent behaviour is encoded in computer programs and the model proceeds according to the rules embedded in those programs. An agent-based model can be thought of as an enormous recursive equation being cranked over and over. What could be more logical and rigorous than that? Of course, codes can contain errors, as can computer software, but this is hardly a damning critique. The modern practice of programming and testing minimizes those errors and, fortuitously, most coding errors become apparent in the implementation stage.

I noted above that agent-based models can include diverse agents, geographic and social space, externalities, and learning. Many agent-based models include all of these features. These models can generate equilibria, emergent patterns and structure, and complexity. All of these can even occur in the same model but on different dimensions, just as in the real economy. Prices may attain something close to an equilibrium, information and trade networks may form patterns, and the inventory levels of suppliers may be complex and unpredictable.

The output flexibility of agent-based models leads some to jump to the inaccurate and unfortunate conclusion that agent-based models preclude equilibrium analysis. True, agent-based models naturally allow for dynamics, but this does not mean that they cannot attain equilibria. These equilibria are not assumed by generated (Epstein, 2003). The generative claim that ‘if you didn't grow it, you didn't show it’ should be ignored at our peril. Proving that an equilibrium exists and showing that it can be attained and maintained are separate findings. But not all agent-based models generate the equilibria predicted by mathematics. They fail because attaining equilibrium often requires slow learning rates and lots of agents. Sometimes, though, they fail because the mathematics contains errors (Page and Tassier, 2004).

Attaining equilibria to complement mathematical analyses (Judd, 1997) is not the reason to use agent-based models. They are better suited to exploring those parts of the economy that are complex or on the boundary between complexity and equilibrium. Even critics of agent-based modelling admit the appeal of exploring complexity, but they question what we learn from individual models. Mathematical theorems prove results for entire classes of functions. Arrow, Debreu and McKenzie proved theorems for any convex preferences, not just for preferences derived from Cobb–Douglas utility functions. Agent-based models, at least for now, assume particular functional forms. Mathematics therefore gives us the kind of general results on which a science has traditionally been built. Agent-based models do not. This is only partly true. These critics are less than honest about the current state of our knowledge (Leombruni and Richiardi, 2005). Although mathematical theorems are general and agent-based models are particular, that is not the whole story. In economics, general results are few and far between. Many papers (a) assume specific functional forms rendering them examples not general truths, or (b) consider restrictive classes of functional forms such as quasi-linear preferences, or (c) rely on dubious assumptions such as the monotone likelihood ratio property or independent signals.

Imagine the space of all possible economic environments as a room. Far too many theorems create small boxes in the corner of that room. Those boxes may not contain many real economies. Agent-based models, though only points (of light perhaps), can be scattered throughout the room wherever we like. We may need boxes to build a science, but a room full of light is better than a stack of boxes in the corner. And ideally, we can use the lights to construct boxes that fill the room.
Several excellent surveys describe the contributions of agent-based modelling as well as the enormous potential of this new methodology (see Tesfatsion and Judd, 2006, for surveys of several fields). This affords me the opportunity to use these pages to explore ideas related to agent-based models. I take three ideas that are fundamental to agent-based models and at the same time not familiar to most economists: *people as objects, complexity, and emergence*. In discussing these ideas, I explain why each is important to the study of economics.

**Economic actors as objects**

As I mentioned, agent-based models contain agents who follow rules. In the language of computer science, these agents are *objects* that exhibit rule-based behaviour. These objects can represent people, families, or firms. In constructing an object, the modeller must consider (a) the nature of the rules, (b) how the rules interact, and (c) the determinants of agent activation (Kirman, 1997). The behavioural rules can vary in their sophistication. The economic agents can follow *simple fixed rules* that are naive and routine. In a spatial Prisoner's Dilemma game, agents can play a strategy that always cooperates, or they can be extremely sophisticated. Incidentally, if agents play an equilibrium strategy in a game, they follow a fixed rule as well, but that simple fixed rule may take some effort to find.

It is in the region between primitive rule following and full cognitive closure where we might expect to find real people and firms. An assumption of naive rules understates human abilities and an assumption of full rationality overstates them, at least in non-trivial contexts. Human behaviour is more dynamic. We adapt and change our behaviours according to what works well. Sometimes we follow higher-order rules that allow us to learn to change our behavioural rules. But this learning algorithm – be it fictitious play, Hebbian learning or experience-weighted learning (Camerer, 2003) – is nothing more than a fixed rule. Sometimes we even apply learning rules on top of learning rules: we learn how to learn. These are all types of individual learning. We also learn socially. We mimic more successful people. Social learning is also rule-based. We have a rule for how we learn from others. Individual and social learning create different dynamics (Vriend, 2000). Social learning supports less diversity than does individual learning.

Agent-based modellers must also make explicit assumptions about the intelligence and adaptability of agents. Regardless though of how sophisticated or adaptive these agents may be, they still follow rules embedded in the computer code. So the agent-based models can be thought of as the recursive accumulation of those rules. Lest this seem unrealistic, economies can also be thought of as accumulated rules. People and firms follow rules, those rules may change, but, nevertheless, the total output of an economy and its allocation are determined by the accumulation of those rules, as are prices.

The conception of agents as objects requires explicit rules for how objects interact with one another. The agents must be situated in an interaction structure (Epstein and Axtell, 1996). These interaction structures can be represented in space or in networks that encode geographic, sociological, or feature-based differences (Riolo, Axelrod and Cohen, 2001). Feature-based, social and geographic spaces are more similar than might be thought. Two agents with similar features or social standing are more likely to interact than two agents with diverse features or social standings, just as two agents at nearby locations are more likely to interact than two agents who are far apart.

Finally, the idea of agents as objects demands explicit consideration of agent activation. In what order
do the agents get called to take their action? Do they get called simultaneously or sequentially? If the former, how are conflicts settled – what if two agents choose the same trading partner? If the latter, is that order independent of the agents’ incentives to update, or do the agents who benefit most by updating their behaviour move first (Page, 1997)? The nature of results can often hinge on how timing is implemented and timing interacts with other features (Nowak, Bonhoeffer and May, 1994).

The interactions between timing, interaction structures, and rules can alter the performance of a model. These interaction effects support the idea of richer model. This last observation leads into what I call the irony of robustness. Agent-based models are considered to be less robust because ‘you can get any result’ by changing a few assumptions (Miller, 1998). Seemingly minor changes in the timing of events or the network structure can have large effects on the outcomes of some models. Herein lies the irony. Results that depend crucially on these assumptions should not be seen as a weakness of agent-based models, as evidence that they have too many moving parts. Instead, the lack of robustness of these models can be seen as a critique of the starker mathematical models. The starker models ignore the very features of the economy that have been shown in the agent-based model to matter (Andreoni and Miller, 1995). As Mason and Wellman (2005) point out in their survey of the market design literature, many mathematical theorems lack detail about how, where, and when trade takes place. We should therefore think of theorems that exclude assumptions about time and place as incomplete. Decades of experiments with human subjects confirm this insight. Minor changes in how we run experiments can have enormous effects on outcomes.

Emergence

Modellers implement agent-based models in computational platforms that permit graphical representations of outcomes. This has had profound implications (both good and bad) for the growth and direction of the methodology. The graphical interfaces have revealed what are called ‘emergent phenomena’: meso- and macro-level phenomena that arise from the micro-level interactions of agents. Agent-based models produce emergent patterns and structures. Emergence was thought by some to be a clever bit of marketing but logically vacuous. And any initial tests for emergent phenomena were based on ocular statistics (Bankes, 2002). Look! Emergence! But since the mid-1990s emergence has become a scientific concept with several definitions.

To understand emergence, we must first recognize that a structure or entity can have multiple levels of explanation. A crowd’s movements can be explained as if the crowd were a single entity or as the accumulation of individuals’ movements. If a entity's actions can be explained equally accurately at a higher level – if the individuals really move as a crowd – then it is emergent. One of the simplest examples of emergence arises in Conway's Game of Life (Poundstone, 1985). Fixed automata rules on a lattice produce gliders. These gliders move diagonally across the space. The movement of the gliders can be explained by an appeal to the micro-level rules of the automata, but it can be more succinctly explained at the level of glider. Hence, the glider can be said to emerge.

In economies and societies, many things emerge: prices, cities, trade patterns, information networks, and cultural norms, to name just a few (Tesfatsion and Judd, 2006). These features of our world matter for economies. Cities matter. Trade networks matter. Culture matters. Social science needs ways of understanding how these things come to be as well as how they influence the performance of economic
Agent-based models offer a route to those understandings that complements our mathematical approaches.

**Complexity**

Agent-based models can generate complexity and allow us to explore its causes, thereby interweaving the methodology of agent-based models with the theoretical idea of complexity. The four main features of agent-based models are diverse agents, situated in an interaction structure, whose actions create interactive effects (externalities), which adapt, evolve or learn each contribute to the level of complexity a model produces (Axelrod and Cohen, 2000). These features can be thought of as choice variables. We can imagine a knob for each feature – a diversity knob, a connectedness knob, an externality knob, and a learning rate knob. The agents can be nearly homogeneous or very diverse. The space can be sparsely connected or highly connected. The interactions can be few and small or numerous and large, and the agents can adapt not at all or instantaneously. By turning these knobs, we can create complexity.

If we set all of the knobs at low levels, the resulting model usually settles into an equilibrium or a simple pattern. Wolfram's amazing cellular automata models and the Game of Life notwithstanding, most models with identical agents loosely connected with mild externalities and little learning do not produce much complexity. They tend to settle into equilibria or cycles. Turning up individual knobs creates complexity: complicated patterns and elaborate interacting emergent structures, such as trading patterns. As we turn the knobs further one of two things happens: equilibrium or chaos.

Often, by turning up the connectedness knob, we lead the system back towards equilibrium. When every agent connects to every other agent the environment becomes simpler for reasons explained by the central limit theorem. Diversity, externalities, and learning all get averaged out and the system stabilizes. In contrast, in many of these same models turning up the externality knob creates chaos. If agents’ actions have large external effects on other agents, the system does not settle down, but spins out of control. Complexity then can lie either between order and order or between order and chaos.

The existence of complexity depends upon having the right level of interplay between the agents. Interplay is a measure of how often and how much the behaviour of other agents influences the behaviour of any individual agent. The four knobs all adjust the level of interplay. As agents become more diverse, they take more extreme actions, increasing interplay. As agents become more connected and more interactive, interplay also increases. More agents have larger effects on each individual agent. Finally, the more agents change their behaviour, the more they cause other agents to change. This too increases interplay.

Social systems differ from physical systems in that these knobs are not fixed. In human systems, the agents can tune these knobs. They can choose to be more or less diverse, connected, interdependent, or reactive. The idea of adjustable levels of interplay raises the question of whether we should expect social systems to generate equilibrium, complexity or chaos. Changes in the level of interplay can transport a system out of equilibrium and into complexity. Alternatively, if agents want order, they can have it by slowing down or becoming less interdependent. Whether equilibrium or whether complexity may be a choice. We might assume that agents seek out equilibria, that they want stability. But agents may also desire complexity, for with complexity comes opportunity. Probably no one wants chaos though, and the ability to dial the knobs back to prevent it is invaluable. Thus, the fact that some parts of the economy appear more complex than others may be predictable based upon the incentives for ramping up or
dampening levels of interplay between the agents.

The future of modelling

To summarize, agent-based modelling offers a new methodology, a new tool for economists and social scientists. One cannot resist the temptation to talk about how existing research presents just the tip of the iceberg, that we have just begun to scratch the surface, but these metaphors fail. Some icebergs should remain sunk and some surfaces should remain unmarred. The case for agent-based modelling cannot be simply one of opportunity – we have a new tool, let's build something with it. We need reasons to believe that the submerged part of the iceberg merits exploring.

Resonance provides one strong reason. Agent-based models contain people and firms embedded in interaction structures. These people and firms have conceptualizations of problems and situations. At times, they adhere to routines. At times, they experiment. And at times, they learn from those who are most successful. Real people and real firms behave similarly. These models also produce emergent structures. And, they sometimes result in complexity and sometimes settle into equilibria. Herein lies a second reason for agent-based models. We should not think of the economy as either having attained equilibrium or to be exhibiting complex dynamics, for it has both properties simultaneously. Parts of the economy equilibrate. Shares of oil production across OPEC members resemble sequences of equilibria that respond to shocks. Other parts do not. The monthly, weekly, daily, hourly, and second-by-second fluctuations of the stock market create complex patterns (Palmer et al., 1994). Agent-based models allow us to explore this complexity, a large and important part of the iceberg.

aggregate demand theory

H. Sonnenschein
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
aggregate demand theory; consumer demand functions; demand theory; individual demand functions; market demand functions

Article

Aggregate demand theory investigates the properties of market demand functions. These functions are obtained by summing the preference maximizing actions of individual agents. The study of aggregate demand theory is primarily motivated by the fact that market demand functions, rather than individual demand functions, are the data of economic analysis. In general, market demand functions do not inherit the structure which is imposed on individual demand functions by the utility hypothesis. Such structure, when present, enables us to obtain stronger predictions from available data.

Here we focus on three aspects of market demand functions. The first is that in certain special cases, market demand functions can be shown to satisfy the classical restrictions that characterize individual demand functions. The second is that aside from these very special cases, the economy cannot be expected to behave as an 'idealized' or 'representative' consumer. Finally, we verify that when the economy is modelled as a continuum of infinitesimally sized agents market demand functions may in some respects be better behaved than individual demand functions. For an elaboration of the material through Example 3 see Shafer and Sonnenschein (1982).

1. This section presents the notation and briefly reviews the properties of individual demand functions. There are \( n \) consumers and \( l \) commodities. The consumption set of each consumer is \( R^l_+ \). The preferences of a consumer are described by a weak ordering \( \succeq \) of \( R^l_+ \). If \( x \succeq y \) we say ‘\( x \) is at least as good as \( y \)’; if \( x \succeq y \) and not \( y \succeq x \), then we write \( x \succ y \) and say ‘\( x \) is preferred to \( y \)’; if \( x \succeq y \) and \( y \succeq x \), we write \( x \sim y \) and say ‘\( x \) is indifferent to \( y \)’. The preference relation \( \succeq \) is continuous if \( \{ (x, y) : x \succeq y \} \) is closed; \( \succeq \) is locally non-satiated if for each \( x \in R^l_+ \) and every \( \eta > 0 \) there exists a \( y \) such that \( \forall x' \in R^l \), \( \lVert x' - y \rVert < \eta \implies x' \not\succeq y \); \( \succeq \) is strictly convex if \( x \succeq y \), \( x \neq y \) and \( 0 < \alpha < 1 \) implies that \( \alpha x + (1 - \alpha) y \not\succeq y \). \( \succeq \) is representable if there exists a ‘utility function’ \( U : R^l_+ \to R \) such that \( x \succeq y \) if and only if \( U(x) \geq U(y) \); \( \succeq \) is homothetic if it is representable by a utility function which is homogeneous of degree 1. It is assumed throughout that preference relations for all consumers are continuous, locally non-satiated and strictly convex. A continuous function \( f : R^l_+ \times R^l_+ \to R^l_+ \) is a candidate consumer demand function if it satisfies (Budget balance) \( p \cdot f(p, l) = l \) for all \( (p, l) \in R^l_+ \times R^l_+ \) and (Homogeneity) \( f(\lambda p, \lambda l) = \lambda f(p, l) \) for all \( \lambda > 0 \) and \( (p, l) \in R^l_+ \times R^l_+ \). At prices \( p \) and income \( l \), \( f(p, l) \) denotes the commodity bundle purchased. If there exists a preference relation \( \succeq \) such that for each \( (p, l) \in R^l_+ \times R^l_+ \), \( f(p, l) \) is the \( \succeq \) maximal element in the set \( \{ x : p \cdot x \leq l \} \), then \( f \) is a consumer demand function.

Let \( f \) be a differentiable candidate consumer demand function. The Slutsky matrix associated with \( f \) is an \( l \times l \) matrix denoted by \( \Sigma \) \( (p, l) \) whose \((h, k)\)th term is defined by

\[
\sigma_{hk}(p, l) = \frac{\partial^2 f_{hk}}{\partial p_h \partial p_k} (p, l) + f_{h}(p, l) \cdot \frac{\partial^2 f_{kl}}{\partial l_j} (p, l).
\]
The classical theorems of demand theory state that, if \( f \) is a consumer demand function, then for all \((p, \mathbf{I})\) \( \sum (p, \mathbf{I}) \) is symmetric and negative semi-definite. The integrability theorem establishes the converse (see Hurwicz and Uzawa, 1971).

Let \( \Delta^{n-1} = \{(x_1, x_2, \ldots, x_n) | x_i \geq 0 \text{ for all } i \text{ and } \sum x_i = 1\} \). Given prices \( p \) and income \( I \), the distribution of income among consumers is defined by a mapping \( \delta : \mathbb{R}_+^n \times \mathbb{R}_+ \rightarrow \Delta^{n-1} \). Thus \( \delta(p, I) \) is the \( i \)th individual’s income when prices are \( p \) and income is \( I \). A candidate demand function \( F \) is a market demand function relative to the distribution of income mapping \( \delta \) if there exists \( n \) consumer demand functions \( f_1, \ldots, f_n \) such that \( F(p, I) = \sum_i f_i(p, \delta_i(p, I))I \) holds for all \((p, I) \in \mathbb{R}_+^n \times \mathbb{R}_+ \). If \((f_1, \ldots, f_n)\) are individual demand functions and if for all \((p, I) \in \mathbb{R}_+^n \times \mathbb{R}_+ \), then market demand is independent of the distribution of income.

2. This section considers the conditions under which market demand functions belong to the class generated by a single consumer. The following classic result, due to Antonelli (1886) and later independently discovered by Gorman (1953) and Nataf (1953), gives necessary and sufficient conditions for a market demand function to be both independent of the distribution of income and generated by a preference relation.

**Theorem 1**: (Antonelli). Market demand is independent of the distribution of income and is preference generated if and only if there is a homothetic preference relation \( \succeq \) such that each consumer demand function \( f_i \) is derived from \( \succeq \). In this case, market demand is also generated by \( f_i \).

Examples 1 and 2 demonstrate that if either the condition that preferences are homothetic or the condition that preferences of all consumers are identical is dropped, then market demand may depend on the distribution of income (for elaboration of these examples, and of Example 3, see Shafer and Sonnenschein 1982).

**Example 1**: Let two consumers have identical preferences on \( \mathbb{R}^2_+ \) that are represented by \( U(x, y) = xy + y \) and let prices be \((1, 1)\). If the distribution of income is \( I_1 = 1, I_2 = 1 \), then aggregate demand for \( x \) and \( y \) is 0 and 2 respectively. If the distribution of income is \( I_1 = 2, I_2 = 0 \), then aggregate demand for \( x \) and \( y \) is \( \frac{1}{2} \) and \( \frac{1}{2} \) respectively.

**Example 2**: Let two consumers have homothetic preferences on \( \mathbb{R}^2_+ \) represented by \( U_1(x, y) = x \) and \( U_2(x, y) = y \). Then market demand depends completely on the distribution of income. If the income share of each consumer is fixed [that is, \( \delta(p, I) \) is a constant vector \( (\delta_1, \ldots, \delta_n) \) for all \((p, I)\)], then homotheticity of each individual preference relation is sufficient for market demand to be utility generated. This result is due to Eisenberg (1961).

**Theorem 2**: (Eisenberg). If the preferences of each agent can be represented by a homogeneous of degree one utility function \( U_i \) on \( \mathbb{R}_+^i \), and if income shares are fixed at \( (\delta_1, \ldots, \delta_n) \in \Delta^{n-1} \), then market demand is generated by the homogeneous of degree one utility function \( U \)

\[
U(x) = \max \prod_{i=1}^n [U(x_i)]^{\delta_i} \quad \text{s.t.} \quad \sum_i x_i = x.
\]

Under the hypothesis of Theorem 2 market demand is determined by maximizing a social welfare function that gives each individual’s preferences, a weight equal to his share of total income. The following example indicates that a fixed distribution of income, but no restrictions on agents’ preferences, is not sufficient to ensure that market demand is utility generated.

**Example 3**: (Hicks, 1957). There are two consumers who share market income equally. Market budgets for two different price ratios are indicated with dotted lines. The choices of the first individual are indicated by a cross and those of the second by a circle. Market demand at the steeper budget is denoted by \( D \) while demand at the flatter budget is denoted by \( D' \). The choice of either individual is consistent with utility maximization; however, since \( D \) is chosen in the aggregate when \( D' \) is available and since \( D' \) is chosen when \( D \) is available, market demand is not utility generated (Figure 1).
Theorems 1 and 2 referred to situations in which the distribution of income was determined exogenously. In a much referenced paper, Samuelson (1956) presented a theorem in which the distribution of income is determined as a solution to a maximization problem. Specifically, it is assumed that for every price–income combination, the government distributes income so as to maximize a Bergsonian social welfare function: let \( \delta \) denote the distribution of income determined by this process. Samuelson’s theorem asserts that under these conditions, market demand relative to \( \delta \) is utility generated. Proofs of the result may also be found in Chipman and Moore (1979), and Dow and Sonnenschein (1983).

**Theorem 3:** Suppose that \( f^i \) is generated by \( U^i \) for \( i = 1, \ldots, n \). If there exists a Bergsonian social welfare function \( W(U^1, \ldots, U^n) \) that is increasing in all its arguments and such that for all \( (p, \delta) \in R_+^l \times R_+ \),

\[
\delta(p, \delta) = \arg\max_{\{d^1, \ldots, d^n\} \in \Delta^{n-1}} W\{f^1(p, d^1), \ldots, f^n(p, d^n)\},
\]

then aggregate demand \( \sum_i f^i(p, \delta) \) is generated by the utility function

\[
U(x) = \max_{\{x^1, \ldots, x^n\} \in \Delta^{n-1}} W\{U^1(x^1), \ldots, U^n(x^n)\} \quad \text{s.t.} \quad \sum x^i = x.
\]

3. Theorems 1–3 identify sets of assumptions under which market demand functions belong to the same class as consumer demand functions. Theorem 4 indicates that in the absence of these assumptions, none of the classical restrictions holds for market demand functions. In particular any values of demand and its derivatives that are consistent with Homogeneity and Budget balance are possible.

**Theorem 4:** (Sonnenschein). Let \( F \) be an arbitrary \( C^1 \) candidate demand function for \( l \) commodities and let \( n \geq l \). Then, for any \( (p, \delta) \in R_+^l \times R_+ \), there exists a market demand function generated by \( n \) consumers with demand functions \( f^1, \ldots, f^n \) such that

\[
F(p, \delta) = \sum_{i=1}^n f^i(p, \delta^i) \frac{1}{n}
\]

and

\[
\frac{\partial f_k}{\partial p_j}(p, \delta) = \sum_{i=1}^n \frac{\partial f^i_k}{\partial p_j}(p, \delta^i) \cdot \frac{1}{n}, \quad \text{for each } k, j.
\]
More general results of this nature exist for market excess demand functions; see Sonnenschein (1973a), Debreu (1974) and Shafer and Sonnenschein (1982, section 4).

4. In this section an example of an economy with a continuum of infinitesimally sized agents is presented in which market demand is continuous despite the fact that individual demand functions are discontinuous: market demand is better behaved than individual demand. The point that is made here is quite general and is of importance in establishing the existence of competitive equilibrium without need for the assumption that preferences are convex; see Debreu (1982, section 4).

Example 4: There are two commodities $x$ and $y$ and the preferences of a consumer of type $a$ are represented by the utility function $U(x, y, a) = x^2 + a^2 \cdot y^2$. The income of each consumer is fixed at unity and the consumption set of each consumer is $\mathbb{R}^2_+$. The price of commodity $y$ in terms of the numeraire commodity $x$ is denoted by $p$. The distribution of agent types is specified by defining the following density function $g$, over the domain of $a$:

$$g(a) = \begin{cases} 
2 & \text{if } a \in \left[ \frac{1}{4}, \frac{3}{4} \right] \\
0 & \text{otherwise}
\end{cases}$$

Strict convexity of preferences is violated for each $a$, and consequently, the demand function of each consumer type is not single valued. The demand function for $y$ as a function of $p$ is given by

$$f^a(p) = \begin{cases} 
\frac{1}{p} & \text{if } p < a \\
0 & \text{if } p > a \\
\left[ \frac{1}{a}, 0 \right] & \text{if } p = a
\end{cases}$$

The graph of $f^a$ is drawn in Figure 2.

Figure 2
The multi-valued function \( f^a \) is not well-behaved in the sense that it jumps at \( a \). Let \( F(p) \) denote market demand at price \( p \). By definition

\[
F(p) = 2 \int_{a=1/4}^{a=3/4} f^a(p) \, da = 2 \int_{a=1/4}^{a=p} (0) \, da + 2 \int_{a=p}^{a=3/4} \frac{1}{p} \, da = \frac{3}{2} \frac{1}{p} - 2.
\]

Thus, market demand is single-valued and differentiable in the entire domain of \( p \), despite the fact that these properties do not hold for any given \( a \). One way to understand the result...
is to observe that for each $p$, the relative mass of consumers whose demand is discontinuous at $p$ is zero. This observation also illustrates the importance of the assumption that each agent is a ‘small’ part of the market and that preferences are dispersed. The result would not hold if the density function was assumed to be

$$
h(a) = \begin{cases} 
1 & \text{if } a \in \left[\frac{1}{4}, \frac{3}{4}\right] \\
\frac{1}{2} & \text{if } a = 1 \\
0 & \text{otherwise}.
\end{cases}
$$

A final result, which illustrates a theorem due to Hildenbrand (1983), gives conditions under which market demand is necessarily downward sloping. Again, the point is that with the continuum of agents market demand may be better behaved than individual demand.

**Theorem 5:** Consider an economy in which all individuals have identical preferences but differ in their incomes. In particular, assume that income is uniformly distributed over the interval $[0, 1]$ and let $f(p, I)$ denote the identical demands of the individuals with income $I$ who face prices $p$. Under the above conditions, the mean demand for each commodity has a nonpositive slope.

A sketch of a proof of the theorem follows: It is well known from consumer demand theory that the sign of the term $\frac{\partial f_k(p, I)}{\partial p_k}$ can be either positive or negative. Since individual substitution effects are nonpositive, to prove the result it is sufficient to demonstrate that the mean income effect is nonpositive.

The income effect as a result of a change in the price of commodity $k$ on the demand for $k$, for an individual with income $I$, is given by

$$
- f_k(p, I) \frac{\partial}{\partial I} f_k(p, I).
$$

Therefore, the mean income effect is given by

$$
- \int_0^1 f_k(p, I) \frac{\partial}{\partial I} f_k(p, I) \, dI = - \frac{1}{2} \left[ f_k^2(p, 1) - f_k^2(p, 0) \right] = - \frac{1}{2} f_k^2(p, 1) \leq 0,
$$

which establishes the result.

How to cite this article

Aggregation refers to the connection between economic interactions at the micro and the macro levels. The micro level refers to the behaviour of individual economic agents. The macro level refers to the relationships that exist between economy-wide totals, averages or other economic aggregates. For instance, in a study of savings behaviour refers to the process that an individual or household uses to decide how much to save out of current income, whereas the aggregates are total or per-capita savings and income for a national economy or other large group. The econometrics of aggregation refers to modelling with the individual–aggregate connection in mind, creating a framework where information
on individual behaviour together with co-movements of aggregates can be used to estimate a consistent econometric model. In economic applications one encounters many types and levels of aggregation: across goods, across individuals within households, and so on. We focus on micro to macro as outlined above, and our ‘individual’ will be a single individual or a household, depending on the context. We hope that this ambiguity does not cause confusion.

At a fundamental level, aggregation is about handling detail. No matter what the topic, the microeconomic level involves purposeful individuals who are dramatically different from one another in terms of their needs and opportunities. Aggregation is about how all this detail distils in relationships among economic aggregates. Understanding economic aggregates is essential for understanding economic policy. There is just too much individual detail to conceive of tuning policies to the idiosyncrasies of many individuals.

This detail is referred to as individual heterogeneity, and it is pervasive. This is a fact of empirical evidence and has strong econometric implications. If you ignore or neglect individual heterogeneity, then you can't get an interpretable relationship between economic aggregates. Aggregates reflect a smear of individual responses and shifts in the composition of individuals in the population; without careful attention, the smear is unpredictable and uninterpretable.

Suppose that you observe an increase in aggregate savings, together with an increase in aggregate income and in interest rates. Is the savings increase primarily arising from wealthy people or from those with moderate income? Is the impact of interest rates different between the wealthy and others? Is the response different for the elderly than for the young? Has future income for most people become more risky?

How could we answer these questions? The change in aggregate savings is a mixture of the responses of all the individuals in the population. Can we disentangle it to understand the change at a lower level of detail, like rich versus poor, or young versus old? Can we count on the mixture of responses underlying aggregate savings to be stable? These are questions addressed by aggregation.

Recent progress on aggregation and econometrics has centred on explicit models of individual heterogeneity. It is useful to think of heterogeneity as arising from three broad categories of differences. First, individuals differ in tastes and incomes. Second, individuals differ in the extent to which they participate in markets. Third, individuals differ in the situations of wealth and income risk that they encounter depending on the market environment that exists. Our discussion of recent solutions is organized around these three categories of heterogeneity. For deeper study and detailed citations, see the surveys by Blundell and Stoker (2005), Stoker (1993) and Browning, Hansen and Heckman (1999).

The classical aggregation problem provides a useful backdrop for understanding current solutions. We now review its basic features, as originally established by Gorman (1953) and Theil (1954). Suppose we are studying the consumption of some product by households in a large population over a given time period $t$. Suppose that the quantity purchased $q_{it}$ is determined by household resources $m_{it}$, or ‘income’ for short, as in the formula:

$$q_{it} = \alpha_i + \beta_i m_{it}$$
Here $\alpha_i$ represents a base level consumption, and $\beta_i$ represents household $i$'s marginal propensity to spend on the product.

For aggregation, we are interested in what, if any, relationship there is between average quantity and average income:

$$q_t = \frac{1}{n_t} \sum_{i=1}^{n_t} q_{it} \quad \text{and} \quad \bar{m}_t = \frac{1}{n_t} \sum_{i=1}^{n_t} m_{it}$$

where all households have been listed as $i=1,\ldots,n_t$. Let's focus on one version of this issue, namely, what happens if some new income becomes available to households, either through economic growth or a policy. How will the change in average quantity purchased $\Delta \bar{q}$ be related to the change in average income $\Delta \bar{m}$?

Suppose that household $i$ gets $\Delta m_i$ in new income. Their change in quantity purchased is the difference between purchases at income $m_{it} + \Delta m_i$ and at income $m_{it}$, or

$$\Delta q_i = \beta_i \cdot \Delta m_i$$

Now, the average quantity change is $\Delta \bar{q} = \sum \Delta q_i / n_t$, so that

$$\Delta \bar{q} = \frac{1}{n_t} \sum_{i=1}^{n_t} \beta_i \cdot \Delta m_i$$

(1)

In general, it seems we need to know a lot about who gets the added income – which $i$'s get large values of $\Delta m_i$ and which $i$'s get small values of $\Delta m_i$. With a transfer policy, any group of households could be targeted for the new income, and their specific set of values of $\beta_i$ would determine $\Delta \bar{q}$. A full schedule of how much new income goes to each household $i$ as well as how they spend it (that is, $\Delta m_i$ and $\beta_i$), seems like a lot of detail to keep track of, especially if the population is large. Can we ever get by knowing just the change in average income $\Delta \bar{m} = \sum \Delta m_i / n_t$?

There are two situations where we can, where a full schedule is not needed:
1. Each household spends in exactly the same way, namely, $\beta_i = \bar{\beta}$ for all $i$, so that who gets the new income doesn't affect $\Delta \bar{q}$.

2. The distribution of income transfers is restricted in a convenient way.

Situation 1 is (common) micro linearity, which is termed *exact aggregation*. Another way to understand the structure is to write (1) in the covariance formulation:

\[
\Delta \bar{q} = \bar{\beta} \cdot \Delta \bar{m} + \frac{1}{n_t} \sum_{i=1}^{n_t} (\beta_i - \bar{\beta}) \cdot (\Delta m_i - \Delta \bar{m})
\]

where we denote the average spending propensity as $\bar{\beta} = \frac{\sum \beta_i}{n_t}$. With exact aggregation there is no variation in $\beta_i$, so that $\beta_i = \bar{\beta} = \bar{\beta}$ and the latter term always vanishes. That is, it doesn't matter who gets the added income because everyone spends the same way. When there is variation in $\beta_i$, matters are more complicated unless it can be assured that the new income were always given to households in a way that is uncorrelated with the propensities $\beta_i$. 'Uncorrelated transfers' provide an example of a Situation 2, but that is a distribution restriction that is hard to verify with empirical data.

Under uncorrelated transfers, we can also interpret the relationship between $\Delta \bar{q}$ and $\Delta \bar{m}$, that is, the macro propensity is the average propensity $\bar{\beta}$. There are other distributional restrictions that give a constant macro propensity, but a different one from the parameter produced by uncorrelatedness. For instance, suppose that transfers of new income always involved fixed shares of the total amount. That is, household $i$ gets

\[
\Delta m_i = s_i \Delta \bar{m}
\]

In this case, average purchases are

\[
\Delta \bar{q} = \frac{1}{n_t} \sum_{i=1}^{n_t} \beta_i \cdot (s_i \Delta \bar{m}) = \bar{\beta} \cdot \Delta \bar{m} \cdot \Delta \bar{m}
\]
where \( \bar{\theta}_{\text{wtd}} \) is the weighted average \( \bar{\theta}_{\text{wtd}} \equiv \sum_i \beta_i s_i / n_t \). This is a simple aggregate relationship, but the coefficient \( \bar{\theta}_{\text{wtd}} \) applies only for the distributional scheme (3); it matters who gets what share of the added income. Aside from being a weighted average of \( \{\beta_i\} \), there is no reason for \( \bar{\theta}_{\text{wtd}} \) to be easily interpretable – for instance, if households with low \( \beta_i \)'s have high \( s_i \)'s, then \( \bar{\theta}_{\text{wtd}} \) will be low. If your aim was to estimate the average propensity \( \bar{\theta} \), there is no reason to believe that the bias \( \bar{\theta}_{\text{wtd}} - \bar{\theta} \) will be small.

Empirical models that take aggregation into account apply structure to individual responses and to allowable distributional shifts. Large populations are modelled, so that compositional changes are represented via probability distributions, and expectations are used instead of averages (for example, mean quantity \( E_i(q) \) is modelled instead of the sample average \( \bar{q}_t \)). Individual heterogeneity is the catch-all term for individual differences, and they must be characterized. Distribution restrictions must be applied where heterogeneity is important. For instance, in our example structure on the distribution of new income is required for dealing with the heterogeneity in \( \beta_i \), but not for the heterogeneity in \( \alpha_i \).

Progress in empirical modelling has come about because of the enhanced availability of micro data over time. The forms of behavioural models in different research areas have been tightly characterized, which is necessary for understanding how to account for aggregation. That is, when individual heterogeneity is characterized empirically, the way is clear to understanding what distributional influences are relevant and must be taken into account. We discuss recent examples of this below.

**Some solutions to aggregation problems**

**Demand models and exact aggregation**

It is well known that demand patterns of individual households vary substantially with whether households are rich or poor, and vary with many observable demographic characteristics, such as household (family) size, age of head and ages of children, and so on. As surveyed in Blundell (1988), traditional household demand models relate household commodity expenditures to price levels, total household budget (income) and observable household characteristics. Aggregate demand models relate (economy-wide) aggregate commodity expenditures to price levels and the distribution of income and characteristics in the population. Demand models illustrate exact aggregation, a practical approach for accommodating heterogeneity at the micro and macro levels. These models assume that demand parameter values are the same for all individuals, but explicitly account for observed differences in tastes and income.

For instance, suppose we are studying the demand for food and we are concerned with the difference in demands for households of small size versus large size. We model food purchases for household \( i \) as part of static allocation of the budget \( m_{it} \) to \( j=1,\ldots,\mathcal{J} \) expenditure categories, where food is given by \( j=1 \), and price levels at time \( t \) are given by \( P_t=(p_{1t},\ldots,p_{Jt}) \). Small families are indicated by \( z_{ii}=0 \) and large families by \( z_{ii}=1 \).

Expenditure patterns are typically best fit in budget share form. For instance, a translog model of the food share takes the form
\[ w_{1it} = \frac{p_1 q_{1it}}{m_{it}} = \frac{1}{D(p_t)} \left[ \alpha_1 + \sum_{j=1}^{J} \beta_j \ln p_{jt} + \beta \ln m_{it} + \beta z_{it} \right] \]

where \( D(p_t) = 1 + \sum_{j=1}^{J} \beta_j \ln p_{jt} \). The parameters (\( \alpha_1 \) and all \( \beta \)'s) are the same across households, and the price levels (\( p_{jt} \)'s) are the same for all households but vary with \( t \). Individual heterogeneity is represented by the budget \( m_{it} \) and the family size indicator \( z_{it} \). We have omitted an additive disturbance for simplicity, which would represent another source of heterogeneity. The important thing for aggregation is that model (5) is intrinsically linear in the individual heterogeneity. That is, we can write

\[ w_{1it} = b_1(p_t) + b_m(p_t) \cdot \ln m_{it} + b_z(p_t) \cdot z_{it} \]

The aggregate share of food in the population is the mean of food expenditures divided by mean budget, or

\[ w_{1t} = \frac{E_t(m_{it} w_{1it})}{E_t(m_{it})} = b_1(p_t) + b_m(p_t) \cdot \frac{E_t(m_{it} \ln m_{it})}{E_t(m_{it})} + b_z(p_t) \cdot \frac{E_t(m_{it} z_{it})}{E_t(m_{it})} \]

The aggregate share depends on prices, the parameters (\( \alpha_1 \) and all \( \beta \)'s) and two statistics of the joint distribution of \( m_{it} \) and \( z_{it} \). The first,

\[ s_{ mA} = \frac{E_t(m_{it} \ln m_{it})}{E_t(m_{it})} \]

is an entropy term that captures the size distribution of budgets, and the second
is the percentage of total expenditure accounted for by households with $z_{it} = 1$, that is, large families. The expressions (6) and (7) illustrate exact aggregation models. Heterogeneity in tastes and budgets (incomes) are represented in an intrinsically linear way. For aggregate demand, all one needs to know about the joint distribution of budgets $m_{it}$ and household types $z_{it}$ is a few statistics; here $S_{mt}$ and $S_{zt}$.

The obvious similarity between the individual model (6) and the aggregate model (7) raises a further question. How much bias is introduced by just fitting the individual model with aggregate data, that is, putting $E_t(m_{it})$ and $E_t(z_{it})$ in place of $m_{it}$ and $z_{it}$, respectively? This can be judged by the use of aggregation factors. Define the factors $\pi_{mt}$ and $\pi_{zt}$ as

\[
\pi_{mt} = \frac{S_{mt}}{E_t(m_{it})} \quad \text{and} \quad \pi_{zt} = \frac{S_{zt}}{E_t(z_{it})}
\]

so that the aggregate share is

\[
W_{1t} = \frac{E_t(m_{it}w_{1it})}{E_t(m_{it})} = b_1(p_t) + b_m(p_t) \cdot \pi_{mt} \cdot \ln E_t(m_{it}) + b_z(p_t) \cdot \pi_{zt} \cdot E_t(z_{it})
\]

One can learn about the nature of aggregation bias by studying the factors $\pi_{mt}$ and $\pi_{zt}$. If they are both roughly equal to 1 over time, then no bias would be introduced by fitting the individual model with aggregate data. If they are roughly constant but not equal to 1, then constant biases are introduced. If the factors are time varying, more complicated bias would result. In this way, with exact aggregation models, aggregation factors can depict the extent of aggregation bias.

The current state of the art in demand analysis uses models in exact aggregation form. The income (budget) structure of shares is adequately represented as quadratic in $\ln m_{it}$, as long as many demographic differences are included in the analysis. This means that aggregate demand depends explicitly on many statistics of the income-demographic distribution, and it is possible to gauge the nature and sources of aggregation bias using factors as we have outlined. See Banks, Blundell and Lewbel (1997) for an example of demand modelling of British expenditure data, including the computation of various aggregation factors.

Exact aggregation modelling arises naturally in situations where linear models have been found to
provide adequate explanations of empirical data patterns. This is not always the case, as many applications require models that are intrinsically nonlinear. We now discuss an example of this kind where economic decisions are discrete.

Market participation and wages

Market participation is often a discrete decision. Labourers decide whether to work or not, firms decide whether to enter a market or exit a market. There is no ‘partial’ participation in many circumstances, and changes are along the extensive margin. This raises a number of interesting issues for aggregation. We discuss these issues using a simple model of labour participation and wages. We consider two basic questions. First, how is the fraction of working (participating) individuals affected by the distribution of factors that determine whether each individual chooses to work? Second, what is the structure of average wages, given that wages are observed only for individuals who choose to work? The latter question is of interest for interpreting wage movements: if average wages go up, is that because (a) most individual wages went up or (b) low-wage individuals become unemployed, or leave work? These two reasons give rise to quite different views of the change in economic welfare associated with an increase in average wages.

The standard empirical model for individual wages expresses log wage as a linear function of time effects, schooling and demographic (cohort) effects. Here we begin with

$$\ln w_{it} = r(t) + \beta \cdot S_{it} + \varepsilon_{it}$$

where $r(t)$ represents a linear trend or other time effects, $S_{it}$ is the level of training or schooling attained by individual $i$ at time $t$, and $\varepsilon_{it}$ are all other idiosyncratic factors. This setting is consistent with a simple skill price model, where $w_{it} = R_t H_{it}$ with skill price $R_t = e^{\kappa(t)}$ and skill (human capital) level $H_{it} = e^{\delta H_{it}} + \xi_{it}$. We take eq. (10) to apply to all individuals, with the wage representing the available or offered wage, and $\beta$ the return to schooling. However, we observe that wage only for individuals who choose to work.

We assume that individuals decide whether to work by first forming a reservation wage

$$\ln w_{it}^* = s^*(t) + \alpha \ln B_{it} + \beta^* \cdot S_{it} + \zeta_{it}$$

where $s(t)$ represents time effects, $B_{it}$ is the income or benefits available when individual $i$ is out of work at time $t$, $S_{it}$ is schooling as before, and $\zeta_{it}$ are all other individual factors. Individual $i$ will work at time
$t$ if their offered wage is as big as their reservation wage, or $W_{it}^* \leq W_{it}^*$. We denote this by the participation indicator $I_{it}$, where $I_{it} = 1$ if $i$ works and $I_{it} = 0$ if $i$ doesn't work. This model of participation can be summarized as

$$I_{it} = 1 [W_{it} \geq W_{it}^*] = 1 [\ln W_{it} - \ln W_{it}^* \geq 0] = 1 [s(t) - \alpha \ln B_{it} + \gamma \cdot S_{it} + \nu_{it} \geq 0]$$

(11)

where $s(t) \equiv r(t) - s^*(t)$, $\gamma \equiv \beta - \beta^*$ and $\nu_{it} \equiv \epsilon_{it} - \zeta_{it}$.

If the idiosyncratic terms $\epsilon_{it}, \nu_{it}$ are stochastic errors with zero means (conditional on $B_{it}, S_{it}$) and constant variances, then (10) and (11) is a standard selection model. That is, if we observe a sample of wages from working individuals, they will follow (10) subject to the proviso that $I_{it} = 1$. This can be accommodated in estimation by assuming that $\epsilon_{it}, \nu_{it}$ have a joint normal distribution. That implies that the log wage regression of the form (10) can be corrected by adding a standard selection term as

$$\ln W_{it} = r(t) + \beta \cdot S_{it} + \frac{\sigma_{\epsilon v}}{\sigma_v} \lambda \left[ \frac{s(t) - \alpha \ln B_{it} + \gamma S_{it}}{\sigma_v} \right] + \eta_{it}$$

(12)

Here, $\sigma_v$ is the standard deviation of $\nu$ and $\sigma_{\epsilon v}$ is the covariance between $\epsilon$ and $\nu$. $\lambda (\cdot) = \phi (\cdot) / \Phi (\cdot)$ is the 'Mills ratio', where $\phi$ and $\Phi$ are the standard normal p.d.f. and c.d.f respectively. This equation is properly specified for a sample of working individuals – that is, we have $E(\eta_{it} | S_{it}, B_{it}, I_{it} = 1) = 0$. For a given levels of benefits and schooling, eq. (11) gives the probability of participating in work as

$$E_t[I_{it} | B_{it}, S_{it}] = \Phi \left[ \frac{s(t) - \alpha \ln B_{it} + \gamma S_{it}}{\sigma_v} \right]$$

(13)

where $\Phi [\cdot]$ is the normal c.d.f.

For studying average wages, the working population is all individuals with $I_{it} = 1$. The fraction of workers participating is therefore the (unconditional) probability that $\alpha \ln B_{it} - \gamma \cdot S_{it} - \nu_{it} \leq s(t)$. This probability is the expectation of $I_{it}$ in (11), an intrinsically nonlinear function in observed heterogeneity $B_{it}$ and $S_{it}$.
and unobserved heterogeneity $\nu_{it}$, so we need some explicit distribution assumptions. In particular, assume that the participation index $\alpha \ln B_{it} - \gamma \cdot S_{it} - \nu_{it}$ is normally distributed with mean $\mu_i = \alpha E_t(\ln B_{it}) - \gamma E_t(S_{it})$ and variance

$$\sigma^2 = \alpha^2 \text{Var}(\ln B_{it}) + \beta^2 \text{Var}(S_{it}) - 2\alpha\beta \cdot \text{Cov}(\ln B_{it}, S_{it}) + \sigma^2_{\nu}.$$  

(14)

Now we can derive the labour participation rate (or one minus the unemployment rate) as

$$E_t[l_{it}] = \Phi \left[ \frac{s(t) - \alpha E_t(\ln B_{it}) + \gamma E_t(S_{it})}{\sigma_t} \right]$$

(15)

where again $\Phi[\cdot]$ is the normal c.d.f. This formula relates the participation rate to average out-of-work benefits $E_t(\ln B_{it})$ and average training $E_t(S_{it})$, as well as their variances and covariances through $\sigma_t$. The specific relation depends on the distributional assumption adopted; (15) relies on normality of the participation index in the population.

For wages, a similar analysis applies. Log wages are a linear function (10) applicable to the full population. However, for participating individuals, the intrinsically nonlinear selection term is introduced, so that we need explicit distributional assumptions. Now suppose that log wage $\ln w_{it}$ and the participation index $\alpha \ln B_{it} - \gamma \cdot S_{it} - \nu_{it}$ are joint normally distribution. It is not hard to derive the expression for average log wages of working individuals

$$E_t[\ln w_{it} | l_{it} = 1] = r(t) + \beta \cdot E_t(S_{it} | l_{it} = 1) + \frac{\sigma_{\nu}}{\sigma_t} \left[ s(t) - \alpha E_t(\ln B_{it}) + \gamma E_t(S_{it}) \right].$$

(16)

This is an interesting expression, which relates average log wage to average training of the workers as well as to the factors that determine participation.

However, we are not interested in average log wages, but rather average wages $E_t(w_{it})$. The normality structure we have assumed is enough to derive a formulation of average wages, although it is a little complex to reproduce in full here. In brief, Blundell, Reed and Stoker (2003) show that the average
wages of working individuals $E [w_{it}] | l_{it} = 1$ can be written as

$$\ln E[w_{it} | l_{it} = 1] = r(t) + \beta \cdot E_t(S_{it}) + \Omega_t + \Psi_t$$

(17)

where $\Omega_t, \Psi_t$ are correction terms that arise as follows. $\Omega_t$ corrects for the difference between the log of an average and the average of a log, as

$$\Omega_t = \ln E_t(w_{it}) - E_t(\ln w_{it}) + \Omega_t.$$

$\Psi_t$ corrects for participation, as

$$\Psi_t = \ln E[w_{it} | l_{it} = 1] - \ln E_t(w_{it}).$$

Recall our original question, about whether an increase in average wages is due to an increase in individual wages or to increased unemployment of low-wage workers. That is captured in (17). That is, $\Psi_t$ gives the participation effect, and the other terms capture changes in average wage $E_t(w_{it})$ when all are participating. As such, this analysis provides a vehicle for separating overall wage growth from compositional effects due to participation.

Blundell, Reed and Stoker (2003) analyse British employment using a framework similar to this, but also allowing for heterogeneity in hours worked. Using out-of-work benefits as an instrument for participation, they find that over 40 per cent of observed aggregate wage growth from 1978 to 1996 arises from selection and other compositional effects.

We have now discussed aggregation and heterogeneity with regard to tastes and incomes, and market participation. We now turn to heterogeneity with regard to risks and market environments.

**Consumption and risk environments**

Consumption and savings decisions are clearly affected by preference heterogeneity, as we discussed earlier. The present spending needs of a large family clearly differ from those of a small family or a single individual, the needs of teenage children differ from those of preschoolers, the needs of young adults differ from those of retirees, and on and on. These aspects are very important, and need to be addressed as they were in demand models above. Browning and Lusardi (1996) survey the extensive...
evidence on heterogeneity in consumption, and Attanasio (1999) is an excellent comprehensive survey of work on consumption.
We use consumption and savings to illustrate another type of heterogeneity, namely, that of wealth and income risks. That is, with forward planning under uncertainty, the risk environment of individuals or households becomes relevant. There can be individual shocks to income, such as a work layoff or a health problem, or aggregate shocks, such as an extended recession or stock market boom. Each of these shocks can differ in its duration – a temporary layoff can be usefully viewed as transitory, whereas a debilitating injury may affect income for many years. In planning consumption, it is important to understand the role of income risks and wealth risks. When there is no precautionary planning, such as when consumers have quadratic preferences, income risks do not become intertwined with other heterogeneous elements. However, when there is risk aversion, then the precise situation of individual income risks and insurance markets is relevant.
A commonly used model for income is to assume multiplicative permanent and transitory components, with aggregate and individual shocks, as in

\[
\Delta \ln v_{it} = (\eta_t + \Delta u_t) + (\epsilon_{it} + \Delta v_{it}).
\]

Here \(\eta_t\) and \(\Delta u_t\) is the common aggregate shock, with \(\eta_t\) a permanent component and \(\Delta u_t\) transitory. The idiosyncratic shock is \(\epsilon_{it} + \Delta v_{it}\), where \(\epsilon_{it}\) is permanent and \(\Delta v_{it}\) transitory.

For studying individual level consumption with precautionary planning, it is standard practice to assume constant relative risk aversion (CRRA) preferences and assume that the interest rate \(r_t\) is small. This, together with the income process above, gives a log-linear approximation to individual consumption growth

\[
\Delta \ln c_{it} = \rho r_t + (\beta + \phi r_t) z_{it} + k_1 \sigma_{A_t} + k_2 \sigma_{it} + \kappa_1 \eta_t + \kappa_2 \epsilon_{it}.
\]  

(18)

Here, \(z_{it}\) reflects heterogeneity in preferences, such as differences in demographic characteristics. \(\sigma_{A_t}\) is the variance of aggregate risk and \(\sigma_{it}\) is the variance of idiosyncratic risk (with each conditional on what is known at time \(t - 1\)), so that these terms reflect precautionary planning. Finally, \(\eta_t\) and \(\epsilon_{it}\) arise because of adjustments that are made as permanent shocks are revealed. At time \(t - 1\) these shocks are not possible to forecast, but then they are incorporated in the consumption plan once they are revealed. In terms of the level of consumption \(c_{it}\), eq. (18) is written as
aggregation (econometrics): The New Palgrave Dictionary of Economics

\[ c_{it} = \exp \left( \ln c_{it-1} + \rho r_t + (\beta + \phi r_t)' z_{it} + \kappa_1 \sigma_{At} + \kappa_2 \sigma_{it} + \kappa_1 \eta_t + \kappa_2 \epsilon_{it} \right). \]

This is an intrinsically nonlinear model in the following heterogeneous elements: \( \ln c_{it-1}, z_{it}, \sigma_{it} \) and \( \epsilon_{it} \).

For aggregation, it seems we would need a great deal of distributional structure. Here is where we can see the role of the risk environment, or markets for insurance for income risks. That is, if there were complete markets with insurance for all risks, then all risk terms vanish from consumption growth. When complete insurance exists for idiosyncratic risks only, then the idiosyncratic terms \( \sigma_{it} \) and \( \epsilon_{it} \) vanish from consumption growth, since less precautionary saving is needed.

Otherwise, the idiosyncratic risk terms \( \sigma_{it} \) and \( \epsilon_{it} \) represent heterogeneity that must be accommodated just like preference differences (and in other settings, participation differences).

In the realistic situation where risks are not perfectly insurable, we require distributional assumptions in order to formulate aggregate consumption. For instance, suppose that we assume that

\( (\ln c_{it-1}, (\beta + \phi r_t)' z_{it}, \epsilon_{it}) \) is joint normally distributed with \( E_t(\epsilon_{it}) = 0 \), and that idiosyncratic risks are drawn from the same distribution for each consumer (so \( \sigma_{it} = \sigma_{It} \) for each \( i \)), and that a stability assumption applies to the distribution of lagged consumption. Blundell and Stoker (2005) show that aggregate consumption growth is

\[ \Delta \ln E_t(c_{it}) = \rho r_t + (\beta + \phi r_t)' E_t(z_{it}) + \kappa_1 \sigma_{At} + \kappa_2 \sigma_{It} + \kappa_1 \eta_t + \Lambda_t. \]

This model explains aggregate consumption growth in terms of the mean of preference heterogeneity, risk terms, and an aggregation factor \( \Lambda_t \). The factor \( \Lambda_t \) is comprised of variances and covariances of the heterogeneous elements \( \ln c_{it-1}, z_{it} \) and \( \epsilon_{it} \). Thus, this model reflects how aggregate consumption will vary as the individual incomes become more or less risky, and captures how the income risk interplays with previous consumption values.

In overview, as micro consumption models are nonlinear, distributional restrictions are essential. On this point, an empirical fact is that the distribution of household consumption is often observed to be well approximated by a lognormal distribution, and so such lognormal restrictions may have empirical validity. Also relevant here is the empirical study of income and wealth risks, which has focused on earnings processes; see Meghir and Pistaferri (2004) for a recent contribution.

**Micro to macro and vice versa**

We now turn to two related uses of aggregation structure that have emerged in the literature.

**Aggregation as a solution to microeconometric estimation**
Consider a situation where the estimation of a model at the micro level is the primary goal of empirical work. Some recent work uses aggregation structure to enhance or permit micro-level parameter identification and estimation. Since aggregation structure provides a bridge between models at the micro level and the aggregate level, it permits all data sources – individual-level data and aggregate-level data – to be used for identification and estimation of economic parameters. Sometimes it is necessary to combine all data sources to identify economic effects (for example, Jorgenson, Lau and Stoker, 1982), and sometimes one can study (micro) economic effects with aggregate data alone (for example, Stoker, 1986). Recent work has developed more systematic methods of using aggregate data to improve micro-level estimates. In particular, one can match aggregate data with simulated moments from the individual data as part of the estimation process.

To see how this can work, suppose we have data on labour participation over several time periods (or groups). We assume that the participation decision is given by the model (11) with normal unobserved heterogeneity, as discussed above. We normalize $\sigma = 1$ and take $s(t) = \psi$, a constant, so that the unknown parameters of the participation model are $\alpha, \gamma$ and $\psi$. The data situation is as follows; for each group $t = 1, \ldots, T$, we observe the proportion of labour participants $P_t$ and a random sample of benefits and schooling values, $\{B_{it}, S_{it}, i=1,\ldots,n_t\}$. Given the (probit) expression (13), estimation can be based on matching the observed proportion $P_t$ to the simulated moment

$$\bar{P}_t(\alpha, \gamma, \psi) = \frac{1}{n_t} \sum_{i=1}^{n_t} \Phi \left[ \psi - \alpha \ln B_{it} + \gamma \cdot S_{it} \right].$$

For instance, we could estimate by least squares over groups, by choosing $\hat{\alpha}, \hat{\gamma}, \hat{\psi}$ to minimize

$$\sum_{t=1}^{T} \left( P_t - \bar{P}_t(\alpha, \gamma, \psi) \right)^2.$$

Note that this approach does not require a specific assumption on the joint distribution of $B_{it}$ and $S_{it}$ for each $t$, as the random sample provides the distributional information needed to link the parameters to the observed proportion $P_t$.

It turns out that this approach for estimation is extremely rich, and was essentially mapped out by Imbens and Lancaster (1994). It has become a principal method of estimating demands for differentiated products, for use in structural models of industrial organization. See Berry, Levinsohn and Pakes (2004) for good coverage of this development.
The basic heuristic that underlies much macroeconomic modelling is that, because of markets, individuals are very coordinated in their actions, so that individual heterogeneity likely has a secondary impact. In simplest terms, the notion is that common reactions across individuals will swamp any behavioural differences. This idea is either just wrong or, at best, very misleading for economic analysis. But that is not to deny that in real world economies there are many elements of commonality in reactions across individuals. Households face similar prices, interest rates and opportunities for employment. Extensive insurance markets effectively remove some individual differences in risk profiles. Optimal portfolio investment can have individuals choosing the same (efficient) basket of securities. The question whether market interactions can minimize the impact of individual heterogeneity is a classic one, and by and large the answers are negative. However, there has been some recent work with calibrated stochastic growth models that raises some possibilities. A principal example of this is Krusell and Smith (1998), which we now discuss briefly. The Krusell–Smith set-up has infinitely lived consumers, with the same preferences within each period, but with different discount rates and wealth holdings. Each consumer has a chance of being unemployed each period, so there are transitory individual income shocks. Production arises from labour and capital, and there are transitory aggregate productivity shocks. Consumers can insure for the future by investing in capital only. Thus, insurance markets are incomplete, and consumers cannot hold negative capital amounts.

To make savings and portfolio decisions, consumers must predict future prices. To do this, each consumer must keep track of the evolution of the entire distribution of wealth holdings, in principle. This is a lot of information to know, just like what is needed for standard aggregation solutions as discussed earlier. Krusell–Smith’s simulations show, however, that this forecasting problem is much easier than one would suspect. That is, for consumer planning and for computing equilibrium, consumers get very close to optimal solutions by keeping track of only two things: mean wealth in the economy and the aggregate productivity shock. This is approximate aggregation, a substantial simplification of the information requirements that one would expect.

The source of this simplification, as well as its robustness, is a topic of active current study. One aspect is that most consumers, especially those with lowest discount rates, save enough to insure their risk so that their propensity to save out of wealth is essentially constant. Those consumers also hold a large fraction of the wealth, so that saving is essentially linear in wealth. This means that there is (approximate) exact aggregation structure, with the mean of wealth determining how much aggregate saving is undertaken. That is, the nature of savings and wealth accumulation approximately solves the aggregation problem for individual forecasting. Aggregate consumption, however, does not exhibit the same simplification. Many low-wealth consumers become unemployed and encounter liquidity constraints. Their consumption is much more sensitive to current output than that of wealthier consumers.

These results depend on the specific formulation of the growth model. Krusell and Smith (2006) survey work that suggests that their type of approximate aggregation can be obtained under a variety of variations of the basic model assumptions. As such, this work raises a number of fascinating issues on the interplay between economic interaction, aggregation and individual heterogeneity. However, it remains to be seen whether the structure of such calibrated models is empirically relevant to actual economies, or whether forecasting can be simplified even with observed variation in saving propensities.
of wealthy households.

Future progress

Aggregation problems are among the most difficult in empirical economics. The progress that has been made recently is arguably due to two complementary developments. First is the enormous expansion in the availability of data on the behaviour of individual agents, including consumers, households, firms, and so on, in both repeated cross-section and panel data form. Second is the enormous expansion in computing power that facilitates the study of large data sources. These two trends can be reasonably expected to continue, which makes the prospects for further progress quite bright.

There is sufficient variety and complexity in the issues posed by aggregation that progress may arise from many approaches. For instance, we have noted how the possibility of approximate aggregation has arisen in computable stochastic growth models. For another instance, it is sometimes possible to derive properties of aggregate relationships with very weak assumptions on individual behaviour, as in Hildenbrand's (1994) work of the law of demand.

But is seems clear to me that the best prospects for progress lie with careful microeconomic modelling and empirical work. Such work is designed to ferret out economic effects in the presence of individual heterogeneity, and can also establish what are ‘typical’ patterns of heterogeneity in different applied contexts. Knowledge of typical patterns of heterogeneity is necessary for characterizing the distributional structure that will facilitates aggregation, and such distributional restrictions can then be refuted or validated with actual data. That is, enhanced understanding of the standard structure in the main application areas of empirical economics, such as with commodity demand, consumption and saving and labour supply, will lead naturally to an enhanced understanding of aggregation problems and accurate interpretation of aggregate relationships. There has been great progress of this kind in the past few decades, and there is no reason to think that such progress won't continue or accelerate.

Bibliography

**How to cite this article**

Aggregation concerns the conditions under which several variables can be treated as one, or macro-relationships derived from micro-relationships. This problem is especially important in production, where, without proper aggregation, one cannot interpret the properties of the aggregate production function. The conditions under which aggregate production functions exist are so stringent that real economies surely do not satisfy them. The aggregation results pose insurmountable problems for theoretical and applied work in fields such as growth, labour or trade. They imply that intuitions based on micro variables and micro production functions will often be false when applied to aggregates.

Article
Aggregation in production concerns the conditions under which macro production functions can be derived from micro production functions. Microeconomic theory elegantly treats the behaviour of optimizing individual agents in a world with an arbitrarily long list of individual commodities and prices. However, the desire to analyse the great aggregates of macroeconomics – gross national product, inflation, unemployment, and so forth – leads to theories that treat such aggregates directly. The aggregation ‘problem’ matters because without proper aggregation one cannot interpret the properties of such macroeconomic models. This is particularly true as regards the production sector.

Leontief’s theorem
Underlying many results on aggregation is a theorem of Leontief (1947a; 1947b). Let $x$ and $y$ be vectors of variables and $F(x, y)$ a twice-differentiable function. It is desired to aggregate over $x$, that is, to replace $x$ with a scalar aggregator function, $g(x)$, such that $F(x) = H[g(x), y]$. This can be done if and only if, along any surface on which $F(x, y)$ is constant, the marginal rate of substitution between each pair of elements of $x$ is independent of $y$. (For a proof, see Fisher, 1993, pp. xiv–xvi.)

**Hicks–Leontief aggregation**

Since optimizing, price-taking agents equate marginal rates of substitution to price ratios, one restriction permitting aggregation over commodities is the assumption that the prices of all goods to be included in an aggregate always vary proportionally. This is called ‘Hicks–Leontief aggregation’ (Leontief, 1936; Hicks, 1939) and is a powerful expository tool. It requires no special assumptions as to the form of utility or production functions, but is applicable only in relatively artificial situations. Under more general circumstances, restrictions on utility or production functions become essential.

**Aggregation in consumption**

Consider a single household. Suppose that we wish to describe behaviour in terms of aggregate commodities such as ‘food’ or ‘clothing’. By Leontief's Theorem, a food aggregate exists if and only if the marginal rate of substitution between any two kinds of food is independent of consumption of any non-food commodity. If a similar restrictive condition is satisfied for all the aggregates to be constructed, then the household's utility function can be written in aggregate terms. Even such restrictive conditions will not always suffice. If we wish to represent the household as maximizing the aggregate utility function subject to an aggregate budget constraint, we must have aggregate prices as well as aggregate consumption goods. This requires that aggregates such as ‘food’ be homothetic in their component variables, again considerably restricting the household's utility function (Gorman, 1959; Blackorby et al., 1970).

Aggregation over agents presents a different set of questions. Suppose that we wish to treat the aggregate demands of a collection of households as the demands of a single, aggregate household. Then, only aggregate income and not its distribution can influence demand. At given prices, this makes the income derivative of every household's demand for a given commodity the same constant. Engel curves must be parallel straight lines. If zero income implies zero consumption, then all households must have the same homothetic utility function (Gorman, 1953).

In general, the only consumer-theoretic restrictions obeyed by aggregate demand functions are those of continuity, homogeneity of degree zero, and the various restrictions implied by the budget constraint (cf. Sonnenschein, 1972; 1973).

**Aggregation in production**

A more detailed survey of much of what follows in this section is given in Felipe and Fisher (2003). The analysis of aggregation conditions for production functions is far richer and the conditions even
more demanding than in the case of demand functions. Moreover, the subject has a complicated history and bears on the very foundations of neoclassical *macroeconomics*, negatively implicating the use of such important concepts as ‘total factor productivity’, ‘natural rate of growth’, ‘capital–labour ratio’, and even such terms as ‘investment’, ‘capital’, ‘labour’, and ‘output’.

To take a simple example, suppose we have two production functions $Q^A = f^A(K^A_1, K^A_2, L^A)$ and $Q^B = f^B(K^B_1, K^B_2, L^B)$ for firms $A$ and $B$, where $K_1 = K^A_1 + K^B_1$, $K_2 = K^A_2 + K^B_2$ and $L = L^A + L^B$ ($K$ refers to capital – two types – and $L$ to labour – assumed homogeneous). The problem is to determine whether and in what circumstances there exists a function $K = h(K_1, K_2)$ where the aggregator function $h(\cdot)$ has the property that $G(K, L) = G[h(K_1, K_2), L] = \Psi(Q^A, Q^B)$, and the function $\Psi$ is the production possibility curve for the economy. Note that we have implicitly assumed that a production function exists for the firm. Further, even within the firm there is a problem of aggregation over factors. Here, we concentrate on aggregation over firms.

Klein (1946a; 1946b) initiated the first debate on aggregation in production functions. He argued that the aggregate production function should be strictly a technical relationship, akin to the micro production function, and objected to utilizing the entire micro model with the assumption of profit-maximizing behaviour by producers in deriving the production functions of the macro model.

However, Kenneth May (1947) pointed out that this program is not generally achievable and, indeed, rests on a misunderstanding of what production functions actually are – even at the micro level. A production function does not tell us what outputs are or can be produced from a given set of inputs. It tells us what the *maximum* output is of a particular commodity, given a vector of inputs and the other outputs that are also to be produced from them.

That Klein's aggregation program is generally unachievable was specifically proved by André Nataf (1948). He showed that such aggregation is possible if and only if all micro production functions are additively separable in capital and labour.

The problem here is as follows. Suppose there are $n$ firms indexed by $v = 1, \ldots, n$. Each produces the same output $Y(v)$ using the same type of labour $L(v)$, and a single type of capital $K(v)$. The $v$th firm has a two-factor production function $Y(v) = f^v\{K(v), L(v)\}$. The total output of the economy is $Y = \sum_v Y(v)$, total labour is $L = \sum_v L(v)$. Capital, on the other hand, may differ from firm to firm. Under what conditions can total output $Y$ be written as $Y = \sum_v Y(v) = \mathcal{F}(K, L)$ where $K = \{K(1), \ldots, K(n)\}$ and $L = \{L(1), \ldots, L(n)\}$ are indices of aggregate capital and labour, respectively? Nataf showed that, where the variables $K(v)$ and $L(v)$ are free to take on all values, the aggregate production function $Y = \mathcal{F}(K, L)$ exists, if and only if every firm's production function is additively separable in labour and capital, that is, if every $Y(v)$ can be written in the form $f^v\{K(v), L(v)\} = \varphi^v\{K(v)\} + \psi^v\{L(v)\}$. Moreover, if one insists that labour aggregation be ‘natural’, with the $L$ appearing in the aggregate production function, then all the $\psi^v\{L(v)\} = c\{L(v)\}$, where $c$ is the same for all firms.

Nataf's theorem provides an extremely restrictive condition for inter-sectoral or even inter-firm aggregation. Evidently, aggregate production functions will not exist unless there are some further restrictions on the problem.
In fact, such restrictions are available; they stem from the requirement that a production function describe efficient production possibilities.

**Capital aggregation**

Consider the simplest case of two factors, with physically homogeneous capital \((K)\) and homogeneous labour \((L)\), where total capital can be written as \(K = \sum K(v)\), efficient production requires that aggregate output \(Y\) be maximized given aggregate labour \((L)\) and aggregate capital \((K)\). Under these simplified circumstances, it follows that \(Y^* = F(K, L)\) where \(Y^*\) is maximized output, since, as was pointed out by May (1946; 1947), individual allocations of labour and capital to firms would be determined in the course of the maximization problem. This holds even if all firms have different production functions and whether or not there are constant returns.

In the (somewhat) more realistic case where only labour is homogeneous and technology is embodied in capital, Fisher (1965) proposed to treat the problem as one of labour being allocated to firms so as to maximize output, with capital being firm-specific. Here, no ‘natural’ aggregate of capital exists.

Given that output is maximized with respect to the allocation of labour to firms, with such maximized output denoted by \(Y^*\), the question becomes: under what circumstances is it possible to write total output as \(Y^* = F(J, L)\) where \(J = \{K(1), ..., K(n)\}\), where \(K(v), v = 1, ..., n\), represents the stock of capital of each firm (that is, one kind of capital per firm)? Since the values of \(L(v)\) are determined in the optimization process there is no labour aggregation problem. The entire problem in this case lies in the existence of a capital aggregate. Since Leontief’s condition is both necessary and sufficient for the existence of a group capital index, the previous expression for \(Y^*\) is equivalent to

\[ Y^* = G\{K(1), ..., K(n), L\} \]

if and only if the marginal rate of substitution between any pair of the \(K(v)\)s is independent of \(L\).

Fisher drew the implications of this condition. He showed that, under strictly diminishing returns to labour \((\frac{dY}{dL} < 0)\), if any one firm has an additively separable production function (that is, \(\frac{dY}{dL} = 0\)), then a necessary and sufficient condition for capital aggregation is that every firm have such a production function. (Throughout, such subscripts denote partial differentiation in the obvious manner.) This means that capital aggregation is impossible if there is both a firm which uses labour and capital in the same production process, and another one which has a fully automated plant. Fisher found that a necessary and sufficient condition for capital aggregation is that every firm's production function satisfy a partial differential equation in the form \(\frac{dY}{dL} / \frac{dY}{dK} = \frac{dY}{dL} = g\left(\frac{dY}{dL}\right)\), where \(g\) is the same function for all firms. More important, on the assumption of constant returns to scale, the case of capital-augmenting technical differences (that is, embodiment of new technology can be written as the product of the amount of capital times a coefficient) turns out to be the only case in which a capital aggregate exists.

This means that each firm's production function must be writeable as \(F(b\sqrt{L}, L)\), where the function \(F(\cdot, \cdot)\) is common to all firms, but the parameter \(b_v\) can differ. Under these circumstances, a unit of one type of new capital equipment is the exact duplicate of a fixed number of units of old capital equipment (‘better’ is equivalent to ‘more’). As we would expect, given constant returns to scale, the aggregate stock of capital can be constructed with capital measured in efficiency units. Fisher (1965)
could not come up with a closed-form characterization of the class of cases in which an aggregate stock of capital exists when the assumption of constant returns is dropped. Nevertheless, as he showed, there do exist classes of non-constant returns production functions which do allow construction of an aggregate capital stock. On the other hand, if constant returns are not assumed there is no reason why perfectly well-behaved production functions cannot fail to satisfy Fisher's partial differential equation given above. Capital aggregation is then impossible if any firm has one of these ‘bad apple’ production functions. To sum up: aggregate production functions exist if and only if all micro production functions are identical except for the capital efficiency coefficient – an extremely restrictive condition.

Working with the profits function rather than with the production function, Gorman (1968) reached similar conclusions to those of Fisher.

Fisher extended his original work. First of all, he analysed (1965) the case where each firm produces a single output with a single type of labour, but two capital goods, that is, \( Y(\nu) = f(K_1, K_2, L) \). Here Fisher distinguished between two different cases. The first is that of aggregation across firms over one type of capital (for example, plant or equipment). Fisher concluded that the construction of a subaggregate of capital goods requires even more stringent conditions than for the construction of a single aggregate. For example, if there are constant returns in \( K_1, K_2 \) and \( L \), there will not be constant returns in \( K_1 \) and \( L \), so that the difficulties of the two-factor non-constant returns case appear. Further, if the \( \nu \)th firm has a production function with all three factors as complements, then no \( K_1 \) aggregate can exist. Thus, for example, if any firm has a generalized Cobb–Douglas production function (with the \( \nu \) argument omitted) in plant, equipment, and labour \( Y = \alpha K_1^\alpha K_2^\beta L^{1-\alpha-\beta} \), one cannot construct a separate plant or separate equipment aggregate for the economy as a whole (although this does not prevent the construction of a full capital aggregate).

The other case Fisher (1965) considered was that of the construction of a complete capital aggregate. In this case, a necessary condition is that it be possible to construct such a capital aggregate for each firm taken separately; and a necessary and sufficient condition (with constant returns), given the existence of individual firm aggregates, is that all firms differ by at most a capital augmenting technical difference. They can differ only in the way in which their individual capital aggregate is constructed.

Second, Fisher (1982) asked whether the crux of the aggregation problem derives from the fact that capital is considered to be an immobile factor. He showed that the aggregation problem seems to be due only to the fact that capital is fixed and is not allocated efficiently. That is true in the context of a two-factor production function. However, if one works in terms of many factors, all mobile over firms, and asks when it is possible to aggregate them into macro groups, the mobility of capital has little bearing on the issue. In fact, where there are several factors, each of which is homogeneous, optimal allocation across firms does not guarantee aggregation across factors. The conditions for the existence of such aggregates are still very stringent, but this has to do with the necessity of aggregating over firms rather than with the immobility of capital. A possible way of interpreting the existence of aggregates at the firm level is that each firm could be regarded as having a two-stage production process. In the first one, the factors to be aggregated, \( X_i(\nu) \), are combined to produce an intermediate output, \( Y(X(\nu)) \). This intermediate output is then combined with the other factor, \( L(\nu) \), to produce the final output.

Aggregation of \( X \) can be done if and only if firms are either all alike as regards the first stage of production, or all alike as regards the second stage. If they are all alike as regards the first stage, then the
fact that $L$ is mobile plays no role. If they are all alike as regards the second stage, then the fact that the $X_i$ are mobile plays no role.

Finally, Fisher (1983) is another extension of the original problem to study the conditions under which full and partial capital aggregates, such as ‘plant’ or ‘equipment’, would exist simultaneously. Not surprisingly, the results are as restrictive as those above. See also Blackorby and Schworm (1984).

**Labour and output aggregation**

Fisher (1968) went on to study the problems involved in labour and output aggregation, pointing out that the aggregation problem is not restricted to capital. Output aggregation and labour aggregation are also necessary if one wants to use a sector-wide or economy-wide aggregate production function.

Fisher again studied aggregation over firms, with labours and outputs shifted over firms to achieve efficient production, given the capital stocks. In the simplest case of constant returns, a labour aggregate will exist if and only if a given set of relative wages induces all firms to employ different labours in the same proportions. Similarly, where there are many outputs, an output aggregate will exist if and only if a given set of relative output prices induces all firms to produce all outputs in the same proportion. Thus, the existence of a labour aggregate requires the absence of specialization in employment; and the existence of an output aggregate requires the absence of specialization in production – indeed, all firms must produce the same market basket of outputs differing only in their scale. (Blackorby and Schworm, 1988, is an extension of Fisher, 1968.)

**Houthakker–Sato aggregation conditions**

Whereas Fisher sought to develop conditions where aggregate production functions would always work, Houthakker (1955–56) and Sato (1975) considered two-factor cases in which the problem was restricted by assuming that the distribution of capital over firms remains constant. In such cases it is obvious that one can aggregate over capital. Houthakker and Sato's contributions (see also Levhari, 1968) were to show the relationships between the fixed distribution of capital and the form of the aggregate production function.

**Fisher's simulations**

But, if aggregate production functions do not exist, how is it that they appear to ‘work’ in the sense that they fit the data well, that the estimated elasticities are close to the factor shares, and that wage rates are approximate the calculated marginal product of labour? We shall have more to say on this below, but here consider another result of Fisher (1971). This paper reports the results of simulations in a simple (heterogeneous capital, homogeneous labour and output) economy in which the aggregation conditions are known not to be satisfied. The principal result is that when, despite this, calculated factor shares just happen to be roughly constant, then the Cobb–Douglas aggregate production function ‘works’ in the above sense, even though the approximate constancy of factor shares cannot be caused by the non-existent aggregate production function. (See Fisher, Solow and Kearl, 1977 for the case of the CES...
Implications for empirical work

Empirically, the non-existence of the aggregate production function poses a conundrum. If aggregate production functions do not exist, there must be some other reason why they seem to work empirically. The answer has been in the literature for a long time (Simon and Levy, 1963; Simon, 1979; Shaikh, 1980), and more recently Felipe (2001) and Felipe and McCombie (2001; 2002; 2003; 2005; 2006a; 2006b) have elaborated upon it. (For an in-depth discussion of these issues see the papers in the Eastern Economic Journal, 2005.) However, like the theoretical arguments underlying the non-existence of the aggregate production function, these arguments have largely been ignored.

The argument is that, because the data used in aggregate empirical applications are not physical quantities but values, the accounting identity that relates definitionally the value of total output to the sum of the value of total inputs can be rewritten as a form that resembles a production function. More specifically, the National Income and Products Account (NIPA) identity states that value added equals the wage bill plus total profits, that is,

\[ V_t \equiv W_t + \Pi_t \equiv w_tL_t + r_tJ_t \]  

where \( V \) is real value added, \( W \) is the total wage bill in real terms, \( \Pi \) denotes total profits (‘operating surplus’, in the NIPA terminology), also in real terms, \( w \) is the average real wage rate, \( L \) is employment, \( r \) is the average \textit{ex post} real profit rate, and \( J \) is the deflated or constant-price value of the stock of capital. (Expression (1) is an accounting identity, not the result of Euler’s Theorem.) In applied aggregate work, the measures of output and capital used are the constant-price values, not physical quantities. We denote them by \( V \) and \( J \), respectively. These are different from \( Y \) and \( K \) used above, which denoted physical quantities. The symbol \( \equiv \) indicates that expression (1) is an accounting identity. Expressing the identity (1) in growth rates yields:

\[ \hat{V}_t \equiv a_t\hat{w}_t + (1 - a_t)\hat{r}_t + a_t\hat{L}_t + (1 - a_t)\hat{J}_t \]  

where \( \hat{\cdot} \) denotes a proportional growth rate, \( a_t \equiv W_tL_t / V_t \) is the share of labour in output, and 
\[ 1 - a_t \equiv r_tJ_t / V_t \]  

is the share of capital. So far no assumption of any kind has been made.

Suppose now that factor shares in the economy are relatively stable. This could be due, for example, to the fact that firms set prices according to a mark-up on unit labour costs. Assume also that \( w_t \) and \( r_t \)
grow at constant rates. Then

$$\hat{V}_t = \gamma + \alpha \hat{W}_t + (1 - \alpha) \hat{R}_t$$

(3)

where $\gamma \equiv \alpha \hat{W}_t + (1 - \alpha) \hat{R}_t$. Integrating (3) and taking antilogarithms,

$$V_t = A_0 \exp(\gamma t) L_t^{a_1} \lambda^{1-a}$$

(4)

Expression (4) is simply the NIPA accounting identity, expression (1), rewritten under the two assumptions mentioned above. It is certainly not a Cobb–Douglas production function, as such does not exist.

What are the implications of this argument? Suppose one estimates the standard Cobb–Douglas regression $V_t = C_0 \exp(\gamma t) L_t^{a_1} \lambda^{1-a}$ and in this economy factor shares are approximately constant and wage and profit rate growth is approximately constant. Then, this regression will yield very good results, since it approximates the identity (4). The statistical fit will be close to unity, $a_1 \approx \alpha$, $a_2 \approx 1 - \alpha$, and $\gamma \approx \lambda$. However, the aggregate production function may not exist, or firms in this economy may be subject to increasing returns to scale, although the regression results might lead us to believe otherwise. On the other hand, if the assumptions about the path of the factor shares and the growth rates of $w$ and $r$ are incorrect, the regression $V_t = C_0 \exp(\gamma t) L_t^{a_1} \lambda^{1-a}$ will not yield good results. Felipe and Holz, 2001, showed using Monte Carlos simulations that the main reason why the Cobb–Douglas regression $V_t = C_0 \exp(\gamma t) L_t^{a_1} \lambda^{1-a}$ often fails is that the approximation of $[a_t \hat{W}_t + (1 - a_t) \hat{R}_t]$ through the constant term $\lambda$ is incorrect. Such widely discussed problems as unit roots or endogeneity of the regressors are not the key issues. This simply means that we have to search for better approximations to the identity. (See Felipe and McCombie, 2001; 2003, for the derivations of the CES and translog approximations to the accounting identity.)

These results have devastating implications for empirical neoclassical macro growth theory, including endogenous growth, and total factor productivity measurement and growth accounting exercises. Indeed, Felipe and McCombie (2006b) have shown using simulations that the true rate of technical progress, computed with the use of firm-level data, is very different from that obtained with the use of aggregate data. Indeed, the two measures of productivity are so far apart that it is concluded that total factor productivity growth calculated with aggregate data is in no way a proxy for the true rate of technological progress.
Why do economists continue using aggregate production functions?

Most economists are not aware of these results, but simply think of the aggregate production function as part of their basic toolkit. Others use such concepts as total productivity growth without realizing that they are assuming the existence of a non-existent construct. Some economists, on the other hand, are aware of the aggregation results and yet continue using aggregate production functions. The reasons for doing so fall under three broad categories:

1. Aggregate production functions are seen as useful parables (Samuelson, 1961–62).
2. So long as aggregate production functions appear to give empirically reasonable results, why shouldn't they be used?
3. For the applications where aggregate production functions are used, there is no other choice.

However, in the light of the aggregation results, none of these reasons seems valid. Samuelson's parable argument was stated in the context of the so-called Cambridge capital theory debates. (It should not be thought that the aggregation problems have no bearing on the Cambridge–Cambridge debates. The discovery that aggregate production functions can violate properties that one expects of production functions, so-called reswitching and reverse capital-deepening, was at bottom a discovery that the aggregate concept used is not a production function at all. The aggregation problem literature shows that this was to be expected.) Samuelson showed that even in cases with heterogeneous capital goods some rationalization could be provided for the validity of the neoclassical parable, which assumes that there is a single homogenous factor referred to as capital, whose marginal product equals the interest rate. But Samuelson's results hold only in very restrictive cases, as we should expect from the aggregation literature. (See also Garegnani, 1970.)

A variation of the parable argument is that the aggregate production function should be understood as an approximation. It is evident that Fisher's (exact) aggregation conditions are so stringent that one can hardly believe that actual economies will satisfy them even approximately. Fisher (1969), therefore, asked: What about the possibility of a satisfactory approximation? Thus, suppose the values of capitals and labours in the economy lie in a bounded set and the requirement is that an aggregate production function lie within some specified distance of the true production surface for all points in the bounded set. Can this happen without the approximate satisfaction of the aggregation conditions? Fisher showed that this cannot reasonably happen by proving that the only way for approximate aggregation to hold without approximate satisfaction of the Leontief conditions is for the derivatives of the functions involved to wiggle violently up and down, an unnatural property not exhibited by the aggregate production functions used in practice.

The second argument is that, despite the aggregation results, neoclassical macroeconomic theory generally deals with macroeconomic aggregates derived by analogy with the micro concepts. Then, the argument goes, why not continue using them? Naturally, the aggregation problem appears in all areas of economics, including consumption theory, where a well-defined micro consumption theory exists. The neoclassical aggregate production function is also built by analogy (Ferguson, 1971).

This argument is untenable. Employing macroeconomic production functions on the unverified premise that inference by analogy is correct is inadmissible. Further, as opposed to the (already suspect) case of
the consumption function, the conditions for successful aggregation of production functions seem far more outlandish.

The third and final argument given for the use of aggregate production functions is that there is no other option if one is to answer the questions for which the aggregate production function is used, for example to discuss productivity differences across nations. But, ‘It's crooked, but it's the only wheel in town’ is not a scientific argument. The profession needs to find a different ‘wheel’.

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The aim of aggregation theory is to link the micro and macroeconomic notions of aggregate demand. One would like such a link to exist for any heterogeneous population, for a large set of all conceivable income assignments, and for a small number of statistics of the income distribution. This cannot be achieved. What can be achieved is critically discussed in Section 2. In Section 3, another important topic of aggregation theory is considered: how does mean demand react to price changes? As an example, the ‘law of demand’ is discussed.

Keywords

aggregate demand; aggregation; behavioural heterogeneity; exact income aggregation; law of demand; monotonicity; revealed preferences; Slutzky substitution effect

Article

1 Introduction

Aggregation theory of demand aims at identifying observable explanatory variables for aggregate demand starting from a microeconomic description of the underlying population of households. In the simple case, where the demand decision of a household is the choice of a commodity vector in a budget set, which is determined by the price vector \( p \) and income \( x \) (total expenditure), the demand behaviour of a household \( h \) is modelled by a demand function \( f^h(p, x) \in \mathbb{R}^I_+ \) (commodity space), which is defined for every strictly positive price vector \( p \in P \) and every income level \( x \geq 0 \). The demand function \( f^h \) might, but need not be derived from preference maximization under the budget constraint.

Aggregate demand is defined as mean demand across the population \( H \), that is to say, \( \frac{1}{|H|} \sum_{h \in H} f^h(p, x^h) \). The population \( H \) is viewed as heterogeneous in income and demand behaviour. Thus, mean demand is determined by the price vector \( p \) and the joint distribution of income \( x^h \) and demand function \( f^h \) across the population \( H \).

This general microeconomic definition of mean demand is sufficiently specific for certain problems in pure theory, for example for the existence problem in general equilibrium theory. In macroeconomics or in applied demand analysis the notion of aggregate demand is quite different. There the explanatory variables for aggregate demand are the price vector and certain statistics \( S(G_x) \) of the income distribution function \( G_x \) such as mean income, a measure of income inequality (for example, the variance of log income) or higher moments of the income distribution. In any case, no household specific variable is used in the aggregate demand function. The aim of the aggregation theory is to link the micro and macroeconomic notions of aggregate demand. More specifically, given an assignment \( (f^h)_{h \in H} \) of demand functions and a set \( x \in \mathbb{R}^H_+ \) of income assignments \( (x^h)_{h \in H} \), one seeks for a representation of mean demand of the following form: there exists a function \( F \) from \( P \times \mathbb{R}^N_+ \) into \( \mathbb{R}^I_+ \) and \( N \) statistics \( S_1(G_x), \ldots, S_N(G_x) \) of the income distribution function \( G_x \), such that

\[
\frac{1}{|H|} \sum_{h \in H} f^h(p, x^h) = F(p, S_1(G_x), \ldots, S_N(G_x))
\]
for all income assignments \((x^h)_h \in H\) in \(\mathcal{X}\) and all price vectors \(p\) in \(P\).

One would like such a representation to exist for any heterogeneous population \(H\), for a large set \(\mathcal{X}\); ideally for all conceivable income assignments, that is, \(\mathcal{X} = \mathbb{R}^H_+\) and for a small number \(N\) of statistics. This, of course, cannot be achieved.

The theory of income aggregation is surveyed in Section 2, where also basic references are given. The main results are:

- a representation of the form (1), which must hold in the case \(\mathcal{X} = \mathbb{R}^H_+\) is an unreasonable strong requirement. Indeed, if a representation exists, then the population \(H\) must be homogeneous in demand behaviour, that is, \(f^h = f^i\) for all \(h \in H\) and furthermore
- if \(N\) is less than the number of households in \(H\) and the common demand function \(f\) has the basic properties of demand theory (budget identity and homogeneity), then either \(f\) is linear in income or at least for one commodity \(i\), the income share function \(W_i(p, x) = \frac{\partial f_i(p, x)}{\partial x_i}\) is oscillating (that is, the derivative \(\partial x_i f_i(p, \cdot)\) changes its sign infinitely often).

Thus, households' behaviour which is modelled by the common demand function is either unreasonably simple or incredibly sophisticated. These results clearly show that the requirement \(\mathcal{X} = \mathbb{R}^H_+\) leads to an ill-posed problem.

For a heterogeneous population \(H\) there exists (see Example 3) a finite partition \(\{\mathcal{X}_k\}_{k \in K}\) of the set \(\mathbb{R}^H_+\) of all conceivable income assignments and for every \(k \in K\) there is a function \(F^k(p, G)\), where \(G\) denotes an income distribution function, such that

\[
\frac{1}{\# H} \sum_{h \in H} f^h(p, x^h) = F^k(p, G)
\]

for every income assignment \((x^h)_h \in H\) in the set \(\mathcal{X}_k\) and for every \(p \in P\).

Thus, for a heterogeneous population \(H\), there is no closed-form definition of an aggregate demand function; there is only a piecewise one, since the aggregate demand functions \(F^k\) and \(F^i\) are different for \(k \neq i\). The less heterogeneous the population the coarser the partition, that is, the smaller is \(#K\). The sets \(\mathcal{X}_k\) of the partition are large (see Example 3), in particular, if \((x^h_0) \in \mathcal{X}_k\), then for every strictly increasing function \(\phi\) the income assignment \(x^h = \phi(x^h_0), h \in H\), also belongs to \(\mathcal{X}_k\) (see Figures 3 and 4).

The aggregate demand functions \(F^k(p, G)\) in (2) require the knowledge of the entire income distribution. In many applications one might assume that the distribution of relevant income assignments in the set \(\mathcal{X}_k\) can be modelled by some few parameters (structural stability of income distributions). For example, if the population is 'very large' one might restrict attention to those \((x^h)\) in \(\mathcal{X}_k\) whose distributions are (approximately) log normal. Then, on this subset of \(\mathcal{X}_k\), mean demand has a representation of the form \(F^k(p, x, \sigma)\), where \(x\) denotes mean income across the population and \(\sigma^2\) is the variance of log income, which can be interpreted as a measure of income inequality.

Another important topic of aggregation theory is to analyse how mean demand of a heterogeneous population reacts to price changes under the ceteris paribus clause that households' income and demand functions remain fixed. In this case mean demand is denoted by \(F(p)\). Among the various desirable dependence structures is certainly the 'law' of demand, which asserts that the vector \(\Delta p \in \mathbb{R}^1\) of price changes and the resulting vector \(\Delta F \in \mathbb{R}^1\) of mean demand changes point in opposite directions, that is, the scalar product \(\Delta p \cdot \Delta F = \sum_{i=1}^I \Delta p_i \Delta F_i\) is negative.

Certainly, the 'law' is not meant to be an empirical law, but a monotonicity property of the mean demand function \(F(p)\) which is defined under a ceteris paribus clause in a mathematical model of a population of households. Thus, the 'law' asserts that the mean demand function \(F\) is strictly monotone, that is,

\[
(p - q) \cdot (F(p) - F(q)) < 0 \text{ for all } p \neq q \text{ in } P.
\]
In particular, every partial mean demand curve is strictly decreasing. This partial monotonicity property, however, is not sufficient for proving the uniqueness and stability of the equilibria for a multi-commodity demand-supply system; one needs strict monotonicity in the multi-commodity version.

Which behavioural assumption on the household level and/or which form of heterogeneity of the population lead to monotone mean demand? To answer this question one assumes that demand functions \( f^h \) satisfy the weak axiom of revealed preferences or, more specifically, that they are derived from preference maximization. Then, partial monotonicity is easily obtained, for example, by excluding inferior goods. However, multi-commodity monotonicity is more difficult to obtain. Trivially, mean demand is monotone if all demand functions \( f^h(p, x^h) \) were monotone in \( p \). This, however, requires that either \( f^h(p, \cdot) \) is linear in income or that the Slutsky substitution effect is sufficiently strong. (For a precise formulation, see the Theorem of Mitjuschin and Polterovich, 1978; law of demand.) Since the Slutsky substitution effect might be arbitrarily small, one is interested in finding alternative assumptions, which do not rely on a strong Slutsky substitution effect. These assumptions should not require that households’ demand functions are monotone. Obviously, to obtain the desirable aggregation effect, the population must be heterogeneous. Thus, in contrast to the problem of income aggregation, heterogeneity does not complicate the analysis, yet it is necessary to obtain monotonicity of mean demand by aggregation. More details are given in Section 3. For example, let \( H \) be a population which is homogeneous in demand behaviour, that is, \( f^h = f, h \in H \) and the common demand function is not monotone. However, the population is heterogeneous in income. Then, for a given income assignment \((x^h)_{h \in H}\), mean demand \( F^H(p) \) is not monotone in \( p \). If one increases now the population size, that is, the number \( #H \) of households tends to infinity and if for increasing \( #H \) the income distribution functions \( G^H \) of households in \( H \) converge to a concave distribution function \( G \), then, for \( #H \) sufficiently large, mean demand \( F^H(p) \) is ‘approximately’ monotone, that is to say, \( L^H(p) \) converges to a monotone function. Consequently, in the limit, that is, for an indefinitely large population which admits a concave income distribution function, mean demand is monotone. The mathematical model for such a limit population cannot be a finite or countably infinite set; it must be an atomless measure space of households, for example, the unit interval \([0,1]\) with Lebesgue measure (continuum of households). If these large populations are heterogeneous in income and demand behaviour, then one can meaningfully pose the problem of ‘smoothing by aggregation’: is mean demand continuous or differentiable without assuming these properties on the household level? The basic reference is Trockel (1984).

Finally, one should mention the literature on ‘behavioural heterogeneity’ initiated by Grandmont (1992). Here the goal is to obtain a stronger property than strict monotonicity of mean demand: diagonal dominance of the Jacobian \( \partial_p F(p) \) of mean demand in the sense that

\[
p_i \partial_p F_i(p) > \sum_{j \neq i} p_j \partial_p F_j(p)
\]

and

\[
p_i \partial_p F_i(p) > \sum_{j \neq i} p_j \partial_p F_j(p)
\]

This diagonal dominance models a strong restriction on the interdependence among the various commodity markets and is the basis for partial equilibrium analysis. For a general discussion of ‘behavioural heterogeneity’ see Hildenbrand and Kneip (2005).

### Income aggregation

The demand behaviour of every household \( h \) in a population \( H \) is modelled by a demand function \( f^h \in \mathcal{A} \). In this section it is not required that demand functions are derived by preference maximization under budget constraints. One only needs that demand functions \( f \in \mathcal{A} \) are continuous functions from \( P \times \mathbb{R}^+ \) into \( \mathbb{R}^+ \) with \( f(p, 0) = 0 \), where \( P \) denotes the set of all strictly
For every income assignment \((x^h)_{h \in H}, x^h \geq 0\), we consider mean demand \(\frac{1}{\# H} \sum_{h \in H} f^h(p, x^h)\). The 'problem of income aggregation' has been defined in the literature by the question: does there exist a function \(F\) from \(P \times \mathbb{R}_+\) into \(\mathbb{R}_+\) such that

\[
\frac{1}{\# H} \sum_{h \in H} f^h(p, x^h) = F(p, \overline{x}), \quad \text{where } \overline{x} = \frac{1}{\# H} \sum_{h \in H} x^h,
\]

for all income assignments in a given set \(\mathcal{X} \subset \mathbb{R}_+^H\) and all \(p \in P\)?

If one asks this question for all conceivable income assignments, that is, \(\mathcal{X} = \mathbb{R}_+^H\), then this is an ill-posed problem since it allows only a trivial solution.

**Theorem:** (Antonelli, 1886): There exists a function \(F(p, \overline{x})\) such that (3) holds on \(\mathbb{R}_+^H \times P\) if and only if the population \(H\) is homogeneous in demand behaviour, that is, \(f^h = f\), and furthermore \(f(p, x)\) is linear in \(x\), that is, \(f(p, x) = \alpha(p)x, \alpha(p) \in \mathbb{R}_+\). Thus, \(F(p, \overline{x}) = \alpha(p)\overline{x}\).

One might ask whether a less restrictive condition than (3) allows for a nontrivial solution. That is to say, one might consider mean demand functions that depend on a wider set of aggregate income variables than just mean income, for example, the variance or higher moments of the distribution of income. The answer is definitely negative.

For every income assignment \((x^h)_{h \in H}\), let \(G_x\) denote its distribution function, that is,

\[
G_x(\xi) = \frac{1}{\# H} \# \{h \in H | x^h \leq \xi\}, \xi \in \mathbb{R}.
\]

**Proposition 1:** There exists a function \(F(p, G_x)\) such that

\[
\frac{1}{\# H} \sum_{h \in H} f^h(p, x^h) = F(p, G_x)
\]

for all conceivable income assignments, that is, \(\mathcal{X} = \mathbb{R}_+^H\), and all \(p \in P\), if and only if the population \(H\) is homogeneous in demand behaviour, that is, all households in \(H\) have the same demand function. Then \(F(p, G_x) = \int f(p, \xi) dG_x(\xi)\).

**Proof:** Consider any two households \(k\) and \(j\) in \(H\), and an income assignment \((x^h)_{h \in H}\) with \(x^k > 0\) and \(x^j = 0\). Now one interchanges the income of households \(k\) and \(j\). This does not change the distribution function of income. Hence property (4) and the fact that \(f^k(p, 0) = f^j(p, 0) = 0\) implies that \(f^k(p, x^k) = f^j(p, x^j)\). Since this holds for all \(x^k > 0\) and \(p \in P\) one obtains \(f^k = f^j\). On the other hand, if \(f^h = f\) for all \(h \in H\), then

\[
\frac{1}{\# H} \sum_{h \in H} f^h(p, x^h) = \int f(p, \xi) dG_x(\xi).
\]

The justification for considering the generalized problem of income aggregation as defined by (4) is based on the view that for large populations, which this survey emphasizes, income distribution functions can often be modelled by some few parameters, for example, log-normal distributions.

By Proposition 1 it is clear that one is forced to restrict the set \(\mathcal{X}\) of admissible income assignments if one wants to escape the case of trivial solutions, \(f^h = f\), to the aggregation problem as...
aggregation (theory) - The New Palgrave Dictionary of Economics
defined by (4). Motivated by the special role which zero income and the assumption \( f(p, 0) = 0 \) play in the proofs of Antonelli's Theorem or Proposition 1 one has considered in the
literature (for example, Nataf, 1948, or Gorman, 1953) a restriction on the domain of individual income:

\[
\chi(a, b) = \{x^h \in \mathbb{R}_+ | 0 < a \leq x^h \leq b \leq \infty \}, \quad a < b.
\]

Proposition 2 shows that this restriction allows merely for some very limited and quite special heterogeneity in demand behaviour of the population \( H \).

**Proposition 2:**

1. There exists a function \( F(p, \mathbb{C}) \) such that (2) holds on \( \chi(a, b) \times \mathbb{R} \) if and only if for every commodity \( i \) and \( p \in P \) the income expansion paths \( f^h_i(p, \cdot), \ h \in H \), are parallel
   (vertically) on the interval \( (a, b) \); (with differentiability) \( \partial x^h_i(p, x) \) does not depend on \( h \in H \) (Figure 1).

Figure 1

\[
f^h_i(p, \cdot)
\]
2. There exists a function $F(p, \bar{x})$ such that (1) holds on $x(a, b) \times P$ if and only if for every commodity $i$ and $p \in P$ the income expansion paths $f_i^h(p, \cdot)$, $h \in H$, are affine and parallel on the interval $(a, b)$; (with differentiability) $\partial x_i^h(p, x)$ does not depend on $h \in H$ and $x \in (a, b)$ (Figure 2).
3. If all individual demand functions \( f^H \) belong to \( \mathfrak{A} \) and are homogeneous in \((p,x)\), then the necessary condition in (i) implies that \( f^H = f \).

**Proof:**

1. (i) Consider any two households \( k \) and \( j \) in \( H \) and an income assignment in \( x(a,b) \) with \( x^k_j \neq x^j_k \). Now one interchanges the income of households \( k \) and \( j \). This does not change the income distribution function. Hence, property (2) implies \( f^k(p, x^k_j) + f^j(p, x^j_k) = f^k(p, x^j_k) + f^j(p, x^k_j) \). Thus \( f^k(p, x^k_j) - f^k(p, x^k_j) = f^j(p, x^j_k) - f^j(p, x^j_k) \). Since it holds for all \( x^k_j \), \( x^j_k \in (a,b) \) and all \( p \in P \) one obtains the claimed property in (i). The converse is trivial.

2. (ii) Instead of interchanging the income of households \( k \) and \( j \) one chooses \( x^k_j + (a,b) \) and \( x^j_k - (a,b) \) for sufficiently small \( \Delta \). Property (1) then implies

\[
f^k(p, x^k_j + \Delta) - f^k(p, x^k_j) = f^j(p, x^j_k) - f^j(p, x^j_k - \Delta) = f^k(p, x^j_k) - f^k(p, x^j_k - \Delta)
\]

by (i), which implies the claimed property in (ii). The converse is trivial.

3. (iii) If the expansion paths \( f^k(p, \cdot) , h \in H \), are parallel on \((a,b)\) for every \( p \in P \), then homogeneity implies that they are also parallel on \((\lambda a, \lambda b) \) for all \( \lambda > 0 \) and \( p \in P \). Hence they
are parallel on \((0, \infty)\) for all \(p \in P\). Continuity and \(f^h(p, \xi) = 0\) then implies the claim.

An alternative approach to allow for heterogeneous populations consists of considering, in addition to income, further explanatory variables for household demand. For example, in applications it is standard practice to stratify the whole population \(H\) by a certain profile \(a = (a_1, a_2, \ldots)\) of observable household attributes, such as household size, age of household head, etc. Let \(H(a)\) denote the sub-population of all households in \(H\) with attribute profile \(a\). Without loss of generality one can assume that \(a \in \mathbb{R}^m\). Let \(G_{x,a}\) denote the joint distribution of function of \(x^h, a^h\) across \(H\). Analogously to Proposition 1 one shows

**Proposition 1'**: There exists a function \(F(p, G_{x,a})\) such that

\[
\frac{1}{\#H} \sum_{h \in H} f^h(p, x^h) = F(p, G_{x,a})
\]

for all conceivable income-attribute assignments and all \(p \in P\) if and only if all sub-populations \(H(a)\) are homogeneous in demand behaviour, that is, \(f^h = f^a\) for all \(h \in H(a)\).

Thus, the whole population need not be homogeneous, yet the joint distribution of \(x^h\) and \(a^h\) across \(H\) has typically a complex dependence structure, and hence, it cannot be modelled by some few parameters, as in the case of income.

**Exact income aggregation**

In the literature on ‘exact income aggregation’, as initiated by Gorman (1953), Lau (1982), and Jorgensen, Lau and Stoker (1982), one seeks for a representation of mean demand which is less restrictive than (3), yet more demanding than (4), that is to say, \(\frac{1}{\#H} \sum_{h \in H} f^h(p, x^h) = \int \left( f(p, S_1(G_X), \ldots, S_N(G_X)) \right) dG_X\) for some continuous function \(F\) from \(P \times \mathbb{R}^N\) into \(\mathbb{R}\) (the commodity space) and some vector of distributional statistics \(S_1(G_X), \ldots, S_N(G_X)\) with \(N < \#H\). This representation is more demanding than (4); it does not require the knowledge of the entire income distribution since \(N < \#H\).

If such a representation exists, then by Proposition 1, \(f^h = f, \forall h \in H, \) and \(f\) is called ‘exactly aggregable’. Thus, the question is whether there are exactly aggregable demand functions which are not linear in income and satisfy the basic restrictions of demand theory?

To simplify the presentation one assumes that all distributional statistics are ‘generalized moments’, that is, \(S_n(G_X) = \int s_n(\xi) dG_X(\xi)\), with continuous functions \(s_n(\cdot)\). Without loss of generality one can require that \(s_n(0) = 0\).

**Proposition 3**: There exists a representation of mean demand of the form

\[
\int f(p, \xi) dG_X(\xi) = F(p, \int s_1(\xi) dG_X(\xi), \ldots, \int s_N(\xi) dG_X(\xi)),
\]

which holds for every income distribution function \(G_X\) of every finite population \(H\) and every price vector in \(P\) if and only if the function \(f\) is of the form

\[
f(p, \xi) = \alpha_1(p)s_1(\xi) + \cdots + \alpha_N(p)s_N(\xi), \quad p \in P \text{ and } \xi \in \mathbb{R}_+.
\]
where $\alpha_\pi(D) \in \mathbb{R}$.

**Proof:** Trivially, (6) implies (5). Assume that (5) holds. Let $G$ denote the set of all income distribution functions for every finite population. Note that for every $C^1$, $C^2 \in G$ and any rational $\lambda$ with $0 \leq \lambda \leq 1$ it follows that $G^\lambda = \lambda C^1 + (1 - \lambda) C^2 \in G$.

The representation (5) implies for every commodity $i$

$$f_i(p, \xi) = F_i(p, s_1(\xi), \ldots, s_N(\xi)), \quad p \in P \text{ and } \xi \in \mathbb{R}^+.$$  

Now one shows that the function $F_i(p, \cdot)$ has a ‘linear structure’ on its relevant domain $D^i = \{ \psi \in \mathbb{R}^N | \psi_n = \int s_n(\xi) dG(\xi), \psi \in G, n = 1, \ldots , N \}$, that is,

$$F_i(p, \psi + \lambda \psi') = \lambda F_i(p, \psi) + (1 - \lambda) F_i(p, \psi')$$

for every $\psi, \psi' \in D$ and any rational $\lambda$ with $0 \leq \lambda \leq 1$. Indeed, $V_n = \int s_n(\xi) dG^\lambda(\xi) = \lambda \int s_n(\xi) dG(\xi) + (1 - \lambda) \int s_n(\xi) dG^2(\xi)$. Hence $\psi^1 + (1 - \lambda) \psi^2 \in D$ since $G^\lambda \in G$ for rational $\lambda$. Consequently, the closure $\overline{D}$ of $D$ is convex. Since $G^\lambda \in G$, one obtains from (5)

$$\int f_i(p, \xi) dG^\lambda(\xi) = F_i(p, \int s_1(\xi) dG^\lambda(\xi), \ldots, \int s_N(\xi) dG^\lambda(\xi)) = F_i(p, \psi^1 + (1 - \lambda) \psi^2).$$

The left hand is equal to $\lambda \int f_i(p, \psi) dG^1(\xi) + (1 - \lambda) \int f_i(p, \psi) dG^2(\xi) = \lambda F_i(p, \psi^1) + (1 - \lambda) F_i(p, \psi^2)$ by (5), which proves (8). Since $F_i$ is continuous, the ‘linear structure’ (8) also holds for any $y^1, y^2$ in the closure $\overline{D}$ of $D$ and any $\lambda$ with $0 \leq \lambda \leq 1$. Since $S_n(0) = 0$ and $f_i(p, 0) = 0$ it follows from (7) that $F_i(p, 0) = 0$. Consequently, by (8), the restriction of the function $F_i(p, \cdot)$ on the convex domain $\overline{D}$ can be extended to a function $\overline{F}_i(p, \cdot)$, which is linear in $y$, that is,

$$\overline{F}_i(p, y) = w_1(p) y_1 + \ldots + w_N(p) y_N.$$

Thus (7) implies (6). The extension is unique if the dimension of the convex domain $\overline{D}$ is equal to $N$.

**Remark:** The proof of Proposition 3 is quite simple since it was assumed that the representation (5) must hold for all income distribution functions for all finite populations. This case is also treated in Heineke and Shefrin (1988), their proof, however, requires differentiability. If one only requires (5) to hold for all income distribution functions of a given population $H$ with $N < \# P$, then it is much more difficult to obtain (6). See Lau (1982) and Heineke and Shefrin (1988).

Note that the global structural specification (6) is very restrictive if the demand function $f \in G$ has the basic properties of static demand theory. In fact, Heineke and Shefrin (1987) show the following result: if $f \in G$ satisfies the budget-identity, is homogeneous in $p$ and $x$ and if no budget share function $W_\lambda(p, x)$ is oscillating (that is, the derivative $\partial x W_\lambda(p, x)$ changes infinitely often its sign), then (6) implies $f(p, x) = \alpha(p) x$.

Indeed, if $f \in G$ satisfies the budget identity, then $0 \leq W_\lambda(p, x) \leq 1$. Let the budget share function $W_\lambda(p, \cdot)$ be non-constant and non-oscillating. Consider the function $\varphi_\lambda(x) = W_\lambda(p, x)$, and the linear function space which is generated by all functions $\varphi_\lambda(x)$, $\lambda > 0$. Heineke and Shefrin (1987) argue that the dimension of this linear space is infinite. By homogeneity, $\varphi_\lambda(x) = W_\lambda(p, \lambda x)$; thus, the linear space $\mathcal{L}$ which is generated by all budget share functions $W_\lambda(p, \cdot), p \in P$ has infinite dimension. Consequently, the demand function $f$ cannot satisfy (6), since (6) implies that $\dim \mathcal{L} \leq N$. Thus, if $f$ satisfies (6) and $W_\lambda(p, \cdot)$ is non-oscillating, then it must be constant, that is, $f(p, \cdot)$ is linear.
As a consequence, for demand functions which have the basic properties of atemporal demand theory including non-oscillating budget share functions, one either has to be satisfied with a representation as in Proposition 1 or one is in the trivial case of Antonelli's Theorem.

Heterogeneous populations

The representations (3), (4), and (5) of mean demand which have been considered up to now imply that the population of households must be homogeneous in demand behaviour, that is, \( f^h = f \), \( h \in H \). The reason for this unsatisfactory fact is due to the very strong requirement that the representations must hold for every conceivable income assignment. This is more demanding than is needed in many applications, since there, changes in individual income are not entirely arbitrary; they might be the result of an underlying process. This point was emphasized by Malinvaud (1956) and (1993). To capture this idea, one starts from an initial income assignment \((x_0^h)\) (status quo), and then one considers a sequence \((x_n^h)\), \( n = 1, 2, \ldots \) or a set \(\mathcal{X}(x_0)\) of income assignments which are viewed as the result of the underlying (unspecified) process. Which properties must the sequence \((x_n^h)\) or the set \(\mathcal{X}(x_0)\) have such that for any assignment of demand functions \( f^h \) the representations of mean demand hold along this sequence or on the set \(\mathcal{X}(x_0)\)?

We give three examples. The first one is well-known. The second and third example generalize substantially the first one.

Example 1: Fixed income shares

Starting from an initial income assignment \((x_0^h)\), one defines the set \(\mathcal{X}(\delta) \subset \mathbb{R}^H_+\) of income assignments

\[
\mathcal{X}(\delta) := \left\{ (x^h) \in \mathbb{R}^H_+ \left| \frac{x^h}{\overline{x}} = \frac{x_0^h}{\overline{x}_0} : \delta^h \right\} \right.,
\]

where \(\overline{x}\) denotes mean income across \(H\).

Given any assignment of demand functions \( f^h, h \in H \), there exists a function \( F \) from \(\mathbb{P} \times \mathbb{R}^J_+\) into \(\mathbb{R}^J_+\) such that mean demand has the representation

\[
\frac{1}{\# H} \sum_{h \in H} f^h(p, x^h) = F(p, \overline{x})\text{ on }\mathcal{X}(\delta) \times \mathbb{P}.
\]

The function \( F \) is defined by \( F(p, \overline{x}) = \frac{1}{\# H} \sum_{h \in H} f^h(p, \delta^h \overline{x}) \). If all \( f^h \) are linear in income then \( F(p, \overline{x}) \) is linear in mean income \(\overline{x}\). Moreover, Eisenberg (1961) and Chipman and Moore (1979) have shown: if all \( f^h \) are generated by a utility function homogeneous of degree one then \( F(p, \overline{x}) \) is also generated by a utility function homogeneous of degree one given by

\[
u(z) = \max_{z^h \in \mathbb{R}^H_+, \sum_h z^h = z} \prod_{h \in H} (\nu(x^h))^{x^h / \overline{x}_0}.
\]

Example 2: Rank preserving income changes

Starting from an initial income assignment \((x_0^h)\) \(h \in H\) one defines the set \(\mathcal{X}(x_0) \subset \mathbb{R}^H_+\) of income assignments \((x^h)\) which have the property that every household keeps his rank position of income, that is, if for two households \(j\) and \(k\), \(x_j^0 = x_k^0\) then \(x_j^h = x_k^h\) and if \(x_j^0 < x_k^0\) then \(x_j^h < x_k^h\). For any \((x_1^h)\) and \((x_2^h)\) in \(\mathcal{X}(x_0)\) there is a strictly increasing function \(\varphi\) such that
\( \phi(x^h_1) = x^h_2, \ h \in H. \) Examples for \( \phi(\cdot) \) are given in Figure 3 (low income is increased, high income is decreased) and Figure 4 (low and high incomes are decreased, middle ones increased) below.
Note that \((x^h) \in \lambda(x_0)\) implies \(x(x) = x(x_0)\) and \((x^h) \not\in \lambda(x_0)\) implies \(x(x) \cap x(x_0) = \emptyset\). Thus, there is a finite partition \(\{Y_i\}\) of \(\mathbb{R}_+^H\) into sets \(Y_i\) of rank preserving income assignments.

Note that for any rank preserving income assignments \((x^h)\) in \(\lambda(x_0)\) one can recover the income assignment from knowing only its distribution function \(G_x\), since \(x^h = G_{x}^{-1}c_0(x_0^h)\) for every \(h \in H\), where \(G^{-1}\) denotes the quantile function (quasi-inverse) of the distribution function \(G\), which is defined by \(G^{-1}(q) = \inf \{x \in \mathbb{R}_+ : G(x) \geq q\}\). Consequently, one obtains:

Given any assignment of demand functions \(f^h\), \(h \in H\), there exists a function \(F(p, G)\) such that mean demand has the representation

\[
The function $F$ is defined by

$$F(p, C) = \frac{1}{\# H} \sum_{h \in H} f^h(p, x^h) = F(p, C) \text{on } \mathcal{X}(\mathbf{x}_0) \times P. \tag{10}$$

There might be larger sets than $\mathcal{X}(\mathbf{x}_0)$ for which the representation (10) holds. For example, if households $k$ and $j$ have the same demand function then one can interchange their rank position. Thus, in defining a set $\mathcal{X}$ for which (10) holds, one should take into account the heterogeneity structure of $(f^h)_{h \in H}$. This is done in the next example.

**Example 3: Common copula**

Let $\{f^1, \ldots, f^N\}$ be the set of distinct demand functions of the given assignment $(f^h)_{h \in H}$. Thus, for $h \in H$ there is an integer $n(h) \leq N$ such that $f^h = f^n(h)$. For every income assignment $(x^h)_{h \in H}$ consider the bivariate distribution function $D_x$, which is defined by

$$D_x(\xi, \eta) := \frac{1}{\# H} \# \left\{ h \in H \mid x^h \leq \xi \text{ and } n(h) \leq \eta \right\}, \xi, \eta \in \mathbb{R}.$$

The distribution function $D_x$ and the price vector $p$ determines mean demand $\frac{1}{\# H} \sum_{h \in H} f^h(p, x^h)$. The marginal distribution functions of $D_x$ are denoted by $G_x$ and $V_x$.

By Sklar's Theorem (see, for example, Nelson, 1999), for every bivariate distribution function $D$ with marginals $G$ and $V$, there exists a copula $C$ (a function from $[0,1]^2$ into $[0,1]$ with certain properties) such that $D(\xi, \eta) = C(G(\xi), V(\eta))$ for all $\xi, \eta \in \mathbb{R}$. Conversely, if $C$ is a copula and $G$ and $V$ are distribution functions, then $C(G(\xi), V(\eta))$ is a bivariate distribution function. Thus, a copula 'couples' the marginals to the bivariate distribution. The copula models the dependence structure of the bivariate distribution function.

Starting from an initial income assignment $(x^h_0)$, one considers the set $\mathcal{X}(x_0, f) \in \mathbb{R}^H_+$ of income assignments $(x^h)$ such that the corresponding bivariate distribution functions $D_x$ have a common copula. Thus, the dependence structure of $(x^h, f^h)$ across $H$ is the same for all $(x^h)$ in $\mathcal{X}(x_0, f)$. It follows that income assignments in the set $\mathcal{X}(x_0, f)$ of rank preserving income assignments is contained in the set $\mathcal{X}(x_0, f)$. Furthermore, given any assignment of demand functions $(f^h)_{h \in H}$, there exists a function $F(p, C)$ such that mean demand has the representation

$$\frac{1}{\# H} \sum_{h \in H} f^h(p, x^h) \equiv F(p, C) \text{ on } \mathcal{X}(x_0, f) \times P.$$

There is a very simple, however, special case which is worthwhile to be mentioned (and could have been discussed at the beginning). If the initial income $x^h_0$ and the demand function $f^h$ of household $h$ are independently distributed across $H$, that is, $D_x(\xi, \eta) = G_x(\xi) V(\eta)$ (the copula of $D_x$ is equal to $C(u, v) = u \cdot v$), then the set $\mathcal{X}(x_0, f) = \{x(0)\}$ is very large; it consists of all income assignments $(x^h) \in \mathbb{R}^H_+$ with the property: $x^h_0 = x^j_0$ implies $x^k = x^j$. Then, one obtains

$$\frac{1}{\# H} \sum_{h \in H} f^h(p, x^h) \equiv F(p, C) \text{ on } \mathcal{X}(x_0) \times P.$$
with \( F(p, G) = \int f(p, \xi) dG(\xi) \) where \( f(p, \xi) = \frac{1}{2H} \sum_{k \in H} f^h(p, \xi) \).

3 Monotone mean demand

The 'law' of demand for a population of households asserts that the vector of price changes \( \Delta p \in \mathbb{R}^l \) and the resulting vector of mean demand changes \( \Delta F \in \mathbb{R}^l \) point in opposite directions, provided the price changes do not affect households' incomes (total expenditure) and demand functions (preferences). Thus, the 'law' asserts that the mean demand function \( F(p) \) is strictly monotone, that is,

\[
(p - q) \cdot (F(p) - F(q)) < 0 \text{ for all } p, q \in \mathbb{R}^l_+ \text{, } p \neq q.
\]

Strict monotonicity of mean demand implies, in particular, that for every commodity \( i \) the partial mean demand function \( F_i \) is strictly decreasing in its own price \( p_i \) and that the mean demand function \( F(\cdot) \) is invertible (existence of an inverse demand function).

The goal of aggregation theory is to derive strict monotonicity of mean demand without assuming that households' demand functions \( f^h(p, x) \) are strictly monotone in \( p \).

Demand functions \( f^h \in \mathcal{D} \) are assumed to be continuous in \( p \) and \( x \) and satisfy the budget-identity \( p \cdot f(p, x) = x \). The function \( f \in \mathcal{D} \) satisfies the Weak Axiom of revealed preferences if for every price-income pair \((p, x)\) and \((p', x')\), \( p \cdot f(p, x) \leq x \) implies \( p \cdot f(p', x') \leq x' \), and satisfies the Axiom of revealed preferences, if \( f(p, x) \neq f(p', x') \) and \( p \cdot f(p, x) \leq x \) implies \( p' \cdot f(p', x') > x' \).

Every demand function which is derived from a continuous, strictly convex and non-saturated preference relation satisfies the Axiom, yet it is not necessarily monotone.

**Theorem:** (Hildenbrand, 1983)

1. The function \( F(p)^0 = \int_0^\infty f(p, x) \rho(x) dx \) is monotone, that is, \( (p - q) \cdot (F(p) - F(q)) \leq 0 \) for all \( p, q \) in \( \mathbb{R}^l_+ \), if \( f \in \mathcal{D} \) satisfies the Weak Axiom of revealed preferences and \( \rho \) is a density which is non-increasing on \( \mathbb{R}^l_+ \) with \( \int_0^\infty \rho(x) dx < \infty \).
2. The function \( F \) is strictly monotone, if, in addition, \( f \) satisfies the Axiom of revealed preferences and the expansion paths \( f(p, \cdot) \) and \( f(x, \cdot) \) have only 0 in common for any \( p, q \) that are not collinear.

**Interpretation:** The underlying micro-model is a population \( H \) of households which is 'indefinitely large'; mathematically, an atomless measure space, for example, the unit interval \([0,1]\) with Lebesgue measure. Every household \( h \in [0,1] \) is modelled by its income \( x(h) \) and the common demand function \( f \). The income assignment \( x(\cdot) \) is an integrable function whose distribution admits a density \( \rho \). Thus, mean demand \( F(p) = \int f(p, x(h)) dx = \int f(p, x) \rho(x) dx \).

Three qsts are relevant:

1. Why a continuum of households? Does the result still hold approximately for a large but finite population?
2. Why a non-increasing income density? Does monotonicity of \( F \) fail if the density is first increasing and then decreasing?
3. Why a common demand function? Does the result extend to heterogeneous populations in income and demand behaviour?

The discussion of these qsts is simplified by assuming that \( f \) is continuously differentiable in \( p \) and \( x \). Then monotonicity of \( F \) is equivalent with negative semi-definiteness (n.s.d.) of the Jacobian matrix \( \partial p f^h(p) \) for all \( p \), that is, \( \sum_{i=1}^l \sum_{j=1}^l \partial^2 p F_{ij}(p) \leq 0 \) for all \( \nu \in \mathbb{R}^l_+ \) and the Weak Axiom for \( f \) is equivalent with n.s.d. of the Slutsky substitution matrix. Consequently, monotonicity of \( F \) follows from the positive semi-definiteness (p.s.d.) of the mean income effect matrix \( h(f, \rho) = \int h(f, x) \rho(x) dx \), where \( h(f, x) = (f(p, x) \partial x f_j(p, x))_{i,j=1, \ldots, l} \).

**Question 1:** The mean income effect matrix for a finite population \( H \), that is, \( \sum_{h \in H} \rho(h) \cdot \partial x f_j(p, x^h)_{i,j=1, \ldots, l} = l_H \) is p.s.d. if and only if for every \( \nu \in \mathbb{R}^l \), \( \nu^T l_H \nu = \frac{1}{2} \sum_{h \in H} \rho(h) \partial x f_j(p, x^h)_{i,j=1, \ldots, l} \geq 0 \).
aggregation (theory): The New Palgrave Dictionary of Economics

where \( g(x) = \frac{1}{2} (v \cdot f(p, x))^2 \). Assume that income \( x^h \) is measured in multiples of \( \Delta \) (euro). Let \( \pi_n = \frac{1}{H} \# \{ h \in H \mid x^h = n \cdot \Delta = : x_n \} \), \( n = 0, 1, \ldots \).

1. (1) \( \frac{2}{\Delta H} \sum_{n=0}^{\infty} \pi_n g'(x_n) = \sum_{n=0}^{\infty} \pi_n g'(x_n) = \frac{1}{\Delta} \sum_{n=1}^{\infty} (\pi_{n-1} - \pi_n) g(x_n) + o(\Delta) \) using the approximation
2. (2) \( g'(x_n) = \frac{1}{\Delta} (g(x_{n+1}) - g(x_n)) + o(\Delta) \).

Consequently, one needs \( \pi_{n-1} \geq \pi_n, n = 1, \ldots \), to obtain a non-negative first term on the right hand side of (1); this is the finite analogue of a non-increasing density. Thus, for a finite population with a small \( \Delta \) (which requires by \( \pi_{n-1} \geq \pi_n \) a large population) one obtains the desired result up to the small term \( o(\Delta) \). For a population \( H = [0, 1] \) one does not need the approximation (2) and hence \( o(\Delta) \), since (1) becomes \( \int g'(x) \rho(x) dx = - \int g(x) \rho'(x) dx \) (by partial integration), which is non-negative for a non-increasing differentiable density \( \rho \).

**Question 2:** The mean income effect matrix \( J(f, \rho) \) is p.s.d. in each of the two extreme cases: either, \( \rho \) is non-increasing and no assumption on the shape of the income expansion path \( f(p, \cdot) \) or, no assumption on \( \rho \) yet linearity of \( f(p, \cdot) \). There must be results in between. Indeed, if the curvature of all income expansion paths \( f(p, \cdot) \) is limited and the unimodal density \( \rho \) is sufficiently skewed, then \( J(f, \rho) \) is p.s.d.

**Example:** All income expansion paths restricted to the interval \( [0, \bar{x}] \) are polynomials of degree \( n \) (note that, no non-linear \( f(p, \cdot) \) can be a polynomial on \( \mathbb{R}^+ \) and \( \rho \) is concentrated on \( [0, \bar{x}] \). Then, \( J(f, g) \) is p.s.d. if and only if the matrix \( M(n, \rho) = (i + j) m_{i+j-1} \) is p.s.d. where \( m_i = \int k^i \rho(x) dx \) (Hildenbrand, 1994, Appendix 6).

Let the densities \( \rho_m \) be as in Figure 5.

**Figure 5**

![Figure 5](http://www.dictionaryofeconomics.com/proxy.library.csi.cuny.edu/article/id=pde2008_A000247&goto=a&result_number=22[15];18[15];2008-12-29)
For every $n$ there exists $m(n) > 0$ such that $\lambda(f, \rho, \sigma)$ is p.s.d. if $m \leq m(n)$; for example, $n = 2$, $m(2) = 0.38 \bar{x}$ or $n = 3$, $m(3) = 0.14 \bar{x}$.

For a more general analysis see Chiappori (1985) and Hildenbrand (1994).

Question 3: A population of households that is heterogeneous in income and demand functions is described by a joint distribution $\mu$ of income and demand functions, that is, $\mu$ is a distribution on $\mathbb{R}_+ \times \mathfrak{D}$. (A reader not familiar with distributions on function spaces might replace $\mathfrak{D}$ by a finite set $\mathfrak{D}_0$.) As before, the marginal distribution of income admits a density $\rho$.

The conditional distribution of demand functions given the income level $x$ is denoted by $\bar{\tau}(\rho, x)$. Then mean demand

$$F(p) := \int_{\mathbb{R}_+ \times \mathfrak{D}} f(p, x) d\mu = \int_{0}^{\infty} \bar{\tau}(\rho, x) \rho(x) dx,$$

where $\bar{\tau}(\rho, x) := \int_{\mathfrak{D}} f(p, x) d\nu(x)$. Consequently, the Theorem or the extensions discussed under Question 2 imply that $F(p)$ is monotone provided the function $\bar{\tau}$ satisfies the Weak Axiom. This approach to derive monotonicity for a heterogeneous population is the most direct, yet not the most general way (see Hildenbrand, 1994).

It is well-known (Hicks, 1956, p. 53) that $\bar{\tau}$ does not necessarily satisfy the Weak Axiom, even if individual demand functions are derived from utility maximization. The following two assumptions (which, again, are not the most general ones) imply that $\bar{\tau}$ satisfies the Weak Axiom:

1. (a) independence: $\nu(x)$ does not depend on $x$
2. (b) increasing dispersion: the distribution $D(x + \Delta), \Delta > 0$, is more dispersed than the distribution $D(x)$, where $D(\xi)$ denotes the distribution (in the commodity space $\mathbb{R}^l$) of individual demand of all households with income $\xi$ at the price $p$ (that is, $D(\xi)$ is the image distribution of $\nu$ under the mapping $f \mapsto f(\rho, \xi)$).

Generalizing the one-dimensional case where the variance is a measure of dispersion one chooses the positive definiteness of the covariance matrix as a measure of dispersion for distributions on $\mathbb{R}^l$. Thus, increasing dispersion means that for $\Delta > 0$, $\text{cov}D(x + \Delta) - \text{cov}D(x)$ is positive semi-definite.

Assumptions (a) and (b) are quite restrictive, in particular, the independence assumption. Therefore one partitions the whole population $H$ into sub-populations $H(a)$ by stratifying with respect to a certain vector $a$ of household attributes (household size, age, …) and then one requires assumptions (a) and (b) for each sub-population $H(a)$. The role of stratifying is to reduce the heterogeneity in demand behaviour. In the extreme case, where stratifying leads to a homogeneous sub-population in demand behaviour, assumptions (a) and (b) are trivially satisfied. If the income density of each sub-population $H(a)$ is non-increasing on $\mathbb{R}_+$ or if the extension discussed in Question 2 apply, the mean demand of each sub-population is monotone and hence also the mean demand of the whole population, since monotonicity is additive.

A more general definition of ‘increasing dispersion’ and a detailed discussion is given in Hildenbrand (1994). For an empirical study of the law of demand, see Härdle, Hildenbrand, and Jerison (1991).

A broader discussion of the law of demand and related properties including cases where income is price dependent is contained in the entry law of demand.

Agricultural economics arose in the late 19th century, combined the theory of the firm with marketing and organization theory, and developed throughout the 20th century largely as an empirical branch of general economics. This emphasis was due to the historical importance of agriculture, and in the United States was made possible by the rich data compiled by the US Department of Agriculture beginning in the mid-19th century. The discipline was closely linked to empirical applications of mathematical statistics and made early and significant contributions to econometric methods. From the 1960s on, as agricultural sectors in the OECD countries contracted, agricultural economists were drawn to the development problems of poor countries, to the trade and macroeconomic policy implications of agriculture in richer countries, and to a variety of issues in production, consumption, environmental and resource economics. This ramified the subject and enlarged its international focus, at the same time as its microeconomic, empirical and policy orientation distanced it from developments in general equilibrium theory, macroeconomic modelling, game theory and axiomatic social choice, which preoccupied many departments of economics throughout the late 20th century.

Retracing the evolution of agricultural economics, especially in the United States, requires an explanation of institutional innovation in 19th-century America (see Taylor and Taylor, 1952). In the midst of the Civil War, President Lincoln created the Federal Department of Agriculture (later the US Department of Agriculture, USDA), empowered to collect a wide range of farm statistics. At the same time, legislation introduced by Vermont's Justin Morrill (previously blocked by the seceded South) was signed in 1862 by Lincoln. The Morrill Act established the Land Grant Colleges (financed through sales of government land) especially in the states of the Old Northwest Territory: Illinois, Indiana, Michigan, Ohio and Wisconsin. Their creation reflected both vast surpluses of land and the drive to improve plant and animal husbandry through applications of chemistry and biology. Eventually, the land grant model was replicated in every state as well as in some other countries. In 1887 the Hatch Act created the Agricultural Experiment Stations of USDA, which functioned together with the Land Grant Colleges to form a system of research, instruction and outreach to farmers (Cochrane, 1993; Kerr, 1987; Moore, 1988). In 1914, extension education and outreach was formalized under the Smith–Lever Act. By the beginning of the 20th century, the application of scientific management to agricultural production created the foundations of the discipline.

Intellectual origins

Agricultural economics in the United States derived from two intellectual streams. The first was neoclassical political economy and the theory of the firm applied to farm production. The second, borne of an economic crisis in American agriculture in the late 19th century, focused on strategies for organized marketing of agricultural commodities through collective bargaining and cooperatives. The first stream may be traced to the 18th-century Enlightenment and a preoccupation with land as a factor...
by the French Physiocrats. François Quesnay's *Tableau économique* (1758) organized a logical explanation of the conversion of land inputs to agricultural outputs and profit, anticipating modern production economics, input–output analysis and general equilibrium theory. His emphasis on surplus production was a touchstone of classical economics and exercised a direct influence over Adam Smith (Eltis, 1975; Smith, 1776, book II, ch. 9).

Like all 18th-century political economists, Smith could not ignore agricultural questions, even if he gave them less primacy than the Physiocrats. Together with Ricardo, Von Thünen and Malthus, he provided commentary on the difficulties of agricultural specialization, returns to land as a factor, issues of space and distance to market, and the long-run relation between arithmetic increases in food supply and geometric increases in demand due to population growth. Many pages of the *Wealth of Nations* dealt with agricultural questions, including the differential capacity for specialization and routinization of agriculture versus industry and the arts of husbandry at the microeconomic level (1776, pp. 16, 143). Echoing the Physiocrats, Smith emphasized the central role of agriculture as a store of national wealth, and noted that compared with manufacturing, agriculture ‘is much more durable, and cannot be destroyed by [the] violent convulsions’ of war and political instability (1776, p. 427). In the same period, Arthur Young assembled comprehensive data on production, rents and land tenure in Great Britain. Serving as editor of the *Annals of Agriculture* from 1768 to 1770, he collected his data and observations into nine volumes of 4,500 pages, which have proved to be of continuing value especially to economic historians (for example, Allen, 1992). Ricardo (1821, p. 44) was famously concerned with returns to land as a fixed factor ‘for the use of the original and indestructible powers of soil’. He also distinguished between productivity enhancements due to augmentation of the soil and improvements in machinery and the capitalization of various investments or policies (such as taxes) into the value of land (1821, pp. 57–61; 246). Von Thünen’s (1828) analysis of the extensive margin and the relationship between distance to market and rent made him, in Marshall's view, the first agricultural economist among economists, who with Cournot provided the inspiration for marginalist economics (Day and Sparling, 1977, p. 93).

It was the neoclassical developments of the late 19th century, however, that provided the main foundations for agricultural economics. Marshall's *Principles* (1890) first clearly established the link from diminishing marginal utility in exchange to decreasing marginal productivity on the supply side. Veblen (1900) dubbed Marshall's work ‘neoclassical’ to distinguish it from classical labour theories of value. The elaboration of Marshall's theory of the firm, and attempts to measure and statistically validate the relationship between input costs, output prices, and farm profits distinguished agricultural economics well into the 20th century, and linked it firmly to the neoclassical syntheses of Hicks (1939) and Samuelson (1947).

To this was added a second stream of marketing and organizational issues growing out of the extended farm depression from the 1870s to the 1890s. Joined with labour interests, farmers sought marketing outlets and modes of organization that would give them greater bargaining power, notably cooperatives popular in northern Europe and Scandinavia, where many recently arrived American farmers originated (Jesness, 1923). Even after the business cycle turned upward after 1897, the Land Grant colleges emphasized farm management. The result was the organization in 1910 of the American Farm Management Association. Farm managers were focused on the physical, technical and scientific aspects of production, especially the new field of agronomy.
Many early agricultural economists regarded farm management as a sub-field, and agricultural economics as an applied version of general economics. Beginning in 1907, at the tenth American Economic Association (AEA) meetings, a session was devoted to ‘What is agricultural economics?’ Thereafter, the AEA regularly included sessions on the economics of agriculture. In 1915 the National Association of Agricultural Economists was formed. In 1917 the AEA meeting was held jointly with the National Agricultural Economics Association and the American Farm Management Association, and talks began on a merger of the latter two. This was realized in 1919 in the form of the American Farm Economics Association, with Henry C. Taylor of the University of Wisconsin as President (Taylor, 1922; Cochrane, 1983). It retained this title until 1968, when it became the American Agricultural Economics Association (AAEA).

**The discipline expands**

As Cochrane (1983, p. 66) observed, ‘the first flowering of agricultural economics as an applied field of economics occurred at the University of Wisconsin in the period of 1900–1920. The second flowering occurred at the University of Minnesota in the period of 1918–1928.’ A department of agricultural economics was established at Wisconsin in 1909 by Henry C. Taylor and colleagues such as Benjamin Hibbard. Taylor's text, *An Introduction to the Study of Agricultural Economics* (1905), applied Marshallian principles to farm production, and developed production functions showing increasing, steady and diminishing returns. Among the most influential leaders in the young subject was Taylor’s student at Wisconsin, John D. Black, who also studied under John R. Commons and Richard T. Ely (who himself authored an influential, though unpublished, 1904 study on the economics and property rights of irrigation). Their emphasis on land and institutions permeated the discipline and was reflected in the journal *Land Economics*, which began publication at Madison in 1925.

Black, a follower of Marshall and John Bates Clark, received his Ph.D. in 1918 and moved to the University of Minnesota, where he remained a dominant force until hired by Harvard in 1927. By the mid-1920s Black's leadership had marked him, together with George F. Warren of Cornell and Edwin G. Nourse of Iowa State, as ‘the most influential economist in the United States dealing with the problems of agriculture’ (Galbraith, 1959, p. 10). Together with a cadre of other young economists working with the Bureau of Agricultural Economics (BAE), created in USDA in 1921, Black set the tone for research in the field from the 1920s until the advent of the Second World War.

Black's text, *Introduction to Production Economics* (1926), became the standard. His emphasis on the theory of the firm was complemented by his colleague Holbrook Working's econometric explorations. Working's 1922 bulletin, ‘Factors Determining the Price of Potatoes in St. Paul and Minneapolis’, was among the first to derive an empirical demand curve (H. Working, 1922; 1925). It was followed by his brother E. J. Working's widely cited 1927 article, ‘What Do Statistical “Demand Curves” Show?’ The Workings and colleague Warren Waite continued to expand research into price analysis in the interwar years. Minnesota's Frederick V. Waugh contributed the first quantitative study of quality characteristics as determinants of prices, recognized as a forerunner of hedonic price analysis. Appearing as ‘Quality Factors Influencing Vegetable Prices’ (1928), it noted that if ‘a premium for certain qualities and types of products is more than large enough to pay the increased cost of growing a superior product, the individual can and will adapt his production and marketing policies to market demand’ (quoted in...
Taylor, Black, Warren and Nourse were followed by a group of young empiricists and econometricians who continued to develop the USDA Bureau of Agricultural Economics (BAE). Tolley, Black and Ezekiel (1924) showed how production surfaces in three dimensions could express diminishing returns to inputs, a concept readily grasped by agricultural field scientists. They then derived cost surfaces showing the relationship between costs, relative prices, and profit maximization. Ezekiel followed this empirical work with his 1930 volume *Methods of Correlation Analysis*, which became a standard text on regression analysis, and in 1938 with a state-of-the-art description of cobweb and recursive models illustrated by the corn–hog cycle. Leontief (1971, p. 5) would call this and other early agricultural economists’ work ‘An exceptional example of a healthy balance between theoretical and empirical analysis …’ and ‘the first among economists to make use of the advanced methods of mathematical statistics’.

By the 1930s departments of agricultural economics had been established in many US universities, where technical and institutional issues affecting agricultural production formed the core subjects. In addition to the leading roles played by Cornell, Illinois, Iowa State, Minnesota, Purdue and Wisconsin, a major research programme was established at the University of California-Berkeley (and a later campus at Davis) with the endowment of the Giannini Foundation. At Iowa State, future Nobel Laureate T.W. Schultz arrived in 1930 with a Ph.D. from Wisconsin, and then served as department head from 1934 to 1943 until leaving for Chicago. Schultz attracted numerous talents including Kenneth Boulding, George Stigler, D. Gale Johnson and Earl O. Heady, several of whom would also leave for Chicago following controversy surrounding oleomargarine and the Iowa butter industry (Beneke, 1998). The butter–margarine dispute was typical of agricultural economists’ conflicts with interest groups in a profession seldom sheltered from political winds, especially at state universities. Partly for this reason, several private universities also made substantial contributions to agricultural economics research. In addition to Black (and later Galbraith) at Harvard, the University of Chicago remained a center of research excellence. At Vanderbilt, Nicholas Georgescu-Roegen, a demand theorist and econometrician, expressed path-breaking insights into the physical process underlying economic activity, and contributed a deep critique of agrarianism and Marxian misunderstandings of agricultural production (Georgescu-Roegen, 1960).

Earl O. Heady remained at Iowa State, creating a post-war engine of applied research, the Center for Agricultural Research and Development (CARD), in 1957. He pioneered the application of programming methods first developed for war planning, analysing how inputs could most efficiently be employed in producing agricultural outputs. This made the discipline a centre for research in applications of optimization theory. Heady authored or oversaw hundreds of mainly empirical production studies, exemplified by Heady and Dillon (1961) and Heady and Candler (1958). He also pioneered the application of computing power to problem-solving in applied economics. This included work on human and animal diet rations and consumption (for example, Waugh 1951; Heady 1951). Farm management also saw optimization applications in work by Hildreth (1957a) among others. By the late 1950s Bellman’s dynamic programming principle was applied to optimal wheat rotations by Burt and Allison (1963). Agricultural economics also began to grapple empirically with uncertainty through stochastic programming methods, including Hildreth's (1957b) work and Hazell's applications (1971).
French economists Boussard and Petit applied Shackle's 'focus loss' concept of uncertainty to agriculture (1967). The application of subjective probability concepts to agriculture was surveyed by Dillon (1971) and Anderson, Dillon and Hardaker (1977).

Yet another outgrowth of optimization theory was analysis of the growth and decline of farms in modern economies, including contributions by German agricultural economists Heidhues (1966) and De Haen (De Haen and Heidhues, 1973). Behavioural adjustment ('supply response') in agriculture was studied using recursive programming models (Henderson, 1959), and generalized by Day (1963), following the path set by Nerlove (1958). Optimal storage rules were analysed by Gustafson (1958). Spatial issues in agriculture analysed best-location decisions (Egbert and Heady, 1961), and interregional supply–demand equilibrium issues (for example, Fox, 1953). An extensive bibliography of spatial and temporal equilibrium models was published by Judge and Takayama (1973).

New frontiers

Two additional applications of optimization theory pushed agricultural economics in the 1960s and 1970s toward new frontiers: natural resources and agricultural development in developing countries. These helped attract a new generation of economists concerned less with domestic farm production than with environmental issues and poverty alleviation in the Third World. Natural resources were analysed as problems of materials shortages and treated as a form of capital, following the early analytical leads of Hotelling (1931) and Ciriacy-Wantrup (1952). Especially after the Paley Commission Report of 1952 led to the creation of Resources for the Future in Washington, DC, a new group of economists applied themselves to these issues. Fisheries were studied by Scott (1955) and Crutchfield and Zellner (1962); groundwater allocation over time was considered as a dynamic programme with stochastic state variables in a series of articles by Burt (for example, Burt, 1966; Burt and Cummings, 1970). These dynamic models were extended to interregional investments in water in studies such as Cummings and Winkelmann (1970). By the 1970s, environmental pollution became a major subject of applied economics, pulling many in the profession away from a restricted view of agricultural issues as matters of yields and production in acknowledgement of the sector's negative external effects and market failures.

Agricultural development in developing countries, meanwhile, was an important area of applied economics in project evaluation, supported by multilateral and bilateral aid agencies such as the World Bank, the Food and Agriculture Organization of the UN (FAO) and US Agency for International Development. At Stanford, the Food Research Institute (1921–95) established an internationally focused research programme. The development problem in the Third World was seen largely as an imbalance between agricultural and manufacturing sectors, with a need to right this balance by drawing low-productivity resources out of agriculture (Lewis, 1954; Mellor, 1966; Timmer 2002). Hollis Chenery at the World Bank exemplified the analysis of agriculture's sectoral role (Chenery and Syrquin, 1975).

However, unlike the United States and some other OECD countries, data limitations in poor countries restricted the early application of optimization models at the microeconomic level. Indeed, T.W. Schultz's famous *Transforming Traditional Agriculture* (1964) relied mainly on stylized representations of 'rational but poor' farmers and descriptive analysis from anthropologists.
Throughout the 1950s and 1960s the agricultural sector continued to contract in the OECD countries, setting the tone for policy debates. Many agricultural economists saw the ‘farm problem’ as one of surplus labour supplying farm commodities in excess of domestic demand. Analysing low agricultural prices as a matter of chronic oversupply, aggravated by rapid technological improvements and productivity gains in the face of inelastic demand, Cochrane (1958) proposed his treadmill hypothesis: rapid and early adopters of productivity-improving technology will reap the lion's share of rents to innovation, as laggards are forced off the farm, while Brewster (1959) considered the social and policy implications of these trends. In the early 1960s, serving as presidential adviser, Cochrane advocated a solution to excess production in the form of federally mandated supply control. When it became clear that the major commodity groups would vote down the enabling referenda, and that its success would raise prices to consumers, President Kennedy abandoned the scheme. Thereafter, although mandated supply control retained adherents (not including Cochrane), US agricultural policy shifted towards exports as a vent-for-surplus.

This opened the way to consideration of agriculture in an open economy, and a new policy emphasis on the macroeconomics of the food sector (Schuh, 1974; 1976; Cochrane and Runge, 1992; Ardeni and Freebairn, 2002; Abbott and McCalla, 2002). In the 1980s, this open economy analysis was supported by the development of large-scale computable general equilibrium models linking agriculture to trade (for example, Hertel, 1997) as well as more traditional macroeconomic sectoral forecasting models (for example, Myers et al., 1987). Together, the large-scale models allowed alternative trade and agricultural policy approaches to be simulated and compared to the status quo (for example, Cochrane and Runge, 1992).

International reach

The intellectual antecedents of agricultural economics make clear that the field has never been restricted to the United States. In 1905, the International Agricultural Institute was founded in Rome as the forerunner of the FAO. In Great Britain, an Agricultural Economics Research Institute was established at Oxford in 1913, and in 1945 became part of the School of Rural Economy, merging with Queen Elizabeth House and the Institute for Commonwealth Studies in 1986. Oxford led the creation of the International Association of Agricultural Economists and helped coordinate its first conference in 1929 at Dartington Hall, Devon and a second in 1930 at Cornell. These were largely Anglo-American meetings, although by the third meeting in Germany in 1934, 19 different countries were represented. At Cambridge, a Department of Estate Management was transformed into a Department of Land Economy in the 1960s. At Wye, an agricultural college was founded in 1894. The college was awarded a royal charter in 1948 and in 2000 its agricultural economics department became part of Imperial College London.

On the Continent, followers of Von Thünen had developed marginalist principles and farm accounting methods in the late 19th and early 20th century represented by the Laur School in Switzerland and the Sering and Serpieri Schools in Germany and Italy. However, their capacity was limited by poor data, few marketing studies, and a weak connection to production economics (Nō u, 1967; Raeburn and Jones, 1990, p. 13). In 1948 a French professional association began, and a Department of Agricultural Economics was created at the Institut National de la Recherche Agronomique (INRA) in 1955 (Petit,
A European Association of Agricultural Economists was founded in 1975 in Uppsala, Sweden. By the late 1980s, it was estimated that 3,000–5,000 European professionals were engaged in full-time agricultural economics research dispersed in hundreds of research institutes, universities and government offices (Hanf, 1988). Among the leaders were the French government's INRA, the Universities of Goettingen and Kiel in Germany, the University of Padova in Italy, Wageningen University in the Netherlands, and the aforementioned activities in Great Britain.

In Canada, agricultural economics began at the Ontario Agricultural College (now the University of Guelph) in 1907. Noteworthy research departments of agricultural economics were established at the University of Guelph, Ontario, McGill University in Montreal, Laval University in Quebec, and the Universities of Manitoba, Alberta, Saskatchewan and British Columbia.

The Australian Agricultural Economics Society was founded in Sydney in 1957, following the models of the US, British and Canadian associations. In 1975, a New Zealand branch of the association was established at a meeting in Christchurch. The leading Australian institution in creating a separate department was the University of New England at Armidale, which in 1958 began a four-year course. Supported by grants from the Commonwealth Bank, a chair of agricultural economics was appointed at the University of Sydney in 1951 (Campbell, 1985). While maintaining the specialty within economics rather than a separate department, major research was also undertaken beginning in the 1950s and 1960s at the University of Adelaide and at the University of Melbourne, and later at the Australian National University in Canberra and the University of Western Australia in Perth. All of these universities were closely linked to the national Bureau of Agricultural Economics (BAE), which became the Australian Bureau of Agriculture and Resource Economics (ABARE) in 1987 (Miller, 1985).

In Russia, interest in agricultural economics may be traced to the establishment in 1865 of the Moscow Agricultural Academy. In 1929 Lenin created the Russian Academy of Agricultural Sciences, following conflicts between Chayanov and Marxist agriculturalists. After Stalin's rise to power in 1930, agricultural research was fully politicized with well-known results, including the purge of many academic researchers (Nazarenko, 2004). In the 1950s, concepts such as profit and cost were revived, and central planners embraced modelling and forecasting. Since the 1990s, agricultural reforms have led to dissension in the Russian discipline (Klyukach, 2004).

In Brazil, the Rockefeller and Ford Foundations and the US Agency for International Development provided core support for agricultural economics research, beginning in the late 1950s. Four US universities were directly involved: Purdue, Wisconsin, Ohio State and Arizona.

In India, a Society of Agricultural Economics was established in 1939. The advent of indicative economic planning in the 1950s stimulated analytical studies to assist in the Plan. Due to the overwhelming importance of agriculture as a supplier of wage goods, the sector attracted considerable analysis, in which Indian agricultural universities, established on the land-grant model, consciously borrowed methods from their US counterparts, notably Earl O. Heady and the CARD group at Iowa State (Bhide, 1994, p. 119).

In China, missionary efforts to promote agricultural research and development by the Presbyterian Church of New York during the first quarter of the 20th century resulted in a Cornell University–University of Nanking collaboration, led beginning in 1914 by John Lossing Buck (Buck, 1973). J. L. Buck's contributions included early agricultural surveys and analysis of Communist production into the 1960s (Buck, 1943; Buck, Dawson and Wu, 1966).
Late 20th century

Since the 1970s, seven broad subjects have defined the most distinctive contributions of agricultural economics: technical change and the returns to human capital investments; environmental and resource issues; trade and economic development; agricultural risk and uncertainty; price determination and income stabilization; market structure and the organization of agricultural businesses; and consumption and food supply chains.

The study of technical change, innovation and returns to investments in human capital in agriculture attracted some of the most talented economists of the post-war generation, such as Zvi Griliches (1957; 1958; 1963; 1964). Anticipating debates among economic growth theorists over ‘embodied’ technical change due to improvement in the quality of capital inputs (versus ‘disembodied’ changes without new net capital investments), Cochrane (1953) criticized Schultz (1953) for failing to account for capital requirements in agriculture and a resulting overemphasis on weather variations in describing growth in yields. Focusing on the direction of agricultural innovation, Ruttan (1956) and Hayami and Ruttan (1971) emphasized the Hicks-non-neutrality of technical change in both labour-saving US and land-saving Japanese agriculture. This approach was extended in a formal framework by Binswanger (1974).

Based on Hicks's (1932) analysis of relative factor prices as the inducement to alternative paths of innovation, the induced innovation argument was extended into an explanation of priority setting by public sector agencies, leading research towards abundant factor use that lowered social costs of production (Peterson and Hayami, 1977, p. 504). How to measure productivity and technical change in agriculture using alternative index numbers attracted both theorists and applied econometricians (for example, Jorgenson and Griliches, 1967; Lau and Yotopoulos, 1971). Finally, analysts considered the welfare gains and losses resulting from farm mechanization (Schmitz and Seckler, 1970).

Agricultural economists also delved into the role of productivity embodied in labour as ‘human capital’, a natural reflection of the huge public investments in research and education by the US land grant system. Surveyed by T. W. Schultz (1971), this line of research attracted work by Peterson (1969), Huffman (1974) and general economists such as Nelson and Phelps (1966), and led to widening emphasis on private and social returns to research including Peterson (1967), Evenson (1967), Evenson and Kislev (1976) and Alston et al. (2000). It also led to analysis of how research ought to be organized in order to maximize its aggregate benefits. Alston, Norton and Pardey (1998) developed a comprehensive summary of this priority-setting problem (see Huffman, 2002; Sunding and Zilberman, 2002).

Environmental and resource issues, as noted, became a significant focus of the profession in the 1970s and beyond, partly in recognition of the pollution and species losses resulting from modern agricultural systems. Surveyed by Lichtenberg (2002), the economics of agriculture and the environment analysed the perverse incentives created by agricultural subsidies and the agency problems of monitoring agricultural practices (for example, Chambers and Quiggin, 1996; Just and Antle, 1990; Segerson, 1988). Induced innovation theory was broadened to explain how technical innovations such as irrigation might give rise to new water quality issues and thus new institutional responses (for example, Runge,
Apart from specific agriculture–environment interactions, resource economists emphasized the critical role of property rights in the use and management of resources, especially those held publicly or in common, notably in developing countries (Runge, 1981; Bromley, 1991; Walker, Gardner and Ostrom, 2000).

Trade and development also dominated agricultural economics research, especially after the mid-1980s, as global trade negotiations increasingly hinged on struggles between heavily subsidized farm sectors in OECD countries and the highly taxed sectors of the developing world (Anderson and Hayami, 1986; Kreuger, Schiff and Valdes, 1991–2; Sumner and Tangermann, 2002). An overview of post-war agricultural trade policy was given by D. G. Johnson (1977); a synthetic treatment of agriculture–trade interactions was provided by Karp and Perloff (2002). Meanwhile, a major share of agricultural economics literature was devoted to microeconomic studies of agricultural change and food insecurity in developing countries, and to macroeconomic linkages with other sectors and global trade (for example, Barrett, 2002; Runge et al., 2003).

Risk and uncertainty are inherent in agriculture and their relevance has drawn interest from many agricultural economists, especially in developing-country decision environments (see Moschini and Hennessey, 2002). Roumassett (1976) conducted an early assessment of risk aversion and the adoption of hybrid rice in the Philippines. Dillon and Scandizzo (1978) analysed risk preferences among small farmers in Brazil, while Moscardi and de Janvry (1977) analysed Mexican maize production and the response to risk. Antle (1987) and Myers (1989) provided econometric tests for risk aversion by farmers while Goodwin and Smith (1995) and Miranda and Glauber (1997) considered why crop insurance contracts fail effectively to pool risk without reinsurance.

Price determination and stabilization of agricultural prices as a focus of research arose as a direct consequence of widespread instability in agricultural commodities markets. Tomek and Robinson (1977) surveyed the post-war literature through the 1970s, including the analysis of Cochrane (1958) and Gray and Rutledge (1971). In response to widespread calls for buffer stocks and other mechanisms to affect prices counter-cyclically, Newberry and Stiglitz (1981) offered a comprehensive (and sceptical) assessment of the advantages of stabilization policy. A more recent survey was developed by Wright (2002).

The organizational structure of farms and the role of economies of scale, scope, technological change, capital and labour mobility were reviewed by Chavas (2002). Farm size was analysed as a function of the opportunity cost of labour and the price of machinery (Kislev and Peterson, 1982). Farm structure and the economics of contracting was also an additional area of risk and agency studies (Allen and Lueck, 1998; Hueth and Ligon, 2001; Knoeber and Thurman, 1995). Despite their declining importance in many rural markets, cooperatives continued to attract analysis (for example, Sexton, 1990).

A final area of broad interest was food consumption and supply chains in the food industry. Taking an industrial organization approach, Sexton and Lavoie (2002) provided an overview, emphasizing vertical and horizontal integration and imperfect competition as forces driving the sector, with implications for consumer choice, nutrition and health.

In the 21st century, the profession has continued to reach beyond the agricultural sector, expanding its scope through numerous applications of relevant economic theory. Meanwhile, the high level of
abstraction in economics characteristic of the last half of the 20th century appears to have given way to new interest in empirical and experimental studies, suggesting that the distance between agricultural economics and its mother discipline may narrow in the years ahead.

Economic analysis of agricultural finance has traditionally focused on access to capital in the agricultural sector. Key concerns have included patterns of non-price rationing in agricultural credit markets, the institutions and contracts that provide credit to agricultural producers, the implications of the conditions of capital access on agricultural growth and rural income distribution, and the role of the public sector in agricultural credit markets. More recently, the analysis of agricultural finance has expanded beyond these credit-centred concerns to consider systemic approaches to rural finance that address risk and insurance, savings services and the provision of credit.

**Article**

Several structural features of the agricultural sector make agricultural finance and financial markets distinctive. First, the demand for agricultural finance is potentially high. Agricultural production processes are roundabout, with outputs and returns coming months or even years (in the case of vineyards and tree crops) after expenditures on productive inputs. The extreme riskiness of agriculture further increases the demand for credit or other contracts that share the risk of the production process. A second distinguishing feature of agricultural finance is that the organization of agricultural production makes it difficult to supply with financial services. In a classic paper, John Brewster (1950) noted that agricultural production differed from industrial production because of its spatial dispersion and its heavy dependence on inherently random inputs provided by nature. These features create what more contemporary economic analysis would call agency problems, meaning that it is difficult for an outsider...
agricultural finance: The New Palgrave Dictionary of Economics
to either monitor directly the quality of labour and management on a farm, or to infer *ex post* the
qualities of those inputs from final agricultural output. As Brewster and others have remarked, the result
is that agriculture tends to be organized in small-scale units, with much of the labour and management
provided by the residual claimant to the production process (that is, it is rare to find large-scale ‘factories
in the field’ except in special historical circumstances, as discussed by Binswanger, Deininger and
Feder, 1995).

Excess demand for financial services

Agriculture thus stands as a sector with potentially high demand for financial services coming from
relatively small-scale, spatially disperse, hard-to-monitor firms. In the contemporary low-income
countries of Asia, Africa and Latin America, where the vast majority of farming households operate tiny
holdings of an acre or two, between 5 and 15 per cent of producers have formal financial contracts
(Braverman and Huppi, 1991). Others are observed to borrow from a variety of informal sources,
typically at nominal interest rates well in excess of those charged by formal financial institutions
(Braverman and Guasch, 1986).

While these observations are not by themselves sufficient to identify an excess demand for financial
services in agriculture, they are consistent with it. Bolstering this interpretation is the fact that the
characteristics of agriculture conform closely to the assumptions that underlie the formal economic
theory of credit rationing. The seminal analysis of Stiglitz and Weiss (1981) assumes precisely the sorts
of information costs and asymmetries that typify an agricultural sector comprising numerous, spatially
disperse firms producing a highly random output. As extended by Carter (1988), this theoretical
perspective suggests that adverse incentive and selection effects will prevent competitive formal lenders
raising interest rates to market clearing levels (because higher rates result in lower expected profits for
lenders as the borrowers still left in the market become increasingly less desirable as clients as interest
rates increase). The result, according to this theory, is an agricultural credit market characterized by
excess demand for formal credit and by a skewed allocation of (relatively cheap) formal credit toward
larger farm units.

Some of this residual excess demand would be expected to spill over to locally based informal agents
(moneylenders, input suppliers and processors). These lenders typically enjoy the twin advantages of
cheaper information (because they are local) and the capacity to accept collaterals that could not be
easily claimed by distant lenders (such as standing crops). Whether these agents are competitive
suppliers of credit, or whether they enjoy spatial monopolies that grant them real market power, remains
an open question (see, for example, Kochar, 1997; Bell, Srinivasan and Udry, 1997).

Implications of excess demand

While there is thus still debate about the degree of excess demand for financial services in agriculture,
its implications are potentially large at two levels. First, excess demand for finance may result in slower
agricultural technological change and growth. Again, examples from low-income countries make this
point most easily. A study of new, input-intensive agricultural export products in Central America found
that annual working capital requirements per hectare exceeded the total annual incomes that farm
families had been earning (Barham, Carter and Sigelko, 1995). The questionable ability of these families to self-finance investments of this magnitude, and to self-insure against the estimated 25 per cent failure rate of these activities, makes clear the economic costs of excess demand for agricultural finance. The deep and well-developed literature on the constrained adoption of input-intensive Green Revolution technologies ratifies this point.

In addition to its effects on the level and growth of agricultural incomes, excess demand for agricultural finance may also have impacts on income distribution within the rural economy. The theoretical analysis of Eswaran and Kotwal (1986) is especially instructive in this regard. Using a single-period general equilibrium model, they show that skewed access to capital, which leaves lower-wealth producers with excess demand for credit, will shift land access and income away from small-scale producer households, despite the intrinsic labour monitoring advantages enjoyed by these producers. The result is an agricultural economy that produces less, and distributes it less equally, than it would in a world of perfect financial markets. Eswaran and Kotwal go on to show that, under these conditions, an agricultural economy can become a prisoner of its own history. Economies that begin with relatively unequal wealth distributions tend to maintain them, while initially more egalitarian economies create more equal income distributions.

More recent theoretical analysis has used dynamic methods to extend the Eswaran and Kotwal analysis, asking whether the effects of excess demand for credit will be so long-lived and dramatic when credit-constrained and other agents have the option of building up their own sources of self-finance via savings over time. While not explicitly focused on agriculture, the analysis of Banerjee and Newman (1993) was an important demonstration that inadequate access to capital can fundamentally distort the occupational and production structure of an economy over the long term. Subsequent work has continued to build on this analytical tradition and has, among other things, shown that inadequate access to capital (in the presence of risk) can lead to a type of structural bifurcation in the agricultural economy. Initially wealthier producers move to a higher level of equilibrium well-being, while the initially poor become mired in a low-level poverty trap (see, for example, Dercon, 1998; Mookherjee and Ray, 2000; Zimmerman and Carter, 2003).

**Policy debates**

While much of this literature on the costs of inadequate access to capital in agriculture is relatively recent, the sense that agricultural financial markets are fundamentally imperfect has driven generations of policy interventions in both high- and low-income nations. Historically, these interventions have included the direct provision of agricultural credit by public lenders, often at subsidized rates. For example, in the United States in 2002 more than 40 per cent of all farm debt to institutional lenders was held by two public entities, the Farm Credit System and the Farm Service Agency (USDA, 2004). While still large, the public provision of agricultural credit in the United States has been trending downward for sometime, signalling the even larger role played by state credit in an earlier era when farms in the United States were smaller and more numerous.

In the low-income countries of Asia, Africa and Latin America, state agricultural banks and other mechanisms of public credit provision became a common feature of the agricultural landscape in the 1960s and 1970s. Interest rates were typically subsidized, and these interventionist policies were
justified on the grounds that private provision of capital was either inadequate, priced at extortionate terms, or simply unavailable, especially for smaller farmers.

However, by the early 1980s, a coherent critique of these policies had emerged, arguing that state banks were financially unsustainable, crowded out private financial institutions, and did not even succeed in channelling credit to small-scale agricultural producers (see Adams, Graham and von Pischke, 1984). Under the pressure of structural adjustment and the broader move toward economic liberalization, state agricultural banks began to disappear from the developing country landscape, and in Latin America, at least, were almost completely gone by the mid-1990s.

While commercial lending to agriculture continues to expand in the United States, the prediction by some that private institutional lenders would fill the gap left by public banks in Latin America and elsewhere in the developing world has been largely unfulfilled (Wenner, Alvarado and Galarza, 2003). While in a few instances there has been renewed interest in public provision of agricultural finance, contemporary policy discussion largely focuses on three alternatives. The first is the provision of agricultural credit by non-financial businesses, such as input suppliers and commodity warehouses. The informational advantages of these informal lenders that permit them to monitor borrowers and lend where formal banks cannot has been more fully developed in recent theoretical literature (Conning, 1999). As mentioned above, this sector remains enigmatic in terms of its efficiency and competitiveness. Nonetheless, there is increasing interest in the reform of collateral laws that might open the door to an expansion of lending by these businesses (Fleisig and de la Peña, 2003). Others have argued that a general strengthening of legally weak landownership rights through systematic land titling programmes will induce greater entry into agricultural markets by private financial institutions (Feder and Akihiko, 1999). However, evidence to date that land title bolsters formal credit supply to agricultural producers (especially small-scale producers) remains thin (Carter and Olinto, 2003).

Micro-finance providers are a second alternative for the future provision of agricultural finance. Like informal lenders, micro-finance institutions can tap into cheap, locally available information about borrowers and their behaviour. They also utilize non-standard collateral assets, including group repayment guarantees in the case of micro-finance programmes that build on the Grameen Bank model of sequenced group loans. However, as Zeller and Meyer (2002) and others have discussed, the very localness of micro-finance institutions (which is the informational key to their ability to lend to small-scale, dispersed borrowers) can become a liability in weather-dependent agriculture where risks across borrowers are strongly correlated. Unlocking the potential for micro-finance lending to provide agricultural credit may thus require mechanisms to insure microfinance lenders, or their clients, against correlated weather risks. Pilot programmes to do just that are currently under development by the World Bank and others (Skees and Barnett, 1999).

The third and final approach to the conundrum of agricultural finance is a more general systemic approach to developing rural (not necessarily agricultural) financial institutions. Motivated in part by the observation that farm families in both wealthy and developing nations derive much of their income from non-agricultural sources, this systemic approach advocates legal and institutional reforms designed to promote the expansion of full-service financial intermediaries in rural areas (Gonzalez-Vega, 2003). Among these reforms are efforts to establish credit bureaus and other institutions that share borrowers’ credit history across multiple lenders. Work such as that by Jappelli and Pagano (2002) suggests that the credit expansion effects of such institutions can be substantial. However, as with the other novel
approaches described here, there is much yet to learn about whether these systemic approaches will suffice to improve the operation of financial markets in agriculture.

Bibliography

How to cite this article

The history of agricultural markets in developing countries reflects attempts to establish the appropriate
government responses to the inefficiencies created by incomplete institutional and physical
infrastructure and imperfect competition. Government intervention in the 1960s and 1970s to resolve
market failures gave way in the 1980s to market-oriented liberalization to ‘get prices right’ and, more
recently, to ‘get institutions right’. But market openness may accentuate the latent dualism of a modern,
efficient marketing sector, accessible only to those with adequate scale and capital, alongside a
traditional, inefficient marketing channel to which the poor are effectively restricted.

Article
Markets aggregate demand and supply across actors at different spatial and temporal scales. Well-
functioning markets ensure that macro and sectoral policies change the incentives and constraints faced
by micro-level decision makers. Macro policy commonly becomes ineffective without market
transmission of the signals sent by central governments. Similarly, well-functioning markets underpin
important opportunities at the micro level for welfare improvements that aggregate into sustainable
macro-level growth. For example, without good access to distant markets that can absorb excess local supply, the adoption of more productive agricultural technologies typically leads to a drop in farm-gate product prices, erasing all or many of the gains to producers from technological change and thereby dampening incentives for farmers to adopt new technologies that can stimulate economic growth. Markets also play a fundamental role in managing risk associated with demand and supply shocks by facilitating adjustment in net export flows across space and in storage over time, thereby reducing the price variability faced by consumers and producers. Markets thus perform multiple valuable functions: distribution of inputs (such as fertilizer, seed) and outputs (such as crops, animal products) across space and time, transformation of raw commodities into value-added products, and transmission of information and risk. Per the first welfare theorem, competitive market equilibria help ensure an efficient allocation of resources so as to maximize aggregate welfare.

The micro-level realities of agricultural markets in much of the developing world, however, include poor communications and transport infrastructure, limited rule of law, and restricted access to commercial finance, all of which make markets function much less effectively than textbook models typically assume. A long-standing empirical literature documents considerable commodity price variability across space and seasons in developing countries, with various empirical tests of market integration suggesting significant and puzzling forgone arbitrage opportunities, significant entry and mobility barriers, and highly personalized exchange (Barrett, 1997; Platteau, 2000; Fackler and Goodwin, 2001; Fafchamps, 2004). Widespread inefficiencies result from incomplete or unclear property rights, imperfect contract monitoring and enforcement, high transactions costs, and binding liquidity constraints. Such failures often motivate government intervention in markets, although interventions have often done more harm than good, either by distorting incentives or by creating public sector market power. The history of agricultural markets in developing countries reflects evolving thinking on the appropriate role for government in trying to address the inefficiencies created by incomplete institutional and physical infrastructure and imperfect competition. The emphasis in the 1960s and 1970s on government intervention to resolve market failures gave way in the 1980s to market-oriented liberalization to ‘get prices right’ and, more recently, to a focus on ‘getting institutions right’.

Past approaches

Agricultural marketing of most major export and food commodities and of modern inputs – such as fertilizer, machinery and hybrid seed – was historically highly regulated by developing country governments into the 1980s, via input price controls and subsidies, oligopolistic input markets, monopsonistic produce marketing boards, pan-seasonal and pan-territorial administrative commodity pricing, oligopolistic processing industries, and fixed wholesale and retail prices. Commodity prices were generally set below market levels, implicitly taxing producers while subsidizing consumers. Marketing channels were typically very inefficient, with centralized storage and processing facilities and government-imposed grades and standards for product quality, although these were not always and everywhere enforced. Sometimes these inefficient systems provided satisfactory coordination of marketing channels, but that was by no means universal. Heavy government presence, especially pan-seasonal and pan-territorial producer pricing, and fixed retail pricing systems and bans on private commerce effectively eliminated most incentives for private arbitrage or investment in fixed capital by marketing intermediaries. Meanwhile, management by government fiat too often facilitated corruption,
In addition to state-run marketing boards, producer marketing cooperatives were prevalent in developing countries at all levels of the marketing chain, ranging from credit unions through farmer cooperatives to wholesale-level cooperatives. Credit unions commonly accumulated funds for input purchase or served as intermediaries for government-subsidized credit programmes. Farmer marketing cooperatives typically facilitated bulk input procurement, price negotiation, and sharing of transportation costs. Wholesale cooperatives mainly assembled bulk commodity lots for sale into government processing and distribution channels. Cooperatives have often worked well in specialized production areas distant from major markets, and with homogenous production of not-so-perishable commodities such as coffee. However, due to high administrative and coordination costs, free-rider problems and political interference, cooperative systems have not lived up to expectations in most developing countries, and many have collapsed.

In contrast to the major export and domestic staple food crops, smaller-scale food commodities for domestic consumption, such as indigenous fruits and vegetables, have almost always operated on a free market basis, with little history of state intervention or price regulation. These markets are characterized by many cash, spot market transfers of product between intermediaries en route from producer to consumer, many small, non-specialized and unorganized buyers and sellers, few if any grades or standards, one-on-one (dyadic) price negotiations, poor market information systems, and mostly informal contracts, largely enforced through social networks (Fafchamps, 2004). Such marketing channels depend disproportionately on rural periodic markets prevalent in most of the developing world, arguably the closest one ever gets to a true ‘free market’: free of government regulation, subsidies and taxes, and lacking public goods such as physical infrastructure, contract law, public market price information systems, or codified product grades and standards. Indeed, they have been termed the ‘flea market economy’ by Fafchamps and Minten (2001).

The emerging problems of state agricultural market control

Given the inherent variability of agricultural production and the significance of agriculture in economic activity and general well-being in developing countries, price stabilization policies were long considered necessary for economic stability. However, a number of problems emerged. First, the fixing of commodity prices below market levels inevitably created a disincentive for agricultural producers. By the late 1970s, low producer prices had led to the stagnation of production and exports and to increased parallel market activity, including cross-border smuggling, in many developing countries, especially in those areas of Africa and Central America that were largely bypassed by the Green Revolution. The second major problem was the fiscal and political sustainability of government agricultural market interventions. The inefficiencies of parastatal marketing boards, along with the repression of private market intermediation, led to unreliable supplies of consumer goods for politically important urban populations. Moreover, those inefficiencies, combined with the numerous subsidies and frequent corruption within government-controlled marketing channels, became too costly for central governments, which faced massive pressure from international donors in the 1980s and 1990s to trim expenditures and to eliminate price controls (Timmer, 1986).
Market-oriented agricultural policy reforms were a centrepiece of economic liberalization in developing countries in the 1980s and 1990s, commonly within the context of broader structural adjustment programmes designed to restore fiscal and current account balance, to reduce or eliminate price distortions, and to facilitate efficient price transmission so as to stimulate investment and production. The new focus was on re-establishing a close correspondence between local and world market prices, so-called border parity pricing. The withdrawal of the state from agricultural market intermediation, specifically price discovery, was seen as a necessary condition in getting prices right, itself a necessary condition for improving market efficiency and stimulating investment and productivity growth (Timmer, 1986).

The market-oriented reforms typically implemented by developing country governments included, on the input side, the liberalization of land and labour markets, decontrol and de-licensing of input production, supply and distribution, removal of input subsidies and price controls, closure of loss-making credit schemes, liberalization of credit markets, and reform of agricultural extension. On the output markets side, reforms included commodity price liberalization, the removal of parastatal monopoly power and commodity movement restrictions, and reduction in tariffs and quotas on imports. The net result of these reforms typically turned on the balance between the pro-competitive effects of reduced government interference in marketing operations – what Lipton (1993) termed ‘market relaxation’ – and the anti-competitive effects of reduction of public goods and services that underpin private market transactions – what Lipton (1993) termed ‘state compression’. Since the two phenomena were typically inextricable in agricultural liberalization initiatives, experiences varied markedly.

The empirical evidence suggests that commodity prices generally increased after market reforms, often stimulating an increase in production, especially of export crops. These price increases also facilitated the emergence of supermarket chains, export-oriented outgrower schemes and export processing zones, and a generalized stimulus to agro-industrialization in developing countries (Reardon and Barrett, 2000; Sahn, Dorosh and Younger, 1997). Increased investment in the downstream marketing channel has transformed the orientation of many agricultural markets from raw commodity towards processed product markets, and with this increased investment came increased competition. In countries such as Chile, India and South Africa, private firms now play a leading role in development of improved seed varieties, producing and distributing inputs, post-harvest processing and modern retailing through supermarkets and restaurant chains (Reardon et al., 2003; Reardon and Timmer, 2005). Both formal and informal traders entered agricultural commodity marketing channels as government controls fell away, from rural periodic markets all the way through urban retail markets.

However, market entry has tended to be limited to certain marketing niches not protected by capital, information or relationship barriers, with substantial bottlenecks in other areas such as inter-seasonal storage and motorized transportation. Neither widespread entry into market intermediation activities nor workably competitive markets emerged everywhere, let alone quickly. For example, because long-haul motorized transportation in rural markets tends to involve considerable sunk costs and some economies of scale due to poor road conditions and high vehicle maintenance costs, entry into this sector of the markets has often been limited after the removal of legal and policy barriers to entry (Barrett, 1997). Meanwhile, the end of pan-seasonal and pan-territorial administrative pricing has brought increased...
price risk, with consequences for investment incentives facing both producers and market intermediaries (Barrett and Carter, 1999).

The elimination of input subsidies and removal of government monopsony power in crop marketing has also often led to reduced access to input financing and increased input prices. The withdrawal of parastatals from core input marketing activities created a void that the private sector often failed to fill due to underdeveloped physical communications, power and transport infrastructure, credit constraints and continued bureaucratic impediments that increased transactions costs for input suppliers. In addition, periodic state and donor-funded input programmes have often reduced profitability and frustrated private investments. Input credit schemes by processors have been used in the post-reform period in an attempt to overcome the low input use resulting from these access problems, for example in the cotton sectors of Mali and Uganda and horticultural export sectors of Kenya and Zimbabwe.

Although the level of reform implementation differed from country to country, in many cases reform was only partially implemented and policy reversals were common (Jayne and Jones, 1997, Kherallah et al., 2002). In important food and export markets, liberalization efforts have been prolonged and incomplete, reflecting the difficulty in relinquishing government control in the face of uncertainty and political pressures to intervene in order to resolve perceived inequities or inefficiencies in market performance. For example, parastatals remain active in the West African cotton sector, the southern African maize sector has not been fully liberalized, and in Indonesia BULOG continues to operate amid private marketing companies. The ebb and flow of market-oriented reforms and the frequency with which governments have engaged in policy reversals has made it terribly difficult to tease out clear patterns in the impact of liberalization measures on the performance of agricultural markets in developing countries.

Post-structural adjustment market reforms

As the weaknesses of reformed agricultural markets in developing countries became evident, development agencies’ and governments’ focus began to shift from merely ‘getting prices right’ to ‘getting institutions right’ so as to address market failures arising from imperfect information, contract enforcement and property rights, and insufficient provision of public goods. Such reforms have used non-price measures in an attempt to develop the public and private institutions necessary for efficient market operations and to reduce transactions costs and business risk.

The post-structural adjustment era has also coincided with international market deregulation through the GATT and its successor, the WTO. Bilateral, regional and global trade agreements have reduced tariff and non-tariff barriers to cross-border flows of raw and processed agricultural commodities, and increased the openness of financial markets, leading to increased capital flow into developing countries, especially in the form of foreign direct investment (FDI). Where structural adjustment reforms had substantially reduced state control over input and output markets, trade and FDI liberalization has paved the way for major investment in post-harvest processing and retailing in developing countries since the 1990s. This ‘new’ capital investment differs from the structural adjustment era reforms in that whereas the focus previously was upstream, in the input, production, and wholesale sectors, more recent emphasis, especially in private investment, has tended to be downstream, in food processing, retail and restaurant markets. The exceptionally rapid diffusion of supermarkets in developing countries, in particular, has also been driven by improved coordination and communication technologies in addition
The rise of supermarket and restaurant chains has changed the fundamental structure and operations of agricultural markets significantly, directing far more market power downstream, often to chains wholly or partly owned by multinational corporations. Commodity procurement by retailers has become more centralized, with consolidated buying points at a regional, even global, level. It is not uncommon for a major supermarket chain located in three different countries to consolidate its procurement in a few large growers in just one of those countries. Global food chains have also established regional procurement nodes – for example, Walmart throughout Asia and Latin America – and in-country commodity procurement for regional firms such as the China Resource Enterprise has been centralized from individual store level to provincial systems (Reardon et al., 2003). These structural shifts have increased contract farming and outgrower schemes between agro-industrial firms and farmers in developing countries, and production of non-staple foods has increased.

Increased foreign investment in agricultural markets in developing countries, however, has produced conflicting results. Increased industrialization of agricultural markets has fostered improved market efficiency and competitiveness, integration of formerly fragmented markets, product diversification through differentiation, and value addition and technology transfer. However, the rapid pace of structural change, with some developing countries accomplishing in a few years what developed countries accomplished over decades, has left limited room for adjustment by smaller, less well-informed and poorly capitalized market actors to new ways of doing business. There is thus growing concern that market openness may lead to the replacement of traditional processors by oligopsonistic multinationals, accentuating the latent dualism of a modern, efficient marketing sector accessible only to those with adequate scale and capital, alongside a traditional, inefficient marketing channel to which the poor are effectively restricted. The tendency towards selection of a few medium- to large-scale firms or producers capable of delivering consistent quality product at large volumes has toughened competition for structurally inefficient producers, and seems to have led to some crowding out of smaller producers (Reardon and Timmer, 2005). Local informal wholesalers and retailers have found themselves having to compete with bigger firms, both for the more efficient producers offering consistent product quality and throughput volumes, and for consumers seeking more services. The emergence of big, concentrated downstream private marketing intermediaries could also potentially lead, once again, to non-competitive agricultural marketing channels, effectively replacing government with private market power.

Increased contract farming, while offering significant potential for smaller growers in the form of guaranteed markets and prices for their produce often coupled with input credit and extension service, has evidently also reduced farmer bargaining power in negotiating contract conditions. These negotiations now take place bilaterally, between individual farmers and the large contracting firm, rather than via collective bargaining by farmer associations with government parastatals.

Conclusion
Agricultural markets play a crucial role in the process of economic development. Yet, by virtue of the spatial dispersion of producers and consumers, the temporal lags between input application and harvest, the variable perishability and storability of commodities, and the political sensitivity of basic food staples, agricultural markets are prone to high transactions costs, significant risks and frequent government interference. The relative power of developing country governments and private domestic or multinational firms in agricultural markets has varied over time. But the fundamental functions of input and output distribution, post-harvest processing and storage, as well as the persistent challenges of liquidity constraints, contract enforcement and imperfect information, have characterized agricultural markets in developing countries under all forms of organization.

agricultural research

Robert E. Evenson
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article reviews contributions made by agricultural research programmes in historical context. Before 1850, when the agricultural experiment station (AES) model was developed, most crop and livestock improvement was due to farmer selection of seeds and livestock breeding. By 1875, a number of plant breeding programmes were in place. Developed countries achieved a green revolution in the first half of the 20th century, developing countries in the second half. A number of countries are now benefiting from the gene revolution. An assessment of social returns to public spending on agricultural research shows these returns to be high.

Article

Before 1850

The earliest form of agricultural research was agricultural invention. The patent systems in Europe date back to the Statute of Monopolies in 1623 in England. During the 18th century, England and France further developed their patent systems. Article 1, Section B of the US Constitution, drawn up in 1787, states that ‘Congress shall have the power to promote the progress of science and useful arts, by securing for limited times for authors and inventors the exclusive right to their respective writings and discoveries.’ The first Patent Act in the United States was enacted in 1790. Many of the earliest inventions, including Eli Whitney’s cotton gin, were agricultural inventions.
Prior to the development of the modern agricultural experiment station in 1843, the ‘botanic garden’ served as the chief research vehicle for plants. Botanic gardens were established in many countries, preserving and further classifying plants and trees in the tradition of Linnaeus. (Today there are 1,500 botanical gardens worldwide. Of these, 698 have germplasm collections for the conservation of ornamental species, indigenous crop relatives and medicinal and forest species, and 119 conserve germplasm of cultivated species, including landraces – that is, distinct types – and wild food plants.) Both plant and animal improvement prior to the modern experiment station was achieved by farmers themselves. Prior to the 18th century, farmers selected seed from each crop to improve the productivity of crop species. (There are approximately 300,000 species of higher plants, that is, flowering and cone-bearing plants. Of these, 270,000 have been identified and described. About 30,000 species are edible and about 7,000 have been cultivated or collected by humans for food; 120 species are important cultivated crops, but 90 per cent of the world's caloric intake is provided by only 30 species.) As populations moved to new locations and production conditions, they created new landraces in each cultivated species. As new landraces were created, three distinct classes were identified. Landraces created in the centre of origin of cultivation were the first class. For rice, as many as three or four centres of origin (that is, locations of first cultivation) for the two cultivated species *Oryza sativa* and *Oryza glaberrima* have been identified. The second class includes landraces created in centers of diffusion (that is, locations where populations diffused the crop). The third class comprised landraces created in the New World countries in the Americas and Oceania.

These landraces were later collected and, along with mutants and uncultivated species in the genus, they constitute the genetic resources used in modern plant breeding programmes based on conventional methods of crossing parental plants. Table 1 summarizes contemporary *ex situ* genebank collections.

Animal improvement actually pre-dates crop improvement. It, too, was achieved by farmers and herdsmen. Most of the breeds of cattle, pigs, poultry, horses, sheep, and so forth were developed in the 16th through 18th centuries. Most were developed in Europe. Work animals, including oxen, horses and water buffalo, were particularly important in agriculture prior to the 20th century, when tractors became the dominant source of power in many countries. Work animals, including the powerful workhorses, important to cultivation, are sensitive to climatic conditions. Animal breeds used in Asia range from the powerful bullocks in North India, weighing more than a ton, to much smaller cattle in the Himalayan mountains.

1850–1900

Agricultural research programmes were changed dramatically with the development of the agricultural experiment station. It is generally accepted that the first truly scientific experiment stations were located in the UK, in the Rothamsted Experiment Station, established in 1843, and in Saxony, where several experiment stations were established in the 1850s. With the experiment station and its formal structure of experiments with ‘treatments’ and ‘controls’, agricultural research became scientific, and by 1900 agricultural science was established as a mature applied science. The application of statistical methods to experiments furthered this development. R. A. Fisher, the statistician at the Rothamsted Experiment Station in the UK from 1919 to 1933, is credited with numerous methodological developments, many of them relevant to modern-day econometrics. Early experiments focused on agricultural chemistry, including the application of chemical fertilizers and related soil amendments. By 1875 or so, formal plant breeding programmes were beginning to be established. It is often thought that formal plant breeding did not take place until after the ‘rediscovery’ of Gregor Mendel's work, first published in 1856, in 1900. But that is not the case: breeding programmes in sugar cane, wheat and many other crops were established before 1900. Sugar cane breeders in Java and Barbados simultaneously discovered techniques to induce flowering in sugar cane plants in 1878, and by 1900 the ‘noble’ canes from their breeding programmes were beginning to transform sugar cane production in several countries.

In the United States, the Hatch Act of 1887 provided funds for experiment stations in every state. Most state experiment stations recognized the synergistic relationship between research and graduate teaching, and formally linked experiment stations with land grant college programmes. It is widely thought that legislation such as the Hatch Act reflected exceptional wisdom on the part of legislators. This was not the case. Prior to the Hatch Act, many states had considerable experience with experiment stations. This was also true for the Land Grant College Act – the Morill Act – in 1862. Some 20 states had established colleges of agriculture prior to 1862. As these programmes matured, veterinary medicine colleges were established in land grant colleges. By 1900, sufficient experimental data were available from state agricultural experiment stations to answer many questions of importance to farmers in the US.
The period 1900 to 1940 was a one of extraordinary achievements by agricultural experiment stations. Plant breeding gains were achieved in most crops planted in temperate zone countries (in effect, temperate-zone developed countries realized a green revolution in this period). Plant breeding gains in sugar cane, coffee, tea and spices (the Mother Country crops) were also achieved in tropical regions. Brazil and Argentina in Latin America realized major gains (Brazil became the world's major producer of coffee and sugar; Argentina the major exporter of beef).

Two major scientific developments in plant breeding were achieved during this period. The first was the development of techniques to produce hybrid crop varieties to take advantage of the 'heterosis' effect in crops. The early development of hybrid techniques took place at Harvard and Yale Universities, but the major achievement was made by Donald Jones at the Connecticut Agricultural Experiment Station in New Haven. Jones developed the 'double cross' method for seed production. Hybrid seed production requires 'selfing' or 'inbreeding' for several generations. Prior to Jones, a single cross was made between two inbred lines to produce hybrid seed; the seed cannot be saved by farmers because the heterosis effect is present only in the hybrid generation. Jones used four inbred lines in a double-cross to produce seed more efficiently. Since Connecticut is not a major corn production state, it was several years before hybrid corn was available to farmers in Iowa. Henry A. Wallace, later a vice-president of the US, was an early leader in developing private industry production of hybrid corn. He established the Pioneer Hybrid Seed Company in 1926.

Zvi Griliches (1957) analysed the adoption of hybrid corn by farmers in different US states. Farmers in Alabama had access to hybrid corn varieties 20 years after farmers in Iowa. This was not because hybrids suited to Iowa farmers were not exhaustively evaluated in Alabama. Alabama farmers did not have hybrid varieties until seed companies established breeding programmes in Alabama to develop varieties suited to Alabama production conditions. Corn has a high degree of photo-period sensitivity. Varieties suited to Alabama were also varieties with longer growing seasons. This same principle applies to the green revolution (see below). No country without a functioning plant breeding programme has realized a green revolution.

The second scientific development was another form of hybridization, inter-specific hybridization or 'wide crossing'. Until the gene revolution, based on 'recombinant DNA' techniques, all plant breeding entailed a 'sexual' cross between two 'parent' cultivars (this continues to be the case for achieving continuous plant improvement). Inter-specific hybridization entails a sexual cross between different species, usually members of the same genus. This was first achieved in sugar cane in 1919 when breeders achieved crosses between Saccharum officianaram, the cultivated species, and Saccharum spontaneum, an ornamental species of sugar cane. Later a third species, Saccharum barberie, was added. By the 1980s, inter-specific hybridization techniques (chiefly embryo rescue techniques) had been developed for most crop species. With these techniques, sexual crosses have been achieved between cultivated species and most or all uncultivated species in the same genus for all important crop species. During 1900–40, developed country agriculture (and some developing country agriculture) was also being affected by the development of farm machinery and tractor power. Stationary tractors and steam engines were developed before 1900. After 1900 the row crop tractor was developed along with improved harvesting and planting machinery. By the 1930s these developments were changing the structure (farm size, off-farm work) of US agriculture. These developments were produced largely by
private sector firms in the farm machinery and farm chemical industries. Patent incentives existed for mechanical, electrical and chemical inventions in this period. They were not developed for genetic inventions until after 1980.

1940–1965

At the end of the Second World War, agricultural research experienced a renaissance in developed countries. This was at least in part because of synergism between public sector agricultural research and private sector R&D in the farm machinery and farm chemical industries. By 1965 supermarkets had crowded out the ‘mom and pop’ grocery stores in most US cities. Poultry production was effectively industrialized by 1965 as confined housing units became the norm. Dairy production was subject to scale economies, and herd size was increasing. Feed management had improved greatly. The widespread use of United States Department of Agriculture grades and standards for livestock was transforming the meat packing industry. By 1965, in all OECD countries total factor productivity growth was faster in the agricultural sector than in the rest of the economy, and this continues to be the case today.

In developing economies, a sense of alarm had been created by the growing recognition that developing countries were in for a population explosion. With improvements in public health measures, death rates, particularly among children, began to decline and life expectancy began to increase. With even modest delays until the birth rate declined, this meant rapid increases in population. The alarm in question centred on food security. Many alarmists of the 1950s, notably Paul Ehrlich (1968), concluded that food production growth could not keep pace with population growth.

The international community (including the World Bank, regional banks, foundations and bilateral aid organizations) responded by developing a system of international agricultural research centers (IARCs). The first two IARCs were the International Rice Research Institute (IRRI) in the Philippines and the International Wheat and Maize Improvement Center (CIMMYT) in Mexico. These two centres were credited with creating a ‘green revolution’ based on high-yielding varieties of rice and wheat introduced to farmers in 1965. Other IARCs, however, contributed to green revolutions in all major food crops.

The green revolution: 1965–2004

The period 1965–2004 was truly extraordinary for agriculture. In 1991 the Soviet Union collapsed, leaving the former Soviet republics in severe recession. This included the agricultural sector. Most, but not all, developing countries experienced a green revolution during this period.

Table 2 summarizes the production of green revolution modern varieties (GRMVs) by five-year period. These data show that the production of GRMVs is increasing over time. Thirty-six per cent of all GRMVs were crossed in an IARC programme. Twenty-two per cent of GRMVs crossed in national agricultural research system (NARS) programmes utilized an IARC-crossed parent or other ancestors. Non-government organizations (NGOs) did not produce GRMVs. None were crossed in developed country programmes and transferred to developing countries. Private sector firms did produce hybrid maize, sorghum and millet varieties (five per cent of GRMVs) but only after improved open-pollinated varieties (OPVs) had been produced by IARC programmes. GRMVs were produced in public sector IARC programs and in NARS programmes in developing countries.

Table 3 summarizes the economic consequences of the green revolution. Production increases are separated into increases from higher crop area planted and increases from higher yields. Yield increases are further separated into GRMV contributions and other input (fertilizer, labour) contributions. In the early green revolution period, production increased by 3.2 per cent a year. Yield increases account for 2.5 per cent a year. In the late green revolution period, production increased by 2.2 per cent per year. Yield increases accounted for 1.8 per cent per year. The sub-Saharan Africa region was an outlier in both periods, with low modern varieties (MV) contributions. The green revolution for sub-Saharan Africa was not accompanied by increased inputs, as it was in Asia and Latin America. (At least 12 countries – Afghanistan, Angola, Burundi, Central African Republic, Congo (Brazzaville), Gambia, Guinea Bissau, Mauritania, Mongolia, Niger, Somalia and Yemen – did not have a Green Revolution. Most are in sub-Saharan Africa.)

**Notes:** Data on food crop production and area harvested are taken from FAOSTAT (2003) on total cereals, total roots and tubers, and total pulses. Asia: Developing Asia minus the countries of the Near East in Asia. Africa: Developing Africa minus the countries of the Near East in Africa and the countries of North-West Africa. Middle East–North Africa: Near East in Africa, Near East in Asia, and North-West Africa. Latin America: Latin America and the Caribbean.
Crop production is aggregated for each region using area weights from 1981. Estimates of production increases due to MVs are from Evenson (2003b). Growth rates of other inputs are taken as a residual. Growth rates are compound and are computed by regressing time series data on a constant and trend variable. The totals for All developing countries are derived by weighting the regional figures by 1981 area shares.

### The recombinant DNA (rDNA) gene revolution

In 1953 Watson and Crick published work (Watson, 1968) that identified the ‘double helix’ structure of DNA and established DNA as the carrier of genetic information. In 1974 Cohen at Stanford and Boyer at the University of California at San Francisco achieved recombinant DNA ‘transformation’ or insertion of ‘alien’ DNA into organisms, and the field of genetic engineering was born (Cohen, 1997). Within a few years many ‘crop biotech’ companies were established. Large agricultural chemical companies were early entries into the field. Today seven life science firms (Monsanto, DuPont, and Dow in the US, Syngenta, BASF, and Bayer in Europe, and Savia in Mexico) dominate the genetically modified (GM) crop products industry. The first GM products introduced in the late 1980s were commercial failures. But bovine somatotrophin hormone (BsT), a product to stimulate milk production, was successfully introduced in 1993.

In 1995 several companies introduced GM crop products for canola (rapeseed), soybeans, maize and cotton. These products fall into two classes: herbicide tolerance and insect resistance (*Bacillus thuringiensis*, B_T). Herbicide tolerance (soybeans, canola and maize) enables weed control with traditional herbicides. This trait has been highly valued by farmers and rapidly adopted. Most of the world's canola and soybeans now have this trait, as does considerable acreage of maize. Insect resistance is achieved by engineering maize and cotton plants to produce B_T toxins that limit insect damage to the plant. This has a particularly important effect on cotton, where insects cannot readily be controlled by insecticides.

GM crop products enable farmers to reduce production costs. Cost reductions depend on mechanization status and insect pest status. Estimates of cost reduction vary by country, with Western European countries having negligible cost reduction potential (less than one per cent, because they produce little cotton, canola or soybeans). The US has significant cost reduction potential, as do many developing countries. It should be noted, however, that cost reduction gains are ‘static’ in nature (that is, they do not cumulate over time). Dynamic gains can be produced only by the development of generations of modern varieties, as reflected in Table 2 for GRMVs. The gene revolution is not a substitute for the green revolution.

The gene revolution has become strongly politicized in recent years. A clear division has emerged between the original European Union countries and North American countries. The European Union position is that the ‘precautionary principle’ should apply, while the North American position is that, in the absence of scientific evidence to the contrary, farmers should be allowed to adopt GM crops (see FAO, 2004).
Griliches (1958) was the first economist to measure ‘returns to research’ by computing returns to hybrid corn research. To do this, he created a cost stream and a benefit stream, and applied present value methods to them. (At a five per cent discount rate the present value of benefits was roughly seven times the present value of costs. Some interpreted this as a 700 per cent rate of return. Of course, it was in fact a benefit–cost ratio.) Griliches computed an internal rate of return to hybrid corn research of 43 per cent. Evenson (2001) reviewed more than 300 studies of returns to research in the decades after the Griliches studies. Table 4 reports a summary of internal rates of return reported in these studies. The project evaluation studies utilized methods similar to those used by Griliches. The statistical studies generally regressed measures of total factor productivity on research stock variables. Some studies were focused on specific commodities, others on aggregate research programmes. Several studies made a distinction between pre-invention science and applied science, and several studies were undertaken of the private sector contribution to agriculture.

- **Africa**: 44, .27 .27 .18 .11 .11 .05 .37

*Source: Evenson (2001)*

The studies are characterized by great diversity in internal rates of return (IRRs), ranging from IRRs of zero to very high levels. Median IRRs are high for all categories. This diversity is consistent with the fact that research is a highly uncertain activity.

Finally, Table 5 utilizes data from the green revolution where GRMV adoption rates were available. The method applied was similar to that which Griliches originally used. These data confirm the estimates in Table 4. Very high returns to IARC research are shown. Returns to NARS programmes are lower, especially in sub-Saharan Africa where many countries did not achieve a green revolution.

Agriculture plays a vital role in economic development by facilitating the transition from a low-income subsistence to a high-income commercial economy. Agriculture promotes economic transformations by supplying food, foreign exchange, labour, and effective demand to the non-farm sectors, and is the dominant force in poverty reduction. A land constraint makes agricultural growth unusually dependent on technological change, while geographically dispersed production units favour a family-size labour force. These in turn lead to a special role for government in achieving rapid agricultural growth.

Article
Economic development is characterized by three transformations: from domination by agriculture to domination by manufacturing and then services; from domination by non-tradable goods and services to a much larger weight of tradable goods and services; and, from a high proportion of poor people living at the edge of basic subsistence to one with few or no such people. If those transformations are to proceed rapidly and efficiently, agriculture must play a vital role. In the course of playing that role, the relative size of agriculture declines drastically while its absolute size increases.

Agriculture has several characteristics that define not only its ability to influence the various transformations but also the means by which it grows and facilitates those transformations. The most important of these are threefold: first, dependence on land and a land constraint that yields rapidly
diminishing returns to increased inputs, making agriculture unusually dependent on technological change for its growth; second, geographically dispersed production units that favour a family-size labour force, with the amount of land and capital per family increasing immensely with rising incomes; and third, derived from the first two, a special role for government in meeting the conditions of rapid agricultural growth. Reinforcing the need for good governance is the increasing need for government-provided institutions for ensuring a healthy, educated labour force as agriculture modernizes.

The size of agriculture

Initially humankind produced the basic means of substance at such low levels of productivity that there was time for little else. Agriculture dominated those subsistence activities. From that initial base, progress could be made only by increased productivity in agriculture, thereby releasing resources for other needs and eventually for luxuries. Even in lower middle-income countries agriculture remains sufficiently large that it continues to play a critical role in transforming the economy. Agriculture's role in employment growth, raising real wage rates and hence reducing poverty is even greater than its role in GDP growth. It continues to be dominant in employment growth at least through upper middle-income status.

Share of GDP

In low-income countries, such as those in most of contemporary Africa, significant parts of Latin America, and, until recently, most of Asia, agriculture accounts for in the order of half of GDP. By the time middle-income status is reached, as it has been in most of contemporary Asia, Latin America and the Middle East, agriculture's relative importance has declined to between 15 and 25 per cent of GDP. With high-income status it declines to under five per cent. However, as the economy is transformed agriculture can still grow rapidly in absolute size. Indeed, the faster agriculture grows in absolute terms the faster its relative importance declines. This is because high-income elasticity of demand by farmers for non-farm goods and services causes those sectors to grow faster than agriculture and all the more so at high rates of agricultural growth (see Mellor, 1995). The decline in the relative size of agriculture is further hastened by the appearance of scale economies in many of the production and marketing services for modern agriculture. As development proceeds, many tasks performed on farms in the early stages of development are more economically produced by large-scale firms. Initially farmers produced their own plant nutrients from composting and manure, but it became much cheaper to buy inorganic fertilizers from immense petrochemical plants. Power initially is derived from humans and animals raised on the farm but eventually from tractors and other machines produced off the farm. The examples are endless.

Share of employment and employment growth

Statistics for agriculture's share of employment in low- and middle-income countries are always far larger than those for its share of GDP. That is substantially because of misclassification. Persons with very small holdings that are insufficient in size to provide even half of family employment or income are
normally classified as farmers, but of course they are more properly classified as rural non-farm population given the way they make their living. Thus, typically even in low-income countries the rural population is divided about equally between those who make their living primarily in farming and those in other rural occupations. Seen this way, farmers represent a similar proportion of employment and GDP. This is not surprising since farm income derives substantially from land ownership, not just from labour, just as in the urban sector income derives substantially from return on capital as well as from labour.

Thus, in a low-income country 80–90 per cent of the population may be rural, half with farming as their principal occupation. By the time middle-income status arrives the share of population that is rural has declined to around 40 per cent and the share principally occupied in farming to less than 20 per cent. In high-income countries the farm population is less than five per cent, two-thirds of those producing the bulk of the farm output.

Agriculture and economic growth

Because of its initially dominant size, agriculture makes several large initial contributions to overall growth (Mellor, 1976.) Growth in agricultural productivity releases labour for the fast-growth non-farm sectors. Agriculture earns foreign exchange that is utilized to import capital goods for the non-farm sector. It provides low-cost food to keep labour costs down as employment in the non-farm sector grows rapidly. Rapid growth in non-farm employment faces rapidly rising, competitiveness-destroying increases in real wage rates if agricultural production does not grow rapidly. Even in an open economy with rapid growth in urban incomes, increased food imports would be so great with a failing agriculture that the real exchange rate would change sharply and push up the cost of food and therefore of labour. Finally, fast-growth agriculture plays the dominant role in employment growth and poverty reduction. In the context of modern open economies and free capital flows, the latter contribution remains the most important for agriculture.

Agriculture and poverty reduction

Statistical data from diverse cross-sectional analyses show that in low- and middle-income countries it is agricultural growth that drives poverty reduction (Ravallion and Datt, 1996.) Further, there is a significant lag in that poverty-reducing impact. The lack of immediate impact led to an incorrect view that agricultural growth does not reduce poverty. It is now known that the lag is due to the large indirect impact of agricultural growth on poverty reduction. There is, however, a major exception to this relation. When land ownership is highly skewed, as for example in much of Latin America, agricultural growth does not significantly reduce poverty. That is because very rich people with large landholdings spend additional income not on employment-intensive rural non-farm goods and services but on capital and import-intensive urban goods and services.

When agricultural incomes are broadly distributed, agricultural growth reduces urban poverty more than does urban growth. This is because urban poverty is a product of rural-urban wage disparities. If rural incomes are stagnant, the rural-urban disparity increases and poor rural people migrate to the cities. If the disparity is large, rural people will be willing to wait a long time in the urban area for a job, living in
poverty in slums. The return to waiting is made up once they get the good urban job. Thus, the greater the income disparity, the longer the queue and hence the greater the number in urban poverty. Measures that make waiting cheaper, such as subsidized housing or even normal urban amenities such as potable water, simply increase the rural-urban disparity and hence the queue. Thus, the way to reduce urban poverty is to raise rural incomes and amenities as rapidly as those in urban areas.

There are three means by which agricultural growth contributes to reduced poverty: lower food prices; increased agricultural employment; and farm income-driven rural non-farm employment.

**Food prices**

Poor people in low-income countries spend in the order of 80 per cent of their income on food. It follows that the real price of food is a primary determinant of the real income of the poor. In a neoclassical economy, increased domestic food production does not reduce the price of food because the international price rules. However, high transfer costs in low-income countries somewhat insulate domestic food prices from international prices. This may be reinforced by trade restrictions. In that case, increasing food production faster than domestic demand will reduce domestic food prices and greatly benefit poor people. The high-yielding rice varieties that brought the Green Revolution to Asia were of low quality, depressing the price of rice consumed by the poor. Market forces may depress the nominal wage as food prices decline, but those same market forces will then increase employment. Hence, the poor tend to benefit from rapid growth in agriculture either through lower food prices or through increased employment (Mellor, 1976.)

Of course, these same processes work in reverse. If agricultural production grows more slowly than domestic demand, food prices tend to rise, reducing the real incomes of the poor. Unfavorable weather reduces agricultural production; prices rise and the poor suffer. Wage rates rarely adjust in the short run, although they do in the long run, in which case higher wage rates reduce employment. In either case the poor lose.

Of course, increasing the supply of food faster than demand is difficult in low-income countries in which population growth is rapid and in which incomes may also be rising. The income elasticity of demand for food is much less inelastic in low-income countries than in high-income countries, and hence income growth has a major effect on the demand for food. For example, the Food and Agriculture Organizational of the United Nations (FAO) and the International Food Policy Research Institute (IFPRI) both show for Africa continued shortfall in supply into the indefinite future. The African poor will continue to suffer from such trends (Eicher and Staatz, 1998.)

**Increased farm employment**

Because agriculture is initially so large, rapid growth does add directly and substantially to employment. However, direct employment growth is small compared with the growth in output. This is because productivity-increasing technological change is the primary source of high growth rates in agriculture. Even though the technology is generally designed to be land-saving, it also increases labour productivity. Thus, for each ten per cent increase in agricultural output employment increases by between less than three per cent and at most six per cent. Thus, the big impact of agricultural growth on employment comes indirectly through the rural non-farm sector.
Increased rural non-farm employment – driven by rising farm incomes

In an open economy, agricultural output that grows faster than demand does not depress prices significantly because of access to international markets. A small decrease in prices brings increased exports. A high growth rate in output without depression of prices raises farm income and reduces poverty in a quite different manner from that of reduced prices. Farmers spend a large and increasing proportion of increments to their income on the goods and services produced by local, rural non-farm workers. Numerous studies show that the bulk of the poor are rural non-farm workers. They largely produce non-tradable goods and services. Because of low quality and high transaction costs they cannot export as an alternative to meeting local demand. When farmers prosper they enlarge their homes and buy local furniture, local tailoring, and a vast panoply of services. That increases employment and eventually real wages in the rural non-farm sector. This is the source of poverty reduction in a low- or medium-income open economy.

Because of the strong multiplier on those expenditures, there is a significant lag in the full effect of agricultural growth on poverty reduction as successive rounds of expenditure occur. Similarly, rich, and especially absentee, landowners spend incremental income largely on capital and import-intensive commodities and services and so have little effect on poverty reduction. These two relations are consistent with the data cited earlier. In very poor agricultures that are growing little or not at all, those in the rural non-farm sector are exceedingly poor because of lack of local demand. In that situation outmigration of the principal male worker and sending back of remittances are important factors holding poverty in check. This is, of course, a socially disruptive means of holding off poverty. Thus it is not surprising that when farm incomes rise rapidly migration beyond commuting range is sharply reduced.

Rural-urban income disparities

It is not uncommon for the urban sector to grow rapidly in low-income countries, even while agriculture stagnates. Foreign aid may be spent largely in the cities, as in Africa, or macro policy stimulates manufacturing growth while the complex processes of agricultural growth are neglected. In that case, urban and rural poverty both surge. At that stage of development it is critical that agricultural production grows rapidly in order to prevent rapid widening of rural urban disparities. As countries move to middle-income status, the problem of rural-urban disparities changes. The rate of growth of urban incomes accelerates – to around six per cent per year. The capacity to absorb migration also increases as the urban proportion of the population increases. Concurrently, the potential for accelerating the agricultural growth rate improves. The demand for high-value agricultural commodities, such as livestock products and fruits and vegetables, grows at a rate of between six and eight per cent, much of which can be efficiently met from domestic production. Thus, in middle-income countries the agricultural growth rate may pick up to between four and six per cent. That would allow rural incomes to roughly keep pace with urban incomes. While not uncommon amongst middle-income countries, such growth rates are by no means universal and require carefully selected government actions.
Characteristics of agriculture that determine the means of growth

Agriculture has very different characteristics from urban industry and therefore different requirements for growth (Eicher and Staatz, 1998.) If those divergent characteristics are not recognized then not only does agriculture grow slowly but poverty reduction halts and-income disparities between rural and urban areas widen. A family-size labour force, the importance of technological change and rural infrastructure, and the consequent importance of government are the dominant characteristics that distinguish the process of agricultural growth from that of other sectors.

The most obvious characteristic of agriculture is that each farm is spread over a wide area. This disperses the workforce and, combined with the complex biological nature of the production process, puts a premium on family-size operating units (commonly including one hired worker) with minimal supervision costs. Size of farm measured by land area or capital investment varies immensely among countries; but the labour force per farm is a virtual constant.

Particularly in low- and middle-income countries in which both land and capital holdings are small as well, the small-scale unit requires support from activities with scale economies. Most of these activities are most efficiently pursued by the private sector. But some are public goods and require public sector activity.

The balance between public and private sectors gradually shifts towards the private sector as development occurs and the private sector cultivates a broadened set of skills. Particularly in low-income countries, such a substantial burden falls on the public sector, in research, extension, enforcement of grades and standards (especially for export), and some aspects of finance and of market information systems, that the government must set difficult priorities. In that context it must continually press to turn activities over to, and encourage, the private sector as that sector's capacity increases.

The key role of government in agricultural growth, in turn, makes the role of the agriculture ministry important as it diagnoses needs and facilitates and complements the private sector. Particularly in early stages of accelerated agricultural growth, the agriculture ministry must have an explicit strategy with clear priorities and sequences in which to take up key activities. When the fashion in development swings towards minimizing the role of government, agriculture is more likely to suffer than other sectors.

Key forces in agricultural growth

Much of what is required for rapid agricultural growth is most appropriately and efficiently undertaken in the private sector, but even the minimum set of required public sector activities is long and complex. Government can do only a few major things at a time. Thus, one of the most important elements of a high growth rate is an at least implicit strategy within which a small number of limiting priorities will be set with an efficient sequence of activities guiding the moving on to new priorities as earlier ones are fulfilled and institutionalized.

The immediate priorities differ from country to country depending on the physical circumstances and the history of interventions. Hence, setting priorities and sequences and even the broad strategy are highly country-specific. A few generalizations are possible. Physical infrastructure and technology institutions are critical in all growth plans, and government is essential to the provision of both. They are also both never-ending tasks, requiring constant improvement, and thus are always a priority. The other constant is the growing importance of the private sector to agricultural growth and the increasing importance of
public sector facilitation of that growth. For agriculture to grow rapidly, good governance is critical — technically competent and committed to agricultural growth and rural development.

**Technological change**

Basic science-based, institutionalized research is essential to thwart the diminishing returns incident to a limited land area, and in any case provides a high rate of return. The varied biological and physical environment of agriculture limits the transfer of technology and thus requires area-specific research systems. Because research results are often public goods, public sector research is critical to agricultural advance. As the private sector expands it will increasingly take on research activities. But even in high-income countries public sector research is a major component of private-public sector partnerships. As farming becomes more complex and dynamic, the educational requirement of farmers increases. Concurrently, many farm children will leave agriculture for education, demanding urban jobs. Thus technology-based agricultural growth creates a strong demand-pull for increased rural education. Because research is so important, and because it is becoming increasingly expensive, depending on expensive equipment and large coordinated teams, low-income countries must set difficult, narrow priorities for their research activities. That is one of the most important and difficult priority-setting exercises in economic development. Typically it is not done well and so research expenditure is not efficient and agricultural growth does not reach its full potential. In parallel with research are systems for the dissemination of research results. These too start heavily in the public sector and then move to a complementary mix with the private sector.

**Physical infrastructure**

Agriculture's contribution to overall economic development is dependent on a steady flow of technology that requires increased inputs and produces increased output. For those processes to proceed rapidly, transaction costs must be reduced. This requires constantly upgraded roads, electrification, and telecommunications. While such physical infrastructure is naturally provided to urban areas, the dispersal of agriculture increases infrastructure costs in rural areas and makes it necessary to sequence provision geographically. Rapid agricultural growth requires educated people in villages to provide agricultural extension, financial institutions, and modern marketing systems. Schools and clinics are of no use without trained staff. These educated people will not live in places without the full set of physical infrastructure. Thus, there is synergy between the requirements of agriculture and the social services for physical infrastructure.

**Private sector input supply and output marketing**

Rising agricultural productivity depends on massive increases in purchased input supplies as the cost of those inputs decreases and the cost of on-farm sources increases. This in turn requires rural financial markets that can mobilize national and international savings for innovating farmers and provide an outlet for farmers' savings when they reap the income benefits of improved technology. Rising incomes and technological advance in marketing require increased quality of farm output,
especially for high-value perishable commodities, and large volumes. Thus, the size and complexity of agricultural marketing increase rapidly. While family labour force-size farms preserve their competitive position in production they are at an increasing disadvantage in meeting quality and volume requirements of modern marketing systems. This challenge is best met by organizing farmers into large units for marketing purposes. This may occur through contract farming provided by large agricultural business firms, or cooperatives, or farmers’ organizations. For the latter, government may play an important role in facilitating farmer organization, but must be careful not to stifle efficiency by making them in effect government institutions.

In setting their own priorities, governments must seek the means to assist the private sector in providing the input and output supply activities, and be careful not to stifle private development with onerous regulation, even while protecting consumer interests and helping to build a favorable reputation for exports.

Change over time in pace and composition of agricultural growth

The sources of agricultural growth change greatly over time. Yield rapidly increases in importance compared with land area. This is because of the combined effect of loss of the land frontier with population growth and exploitation and rapid increase in the efficiency of producing improved technology. The input composition switches to purchased inputs such as fertilizer and chemical pest control and off-farm marketing and processing. This rapidly increases productivity of labour and raises income.

The output composition commences with domination by cereals and root crops as the low-cost sources of calories. As incomes rise the demand for income-elastic livestock and horticultural products grows very rapidly. These are labour-intensive commodities for which physical conditions in low- and middle-income countries are usually suitable. These commodities are little restricted by land area since a modest shift of area from extensive crops allows a large increase in their production, and so the overall growth rate accelerates. An agriculture dominated by cereals is unlikely to exceed a three per cent growth rate for more than a few years. But when livestock and horticulture come to occupy over half the agricultural GDP, as happens in middle- and high-income countries, the growth rate can accelerate to between four and six per cent.

The importance of trade to agricultural growth

In low-income countries demand for agricultural products grows slowly. Consumption is largely of cereals, incomes grow slowly and demand is inelastic. At that early stage of development, agriculture has considerably greater capacity to grow than domestic markets can absorb, and achieving that growth is vital to poverty reduction and also to overall GDP growth rates. Thus, what Hla Myint (1958) referred to, as ‘vent for surplus’ is important to agriculture playing its role. That is to say, agricultural production must grow faster than domestic demand and the surplus exported. This drives the domestic employment multipliers as well as paying for imported capital equipment critical to overall growth.

For agricultural exports to grow a country must produce efficiently, providing constantly improving physical infrastructure to bring down transaction costs, and constantly increasing productivity through
technological change and an effective private sector capable of adapting to rapidly changing markets and constantly rising quality standards. However, these favourable policies can be nullified by unfavourable macro policy, particularly including overvalued exchange rates. Those are the most important requisites of export success. Globalization, based on declining costs of transport, facilitates access to markets, but also brings competition. Countries lagging in provision of physical infrastructure, technological change, and efficient macro policy will be losers from globalization.

Trade protection by high-income countries has been an important barrier to export success even when low- and middle-income countries become efficient and productive. Protection is particularly onerous for cotton, widely grown in quite poor countries and heavily protected and subject to export subsidies from high-income countries. Protection may also be subtle, using health rules to make it difficult for poor countries to enter high-income markets. Thus, the rate of growth of agriculture is dependent in part on negotiations to reduce both trade barriers erected by high-income countries against high-value agricultural commodities and agricultural subsidies more generally.

Foreign aid, agriculture and development

Successful late starters in economic development exceed the growth rate of the front-runners because they can catch up by drawing capital and, more important, technology and the pure science base for creating technology from their now wealthier predecessors. Foreign aid can play an important role in those transfers. This has been dramatically the case in agriculture. In Asia, the scientific base for the startling technological breakthroughs of the Green Revolution was laid by foreign aid that sponsored the key research institutions, in Mexico, then the Philippines, and finally in many other countries. These efforts were complemented by assistance to development of a host of national institutions vital to the spread of the Green Revolution and to increasing the effectiveness of agriculture ministries.

A variety of factors, including the rise of specialized lobbies that distort the distribution of foreign aid between directly productive and social activities and away from national institutions to local institutions and, most important, from national institution building to local activities, caused foreign aid to lose its effectiveness.

The late starters, particularly in Africa, were the big losers from this shift. For the late starters to achieve faster growth than their immediate predecessors will require a return to basics. A great deal has been learned about the details of agricultural growth and its contribution to overall economic development. That new information can accelerate growth beyond previous levels. But the basic principles have not changed and there must be a reversion to these if the new knowledge is to be useful. Africa and a few low-income countries in Asia and Latin await that renaissance.

Abstract

The 1978 US airline deregulation benefited passengers through lower fares and expanded service. Airline privatization and liberalization elsewhere in the developed world has since had similar effects. Still, there have been some unanticipated effects: hub-and-spoke networks have efficiency appeal, but they also increase congestion and confer market power on dominant airlines; price discrimination is widespread; loyalty programmes exacerbate market power concerns; airline finances are subject to extreme cyclic volatility; and labour is a significant residual claimant on profits. Airline competition and industry structure remain in flux: entry and exit are commonplace, as is experimentation with new pricing and products.

Keywords

airline deregulation; airline industry; market power; price discrimination; principal–agent conflict

Article

Since the mid-1970s, privatization and deregulation have transformed domestic passenger airline markets in many developed economies. From its infancy through the early 1970s, scheduled passenger air service was considered a public utility nearly everywhere in the world. In most countries, this took the form of state-owned national airlines, often operating with significant government subsidies. US airlines were privately owned, but prices and entry decisions were controlled by federal regulators. California and Texas provided limited but notable exceptions, where small airlines providing only intra-state service operated free of most economic regulation. Their substantially lower fares and higher load factors relative to regulated operations foreshadowed the possible impact of deregulation. The United States legislated federal airline deregulation in 1978, replacing government decision-making with carrier determination of pricing, entry, and network configuration. Within 20 years, similar reforms faced newly privatized and entrant carriers operating within Europe, Asia and Australia. Most
international air travel, however, remains heavily regulated through bilateral government agreements, apart from intra-European Union flights and a few examples of ‘open skies’ pacts that allow broad freedom in entry and pricing. Deregulation yielded numerous benefits, best documented for the US domestic market due to public availability of detailed, high-quality data. The most striking and robust finding is that fares are substantially lower and passengers are better off under deregulation than they would have been under continued regulation (in the United States) or state ownership (in many other countries); see, for example, Borenstein (1992), Morrison and Winston (1995) and Borenstein and Rose (2006). Facilitating lower prices were decreased costs per available seat–mile and increased load factors, resulting from a mix of operational reorganization, service changes, and efficiency gains. In the United States deregulation-induced transfers from labour to consumers were initially modest, though labour costs and contract negotiations have since become focal in competition between formerly regulated ‘legacy’ carriers and discount airline entrants in many markets. Labour transfers generally account for a more substantial share of cost reductions for newly privatized carriers. While price declines conformed to expectations, not all responses to deregulation were anticipated. First, legacy airlines in the United States rapidly reconfigured their operations from point-to-point to hub-and-spoke networks, in which coordinated ‘banks’ of flights arrive at a centrally located airport, allow passengers to change planes, and depart a short time later. This allows airlines to offer relatively frequent, albeit connecting, service on a large number of city pairs without dedicating aircraft to serving each route non-stop. Legacy carriers outside the United States generally operated some form of hub-based network even prior to reform, due largely to relatively thin domestic markets and bilateral agreements that restricted international service to operate through a few gateway airports. Hub-and-spoke operations initially were thought to confer significant efficiency improvements, facilitating greater flight frequency and higher load factors for all but the most dense markets, though it was recognized that passengers preferred non-stop service, all else equal. Over time, the benefits of hubs have been called into question. Coordinated banks of flights increase congestion costs and delays at hub airports and reduce system-wide aircraft utilization rates; airline dominance of local traffic in and out of their hubs raises concerns about market power; many hubs have been created, then abandoned, as airlines attempted to discern the optimal number and characteristics of hub airports. Second, average real price declines masked an explosion in pricing complexity. From a pair of distance-based coach and first-class fares on each route, airlines sprouted a dozen or more fare offerings. Prices on a single carrier-route may differ by the time or day of travel, how far in advance a ticket is purchased, the length of stay, and whether the stay includes a Saturday night. Economists have debated the extent to which fare variation reflects efficient competitive peak-load pricing or potentially less efficient price discrimination, but both effects are undoubtedly significant in most markets. Third, market power concerns, focal at hub airports generally dominated by a single carrier, have been exacerbated by the diffusion of various loyalty programmes. Best-known are frequent flyer programmes, which reward passengers for concentrating their business with a single carrier, but similar programmes were also created for travel agents, who booked about 85 per cent of all tickets in the early deregulation days. Nonlinear reward schemes benefit the largest carrier in a market and increase switching costs among their participants. These programmes also generate principal–agent conflicts: travel agents benefit from directing passengers to flights that may be slightly more expensive or less desirable in
exchange for side payments from the carrier. Similarly, in exchange for free personal travel, business passengers choose flights for which their employer may have to pay more.

Fourth, extreme cyclic volatility of airline finances has raised concerns about the ‘core’ of the competitive equilibrium. The industry reaped large profits when demand was strong relative to capacity and fuel prices were low (the late 1980s and late 1990s) and reported huge losses when fuel prices rose and demand weakened, generating excess aircraft capacity and a wave of bankruptcies (the early 1980s, 1990s and 2000s). Debate continues over whether this profit volatility should spark concern or is part of the normal functioning of an industry with high fixed costs, slow capacity adjustment, fluctuating operating costs (particularly fuel), and highly cyclical and unpredictable demand. Is this any different from the steel, computer memory chip, or software industries which also have exhibited extreme swings? Economic research has provided few answers as yet.

Finally, airline labour has been at the heart of continuing concern and stress. At most legacy carriers, pilots and mechanics have negotiated very lucrative contracts during good times, effectively sharing in the high profits. When profits declined, however, downward adjustment of wages has been slow. Entry or expansion by new airlines with substantially lower labour pay scales is fairly easy, particularly during downturns when excess capacity makes aircraft leases cheap and easily available. During downturns, wages at established carriers may differ most from competitive wages, leaving incumbents vulnerable to new competition and financially constrained in their ability to respond aggressively. The rise of low-cost carriers and intensity of legacy carrier wage and benefit cuts in the most recent industry downturn raise significant questions for the future position of airline employees.

Many of the research results from early post-deregulation studies have been reopened in the face of dramatic industry evolution over recent years. The challenge to both economists and industry participants is to infer the long-run equilibrium structure of the industry. What is the stable number of airlines in a given geographic market? What sort of competition is feasible? Are hub networks viable in the face of point-to-point competition? What is the long-run role of labour as a quasi-equity holder? These questions remain for future researchers to address.

S. Rao Aiyagari was 45 years old when he died in 1997, just as his approach to dynamic macroeconomic research was gaining recognition. Rao's vision was motivated by empirical observations and academic debates stemming from the different implications of aggregate and individual economic data. In particular, individual earnings, saving, wealth and labour exhibit much larger fluctuations over time than per-capita averages, and accordingly significant individual mobility is hidden within these cross-sectional distributions. Rao became convinced that this kind of heterogeneity and individual dynamics has important implications for the understanding of aggregate economic data and can provide new insights on the role of various economic policies.

The Aiyagari–Bewley economic model, proposed by Bewley (1986) and developed further in Aiyagari (1994; 1995), has become a leading model for modern dynamic macroeconomics. The economy is populated with heterogeneous infinitely lived agents subject to uninsurable idiosyncratic income risks. Possible long sequences of adverse income shocks naturally lead to borrowing constraints on individuals, and consequently fluctuations in consumption can be mitigated only by precautionary individual savings. Since agents’ histories of income shocks are different, the model generates equilibrium cross-section distributions of wealth, saving and consumption, which reflect the fact that borrowing constraints are tighter for wealth-poor agents. These cross-sectional distributions are contrasted with or calibrated to fit their empirical counterparts in the data, and their responses to various policy changes can be analysed. Solving for the equilibrium in dynamic models with heterogeneous agents is complicated, and Rao was among the pioneers in developing and applying numerical solution techniques for that purpose.
In his most influential paper (Aiyagari, 1994), Rao investigated the implications of precautionary saving due to individual earning risks and borrowing constraints for aggregate savings. He found that the contribution of uninsured idiosyncratic risks to aggregate saving is modest for plausible values of risk aversion, variability and persistence of earnings (at most three per cent), but can be significantly larger with higher variability and persistence parameters of the earning stochastic process. Access to asset markets in that model enables agents to cut consumption volatility by half, and enjoy a welfare gain of 14 per cent of per-capita consumption compared with the equilibrium with no access to assets markets. The model generates a wealth distribution that is positively skewed, more dispersed than income distribution, and inequality is significantly higher for wealth than for income. Precautionary savings generated by uninsured idiosyncratic shocks and borrowing constraints motivated Rao to examine the recommendation to eliminate tax on capital income (Lucas, 1990). Aiyagari (1995) showed that for the Aiyagari–Bewley economies this dictum may be wrong because the frictions in these models result in agents’ behaviour that is closer to that in overlapping generations (OLG) models. Precautionary saving can lead to over-accumulation of capital in equilibrium, so that positive taxes on capital are needed to bring the pre-tax return on capital to equality with the rate of time preferences, at any point in time as well as in the long run. In contrast to OLG models, where government debt can also be used to reduce excessive saving, in Aiyagari–Bewley economies the demand for such assets becomes infinite when the interest rates approaches the rate of time preferences. The suitability of the model for addressing such fundamental issues is evidenced by the fact that a decade later it was still being used to study the same issue, albeit with different conclusions (Werning, 2005).

Rao has examined many other implications of cross-sectional distributions generated by frictions in capital markets and uninsurable idiosyncratic risks, such as asset pricing and trading patterns (Aiyagari and Gertler, 1991), setting taxes in a median-voter context (Aiyagari and Peled, 1995), marriage patterns and investment in children (Aiyagari, Greenwood and Guner, 2000; Aiyagari, Greenwood and Ananth, 2002). He also studied the equilibrium implications of market frictions and borrowing constraints that emerge endogenously from private information on individual earnings (Aiyagari and Williamson, 2000). Many other influential papers have adopted his framework of uninsurable idiosyncratic risks for the study of various phenomena, including, for instance, Kocherlakota (2005) on optimal taxation, Krueger and Perri (2006) on the joint evolution of income and consumption, and Storesletten, Telmer and Yaron (2004) on age-dependent income and consumption inequality.

Rao's earlier theoretical work focused on the links between dynastic and OLG models, and provided the deep theoretical understanding of dynamic models that he applied in his subsequent work. He examined whether the two models become similar in terms of equilibrium existence, optimality and cyclicality, with and without money, when the life of each generation and the period of overlap across generations are sufficiently long, or when generations are linked through altruism (for example, 1985; 1988; 1989). Additional work with Wallace and others examined the role for policy in search equilibrium models of money (for example, Aiyagari, Wallace and Wright, 1996; Aiyagari and Wallace, 1997). Aiyagari published more than 30 influential papers during his 18-year career as an economist. The force of his work and ideas and their impact on his colleagues are evidenced by the continued appearance of his co-authored papers for many years after his unexpected death, exhibiting some of the most innovative dynamic macroeconomic research.

Akerlof, George Arthur (born 1940)

Brian G.M. Main
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

George Akerlof is forever associated with his landmark 1970 paper, ‘The market for “lemons”’, which transformed the way economists approach markets where there is a difference between the transacting agents in the information they possess. This concept of asymmetric information, with its major impact on many fields of economics, was singled out when, in 2001, he was awarded the Nobel Memorial Prize in Economics (along with Michael Spence and Joseph Stiglitz). A more comprehensive assessment of his contribution to economics would be as providing a better behavioural underpinning for macroeconomics as a major figure in the New Keynesian movement.

Akerlof, G.; asymmetric information; caste system; efficiency wage theory; Friedman, M.; neuroeconomics; New Keynesian Economics; inflation-unemployment trade-off; market for lemons; social norms

Article

George Akerlof's father came to the United States from Sweden to obtain a Ph.D. at the University of Pennsylvania, and remained in the country to pursue a career as a research chemist. He met George's mother while she was a graduate student in chemistry. Hers was an academic family. George's great grandfather was among the earliest graduates from the University of California at Berkeley (in 1873), and his grandfather also graduated from Berkeley. Other members on that side of the family also established successful academic careers. George grew up on the East Coast, where his father held a series of posts, variously at Yale University, at the Mellon Institute in Pittsburgh and at Princeton University, before running his own independent research firm in the Princeton area. Indeed, it was witnessing the uncertainty surrounding his father's continuing employment, dependent as it was on securing government research grants, which first turned George Akerlof's mind to macroeconomic
themes such as unemployment. As an undergraduate at Yale he majored in mathematics and economics, and in the fall of 1962 he entered graduate school at MIT, where he had the good fortune to find himself one of an exceptionally talented cohort of students. His doctoral supervisor was Robert Solow (Nobel Laureate 1987). Akerlof joined the Berkeley faculty in the fall of 1966 and, although he has spent extended periods away from Berkeley – at the Indian Statistical Institute in New Delhi, the Council of Economic Advisors, the Federal Reserve Board (where he met his wife, Janet Yellen), the LSE, and the Brookings Institution – he has remained closely identified with Berkeley ever since.

The ‘Market for “lemons”’ paper

For the generations of economics students trained since 1970, when asked to single out a favorite economics article, it is a pretty safe bet that the most popular article would be George Akerlof's (1970) paper on asymmetric information, ‘The market for “lemons”’. Part of this paper's appeal lies in its modelling approach. While mathematically rigorous, it is derived from close observation of the world. Care is taken to incorporate realistic economic detail, yet the results obtained provide tremendously powerful insights. The reader is left with an understanding of an important market situation that was previously obscure and, in addition, is offered policy options whereby economic well-being can be improved. This general approach characterizes all of Akerlof's work.

The ‘lemons’ paper starts by offering an analysis of the second-hand car market in which the existence of lower-quality vehicles (the eponymous ‘lemons’) can disrupt the workings of the market – to the extent that the usual economic law of lowering the price in the face of an excess of supply (or difficulty experienced in selling into the market) simply makes matters worse. Rather than bringing about a market equilibrium through matching supply and demand, the lower price drives out the better-quality cars remaining in the market and this further depresses demand.

The problem arises from an asymmetry of information that exists between those supplying used cars into the market (they know, in considerable detail, just how good or otherwise their present car is) and those who are buying in the market (they can obviously inspect the car, but are left with substantially less knowledge than the seller). If those on the demand side use the price as an indication of the average quality of car traded, this can cause demand to decline in the face of falling prices – if, as seems reasonable, the suppliers with better-quality cars withhold them as the price falls, leaving only the poorer-quality cars to be offered at lower prices. Note that this problem does not arise in the new car market. While this market is, unfortunately, not free from ‘lemons’, the probability of being stuck with a lemon can be ascertained from sources such as consumer reports. The fraction of new cars entering the market as lemons does not vary with the price or discount offered on new cars.

Varian (1992, p. 469) offers the following simple characterization of the model. Assume there is a quality-of-car index $q$, which is uniformly distributed between 0 and 1. Additionally, assume the demand for cars is a function of this quality to the extent that the price offered for cars of quality $q$ is exactly $(3/2)q$ and that, on the other side of the market, suppliers with a car of quality $q$ would be willing to sell for price $q$ or better. There is clearly scope for mutually beneficial trade in this market, as any price between $q$ and $(3/2)q$ leaves both the buyer and seller of a car with quality $q$ better off.

On the other hand, if the buyer is unable to perceive the quality of the car but has to rely on the average quality of cars traded in the second-hand market as a measure of the expected quality of any car purchased, then the price offered is $(3/2)q^*$, where $q^*$ is the average quality in the market.
But on the supply side, of course, sellers know the exact quality of their cars and, for any price \( p \), only those with quality \( p \) or lower will offer cars for sale. Thus, the observed quality of cars traded at price \( p \) will be \( p/2 \). However, at quality \( p/2 \) there will be no cars demanded, as cars of this average quality fetch an offer of only \((3/2)q^*=(3/2)(p/2)=(3/4)p\). So no cars will traded at this price. But nor will a fall in the price offer any improvement because, if price falls, then so too will the quality of car offered to the market and the average quality of cars observed. As things stand, there is no price that will allow cars to be traded. Potentially mutually advantageous trades are not made. Economic welfare is lower than it might be. The culprit is, of course, asymmetric information.

It is the inability of the supply side of the market (which possesses the hidden information about car quality) to meaningfully communicate this information to the buyers that undermines the potential for mutually advantageous trades. The existence of lemons inhibits the proper functioning of the market. Akerlof points out that the inability of older people to secure health-care insurance, the inability of minorities to secure decent employment prospects, the external costs of dishonest business practices, and the difficulty developing countries experience in establishing capital markets can all be viewed as manifestations of the same 'lemons' problem, i.e., asymmetric information.

In awarding the 2001 Nobel Memorial Prize in Economics to George Akerlof, Michael Spence and Joseph Stiglitz, the Royal Swedish Academy of Sciences cited 'their analyses of markets with asymmetric information'. In reviewing the contributions of these prize winners, Rosser (2003) identifies a nascent discussion of this idea in the earlier economics literature, but there is little doubt that it was with the publication of Akerlof’s 1970 ‘Market for “lemons”’ paper that the metaphorical light bulb was switched on in the economics community and the idea of asymmetric information started to become integrated into economics. As a recent survey by Riley (2001) makes clear, this concept is now an important feature of modern approaches to development economics, financial economics, industrial organization, international economics, labour economics, and many other areas. It is now difficult to imagine the world of economics without this insight.

Other work

While for many people the ‘lemons’ paper stands as a seminal example of the power of microeconomic analysis, the underlying motivation that led Akerlof to investigate this area was actually macroeconomic. Cyclical fluctuations in the car market were seen as a major destabilizing factor in the macroeconomy: hence the original research effort. Throughout his career Akerlof has been driven by a desire to develop macroeconomics in a way that allows problems such as unemployment to be better understood. Never happy with the neoclassical synthesis and distinctly critical of the New Classical economics, Akerlof has been a major contributor to the development of New Keynesian Economics (2002). Indeed, his work can be seen as a lifetime effort to create a better behavioural micro-foundation to macroeconomics – continuing in the tradition started by Keynes’ (1936) General Theory.

Caste and identities

In subsequent work the ‘lemons’ paper was soon developed into an analysis of caste systems (1976; 1985), in which irrational and economically inefficient belief systems can be sustained out of a concern
for individual well-being, albeit at the cost of society's overall welfare. This work is typical of Akerlof's approach to economic theory in that it seeks to broaden our view of economic exchange from the simplistic dyad of buyer and seller (the focus of so much economic analysis) to admit the real possibility that such exchanges are heavily conditioned by the existence of wider social forces. In this specific case, people adhere to what are obviously dysfunctional behaviours because, in their individual calculus, the costs of being seen to break such conventions (and hence being outcaste) outweigh any individual short-term gains. Thus, individually rational action leads to a macroeconomically inefficient outcome.

More generally, people can be seen as exhibiting patterns of behaviour that are consistent with chosen identities but would be otherwise difficult to explain (Akerlof and Kranton, 2000). Such identities are chosen in an attempt to fit most comfortably into society, given people's individual circumstances. The choice of identity brings with it a set of behaviours and an exposure to the behaviour of others with whom one identifies. This stream of work represents a major step in bridging the gap between economics and sociology that is so aptly summarized by James Duesenberry (quoted in Granovetter, 1985, p. 485): ‘economics is all about how people make choices; sociology is all about how they don't have any choices to make.’

This approach led Akerlof to empirical analyses of the dramatic rise in out-of-wedlock births (Akerlof, Yellen and Katz, 1996) and the marked increase in the number of men living without children (1998). These papers demonstrate that the rise of children born to unmarried mothers and the increase in men living outside of households with children can each be ascribed to changing norms (the notion of the shotgun marriage and the destigmatization of out-of-wedlock births) that have more to do with changing technology (birth control) and the social reaction to these changes than to any wealth or incentive effects arising from welfare programmes.

This enthusiasm to engage with real-world data and empirical work is another salient characteristic of Akerlof's work. Somewhat unusually, for a theorist of major repute, he has throughout his career undertaken empirical studies of the major social and economic policy issues of the day. Thus, in addition to the analysis of family structure and poverty mentioned above, he has studied the distribution of employment and unemployment experience (Akerlof and Main, 1980, 1981), job mobility (Akerlof, Rose and Yellen, 1988), German reunification (Akerlof, Rose, Yellen, and Hessenius, 1991), financial malfeasance (Akerlof and Romer, 1993), and the inflation-unemployment trade-off (Akerlof, Dickens and Perry, 1996, 2000). Akerlof's intellectually open and outgoing approach to his work also shows in the wide range of co-authors involved in his theoretical work, including, for example, Akerlof and Miyazaki (1980), Akerlof and Milbourne (1980), Akerlof and Katz (1989), Akerlof and Yellen (1990), and Akerlof and Kranton (2005). As will be seen below, his collaboration with Janet Yellen has been the most sustained and intellectually productive.

Near-rational economic behaviour

While the ‘lemons’ paper is undoubtedly his most famous, the stream of papers that best demonstrates Akerlof's New Keynesian pedigree starts with Akerlof (1969). This paper investigates structural unemployment in a framework that sees firms as being in monopolistic competition and having staggered price setting, with wages emerging as bargains struck between firms and workers. With Taylor's (1979) incorporation of rational expectations, this links directly to the overlapping contracts approach that now lies at the heart of the New Keynesian model. Akerlof also deployed this approach in
the study of monetary policy (1973; 1978; 1979). Here, simple monitoring rules by agents of their bank balances are shown to make both monetary and fiscal policy effective. Extending this approach more generally, Akerlof and Yellen (1985) demonstrate that what appear as rule-of-thumb behavioural rules deployed in economic decision-making actually bring with them substantial savings in computational costs (and deal with the bounded rationality problem) while, at the same time, imposing only second-order costs on the agent by way of lost economic efficiency. In this sense, such rules of thumb are quite sustainable and sensible modes of behaviour. The insights of this paper have far-reaching implications. Accepting the existence of such behaviour not only points to why monetary policy might be effective but also explains why there can, indeed, be significant trade-offs between inflation and unemployment, particularly at low rates of inflation (Akerlof, Dickens and Perry, 1996, 2000).

Friedman’s (1968) original attack on the notion of a long-run trade-off between inflation and unemployment was further strengthened by the incorporation of rational expectations by the New Classical economists, Lucas (1972) and Sargent (1971). Deploying the Akerlof and Yellen (1985) insight of near-rational behaviour towards inflation, Akerlof, Dickens and Perry (2000) demonstrate that at low rates of inflation, such as were typical in the 1950s and are now prevalent once again, there can be an empirically significant trade-off between inflation and unemployment. The fact is that in setting wages and prices economic agents (business people, wage negotiators and so on) do not behave exactly as economic models of rational expectations would suggest – at least not when inflation is moderate and the costs of deviating from such rationality are modest when compared with the informational and computational costs involved.

Sociologically based efficiency wage theory

In attempts to explain the unemployment that fiscal and monetary policy is often deployed to remedy, a standard question is why in the face of unemployment wages do not simply decline, so restoring equilibrium in the market. The answer is, of course, that cheaper is not always better. In a paper evocatively titled ‘Jobs as dam sites’, Akerlof (1981) explains that, just as it makes poor economic sense to construct a lower-quality dam on a prime site (no matter that it may be cheaper), so it may not make economic sense to hire cheaper labour even when available. These ideas, further developed in Akerlof (1982) and most elegantly expressed in Akerlof and Yellen (1990), provide a sociologically rooted explanation for efficiency wages.

The key idea here is that the exchange between employer and employee is rich and complex, extending well beyond the narrow instrumental delivery of labour in return for wages. Workers who display ‘consummate’ cooperation in playing their part to achieve the objectives of the organization are much preferred to those exhibiting ‘perfunctory’ cooperation (see Williamson, Wachter and Harris, 1975, p. 266). Part of the key to ensuring the higher-productivity outcome is being seen to pay a fair wage. The concept of fair wage-effort is socially determined, and both equity theory from social psychology and social exchange theory from sociology offer explanations of how workers react when this balance is disturbed. From this perspective, the financial savings from lowering wages can be a poor bargain when set against the impact on the productivity of the workforce. In the face of such rigidity coming about through the individually rational decisions of employers, there is clear scope for macroeconomic policy
to effect a coordinated move to a higher level of employment. This is a key insight of the efficiency wage model of the labour market (Akerlof and Yellen, 1986).

Psychologically based models

The incorporation of psychological insights into economics has proved highly successful in recent years, as indicated by the award of the Nobel Prize in 2002 to Daniel Kahneman. Akerlof and Dickens (1982) is an early contribution to this movement, drawing on the notion of cognitive dissonance whereby individuals choose their beliefs or view of a situation in such a way that renders them the greatest comfort or happiness. In this way, it is possible to explain many common phenomena that otherwise seem to make little economic sense, such as the widespread flouting of workplace safety standards. In some ways the more recent work in Akerlof and Kranton (2005) on choice of identity can be seen as a sociological version of this same phenomenon. The common theme is that social actors are capable of choosing the frame through which they view their circumstances and, unsurprisingly, can be expected to choose an approach that, given the situation in which they find themselves, offers them the greatest comfort. To an external observer this can often result in behaviours that are perplexing. Thus, in Akerlof (1991) a psychologically based explanation is offered for the widely documented phenomenon of people acting in ways that seem too short-sighted to be in their interest. This is seen in the widespread failure to make adequate provision for retirement or to save enough in general. Drawing on a personal experience during a year living in India during the late 1960s, Akerlof recounts how day after day he procrastinated over mailing off a promised package to Joseph Stiglitz. This is developed into a model that demonstrates why in repeatedly opting for what appears as the best short-term course of action (to procrastinate) one is often left in a situation that in retrospect one may regret. The insights offered by this model of economic behaviour are both powerful and far-reaching, and later proponents, such as David Laibson (1997), have extended the area into neurological studies of the brain under the heading ‘neuroeconomics’.

Conclusion

If economists were ever to adapt the psychologist's stimulus-response technique into a game of declaring a famous economist's name as a stimulus and then noting the response, it seems clear that the overwhelming response to ‘George Akerlof’ would be ‘lemons’. This would, at the same time, be both a sufficient response and an insufficient response. As the above discussion has shown, it is insufficient to try to capture such a major body of important studies by reference to one paper. Akerlof has not only dealt with asymmetric information but, as a major contributor to modern Keynesian economics, has also confronted the major macroeconomic issues of the day, most notably by providing the behavioural underpinnings to explain the efficacy of interventionist economic policy.

Yet the ‘lemons’ response could arguably be judged sufficient in the sense that the ‘lemons’ paper contains all of the elements that make Akerlof's approach to economic theory so different and so potent. Mark Granovetter (1985) criticizes economic models as either totally ignoring the influence of social structures and relations or else going to the other extreme, by being oversocialized in the sense that there are really no choices left for agents to make. Akerlof is one of a small but growing set of economists
who manage to position their models on the middle ground. Far from Friedman's (1953) positive economics approach, which regards assumptions as something to be minimized and whose realism is of no consequence as long as the predictive power of the model holds up, Akerlof adheres to an approach that utilizes models based on closely observed empirical examples. The fact that the most observers believe that monopolistic competition is the norm means to Akerlof that such a feature must appear in the model. A model utilizing perfect competition might be able to do just as well, but would be rejected in the face of Akerlof's pragmatic goal of making his models as near to the observed reality as possible while still being tractable.

‘The market for “lemons”’ will almost certainly stand as Akerlof's best-known contribution, having provided the impetus for radical new ways of looking at events in so many areas of economics. But it is also an excellent exemplar of a different approach to economic modelling. It is this pragmatic approach to economic modelling that makes all of Akerlof's contributions so worthwhile.

Åkerman, Johan Gustav (1888–1959)

K. Velupillai

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Åkerman, Johan Gustav; capital theory; fixed capital; Wicksell, Knut

Article

Gustav Åkerman received perhaps the supreme accolade for any economist working in the theory of capital, Knut Wicksell's endorsement. Wicksell concluded his masterly review of the first part of Åkerman's doctoral dissertation with the following acknowledgement: 'I am convinced that on the whole the author has made a really significant contribution to the theory of capital' (Wicksell, 1934, Appendix 2(a), p. 273).

Born in 1888, Åkerman obtained his doctoral degree from the law faculty of the University of Lund in the days before economics as a subject had independent status, in 1923. He was appointed Docent (Associate Professor) in Lund the same year, on the strength of his brilliant doctoral dissertation, 'Realkapital und Kapitalzins'. He was subsequently appointed Professor of Political Economy and Sociology at what was later to become the University of Gothenburg in 1931, and remained there until his retirement. He died in 1959.

Wicksell's famous two-part review article (the second part being on 'Åkerman's Problem') of the first volume of his dissertation assured him international fame. The first volume of his dissertation dealt with the static problems of fixed-capital systems and the second volume with dynamic problems for analogous systems. His method of analysis, in the Austrian tradition, was very similar to Böhm-Bawerk's approach: copious numerical and special examples to illustrate subtle and deep general propositions. It is to his great credit that he seldom went wrong in deriving propositions by this primitive method; as a testimony to his insights we can cite concepts and issues at the frontiers of capital theoretic debates that owe much to the results of his dissertation of 1923–4: Wicksell effects, truncation of production flows, transverse flows, to name but a few.

He was perhaps also the first (after the early classical economists) to try to approach the problem of fixed capital as joint products – a method made famous by von Neumann and Sraffa in more recent times.
Even before his capital theoretic writings, he had engaged the grand old man of Swedish economics, Knut Wicksell, in a debate in the pages of the *Ekonomik Tidskrift* (1922) on the latter's proposals on norms for price stabilization. His later work was mostly on practical problems of economic policy.

somewhat lesser known internationally than his elder brother Gustaf, Johan Henrik Åkerman was, however, much better known inside Sweden. He was a prolific contributor to the theoretical, methodological, epistemological and policy debates in Sweden for almost 50 years. He challenged almost single-handedly (at least inside Sweden) the methodological position of the so-called Stockholm School and made valiant (but unsuccessful) attempts to provide an alternative vision which he described as the ‘Lund School’ method.

Johan Henrik Åkerman was born in Stockholm in 1896, graduated from the Stockholm Business School in 1918, and then spent two terms at Harvard University (1919–20) working with Warren M. Persons. On his return to Sweden, he continued his postgraduate studies in the Universities of Uppsala and Sweden. He obtained his PhD (Fil.Dr.) in 1929 from the University of Lund, where he was appointed Associate Professor in Political Economy and Economic Statistics in 1932. In 1943 he was appointed Professor in Political Economy in Lund, and retained that position until his retirement in 1961. His scientific publications of more than 150 items included several books, some of which were translated into English and German. He was almost totally deaf from a very early stage in his life and totally deaf during his tenure as Professor in Lund. He died in 1982.

Johan Åkerman's outstanding doctoral dissertation had the title On the Rhythm of Economic Life (Om Det Ekonomiska Livets Rytmik). It was an ambitious attempt to codify, theoretically and empirically, all aspects of the problem of fluctuations in economic life. It was based on the theoretical framework of Wicksell's Geldzins und G•terpreise (1898) and Cassel's ‘Om kriser och dåliga tider’ (On crises and bad times), Ekonomisk Tidskrift, 1904; and on the empirical methodology of the budding NBER work. Åkerman's dissertation was perhaps the earliest attempt to apply spectral analysis for studying time series phenomena in economics. His main examiner for the doctoral degree was Ragnar Frisch, whose more influential later work on ‘Propagation problems and impulse problems in dynamic
economics’ (1933) owes much to Åkerman's specific considerations of Wicksell's celebrated 'rocking-horse' example. This latter example, delineating one influential strand in business cycle methodology – the stochastic approach – stressed the important distinction between sources of propagation and impulse mechanisms. It is to Åkerman's great credit that he was able to revive and place in the centre of discussion on business-cycle methodology this important distinction, which was initially stressed by Wicksell in an obscure footnote to a review article in the *Ekonomisk Tidskrift*, 1918. It is both important and topical in view of recent developments in equilibrium business cycle theories, where these issues are central. Indeed, Åkerman's dissertation could claim to be an early manifesto of aspects of the New Classical Economics.

In the 1930s and 1940s Åkerman's research interests shifted towards methodological and epistemological problems – mainly under the influence and impact of the works of members of the Stockholm School (and later the Keynesians). He was severely critical of the rationality and individualistic assumptions underlying the then popular macroeconomic theories (and their microeconomic underpinnings). He developed a highly original alternative modelling strategy for macroeconomics based on a so-called dual principle of ‘causal’ and ‘computing’ (‘Kalkyl’) models where institutional details and socio-economic classes were explicit factors. His research and reflections on these matters, spread over a period of 30 years, were summarized and elegantly delivered as a lecture on the occasion of his retirement (‘Avskedsföreläsning’) from the Professorship in Lund on 9 May 1961 (‘Fyra methodologiska moment’, *Ekonomisk Tidskrift*, 1961). The depth of his understanding of recent developments in economic analysis, and the scope of his comprehensive references to epistemological developments in theoretical physics and relevance to economic theory, were displayed in that last masterly lecture.

His lifelong interest in the political economy of business cycles was also reflected in a highly original work on political business cycles, *Ekonomiskt Skeende och Politiska Förändringar*. He was continuing a Swedish tradition on this subject – and quite independently of Kalecki's important work on political business cycles – initiated by Herbert Tingsten's inter-war work on *Political Behaviour: Studies in Election Statistics* (1937).

Retrospectively, it is significant that Johan Åkerman's two pioneering studies on problems of fluctuations in mixed economies have their counterpart in research in the frontiers of the theory and empirical analysis of business, political and economic cycles even today.

Albert the Great, Saint Albertus Magnus (c.1200–1280)

Odd Langholm

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Albert the Great; Aquinas, St. T.; Aristotle; just price; labour; private property; usury; value

Article

Albert the Great, doctor universalis, was the foremost German philosopher and theologian of the Middle Ages. He was born in the village of Lauingen on the Danube and became a member of the Dominican Order while studying at Padua. He subsequently studied at Paris, and eventually taught there as well as in Dominican houses in Germany, primarily Cologne, where he became Regent Master of Studies and where he died. Albert served as Bishop of Regensburg, was German Provincial of his Order and Master of the Sacred Palace of the Pope, but repeatedly returned to Cologne to devote himself to study and teaching. He composed a comprehensive set of commentaries on the works of Aristotle and is considered the founder of Christian Aristotelianism. He was canonized and named a Doctor of the Church in 1931. Ten years later he was declared patron ‘of all who cultivate the natural sciences’, which indicates his main area of interest. In what is now called economics he is overshadowed by his famous student Thomas Aquinas, but in fact he made important contributions of his own. They are found in his comments on Scripture and on the theological Sentences of Peter Lombard as well as in some of his Aristotelian works. On the Nicomachean Ethics he composed a close textual commentary, and later a freer Ethica. His Politica is the first complete Latin commentary on Aristotle's Politics.

Two striking features of Albert the Great's discussions of matters relating to material wealth and economic activity are his empirical orientation and the store he sets by human labour. He argues that private property is the best arrangement in civil society because common ownership engenders strife, pointing to the observable fact that those who reap less than their labour share under communism are likely to protest and cause trouble (Politica, II.2). In Book V of the Nicomachean Ethics, Aristotle discusses justice in relation to barter between persons of different occupations and states obscurely that as one person is to another person, thus are their respective products to each other. Albert the Great interprets this formula in terms of respective input: as a farmer is to a shoemaker in labour and expenses, thus the product of the shoemaker is to the farmer's product (Ethica, V.2.9). This solution is explained

by a factual observation: unless a carpenter receives for a bed what it cost him to make it, he will not make any more beds (Ethica, V.2.7). In his commentary on the Sentences, Albert's approach and conclusion are different. In the absence of economic coercion and fraud, the just price is that at which a good sold can be valued according to the estimation of the market at the time of the sale (Comm. Sent., IV.16.46). If these arguments are combined, what Albert asserts is that the competitive market determines value but that unprofitable goods will be withdrawn from the market.

Albert discussed the purposes and properties of money and warns against debasement of the currency. Examining usury in the same context, he rejects the ‘barren metal’ theory falsely attributed to Aristotle. Lending for profit is a perverse use of money, which makes it seem as though money reproduces itself (Politica, I.7). Usury is a form of economic coercion because it is paid with a conditional, not an absolute, will. The payment is voluntary only in the sense in which, according to Aristotle, the captain of a ship in peril jettisons cargo voluntarily (Comm. Sent., III.37.13). But the full force of Albert the Great's denunciation of usury comes through in one of his Gospel commentaries: ‘By hard labour [the borrower] has acquired something on which he could live, and this the usurer, suffering no distress, spending no labour, fearing no loss of capital by misfortune, takes away, and through the distress and labour and changing luck of his neighbour collects and acquires riches for himself’ (Super Lucam, 6.35).

alienation

Jonathan Wolff
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The term ‘alienation’ is associated especially with the early writings of Karl Marx, for whom the core idea was that of human beings becoming detached from part of their ‘essence’. At one stage Marx hoped to demonstrate that all of the concepts of classical economics could be derived from the concept of alienation. As he matured, exploitation and surplus value replaced alienation at the heart of his analysis. Nevertheless, Marx's observations regarding alienation remain insightful to this day.

Keywords

alienation; capitalism; classical economics; communism; Engels, F.; exploitation; Feuerbach, L.; Hegel, G. W. F.; historical materialism; Marx, K. H.; Smith, A.; surplus value

Article

Although the word ‘alienation’ is commonly used to express an idea of, perhaps, resentful dislocation, within social theory its central use is to be found in the early writings of Karl Marx (1818–83), and especially his Economic and Philosophical Manuscripts, also known as the Paris Manuscripts, of 1844. Marx did not invent the concept; it was widely used by the group of Young Hegelian philosophers with whom he associated in the early 1840s, and especially by Ludwig Feuerbach, in his account of religious alienation. In turn, these thinkers had been influenced by Hegel's concept of externalization.

The term itself cannot be given a single, uncontroversial definition; rather, it seems a marker for a constellation of ideas, not always present in every use. A common understanding sees alienation as a subjective feeling. For Marx, however, alienation is an objective fact about the world, and in its core use we can often distinguish three constitutive elements. The most easily observable aspect is that human beings become detached from something that properly belongs to them. This implies, of course, a second element; a normative claim about how things ought to be, that is, their non-alienated state. Finally, and most metaphysically ambitious, that from which man has become separated nevertheless returns in some ‘alien’ form; by this means human beings are not only estranged from but also
Marx's use of the idea of alienation went through a number of phases. The first takes over and extends Feuerbach's concept of religious alienation. The second is the most ambitious: alienation is used as an explanatory concept in the sense that it is claimed that all the categories of economics can be generated from an analysis of the concept of alienation. This neo-Hegelian phase, however, was short-lived, not surviving beyond the *Economic and Philosophical Manuscripts*; Marx was shortly to become aware that a priori philosophy was not the best tool for economic analysis. In a third phase the idea of alienation was retained as a central concept in the understanding of the effect of capitalism on human beings, and held out the promise of emancipation. This, however, faded in to a fourth and final phase where, although, the same ideas were present, the term itself was used less and less, and Marx's key concept for the analysis of capitalism became surplus value or exploitation.

**Religious alienation: the influence of Feuerbach**

The young Marx wrote for a philosophical audience which had accepted Feuerbach's reversal of traditional theology in which he asserted that human beings had created God in their own image; indeed this is a view with a long history. Feuerbach's distinctive contribution was to argue that worshipping God diverted human beings from enjoying their own human powers. While accepting much of Feuerbach's account, Marx criticized Feuerbach on the grounds that he had failed to understand why people fell into religious alienation and so was unable to explain how it could be transcended. Marx's explanation, of course, was that religion was a response to alienation in material life, and could not be removed until human material life was emancipated, at which point religion would wither away. This was discussed in Marx's 1843 essay *Contribution to the Critique of Hegel's Philosophy of Right: Introduction*, and, very briefly, in the *Theses on Feuerbach* of 1845.

Precisely what it is about material life that creates religion was not set out by Marx with complete clarity. However, it seems that at least two aspects of alienation are responsible. One is alienated labour, which will be explored shortly. A second is the need for human beings to assert their communal essence. Marx argued that, whether or not we explicitly recognize it, human beings exist as a community, and what makes human life possible is our mutual dependence on the vast network of social and economic relations which engulf us all, even though this is rarely acknowledged in our day-to-day life. Marx's view appeared to be that we must, somehow or other, acknowledge our communal existence in our institutions. At first it is 'deviously acknowledged' by religion, which creates a false idea of a community in which we are all equal in the eyes of God. After the post-Reformation fragmentation of religion, when religion is no longer able to play the role even of a fake community of equals, the state fills this need by offering us the illusion of a community of citizens, all equal in the eyes of the law. But the state and religion will both be transcended when a genuine community of social and economic equals is created.

Here we see all three aspects of alienation. Human communal existence has come apart from its essence through the invention of God. The normatively correct situation for humans, however, is one in which they enjoy their essence on earth. Finally, our own communal essence returns to dominate us in the alien form first of religion and then of the political state.

**Alienated labour as the foundation of economics: the Neo-Hegelian phase**
It is commonplace to observe that Marx transformed a critique of religion into a critique of society. The *Economic and Philosophical Manuscripts* is an important element in this early critique. Here Marx famously depicts workers under capitalism as suffering from four types of alienated labour. First, they are alienated from their products, in at least two ways: they may not understand what they are making, and, as soon as it is created, is taken away from them. Second, they are alienated in productive activity (work) which is experienced as a torment, often requiring the performance of mindless or back-breaking toil. Third, they are alienated from their species-being. The distinctive feature of human beings is their productive and creative power. Yet under capitalism humans produce blindly and not in accordance with their truly human powers. Consequently, argues Marx, workers feel free only when away from work, engaged in activities that they share with animals; eating, drinking and having sex. Hence they are alienated from their distinctively human powers. Finally, they are alienated from other human beings, where the relation of exchange replaces mutual need.

These categories overlap in some respects, but this is no surprise given Marx's remarkable methodological ambition in these writings. Essentially he attempted to apply a Hegelian deduction of categories to economics, trying to demonstrate that all the categories of bourgeois economics – wages, rent, exchange, profit, and so on – were ultimately derived from an analysis of the concept of alienation. Consequently, each category of alienated labour was supposed to be deducible from the previous one. However, Marx got no further than a rather unconvincingly attempt to deduce categories of alienated labour from each other. Quite possibly in the course of writing he came to understand that a different methodology was required for approaching economic issues. Nevertheless, we are left with a very rich text on the nature of alienated labour.

**Alienation and emancipation**

Marx based his account of capitalism not, at this stage, on independent empirical study, but on his readings of the works of the classical economists, most notably Adam Smith; much of the descriptive content of the idea of alienated labour from was derived his reading of *The Wealth of Nations*. However, by setting it within the theory of alienation he was able to depict capitalism as a world which was by its nature contrary to the human essence, and therefore with an inbuilt tendency to its own destruction. The bridge between Marx's early analysis of alienation and his later social theory is the idea that the alienated individual is ‘a plaything of alien forces’, albeit alien forces which are themselves a product of human action. In our daily lives we take decisions that have unintended consequences, which then combine to create large-scale social forces which may have an utterly unpredicted effect. In Marx's view the institutions of capitalism – themselves the consequences of human behaviour – come back to structure our future behaviour, determining the possibilities of our action. For example, for as long as a capitalist intends to stay in business he must exploit his workers to the legal limit. Whether racked by guilt or not, the capitalist must act as a ruthless exploiter. Similarly, the worker must take the best job on offer; there is simply no other sane option. But by doing this we reinforce the very structures that oppress us. The urge to transcend this condition, and to take collective control of our destiny – whatever that would mean in practice – was one of the motivating and sustaining elements of Marx's attraction to communism.

However, Marx's idea of emancipation – of a non-alienated society – has largely to be inferred from its
negative. There are, however, two short passages in the early writings which are often cited in this context. The more famous is from the *German Ideology*, co-authored with Engels in 1845, and like many of their works unpublished in their lifetime. Here Marx and Engels described future society as a rural idyll, lived in complete freedom to order one's own life. Recent scholarship, however, casts doubt on whether this passage, which is quite unlike anything else written by Marx and Engels, was intended as a serious contribution to the development of their view (Carver, 1998).

A second short passage appears at the end of the text ‘On James Mill’ (1844) in which non-alienated labour is briefly described in terms which emphasize both the producer's immediate enjoyment of production as a confirmation of his or her powers, and the idea that production is to meet the needs of others, thus confirming for all parties our human essence as mutual dependence. Both sides of our species essence are revealed here: our individual human powers and our membership in the human community.

### Alienation and the rise of ‘surplus value’

As Marx turned to economics he found philosophy of decreasing use and interest, and as he matured as a social thinker the concept of alienation becomes less and less prominent. This has led some commentators, notably Althusser, to argue that there was an ‘epistemological break’ between Marx's early, humanist, phase, and a later scientific phase, incorporating the first volume of *Capital* (1867).

Although the publication, since Althusser's famous essay (Althusser, 1970), of many of Marx's writings of the 1850s shows that there is something closer to a natural development of ideas rather than a decisive break, it is true that the concept of alienation does not play the central role in Marx's later economic writings that it did in his early writings. Nevertheless, even in *Capital* there are descriptions of the labour process under capitalism which bear close comparison with the arguments of the 1844 manuscripts, and a discussion of ‘commodity fetishism’ in *Capital* is very close indeed to the idea of alienation.

### Conclusion

Although Marx's economic theories play little role in contemporary economic analysis, and his theory of historical materialism is valued more for its small-scale insights rather than its long-term predictions, Marx's theory of alienation remains of great interest. On a descriptive level, Marx's account of the conditions of work under capitalism remain highly relevant if not to the developed world, then clearly to the major developing economies. Furthermore, the idea that human beings can become trapped within structures they have created for themselves is a deep insight that is constantly being rediscovered especially within the feminist and environmental movements. Marx's ideas concerning alienation are an inspiration even to those who are unaware of their source.

Allais paradox

Maurice Allais
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The ‘Allais paradox’ is that risk-averse persons’ choices between alternatives tend to vary according to the absolute amounts of potential gain involved in different pairs of alternatives, even though rational choice between alternatives should depend only on how the alternatives differ. But there is no paradox once we accept the non-identity of monetary and psychological values and the importance of the distribution of cardinal utility about its average value.

Keywords

Allais paradox; Allais, M.; Bernoulli, N.; cardinal utility; de Finetti, B.; expectations; Harsanyi, J. C.; independence; preferences; propensity for risk; psychological versus monetary value; random choice; psychology of risk; Samuelson, P. A.; Savage, L. J.; St Petersburg paradox; von Neumann and Morgenstern

Article

The St Petersburg paradox and the Bernoullian formulation

Let there be a random prospect $g_1, \ldots, g_b, \ldots, g_r, \ldots, p_1, \ldots, p_b, \ldots, p_n (\sum_i p_i = 1)$ giving the probability $p_i$ of positive or negative gains $g_i$. The early theorists of games of chance considered that a game was advantageous when the mathematical expectation

$$M = \sum_i p_i g_i (1 \leq i \leq n)$$  

(1)
was positive (Allais, 1952b, pp. 68–9).

The principle of the mathematical expectation of monetary gains has proven to be open to question in the case of the *St Petersburg Paradox* outlined by Nicolas Bernoulli. For this game, we have:

\[ g_i = 2^i, \quad p_i = 1 / 2^i, \quad n = \infty \]

so that \( M = \infty \). However, if the unit of value is the dollar, it can be seen that for most subjects, the psychological monetary value of the game (that is the price they are ready to pay for this random prospect) is generally lower than 20 dollars. This, at first sight, involves a paradox. To explain this paradox, Daniel Bernoulli (1738) considered the mathematical expectation of cardinal utilities \( u(C + g_i) \) instead of the mathematical expectation of monetary gains, \( C \) being the player's capital. Thus the formulation (1) is replaced by the Bernoullian formulation

\[
\begin{align*}
  u(C + V) &= \sum p_i u(C + g_i) \\
  \text{(2)}
\end{align*}
\]

in which \( V \) is the psychological monetary value of the random prospect. He proposed to take the logarithmic expression \( u = \log(C + g) \) as cardinal utility (Bernoulli, 1738; Allais, 1952b, p. 68; 1977, pp. 498–506; 1983, p. 33). It can then be shown that we have approximately \( V \sim a + [\log C / \log 2] \) with \( a = 0.942 \), which yields \( V \sim 14 \) or 18 US dollars for \( C \) equal to 10,000 or 100,000 dollars respectively (Allais, 1977, p. 572).

**The neo-Bernoullian formulation**

In order to measure cardinal utility from random choice, von Neumann and Morgenstern demonstrated in the *Theory of Games* (1947), on the basis of a set of more or less appealing postulates, the existence of an index \( B(C + g) \), such that

\[
\begin{align*}
  B(C + V) &= \sum p_i B(C + g_i) \\
  \text{(3)}
\end{align*}
\]

in which the index \( B(C + g) \) is independent of the random prospect considered, but depends on the subject (von Neumann and Morgenstern, 1947, pp. 8–31 and 617–32; Allais, 1952b, p. 74; 1977, pp. 521–3, 591–603; 1983, p. 34). Using other sets of postulates, Marschak, Friedman and Savage, Samuelson, Savage, etc. (Marschak,
Allais paradox: The New Palgrave Dictionary of Economics

1950 and 1951; Friedman and Savage, 1948; Samuelson, 1952; Savage, 1952 and 1954; Allais, 1952b, pp. 74–5, 88–92, and 99–103; 1977, pp. 464–5, 508–14; 1983, pp. 33–5) came to the same formulation (3), which may be referred to as the neo-Bernoullian formulation, but its interpretation differs depending on the postulates adopted. While von Neumann and Morgenstern believed, at least initially, that $B \equiv u$, the $p_i$ being objective probabilities (Allais, 1952b, p. 74; 1977, pp. 591–2), Savage held that cardinal utility is a myth (Savage, 1954, p. 94), and that the neo-Bernoullian index $B$ alone is real, the $p_i$ being subjective probabilities, the existence of the function $B$ and the $p_i$ being proven on the basis of the axioms considered. Some authors (e.g. de Finetti, Krelle, Harsanyi) admit the existence of cardinal utility $u$, but they consider that $B \neq u$, and the index $B$ is deemed to take account of the relative propensity for risk corresponding to the distribution of cardinal utility (de Finetti, 1977; Allais, 1952b, pp. 123–4; 1983, pp. 30–31).

Whereas von Neumann's and Morgenstern's opinion, accepted by most authors, is that the crucial axiom of their theory is axiom 3 Cb, I consider that their axioms 3 Ba and 3 Bb are the crucial ones (Allais, 1977, pp. 596–8). However, one way or another, irrespective of the nature of the axioms from which it is derived, the neo-Bernoullian formulation boils down to assuming the independence of the $B_i$ for given values of the $p_i$. This is the principle of independence (Allais, 1952b, pp. 88–90 and 98–9; 1977, pp. 466–7).

The Allais paradox

When I read the Theory of Games in 1948, formulation (3) appeared to me to be totally incompatible with the conclusions I had reached in 1936 attempting to define a reasonable strategy for a repetitive game with a positive mathematical expectation (Allais, 1977, pp. 445–6). Consequently, I viewed the principle of independence as incompatible with the preference for security in the neighbourhood of certainty shown by every subject and which is reflected by the elimination of all strategies implying a non-negligible probability of ruin, and by a preference for security in the neighbourhood of certainty when dealing with sums that are large in relation to the subject's capital (Allais, 1952b, pp. 84–6, 88–90, 92–5; 1977, pp. 451, 466–7, 491–8).

This led me to devise some counter-examples. One of them, formulated in 1952, has become famous as the ‘Allais Paradox’. Today, it is as widespread as its real meaning is generally misunderstood. This counter-example consists of two questions, the gains considered being expressed in (1952) francs [one million (1952) francs is roughly equivalent to 10,000 (1985) dollars].

- Do you prefer Situation A to Situation B?
  - Situation A
    - certainty of receiving 100 million.
  - Situation B
    - a 10 per cent chance of winning 500 million,
    - an 89 per cent chance of winning 100 million,
    - a 1 per cent chance of winning nothing.
- Do you prefer Situation C to Situation D?
Situation C
- an 11 per cent chance of winning 100 million,
- an 89 per cent change of winning nothing.

Situation D
- a 10 per cent chance of winning 500 million,
- a 90 per cent chance of winning nothing.

It can be shown that, according to the neo-Bernoullian formulation, the preference $A > B$ should entail the preference $C > D$, and conversely (Allais, 1952b, pp. 88–90; 1977, pp. 533–41).

However, it is observed that for very careful persons, well aware of the probability calculus and considered as rational, and whose capital $C$ is relatively low by comparison with the gains considered, the preference $A > B$ can be observed in parallel to the preference $C < D$. Since the neo-Bernoullians consider the axioms from which they deduce the neo-Bernoullian formulation as evident, they consider this result a paradox.

In 1952, Savage's answers to these two questions contradicted his own axioms. The explanation he gave is somewhat surprising. It boiled down to stating: ‘Since my axioms are totally evident, my answers, which are indeed incompatible with my axioms, are explained by the fact that I did not give the matter enough thought’ (Savage, 1954, pp. 101–103).

**Empirical research**

After analysing the answers to the 1952 Questionnaire (Allais, 1952d). I found that the rate of violation of the neo-Bernoullian formulation corresponding to the Allais Paradox was approximately 53 per cent (Allais, 1977, p. 474).

This violation example is not an isolated one (Allais, 1977, pp. 636–6, n. 15). There is even one test for which the rate of violation is 100 per cent. It is based on the comparative analysis of, on the one hand, the monetary value $x'$ attributed to a probability of 1/2 of winning a sum between 0.0001 and 1000 million, with a probability of 1/2 of winning nothing at all; and, on the other hand, of the monetary value $x''$ attributed to a probability $p_i$ between 0.25 and 0.999 of winning 200 million, with a probability $1 - p_i$ of winning nothing at all. The two indexes $B_{1/2}$ and $B_{200}$ deduced from these two series of questions, which according to the neo-Bernoullian formulation should be totally identical up to a linear transformation, in fact are completely different for all the subjects who answered the questions. Such was in particular the case of de Finetti (Allais, 1977, pp. 612–13, 620–31; 1983; pp. 61–2 and 110–11, n. 146).

Much empirical research has been carried out since 1952. It has shown that many subjects who can be viewed as rational may behave in contradiction with the neo-Bernoullian formulation (e.g. MacCrimmon and Larsson, 1975; Allais, 1977, pp. 507–8, pp. 611–54). Confronted with these results, the neo-Bernoullians always explain these violations as ‘anomalies’, ‘errors’, ‘insufficient thought by the subjects’, or ‘ill constructed and inconclusive’ experiments made by incompetent persons, ‘inexperienced in experimental psychology’ (e.g. Amihud, 1974 and 1977; Morgenstern, 1976). But these statements do not hold in the face of the very numerous violations observed by the many
Allais paradox: The New Palgrave Dictionary of Economics

Researchers, following different methods and operating in different countries at different times (Allais, 1977, pp. 541–2; 1983, p. 66).

The Allais paradox, a simple illustration of Allais's general theory of random choice

These violations can be explained very simply. Limiting consideration to the mathematical expectation of the $B_i$ involves neglecting the basic element characterizing psychology vis-à-vis risk, namely the distribution of cardinal utility about its mathematical expectation (Allais, 1952b, pp. 51–5, 96–7; 1977, pp. 481–2, 520–23, 550–52; 1983, pp. 30–31), and in particular, when very large sums are involved in comparison with the psychological capital of the subject, the strong dependence between the different eventualities ($g_i$, $p_i$), and the very strong preference for security in the neighbourhood of certainty.

My 1952 inquiry (Allais, 1952d; 1977, pp. 447–9, 451–4, 604–54; 1983, pp. 28 and 41) showed that all the subjects questioned were able to answer questions on the intensity of their preferences for different possible gains, setting aside any consideration of random choices (only a few neo-Bernoullian authors refused to answer these questions) (Allais, 1943, pp. 156–77; 1952b, pp. 43–6; 1977, pp. 460–61, 475–80, 614–17, 632–3). The analysis of the answers made it possible to design a well defined cardinal utility curve, the structure of which is the same for all the subjects up to a linear transformation. It portrays their answers on average remarkably well (Allais, 1984a and 1984c).

This result is all the more significant in that this expression of cardinal utility shows a very striking similarity to the expression for psychophysiological sensation as a function of luminous stimulus, determined by Weber's and Fechner's successors (Allais, 1984c, § 4.3 and Charts III and XXV).

The existence of a cardinal utility $u(C + g)$ being proven and the neo-Bernoullian index $B(C + g)$, if it exists, being defined also up to a linear transformation, it can be shown that the two indexes are necessarily identical up to a linear transformation (Allais, 1952b, pp. 97–8, 103, 128–30; 1977; pp. 465, 483, 604–607; 1983, pp. 29–30; 1985).

As a consequence the neo-Bernoullian formulation reduces to considering the mathematical expectation of cardinal utility alone, neglecting its dispersion about the average. In so doing, it neglects what may be considered as the specific element of risk (Allais, 1952b, pp. 49–56; 1983; pp. 35–41).

In fact the cardinal utility corresponding to a monetary value $V$ of a random prospect should be considered as a function

$$u(C + V) = F[u(C + g_1), ..., u(C + g_i), ..., u(C + g_n), p_1, ..., p_i, ..., p_n]$$

(4)

of cardinal utilities $u_i$ corresponding to the different gains $g_i$. Since utilities $u_i$ are defined up to a linear transformation, it can be shown that (Allais, 1977, pp. 481–3, 550–52, 607–609; 1985, § 12 and 22)

in which $\Delta$ is any constant (property of cardinal isovariation). Consequently it can be shown that relation (4) can be written

$$u(C + V) = \bar{u} + R(\mu_2, \ldots, \mu_b, \ldots, \mu_{2n-1})$$

(6)

in which $\bar{u}$ represents the mathematical expectation of the $u_i$ and the $\mu_l$ represent the moments of order $l$:

$$\mu_l = \sum_i p_i(u_i - \bar{u})^l.$$  

(7)

The ratio $\rho = \frac{R}{\bar{u}}$ can be considered as an index of the propensity for risk. For $\rho = 0$, the behaviour is Bernoullian; for $\rho > 0$, there is a propensity for risk; for $\rho < 0$, there is a propensity for security. For a given subject, $\rho$ can be nil, positive or negative, depending on the domain of the field of random choices considered (Allais, 1983, pp. 35–41; 1985).

The mistake made by the proponents of the neo-Bernoullian formulation is to want to impose restrictions on the preference index

$$I = f [g_1, \ldots, g_i, \ldots, g_n, p_1, \ldots, p_b, \ldots, p_n]$$

(8)

of any subject other than those corresponding to conditions of rationality, such as the existence of a field of ordered random choice or the axiom of absolute preference. According to this axiom, taking two random prospects $g_i$ and $g'_i$ such that $g_i > g'_i$ for any $p_i$, the first is obviously preferable to the second (Allais, 1952b, pp. 38–41; 1977, pp. 457–8, 530–35; 1985, § 31.3).

Imposing other restrictions would, in the case of certain goods $(A), (B), \ldots, (C)$, reduce to imposing special restrictions on the preference index $I(A, B, \ldots, C)$ which no author has ever envisaged. In fact, to have a marked preference for security in the neighbourhood of certainty together with a preference for risk far
from certainty is not more irrational than preferring roast beef to chicken (Allais, 1952b, pp. 65–7; 1977, pp. 527–33; 1983, pp. 39–40; 1985, § 31.3).

**From The St Petersburg paradox to the Allais paradox**

In sum, just as the St Petersburg Paradox led Daniel Bernoulli to replace the principle of maximization of the mathematical expectation of monetary values by the Bernoullian principle of maximization of cardinal utilities, the Allais Paradox leads to adding to the Bernoullian formulation a specific term characterizing the propensity to risk which takes account of the distribution as a whole of cardinal utility (Allais, 1978, pp. 4–7; 1977, pp. 548–52; 1983, pp. 35–42).

Neither the St Petersburg nor the Allais Paradox involves a paradox. Both correspond to basic psychological realities: the non-identity of monetary and psychological values and the importance of the distribution of cardinal utility about its average value.

For nearly forty years the supporters of the neo-Bernoullian formulation have exerted a dogmatic and intolerant, powerful and tyrannical domination over the academic world; only in very recent years has a growing reaction begun to appear. This is not the first example of the opposition of the ‘establishments’ of any kind to scientific progress, nor will it be the last (Allais, 1977, pp. 518–46; 1983, pp. 69–71, 112–14).

The Allais Paradox does not reduce to a mere counter-example of purely anecdotal value based on errors of judgement as too many authors seem to think without referring to the general theory of random choice which underlies it. It is fundamentally an illustration of the need to take account not only of the mathematical expectation of cardinal utility, but also of its distribution as a whole about its average, basic elements characterizing the psychology of risk.

Maurice Allais was born on 31 May 1911, in Paris. Originally a student at the Ecole Polytechnique he moved later to the Ecole Nationale des Mines (ENMP hereafter). He gained the doctorate of engineering of the University of Paris in 1949. He is currently director of Research at the Centre National de la Recherche Scientifique (CNRS) and Professor of Economic Analysis at the ENMP. The CNRS awarded him a gold medal in 1978, the first time this award was given to an economist. He was awarded the Nobel Prize for Economics in 1988.

His initial professional activity led him toward problems of applied economics and regulation. In France, the corps of mining engineers, one of the greatest branches of the civil service, is entrusted with the regulation of mining and energy and is very influential in the definition and control of public industrial policy. In some sense Allais’ theoretical works are an attempt to find rational public economic public decisions. The title of his first book, *A la recherche d’une discipline économique. Première Partie: l’économie pure* (1943) is very significant in this respect. One feels in Allais’ thought a deep reluctance to accept any theory which cannot be made operative (1978a). Thus a very important part of his activity, which will not be surveyed here, is devoted to applied economic studies, always, directly supported by a theoretical analysis (see 1954; 1956a; 1977). In the brilliant tradition of Dupuit, Colson and Divisia this aspect of Allais’ work has been essential for the development of the school of French economist...
engineers. Allais educated several generations of researchers and public managers: M. Boiteux, G. Debreu and E. Malinvaud were among his students.

In the line of descent from Walras, Fisher and Pareto, Allais’ theoretical contributions are basic in four fields: general equilibrium and optimal allocation of resources (‘rendement social’ or ‘efficacité maximale’ in Allais’ terminology), capital and growth, money and business cycle, risky choices. Allais is primarily a theorist of interdependence and optimum. It is impressive to observe that the research programme defined at the start in Allais (1943) has been almost wholly fulfilled, even though some of the initial basic assumptions have been drastically revised. When published in 1943, Allais’ book was one of the most complete reports on general equilibrium and optimum theories, comparable to Hicks's *Value and Capital* and Samuelson's *Foundations of Economic Analysis*. Let us emphasize its differences. Allais gives the earliest formalization of an intertemporal general equilibrium and, in particular, all the arbitrage conditions between capital goods and land are made explicit. Then, the first results on global stability of Walrasian *tâtonnement* are proved by means of Lyapunov's second method under assumptions equivalent to gross substitutability (see Negishi, *Econometrica* (1962), for a report in English). The book also contains a complete account of optimum theory in terms of distributable surpluses and a precise and correct statement of the two welfare theorems. Finally, Allais outlined a theory of optimum population. Later, Allais’ opinion on the relevance of the Walrasian model changed markedly (1967b; 1968; 1971; 1981). He would now define a state of general equilibrium as a position in which no distributable surplus can be obtained, and describes the whole motion of the system as governed by the search for such surpluses. In some way this new view is a true merging of general equilibrium and optimum theories (1981).

His main contributions to capital and growth theory are expressed in Allais (1947; 1960; 1962). First, and sometimes with a lead of 15 years, he found most of the results of so-called neoclassical theory of growth, including the famous golden rule of accumulation. Allais worked out a complete theory of capitalistic processes with a rigorous formalization of the concept of characteristic function first proposed by Jevons in 1871, by which is meant the sequence of past expenditures on primary inputs which have generated the present national income. The systematic use of this concept allowed Allais to build up a theory of economic growth. But its use has been even more fruitful in the analysis of capitalistic efficiency. Allais proved in 1947 that, in a stationary state, a zero rate of interest maximizes real income. This is the first version of the golden rule of accumulation obtained by Phelps some 14 years later. In 1962 Allais widened this result and demonstrated that in steady states a capitalistic optimum is attained when the rate of interest is equal to the rate of growth (it is to be noted that Allais himself acknowledges that J. Desrousseaux had been the first to get this result in 1959, in a non-published paper). Thus Allais was completing his theory of optimal allocation of resources with a theory of capitalistic optimum.

To analyse intertemporal optimality, he assumes that each agent has preferences, on present and future consumption, possibly different in different periods. Hence it becomes possible to consider the psychological evolution of an individual over his lifetime, unlike the usual approach. In other respects Allais has been very careful to test the explicative power of his capitalistic optimum theory, by comparing the growth processes in different countries and trying to evaluate in every case the gap between the capitalistic optimum and the real state of accumulation.

Allais must be also considered as a major actor in the revival of the quantity theory of money (1956b; 1956c; 1965a; 1966; 1969; 1970; 1972; 1974). The reduced form of the model explaining the dynamics
of national monetary expenditure is very similar to Cagan's contemporary formulation. But Allais claims that his model has very different foundations because it is supported by an alleged psychological law of the perception of time. The solutions of the integro-differential equation describing the evolution of income are shown to have three limit cycles, depending upon initial conditions. It is then possible to explain local stability of a steady state equilibrium, business cycles and hyperinflation state with the same basic model.

The last aspect of Allais’ work concerns choice under risk (1953b; 1953c; 1979). As usual, Allais’ approach is both theoretical and empirical. He builds up his analysis on the basis of experimental psychological tests conducted in 1952 (see Allais, 1953c, for a partial statement). For Allais the theory of choice under risk went, historically, through four steps. At first it was assumed that the mathematical expectation of the monetary gain was the natural evaluation of a lottery. Then the mathematical expectation of the gain in utility was used. The third step then considered subjective probabilities. The American school (Friedman, Marschak, von Neumann, Morgenstern, Samuelson and Savage) takes into account only these three steps. So Allais claims that a fourth step must be reached: the value of a lottery is a functional depending upon the probability density parameterized by the gains. In effect the expected utility hypothesis implies a special such functional, so this last step seems very natural. Allais systematically criticizes the axioms on which the Bernoullian principle is based. According to him such axioms cannot help to define rationality in an uncertain environment. Through convincing examples he specially refutes Savage’s independence and Samuelson’s substitutability axioms. The major argument is in short that in the neighbourhood of certainty, a rational agent will prefer absolute safety. Then Allais proposes an alternative definition of rationality in risky situations: the set of choices must be ordered, an absolute preference axiom must be satisfied (that is, if a lottery gives in every case larger gains than another, then any agent will prefer the first one) and only objective probabilities must be considered. The first two axioms seem quite reasonable and it is difficult, according to Allais, to disprove the last one. But it is clear that a decision rule following the Bernoullian principle cannot be deduced from these three axioms. They imply the use of a functional of more general form than the mathematical expectation of the psychological evaluation of gains. In fact Allais argues that the Bernoullian principle only takes into account the dispersion of the gains whereas the dispersion of their psychological values is pertinent.

Finally, Allais applies his theory of behaviour under uncertainty to a general equilibrium model (1953a). He demonstrates this through an example where a competitive allocation of risks leads to an optimal allocation of resources, and where such an allocation can be obtained as a competitive equilibrium with an appropriate redistribution of initial endowments.

Article

Allen was born on 3 June 1906 at Stoke-on-Trent, and died on 29 September 1983 at Southwold. He was knighted in 1966 and made a Fellow of the British Academy in 1952. He was educated at the Royal Grammar School, Worcester, and Sidney Sussex College, Cambridge. From 1928 he was assistant, then lecturer, then reader in economic statistics at the London School of Economics, becoming professor of statistics in 1944 and emeritus professor in 1973.

During the war, he was a statistician in H.M. Treasury from 1939 to 1941; from 1941 to 1942 he was Director of Records and Statistics for the British Supply Council in Washington, and from 1942 to 1945, he became British Director of Research and Statistics for the Combined Production and Resources Board in Washington. His other principal activities were as statistical adviser for H.M. Treasury (1947–8); member of the Air Transport Licensing Board (1960–72); and member of the Civil Aviation Authority (1972–3). He was President of the Econometric Society in 1951 and President of the Royal Statistical Society in 1969–70. He was also consultant to many international and professional organizations.

Allen was an economic statistician, mathematical economist and econometrician of exceptional competence and breadth of knowledge. His early and most original research, carried out in part with J.R. Hicks and A.L. Bowley, was on the theory of value, utility and consumers’ behaviour: for example, Hicks and Allen (1934), Allen (1935), and Allen and Bowley (1935), the last an outstanding work on the econometrics of family budgets.

In the late 1930s he embarked on a series of successful textbooks based on his lectures. His *Mathematical Analysis for Economists* (1938) was intended to help students of economics whose training in mathematics was typically much less thorough than it is now. After the war, in addition to

numerous papers on economic and statistical topics, including one reflecting his wartime work in Washington (Allen, 1946), and a compilation of papers on international trade statistics (Allen and Ely, 1953), he continued the good work begun in 1938 with a succession of books on macroeconomics and the mathematical and statistical tools required in its study. Thus Statistics for Economists (1949) is an introduction to statistical methods in their application to economic material; Mathematical Economics (1956) is a text on economic theory, written in mathematical terms, which takes account of the growth of econometrics and the use of increasingly sophisticated mathematics by economists; Basic Mathematics (1962) provides a general introduction to mathematical ideas, applicable in both the natural and the social sciences; Macro-Economic Theory (1967) treats deterministic models from a positive rather than an optimizing or policy-oriented point of view; his 1975 work deals comprehensively with the design, construction and use of index numbers, paying full attention to both the economic and the statistical aspects of the subject; his last book (1980) is an introduction to national accounting, concentrating on the main aggregates at current and constant prices and illustrated by means of recent British official estimates.

Allen was an assiduous disseminator of ideas. His textbooks were translated into many languages and he continued to lecture until shortly before his death. As head of the Statistics Department of the LSE he was instrumental, with the help of M.G. Kendall, in expanding it from a staff of five in 1944 to one of 28, of whom seven were professors.

altruism in experiments

James Andreoni William T. Harbaugh and Lise Vesterlund
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

We call an act altruistic when it is a sacrifice that benefits others. We discuss how experiments have demonstrated that altruistic choices appear to follow the same regularity conditions as those assumed for private goods. In particular they vary rationally in response to changes in prices and circumstances. We show how experiments have distinguished between different economic models of how concern for others enters utility functions, and have explored the implications of those models for charitable giving, labour markets, and trust. We also discuss the experimental evidence for differences in altruism by gender, and work on altruism's cultural, developmental, and neural foundations.

Keywords

altruism; altruism in experiments; centipede game; cooperation; crowding out; dictator game; efficiency wages; experiments; gift exchange; moral hazard game; Prisoner's Dilemma; public goods games; Rawls, J.; reciprocity; repeated games; reputation; revealed preference; trust game; ulterior motives; ultimatum game; utilitarianism; warm-glow

Article

Unlike experiments on markets or mechanisms, experiments on altruism are about an individual motive or intention. This raises serious obstacles for research. How do we define an altruistic act, and how do we know altruism when we see it?

The philosopher Thomas Nagel provides this definition of altruism: ‘By altruism I mean not abject self-sacrifice, but merely a willingness to act in the consideration of the interests of other persons, without the need of ulterior motives’ (1970, p. 79). Notice that there are two parts to this definition. First, the act must be in the consideration of others. It may or may not imply sacrifice on one's own part, but it does require that the consequences for someone else affect one's own choice. The second aspect is that one does not need ‘ulterior motives’ rooted in selfishness to explain altruistic behaviours. Of course, ulterior
motives may exist alongside altruism, but they cannot be the only motives. If this is our definition of altruism, then how do we know altruism when we see it? The answer, unfortunately, is necessarily a negative one – we only know when we do not see it. Altruism is part of the behaviour that you cannot capture with a specifically defined ulterior motive. Experimental investigation of altruism is thus focused around eliminating any possible ulterior motives rooted in selfishness. One of the central motives that potentially confounds altruism is the warm-glow of giving, that is, the utility one gets simply from the act of giving without any concern for the interests of others (Andreoni, 1989; 1990). While it is possible that warm-glow exists apart from altruism, it seems most likely that the two are complements – the stronger your desire to act unselfishly, the greater the personal satisfaction from doing so. Indeed, the two may be inextricably linked. Having a personal identity as an altruist may necessarily precede altruistic acts, and maintaining that identity can only come from actually being generous.

In what follows we will highlight the main experimental evidence regarding choices made in the interests of others, and the systematic attempts in the literature to rule out ulterior motives for these choices. Since these serious and repeated attempts to rule out ulterior motives have not been totally successful, the experimental evidence, like Thomas Nagel, favours the possibility of altruism.

**Laboratory experiments with evidence of altruism**

In describing the games below, we adopt the convention of using Nash equilibrium to refer to the prediction that holds if all subjects are rational money-maximizers.

**Prisoner's Dilemma**

There have been thousands of studies using Prisoner's Dilemma (PD) games in the psychology and political science literatures, all exploring the stubborn nature of cooperation (Kelley and Stanelski, 1970). Roth and Murnigham (1978) explored PD games under paid incentives and with a number of different payoff conditions. Their study confirmed to economists that cooperation is robust. Sceptics noted, however, that cooperation need not be caused by altruism. First, inexperience and initial confusion may cause subjects to cooperate. Second, subjects in a finitely repeated version of the game may cooperate if they each believe there is a chance someone actually is altruistic. Behaviourally this ‘sequential equilibrium reputation hypothesis’ (Kreps et al., 1982) does not actually require subjects to be altruistic, but only that they believe that they are sufficiently likely to encounter such a person. Andreoni and Miller (1993) explore these two factors by asking subjects to play 20 separate ten-period repeated PD games. A control treatment had subjects constantly changing partners, thus unable to build reputations. They find significant evidence for reputations, but that these alone cannot explain the level of cooperation, especially at the end of the experiment. Rather, they estimate that about 20 per cent of subjects actually need to be altruistic to support the equilibrium findings. This finding is corroborated in other repeated games, such as Camerer and Weigelt's (1988) moral hazard game, McKelvey and Palfrey's (1992) centipede game, and in a two-period PD of Andreoni and Samuelson (2006).

**Public goods**
Linear public goods games have incentives that make them resemble a many-person PD game. Individuals have an endowment $m$ which they each must allocate between themselves and a public account. Each of the $n$ members of the group earns $\alpha$ for each dollar allocated to the public account. By design, $0 < \alpha < 1$, so giving nothing is a dominant strategy, but $\alpha n > 1$, so giving $m$ is Pareto efficient. The results of these games are that average giving is significantly above zero, even as we change $n$, $m$ and $\alpha$ (Isaac and Walker, 1988; Isaac, Walker and Williams; 1994) and whether the play is with the same group of ‘partners’ or with randomly changing groups of ‘strangers’ (Andreoni, 1988). Hence, reputations play little role in public goods games (Andreoni and Croson, 2008; Palfrey and Prisbrey, 1996).

In his review of this literature, Ledyard (1995) notes that, with a dominant strategy of giving zero, any error or variance in the data could mistakenly be viewed as altruism. Thus, to determine what drives giving one needs to confirm that subjects understand the dominant strategy but choose to give anyway. Andreoni (1995) develops a design to separate ‘kindness’ from ‘confusion’ in linear public goods games. Rather than paying subjects for their absolute performance, in one treatment he paid subjects by their relative performance. Converting subjects’ ranks into their payoffs converts a positive-sum game to a zero-sum game. It follows that even altruists have no incentive to cooperate when paid by rank (that is, under the usual definition of altruism where people love themselves at least as much as they love others). Cooperation by subjects in the treatment group, therefore, provides a measure of confusion. Andreoni finds that both kindness and confusion are significant, and about half all cooperation in public goods games is from people who understand free riding but choose to give anyway.

To establish that giving is deliberate, however, does not necessarily mean it is based in altruism; it could, instead, be from warm-glow. Two papers, using similar experimental designs but different data analysis methods, explore this question by separating the marginal net return that a gift to the public good has for the giver and for the recipient. The ‘internal return’ experienced by the giver should affect warm-glow and altruism, but the ‘external return’ received by the others affects only altruism. Palfrey and Prisbrey (1997) find that warm-glow dominates altruism, while Goeree, Holt and Laury (2002) find mostly altruism. Combining this evidence, it appears that both motives are likely to be significant.

Another way to test for the presence of altruism and warm-glow is to choose a manipulation that would have different predictions in the two regimes. Andreoni (1993) looks at the complete crowding out hypothesis, which states that a lump-sum tax, used to increase government spending on a public good, will reduce an altruist’s voluntary contributions by the amount of the tax. He employs a public goods game with an interior Nash equilibrium. Suppose subjects care only about the payoffs of other subjects (altruism). Then if we force subjects to make a minimum contribution below the Nash equilibrium, this should simply crowd out their chosen gift, leaving the total gift unchanged. If they get utility from the act of giving (warm-glow), by contrast, crowding out should be incomplete. Andreoni finds crowding at 85 per cent, which is significantly different from both zero and 100 percent. This confirms the findings from the last paragraph; both warm-glow and altruism are evident in experiments on public goods. Similar findings are presented in Bolton and Katok (1998) and Eckel, Grossman and Johnston (2005).
Altruism in experiments: The New Palgrave Dictionary of Economics

This line of research began with the ultimatum game, where a proposer makes an offer on the split of a sum of money. If the responder accepts, the offer is implemented, while if she rejects both sides get nothing. Guth, Schmittberger and Schwarze (1982) find that proposers strike fair deals and leave money on the table. Is this altruism, or just fear of rejection? To answer this question Forsythe et al. (1994) also examine behaviour in a dictator game that cuts out the second stage, leaving selfish proposers free to keep the whole pie for themselves, and leaving altruists unconstrained to give a little or a lot. While keeping the entire endowment is the modal choice in the dictator game, a significant fraction of people give money away. On average, people share about 25 per cent of their endowment. This seems to indicate significant altruism.

Again, researchers have explored numerous non-altruistic explanations. One is that, while the dictator's identity is unknown to the recipient, it is not unknown to the researcher. This lack of ‘social distance’ could cause the selfish but self-conscious subjects to give when they would prefer not to. Hoffman et al. (1994) take elaborate steps to increase the anonymity and confidentiality of the subjects so that even the researcher cannot know their choices for sure. They find that this decreases giving to about 10 per cent of endowments. However, this ‘double anonymous’ methodology creates problems of its own. Bolton, Katok and Zwick (1998) argue that greater anonymity makes the participants sceptical about whether the transfers will be carried out. Bohnet and Frey (1999) find that reducing the social distance increases equal splits greatly, but in their anonymous treatments giving again averages 25 per cent (see also Rege and Telle, 2004).

Andreoni and Miller (2002) take a different approach. They note that, if altruism is a deliberate choice, then it should follow the neoclassical principles of revealed preference. They gave subjects a menu of several dictator ‘budgets’, each with different ‘incomes’ and different ‘prices’ of transferring this income to another anonymous subject. By checking choices against the generalized axiom of revealed preference, they show that indeed most subjects are rational altruists, that is, they have consistent and well-behaved preferences for altruistic giving in a dictator game. They also show substantial heterogeneity across subjects, with preferences ranging from utilitarian (maximizing total payments to both subjects) to Rawlsian (equalizing payments to both subjects). Interestingly, men and women are on average equally altruistic in this study, but vary significantly in response to price. Andreoni and Vesterlund (2001) show that men are more likely to be utilitarian, and women are more likely to be Rawlsian. This implies that men are significantly more generous when giving is cheap (that is, it costs the giver less than one to give one), but women are significantly more altruistic when giving is expensive (costs greater than or equal one to give one). Which is the fairer sex, therefore, depends on the price of giving (see also Eckel and Grossman, 1998, on dictator games when the price is one).

Trust games and gift exchange

When someone buys a loaf of bread from a baker, there is a moment when one party has both the bread and the money and the incentive to take both. Why don't they? Similarly, why are some car mechanics truthful, and why do some workers put in an honest effort even when they are not monitored? These questions have been studied under names of trust games and gift exchange.

In the trust game, two players are endowed with M each. A sender chooses to pass $x$ to a receiver. A
receiver receives $kx$, where $k > 1$. The receiver then chooses a $y$ to pass back to the sender. Senders earn $M - x + y$, while receivers earn $M + kx - y$. Since $y = 0$ is a dominant strategy for receivers, $x = 0$ is the subgame perfect equilibrium strategy for senders. That is, since the baker keeps both the bread and the money, no exchange is attempted. Despite this dire prediction, $x$ and $y$ are often positive, and $y$ is typically increasing in $x$. While there is tremendous variance, the average $y$ is often slightly below the average $x$ (Berg, Dickhaut and McCabe, 1995).

The gift exchange game is a nonlinear version of the trust game above. Fehr, Kirchsteiger and Riedl (1993) adapted the Akerlof (1982) labour market model of efficiency wages. Some subjects play the roles of firms and offer labour contracts to workers. The contracts stipulate a wage and an expected effort level of workers. Since effort is costly and unobservable, it should be minimal. The subjects playing the role of firms should expect low effort, and offer low wages. However, in the experiment wages are high and effort rises with the wage offer, just as Akerlof predicted.

Trust and gift exchange games are often used to argue for the importance of reciprocity. Reciprocity is, however, an ulterior motive – giving in order to either generate or relieve an obligation is not altruism by the definition in our introduction. How much of the exchange can be attributed to altruism alone? Cox (2004) separates these motives by comparing senders in a trust game with those in a dictator game. As dictators have no ulterior motive of generating an obligation, their behaviour can be used to estimate the altruism of senders. For receivers he uses a control group whose $x$ is determined at random by the experimenter. These receivers have no obligation to the sender, thus their transfers serve as a measure of the receivers’ altruism. Cox finds that 60 per cent of an average sender's $x$ and 42 per cent of the average receiver's $y$ is motivated by altruism. Thus, while reciprocity is clearly present, altruism is not replaced in this exchange (see also Charness and Haruvy, 2002; Gneezy, Guth and Verboven, 2000).

While some have criticized whether gift exchange in the laboratory is robust to small changes in parameters and presentation (Charness, Frechette and Kagel, 2006), others have challenged gift exchange in the field. List (2006) looks for gift exchange on the trading floor of a sports card market. He conducts a series of experiments that move incrementally from a standard laboratory game with a neutral presentation to actual exchanges on the floor. While he finds that gift exchange (higher-quality product in return for higher price) is not totally extinguished in the actual market, he also finds that reputation is far more important in determining the quality provided by sellers. Gneezy and List (2006) follow up with a labour market experiment. They recruited students to do a one-day job working in a library. The treatment group was told, unexpectedly, that their wage would be 167 per cent of the agreed wage. These subjects were significantly more productive in the first 90 minutes of work than the control subjects. However, after a one-hour lunch break, there was no difference between the productivity of treatment and control. They conclude that gift exchange in actual labour markets may have no long-term effects.

Conclusion

There is ample consistent evidence of altruism in experiments. This follows both from studies that have taken great effort to remove any ulterior motives, as well as studies that provide manipulations that should influence altruism. While the existence and importance of altruism seem well established in the laboratory, many questions that could help us understand and amplify altruism remain unanswered.
First, where do altruistic preferences come from? One notion is that they come from culture. Evidence of this is suggested by differences in behaviour in experiments in different countries (Roth et al., 1991; Henrich et al., 2001). Another notion is that they are acquired as part of psychological development and socialization, as seen in economic experiments using children as subjects (Harbaugh and Krause, 2000). A third possibility for altruism is that we are innately wired to care. Harbaugh, Mayr and Burghart (2007) use fMRI to show that neural activation in the ventral striatum is very similar when money goes to the subject and when it goes to a charity, and that the relative activations actually predict who will give. Tankersley, Stowe and Huettel (2007) show that posterior superior temporal sulcus activation is higher for people who report more helping behaviour outside the lab.

Second, is altruism significant outside the laboratory? The laboratory is, after all, a unique environment. Field experiments on fundraising, such as List and Lucking-Reiley (2002), show the potential of this method for finding good evidence of altruism outside the laboratory, but without giving up all experimental control.

Finally, how does altruism combine with other ulterior motives? Are warm-glow and altruism inextricably linked, and can we use mechanisms that act on warm-glow to amplify altruism and overcome free riding? Does voting to force everyone to provide a public good provide a warm-glow benefit to the voters? Economic experiments may be a productive method for answering these questions, and for using the knowledge of altruism that results to improve the institutions within which altruist economic agents interact.

altruism, history of the concept

Philippe Fontaine
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article describes the incorporation from the early 1960s of seemingly unselfish behaviour into economics. Faced with the problem of accounting for such behaviour in a discipline that often relies on the selfishness assumption, some economists used the notion of sympathetic preferences within the self-interest model, whereas others tried instead to supplement that model with an ethically inspired model. It is unclear that in investigating seemingly unselfish behaviour, economists have gained a better understanding of its actual motivations, but in the process they have been led to take more seriously other conceptions of human being than economic man.

Article

Dennis Robertson once asked: ‘What does the economist economize?’ (1955, p. 154). His answer was: ‘[T]hat scarce resource Love – which we know, just as well as anybody else, to be the most precious thing in the world’. He meant that a better understanding of the economy had the happy consequence of allowing people to conduct their business without having to rely excessively on social virtues. For upholders of economic man, that was certainly a good justification for doing without ‘love’. And had it not been for a study of philanthropy, conducted in the late 1950s, they might well have continued to ignore ‘love of human kind in general’, as dictionaries usually define it.
The reintroduction of what is regarded today as ‘altruism’ into contemporary economics, following Edgeworth's (1881, p. 53n) first modern formulation in the late 19th century, came out of this effort to understand philanthropy, and not, as conventional wisdom suggests, from the publication of Gary Becker's (1974) ‘A Theory of Social Interactions’, which was but one tardy sequel to it. In writing a history of recent work on unselfishness, therefore, it is crucial that Becker's two chief results in that article, namely, the invariance proposition and the ‘“rotten kid” theorem’, do not mask the sheer diversity of research before the mid-1970s nor the tensions that persisted afterwards. In what follows, we describe the key moments that preceded the inclusion of an ‘altruism’ heading in the Journal of Economic Literature (JEL) classification system for journal articles at the end of 1993.

Understanding philanthropy

After private foundations fell under increasing regulatory scrutiny in the early 1950s (Hall, 1999) and their tax status was attacked in the early 1960s (Frumkin, 1999), their leaders found it opportune to approach economists for advice. In effect, Donald Young, President of the Russell Sage Foundation (RSF), asked Solomon Fabricant, Director of Research at the National Bureau of Economic Research (NBER), to think about the possibility of investigation into the economic aspects of philanthropy. The RSF eventually funded a study of this phenomenon in the American economy, which was conducted by the NBER between 1959 and 1962 under the supervision of the economist Frank G. Dickinson, who was assisted by an advisory committee. The first meeting of the committee took place in late 1959. A few members of the NBER staff, notably Becker, attended the meeting. Some work stemming from it, notably by Fabricant and Dickinson, and dealing mostly with definitional and empirical aspects, benefited from a limited circulation. That explains why Becker wrote the obscure and unpublished ‘Notes on an Economic Analysis of Philanthropy’ in April 1961. He later identified this article as the first expression of his interest in social interactions, but it was originally just another effort to extend the utility maximization assumption to the study of ‘non-economic’ topics. Becker's ‘Notes’ was not the only outgrowth of the NBER project. In addition, a conference, envisioned by Dickinson, took place in June 1961, bringing together a number of economists, among whom William Vickrey and Kenneth Boulding gave papers and James Buchanan simply attended.

By the early 1960s, then, the study of philanthropy had provided an opportunity for a handful of economists to explore aspects of seemingly unselfish behaviour. Following Dickinson's remark, in late 1959, that philanthropy was not in the mainstream of economic analysis, Becker (1961), Vickrey (1962) and Boulding (1962) suggested that there were no theoretical impediments to its understanding. ‘It can be dealt with quite easily in utility theory’, wrote Boulding, ‘by considering the utility of one person a function not only of his own wealth or his own income, but a function of the wealth and income of others’ (1962, p. 61). Essentially Becker and Vickrey agreed. Utility interdependence, in its modern form, had long been around and it appeared to be the proper tool to tackle philanthropic behaviour, even if there could be variations in the arguments to be included in the giver's utility function. There was, however, a more significant difference. Becker was not especially concerned with the motivations of philanthropic behaviour, whereas Boulding and Vickrey were: they believed utility theory could not elucidate the variety of motivations for philanthropy. Accordingly, Boulding emphasized the sense of community (and the associated capacity for empathy) as the essence of ‘genuine philanthropy’, while
Vickrey saw social distance as the significant factor. Following the work of Becker, Vickrey and Boulding, various research efforts gave momentum to the study of philanthropy. Interested as he was in the effects of fiscal systems on income redistribution, Buchanan could easily relate to the theme of the philanthropy conference. As was the case for Becker and Boulding, his work at the intersection of economics and other social sciences made the whole undertaking of studying a form of seemingly unselfish behaviour especially appealing to him. His own views on the free-rider problem led him to distinguish between the expediency criterion and moral law as the two main determinants of an individual’s choice, and to connect their relative strength to group size (Buchanan, 1965). The individual was said to follow moral law in small-group interactions and turn into a utility maximizer as soon as group size grew – the ‘large-group ethical dilemma’. In his presidential address to the American Economic Association a few years later, in December 1968 when social crisis was at its height, Boulding (1969), too, felt it timely to contrast two sets of common values guiding human behaviour: the ‘economic ethic’ and the ‘heroic ethic’, with the former centring on cost–benefit analysis and the latter emphasizing the sense of identity.

After his resignation from the University of Virginia in 1968, Buchanan visited UCLA where a number of economists, including Armen Alchian and William Allen (1964) and Jack Hirshleifer (1967), had studied seemingly unselfish behaviour. These authors had reached the conclusion that its treatment did not require a fundamental reconsideration of the behavioural assumptions of economic theory. Buchanan had doubts. Although he recognized the merits of enriched utility functions for the study of seemingly unselfish behaviour, Buchanan warned that they did not unveil the variety of human motivations. Consequently, he argued, the inclusion of ‘non-economic’ arguments, such as love or concern for the welfare of others, into the utility function did not necessarily improve the predictive power of theory.

Understanding altruism

In the context of adverse circumstances for foundations, the 1962 conference was meant to correct the inadequacy of knowledge about the economic aspects of philanthropy. In 1971, Edmund Phelps sent a grant proposal to Orville Brim, Jr., then President of the RSF, to ask support for the organization of a conference to be held in New York City. Here, too, the idea of the conference emerged in a difficult political environment. With the Tax Reform Act of 1969 imposing new regulations, foundations leaders were under pressure to defend philanthropy from any further threat. Unlike its predecessor, however, the conference contemplated by Phelps would not deal with an instance of seemingly unselfish behaviour, but with altruistic behaviour in general.

Pointing to the extension of the domain of economics to neglected topics such as crime and war, to the disenchantment with classical liberalism that accompanied the intensification of economic problems and the deepening of social crisis in the United States, and to new developments in the analysis of markets such as the relaxation of the assumption of perfect information, Phelps concluded: ‘the time has arrived for a theory of altruism’ (Phelps to Brim, 19 October 1971). That the conference was meant to deal with a topic, the definition of which was still unclear to many, including Phelps himself, speaks volumes about the appeal of seemingly unselfish behaviour in social science at a time when ‘the amount of divisiveness and conflict in a society’ – to use Mancur Olson’s (1971, p. 173) words – occasioned serious concern.
Phelps's consideration of possible participants reveals that what the profession has come to call ‘altruism’ was in the early 1970s a heterogeneous body of knowledge comprising disparate analyses of human behaviour. Phelps first contacted Kenneth Arrow, Paul Samuelson and Vickrey, who all agreed to present papers. In his proposal, Phelps mentioned Boulding, Thomas Schelling, Becker, James Mirrlees, Peter Hammond, Sydney Winter, Alchian, Duncan Foley and Scott Boorman. Among non-economists, philosophers had the lion's share in an otherwise odd group including John Rawls, Tom Nagel, Marshall Cohen, Erving Goffman, Edward Banfield, Bernhard Lieberman and Sydney Morgenbesser. Several of these researchers were part of a movement in the late 1960 and early 1970s to connect moral philosophy with economics and other social sciences. And many of them were concerned with the respective role of self-interest and ethics in the explanation of human behaviour.

Amartya Sen did not appear in the list above but he attended the conference. His call for reconsidering the economic theory of human behaviour fitted in well with the overall preoccupation of the conference with ethics. In his LSE inaugural lecture, ‘Behaviour and the Concept of Preference’, Sen (1973) offered valuable insights into the relationships between choices and individual preferences, showing that the same choice (use and reuse of glass bottles) could correspond to four distinct cases in terms of the agent's underlying preferences. The first three cases represented the preferences of a selfish, sympathetic and socially conscious individual, respectively; they were consistent with utility theory. The fourth case, which Sen (1977) later associated with the notion of ‘commitment’, was of a different sort, however. It shows that moral considerations could influence individual choice in such a way as to undermine the correspondence between choice and preference on the one hand and preference and welfare on the other. The maximization framework with utility interdependence told some truth about seemingly unselfish behaviour, but not the only truth.

However, not all students of seemingly unselfish behaviour found ethics illuminating. At about the same time as Sen's LSE lecture was published in August 1973, Arthur Seldon, from the Institute of Economic Affairs (IEA), the London-based think-tank, was completing the preface to *The Economics of Charity: Essays on the Comparative Economics and Ethics of Giving and Selling, with Applications to Blood*. Unlike Sen and others, the main contributors to the collection, including Alchian, Allen and Gordon Tullock, were doubtful about the possibility of learning something significant economically from an ethical approach to unselfish behaviour. They preferred instead to explore the potentialities of utility theory.

In the early 1970s, economists were undoubtedly showing greater interest in what was now occasionally called ‘altruism’, but a unified theory was still lacking. The plurality of viewpoints reflected varied motivations, with some striving to renew the understanding of small-group interactions and others discussing either the moral dimension of economic behaviour or the economic dimension of moral behaviour. In the literature, there emerged a dividing line between the advocates of *homo economicus* and the supporters of *homo ethicus*, which became more pronounced with the publication of Becker's ‘A Theory of Social Interactions’ (1974) and Phelps's *Altruism, Morality, and Economic Theory* (1975), a collection of essays resulting from the New York conference.

### The polarization of the mid-1970s

Becker's 1974 article was originally titled ‘Interdependent preferences: charity, externalities and income taxation’: it was renamed in September 1969 – a change that revealed Becker's intention to broaden his
Altruism, history of the concept: The New Palgrave Dictionary of Economics

frame of analysis from the issue of charity to the treatment of seemingly unselfish behaviour in general. The article was published in the same issue of the *Journal of Political Economy* as Robert Barro's ‘Are Government Bonds Net Wealth?’ (1974). It would be unreasonable to think of Barro's analysis of government budget deficits as a simple application of Becker's ‘rotten kid’ statement, but some cross-fertilization occurred, especially since Becker's manuscript had spent some six years in his files and Barro had commented on it. Becker also knew Barro's article, a draft of which had been presented, in 1973, in the Money and Banking workshop run by Milton Friedman in Chicago. That Becker and Barro discussed seemingly unselfish behaviour is evidenced by the fact that the latter's former wife suggested the phrase ‘rotten son’ to the former who later turned it into ‘rotten kid’ in his eponymous ‘theorem’ (Barro to Fontaine, 3 April 2001).

Becker proposed, in contrast to what he called the ‘usual theory of consumer choice’, which places in the utility function of the giver his own consumption together with the amount of his charitable giving, a ‘social interactions’ approach, which replaces the amount of charitable giving with the consumption of beneficiaries, as financed by their income and the amount of charitable giving they receive. In the context of the family, Becker reached the conclusion ‘that if a [benevolent] head exists, *other members also are motivated to maximize family income and consumption, even if their welfare depends on their own consumption alone.* This is the ‘‘rotten kid’’ theorem’ (1974, p. 1080).

Against the background of a family break-up, Becker showed that the conditions for family cohesion were not so demanding as to require that all family members have sympathetic preferences or so unrealistic as to imply that all family members are selfish. Regarding the recipients of the head's generosity, he endorsed Friedman's (1953) influential argument and made it clear that only ‘as-if altruism’ was involved. Yet the head had sympathetic (‘altruistic’) preferences. In other words, his transfers were said to result from sympathy, which was explained by the fact that ‘the marriage market is more likely to pair a person with someone he cares about than with an otherwise similar person that he does not care about’ (Becker, 1974, p. 1074n).

Assuming continuity between family and other groups, Becker extended his results to the ‘synthetic “family”’, consisting of a charitable person and all recipients of his or her charity, and to a number of other multi-person interactions. Here again, due to offsetting changes in transfers from the sympathetic benefactor, a redistribution of income among ‘members’ left their own welfare unchanged. To the problem represented by the possibility that opportunistic tendencies can surface in groups characterized by the interactions of selfish individuals and therefore prevent socially desirable outcomes, in the mid-1970s Becker offered a solution centred on the sympathetic preferences of certain individuals in society. To many today, this answer will seem ad hoc, but, at a time when much was said about the unresponsiveness of people to each other's lot, it went against the stream. With the increase in macroeconomic volatility, its policy implications were, however, straightforward: due to offsetting private transfers, one could hardly count on social and economic policies to change the distribution of resources (see Barro, 1974).

Though it can be argued that ‘A Theory of Social Interactions’ played a significant role in the history of unselfishness research, it should be remembered that its main objective was to analyse the economic implications of interactions within various groups. Phelps (1975), by contrast, meant to offer a contribution to the ‘theory of altruism’. As such he aimed at understanding a variety of behaviours, the motivations of which were seemingly unselfish. While Becker had provided a coherent framework...
centred on maximization with utility interdependence to analyse social interactions, the essays in Phelps's collection illustrated the complexity, indeed vagueness, of ‘altruism’ as soon as one ventures beyond the self-interest model.

In dealing with unselfishness, Phelps's book actually considered a great variety of behaviours and motivations. Accordingly, contributors strove to classify them so as to identify their similarities and differences. When Arrow (1975) discussed Richard Titmuss’s analysis of blood giving and its motives, for instance, he introduced a distinction between benefiting from the satisfactions obtained by others, benefiting from one's contributions to these satisfactions and the idea that ‘each performs duties for the other in a way calculated to enhance the satisfaction of all’ (1975, p. 17), but he refrained from providing an economic translation of Titmuss's reference to a sense of obligation to strangers. Arrow acknowledged the possibility that individuals act according to a categorical imperative, but noted: ‘I should add that, like many economists, I do not want to rely too heavily on substituting ethics for self-interest’ (1975, p. 22).

Others in the volume were probably more willing to take note of ethical motivations if only because they could serve to justify opposition to governmental regulation in various areas. In ‘The Samaritan's Dilemma’, Buchanan (1975) showed that the expectation of other-oriented behaviour could lead the potential beneficiary to behave opportunistically. Of particular interest in Buchanan's approach was the association of the undesirable consequences of other-oriented behaviour with the prevalence of the expediency criterion (the selfishness of agents) in society and the conclusion that commitment à la Schelling offered a solution to that problem. This solution, Buchanan realized, was threatened by the weakening adherence to ethical rules resulting from increase in group size.

The last three essays in Phelps's volume came back to the issue of philanthropy. Of particular interest was Bruce Bolnick's (1975) acknowledgement that a number of writers had ‘rendered such behavior susceptible to the traditional tools of economic analysis’ and his concomitant remark that ‘a more fundamental issue is uncovered: What types of motivation underlie philanthropic activity?’ (1975, p. 197). In the same vein, Bolnick pointed to the difference between trying to understand seemingly unselfish behaviour and studying the consequences of the inclusion of utility interdependence in the maximization framework in terms of optimality conditions (see, for example, Hochman and Rodgers, 1969; Kolm, 1969; Thurow, 1971). The latter approach Bolnick saw as ‘unsatisfying as a behavioral theory’ (1975, p. 198) and accordingly argued that social rewards and psychological consistency had to be taken into account not only for small groups but also for larger ones. In the process, Bolnick mentioned the justification in terms of empathetic identification, as suggested by Boulding (1962) and Vickrey (1962), but expressed uneasiness with its limitation to close-knit groups.

Despite notable efforts to go beyond the self-interest model, Altruism, Morality, and Economic Theory failed to identify the main features of the ‘commitment model’. The fact that ethical considerations had to be taken into account in the analysis of seemingly unselfish behaviour did not mean that the self-interest model failed on most accounts or that another model could claim greater explanatory power. It is understandable therefore that in his Introduction to the volume Phelps (1975) wavered: ‘Can altruistic behavior be fit into some version of the economist's beloved model of utility maximization subject to constraints? Or must that model be importantly modified and hooked up to some complementary body of analysis to yield a satisfactory product?’ (1975, p. 2). Jean-Jacques Laffont (1975) conveyed some of these tensions when he uncharacteristically defined the behaviour of homo economicus as selfish, not
self-interested, and contrasted it with ‘Kantian’ behaviour.

The self-interest view of unselfishness

With the studies of seemingly unselfish behaviour within the framework of utility maximization with interdependence, the question of the arguments to be included in the utility function became more relevant than that of the actual motivations of behaviour, though these arguments have occasionally been equated with motives for action. The malleability of utility functions made it possible for economists to consider a variety of influences on the satisfaction of the individual besides own consumption. It even allowed for the inclusion of biological arguments into the utility function. Becker's (1976a) review article on Edward Wilson's (1975) controversial *Sociobiology* provides an interesting illustration. To Wilson, who suggested that biology might enlighten the analysts of social behaviour, Becker, who by that time saw himself as one of them, replied that economics too had its merits in terms of explaining the ‘social’ (for illustrations of the ‘economic approach’, see Becker, 1976b). Thus, though Becker accepted Wilson's definition of *altruism* as behaviour that reduces one's genetic fitness to the benefit of another’s, he also pointed out that ‘altruism’, because of its effects on the behaviour of beneficiaries, could increase the genetic fitness of the ‘altruist’. In emphasizing the positive outcome of unselfish behaviour for the ‘altruist’, Becker complicated the emerging discourse on the essentially selfish nature of human behaviour, as derived from the view that ‘altruism’ is detrimental to its author (Dawkins, 1976).

There was indeed something accidental about Becker's considering the biological basis of social behaviour and writing about sociobiology, but for economists taken by the ‘economic approach’ there was good reason to address unselfishness: economics could not hope to embrace anthropological, sociological and political subjects without at the same time breaking away from the advocacy of behavioural assumptions that pictured the economic agent as a non-social being.

The second half of the 1970s offered several examples of authors, among whom were Hirshleifer and Tullock, who advocated the expansion of the ‘economic’ and wrote on unselfishness as well. It is hardly surprising therefore that these two commented on Becker's article in the *Journal of Economic Literature*. Hirshleifer (1977a), whose extremely well-documented ‘Economics from a Biological Viewpoint’ had just appeared in the *Journal of Law and Economics*, another symbol of the expansionist ambitions of economics, noted that the ‘ “rotten kid” theorem’ obtained only if the ‘altruistic’ head had the last word in the decision sequence (Hirshleifer to Becker, 13 December 1976; see also Hirshleifer, 1977b). Hirshleifer's proviso suggested paradoxical implications. If the ‘head’ did not have the last word, the theorem lost its strength as a demonstration that selfish individuals were dissuaded from behaving opportunistically in groups; if he or she did, on the other hand, it might be presumed that some of the problems dealt with in the ‘theorem’ lost significance.

Unlike Becker, Tullock (1977) preferred a model of unselfishness in which the giver derives utility from the mere act of giving. In his comment, he made the interesting point that in Becker's model the giver does not necessarily know the preference ordering of recipients. Becker thought this problem irrelevant since his model was concerned with family, not government, transfers (Becker to Tullock, 14 December 1976). Such a justification, it should be noted, could undermine the claim that his argument reached beyond the kin selection explanation of unselfishness by biologists.
As Hirshleifer's and Tullock's reactions to Becker's inroad into sociobiology illustrate, some economists were interested in biology. Though the impetus came from the heated debates surrounding the publication of *Sociobiology*, the ongoing redefinition of territories in social science was the determining factor. In his review of the literature on the relationships between economics and biology, Hirshleifer (1977a) noted that ‘the social sciences generally can be regarded as in the process of coalescing’ (1977a, p. 3) and he concluded that ‘economics can be regarded as the general field, whose two great subdivisions consist of the natural economy studied by the biologists and the political economy studied by economists proper’ (1977a, p. 52). Clearly, economists were unwilling to see their attempts at investigating the ‘social’ threatened by similar ambitions on the side of natural scientists (see Hirshleifer, 1985, who later spoke of ‘competing imperialisms’ but acknowledged their complementarities), especially since these attempts continued to be regarded suspiciously by some in the profession. Accordingly, economists took every occasion to emphasize economics’ lessons for the natural sciences. Becker did this and so did others, including Boulding (1978), Hirshleifer (1977a), Schelling (1978), Tullock (1978; 1979), who all took an interest in studying ‘non-economic’ behaviour. Though these various initiatives enjoyed greater visibility with the organization of a session on ‘Economics and Biology: Evolution, Selection, and the Economic Principle’ at the meeting of the American Economic Association in December 1977, from the early 1980s unselfishness research was conducted independently of sociobiology. With ‘economics imperialism’ gradually entering the mainstream (see Stigler, 1984; Hirshleifer, 1985), the interest of economists turned to the more general study of the relationships between economics and biology (see for example, Hirshleifer, 1982; Nelson and Winter, 1982; Samuelson, 1985), and it is only in the early 1990s that the question of unselfishness surfaced again in this kind of literature (Tullock, 1990; Simon, 1990; 1992; 1993; Bergstrom and Stark, 1993; Samuelson, 1993).

By the early 1980s, the self-interest view of unselfishness was well established in the profession: it associated ‘altruism’ with the fact that an individual's utility function depended on another's well-being. Becker's (1981, p. 2) ‘Altruism in the Family and Selfishness in the Market Place’ illustrated the main orientations of that view when he noted that his was a definition of altruism that concerned behaviour, not ‘a philosophical discussion of what “really” motivates people’, and that ‘altruism’ was more common in the family than in the market place because of its greater relative efficiency in the former (1981, p. 10).

The departures from ‘altruism’ à la Becker were encouraged by the political debates of the 1980s. With the macroeconomic volatility of the 1970s, the bearing of economics on policy matters began to be challenged. The conclusion, that due to offsetting transfers from ‘altruists’ one could hardly count on social and economic policies to change the distribution of resources, found continuation in various remarks about the ‘ungovernability’ of modern societies (see Olson, 1982, p. 8). And with the beginning of Ronald Reagan's first presidency and its economic programme turning away from demand management, the link between the ineffectiveness of governmental redistribution and the existence of sympathetic transfers took up a broader significance; it could be taken as another argument for lesser state intervention.

With significant changes in economic and social policies looming on the horizon in the first half of the 1980s, notably ‘the control of federal spending, the reduction or elimination of a wide variety of social entitlement and redistributive schemes … and the aggressive reduction of tax rates on
incomes’ (Bernstein, 2001, p. 164), a number of economists were led to re-examine the strength of the ‘Ricardian equivalence’ theorem’ and the ‘‘rotten kid’ theorem’, two results that were closely associated with the unselfishness literature.

Becker's (1981) article appeared in February at a time when President Reagan's programme was being presented. That programme carried with it a vision of the workings of society that some of Reagan's predecessors considered mistaken, precisely because it gave inadequate weight to the failures of the invisible hand of the market. In the 1960s and 1970s, some may have thought seemingly unselfish behaviour a solution to the opportunistic tendencies capable of emerging in groups – small and perhaps large as well – but in the 1980s there was growing scepticism towards that possibility as well as gradual realization that ‘altruism’ à la Becker was not necessarily a positive force (see, for instance, Wintrobe 1983).

Building on Becker's model, B. Douglas Bernheim, Andrei Shleifer and Lawrence H. Summers (1985) included a strategic component into family transfers. The authors did not reject the possibility of sympathetic transfers from parents (or testators), but stressed above all their intention to control the beneficiaries’ behaviour. In departing from Becker's model, the authors noted that the ‘Ricardian equivalence’ theorem’ did not hold in theirs (1985, p. 1046) and that the ‘‘rotten kid’ theorem’ was valid only under special circumstances (p. 1048). At least from that perspective, there was ground for reconsidering the presumed ineffectiveness of public policies.

Yet the authors preferred instead to review some macroeconomic implications of their model. When contrasted with Becker's, theirs was especially interesting because it reached the conclusion that the influence of parents over their children went further than simply dissuading opportunism within the family. While Becker's model was turned towards the absorption of the negative effects of economic and social change by the ‘head’ of the family, Bernheim, Schleifer and Summers, in emphasizing parents’ influence on ‘decisions by their children concerning education, migration and marriage’ (1985, p. 1073), identified family as a factor of economic and social change. In the context of the breakdown of the traditional family unit, that conclusion could surprise, but it could also appear as the recognition that, with the loosening of family bonds, not only sympathy but also strategy was needed to prevent opportunism.

Further clarification in terms of policy implications came from Bernheim (1986) and Bernheim and Bagwell (1988), who instead of directly challenging the neutrality implications of Barro's (and Becker's) analytical framework pointed to its unsuitability to analyse the effects of public policies. In rejecting the ‘Ricardian equivalence hypothesis’, these authors suggested a different analytical framework in which the linkages between families, more than the ‘dynastic family’ à la Barro, were especially important. On the basis of these linkages, Bernheim and Bagwell (1988) established strong neutrality results, the practical implications of which they eventually dismissed on the grounds of being unrealistic. Perhaps because changes affecting family since the 1970s gained more visibility by the end of the 1980s, a number of presuppositions, characterizing Becker's and Barro's notion of family as that of a ‘big happy family’ behaving as if it maximized a single utility function (Bernheim and Bagwell, 1988, p. 333), became gradually untenable. At the very least, the complexity of intra-family relationships seemed to call for alternative representations.

The changes in perspective can easily be realized when one considers Assar Lindbeck and Jörgen W. Weibull's (1988, p. 1165) argument about the inefficient outcomes generated by ‘altruism’. In an
altruism, history of the concept: The New Palgrave Dictionary of Economics

In the intertemporal setting, the authors argued, gift-giving leads to social inefficiencies because the recipient can act strategically and thus induces the donor to give more than he or she was prepared to (see also Bruce and Waldman, 1990). Though reminiscent of Buchanan’s ‘Samaritan's Dilemma’ of the mid-1970s, the argument differed in that it allowed for unselfish preferences on both sides (see also Kimball, 1987). Like Buchanan’s, it suggested a solution in terms of commitment à la Schelling, with the donor making a binding commitment to the level of support provided to the recipient; and, like Buchanan’s, the argument included the proviso of the difficult practical enforceability of that solution. Unlike Becker's suggestion, unselfishness did not suffice to remove opportunistic tendencies in social interactions; it could even encourage them.

In the same vein, Bernheim and Stark (1988, p. 1034) saw the ‘“rotten kid” theorem’ as rather ‘special’ and even identified ‘a variety of circumstances in which members of a group would actually prefer to interact with less altruistic individuals, and in which the efficiency of resource allocation is inversely related to the prevailing degree of altruism’ (for a perhaps more positive, though nuanced, view, see Bergstrom, 1989). In addition to the criticisms levelled at Becker, that article called into question the customary distinction between family and the market in terms of behavioural assumptions. To the extent that ‘altruism’ tended to induce exploitability, it was suggested that ‘family decisions were more properly modelled as negotiations among primarily self-interested (read: ‘selfish’) agents (Bernheim and Stark, 1988, p. 1044). As far as society was concerned, similar conclusions apply: ‘altruism’ did not necessarily limit negative externalities. Worse still, unless it reached high levels, there were indications of its being a ‘counterproductive social force’.

In view of the above, it may be concluded that a decade and a half after Becker and Barro had produced their results, there were serious misgivings about the generality of their application. Given that unselfishness research owed some of its impetus to the realization of the undesirable consequences of selfish behaviour in terms of the provision of public goods and considering that government intervention could be regarded as a solution to that problem, there was some irony in James Andreoni’s (1990) conclusion that economic and social programmes could increase the total provision of public goods because not merely sympathetic but also selfish considerations motivated giving.

In studying privately provided public goods, Andreoni (1988) interpreted various neutrality results as many limitations of the ‘pure altruism model’, which he identified with the definition of the utility function of the giver as including his own consumption and the total supply of public good. Citing in passing Margolis (1982), Sugden (1984) and Bernheim, Shleifer and Summers (1985), he called for a new approach characterized by ‘non-altruistic motives for giving’ (Andreoni, 1988, p. 72). In subsequent works, however, Andreoni (1989; 1990) clarified his own alternative model by resorting to the warm-glow hypothesis, whereby he meant that the utility function of the giver also included his personal contribution to the public good. Combining altruism à la Tullock with altruism à la Becker, this ‘impure altruism model’ was said to be more consistent with empirical evidence contradicting neutrality.

Throughout the Reagan years, there were a variety of results in economics contradicting neutrality. Given the increase in the government debt over that period, it was clear that ‘lesser state intervention’ meant not so much strict control of federal spending as its reorientation in the context of tax reduction. From that perspective, the results obtained by Andreoni and others suggested that the existence of sympathetic transfers could not be taken as a serious justification for the ineffectiveness of national policies. Accordingly, the emphasis was shifted towards examining the power of government
intervention to remedy the undesirable social consequences not only of selfish but also self-interested behaviour. When it is remembered that Becker presented the existence of a sympathetic head as a solution to the difficulty of achieving socially desirable outcomes in various groups of otherwise selfish individuals, it is hardly surprising that the literature emphasizing the limits to ‘altruism’ was led to confront Becker’s work on the family. In their variety, these critics did not call into question the utility maximization framework. For others, however, that framework showed significant inadequacies when it came to explaining seemingly unselfish behaviour.

Alternative views of unselfishness

Just as Becker’s (1974) ‘A Theory of Social Interactions’ epitomizes the self-interest view of unselfishness, so Sen’s (1977) ‘Rational Fools’ represents the alternative views though the latter go beyond the well-known distinction between ‘sympathy’ and ‘commitment’. While Sen delivered his ‘Rational Fools’ lecture at Oxford University in October 1976, Margaret Thatcher was already the leader of the Conservative Party and when the lecture was published in the summer of 1977 she was only a couple of years from being Prime Minister. That was a time of transition to economic liberalism. Thatcher’s intention to dismantle collectivist public policies raised doubts within her own party and in society at large. The fact that Sen, a professor at the London School of Economics since 1971, proposed ‘a critique of the behavioral foundations of economic theory’ (the subtitle of his 1977 article) was a reminder that from the 1960s the debates on public policy in Britain had been marked by the strengthening of a vision endorsing the invisible hand of the market and economic man.

For Sen, sympathy or concern for others’ welfare (‘altruism’ for most economists) was part of the self-interest model, whereas ‘commitment’ was not. He wrote:

The former corresponds to the case in which the concern for others directly affects one's own welfare. If the knowledge of torture of others makes you sick, it is a case of sympathy; if it does not make you feel personally worse off, but you think it is wrong and you are ready to do something to stop it, it is a case of commitment … It can be argued that behavior based on sympathy is in an important sense egoistic, for one is oneself pleased at others’ pleasure and pained at others’ pain, and the pursuit of one's own utility may thus be helped by sympathetic action. It is action based on commitment rather than sympathy which would be non-egoistic in this sense. (Sen, 1977, p. 326)

Perhaps because it was difficult for economists to think of an unselfish person as someone who is motivated by the welfare of others and yet benefits personally from his or her action, Sen stressed exaggeratedly both the interestedness of sympathetic agents and the indifference of committed ones. Another aspect of Sen's approach was to link commitment to groups and then distinguish it from ‘impartial concern for all’, as illustrated by ethical preferences à la Harsanyi (Sen, 1977, p. 336). In following that lead, Sen was echoing the earlier distinction between two sets of values, the ‘economic ethic’ and the ‘heroic ethic’, which Buchanan (1978) was now presenting under the guise of two motivational forces, ‘self-interest’ and ‘community’, the latter of which he continued to connect with
group size. In the context of a changing society, which some saw as regressing economically because of the inadequate attention being given to the invisible hand mechanism, Sen felt the need to remind his readers that in addition to contributing to social harmony the economy required a degree of social cohesion and that the latter was facilitated by the individuals’ sense of commitment to groups. Accordingly, economics’ behavioural assumptions needed to be reconsidered so as to allow for commitment. David Collard (1978), in one of the first monographs on the subject of unselfishness, illustrated this orientation when he argued that once all self-interested motivations were allowed for, there was still room for ‘a truly altruistic residual’ (1978, p. 5).

By the early 1980s, it was clear that the sympathy-based view of seemingly unselfish behaviour was not the whole story. In two voluminous articles, the French economist Serge-Christophe Kolm (1981a; 1981b) showed the complexities of ‘altruism’ and linked them to the prevailing schizophrenia associated with Das Adam Smith Problem. To some extent, Margolis's Selfishness, Altruism, and Rationality (1982) shifted the problem to the coexistence of two selves (or two utility functions representing an individual's self-interested preferences and his group-interested preferences, respectively) in economic man. For economists accustomed to distinguishing between economic man and moral man, Margolis's approach was disturbing. Olson, who reviewed the manuscript for Cambridge University Press, urged Margolis to reframe the argument so as to bring it within standard economic theory (Margolis to author, 17 May 2001), but Margolis felt that his model of individual choice was more ‘consistent with the way human beings are observed to behave’ (1982, p. 3).

It is unclear whether Margolis's overall approach influenced economists. Yet his distinction between ‘participation altruism’ – in which the economic agent gains satisfaction from giving resources away to the benefit of others – and ‘goods altruism’ – in which the economic agent gains satisfaction from an increase in the goods available to others – gave structure to later attempts, such as Andreoni’s, to combine these two kinds of altruism.

Among the alternative views of unselfishness, the British economist Robert Sugden's (1982) deserves special mention since it proposed to reconstruct the public good theory of philanthropic behaviour, which assumed that ‘the total amount of a charitable activity is an argument in the utility functions of its donors’ (1982, p. 350). Having in mind the British context in which large charities exist, Sugden saw one promising option as the dropping of the utility maximization assumption and the concomitant admission that ‘some individuals act on moral principles rather than on pure self-interest’ (1982, p. 349). He reached the conclusion that ‘the conventional argument that private philanthropy leads to the under-supply of charitable activities cannot be sustained’ (1982, p. 350). In the highly charged political environment of Thatcher's first administration, such a conclusion could easily be read as another argument for lesser government intervention.

As we have seen, in the mid-1970s the ineffectiveness of economic and social policies was often justified by the existence of sympathetic transfers, but by the mid-1980s some doubted the suitability of Becker's (and Barro's) ‘altruism’ theories to analyse the effects of public policies. Interestingly, in a later article, Sugden (1984) explicitly dissociated his effort from ‘theories of altruism’ – by which he meant representations of behaviour in terms of concern for others. He proposed a theory of reciprocity in which, because of a Kantian rule, an individual feels obliged to make an effort (in the production of some public good) that matches others’ in the group (on a more general perspective on reciprocity, see Kolm, 1984). Here again, the British context was of some significance, as Sugden made clear when he...
altruism, history of the concept: The New Palgrave Dictionary of Economics

mentioned the role of unpaid donors in blood procurement as an example of the supply of public goods through voluntary contributions. Sugden made the ‘assumption that most people believe free riding to be morally wrong’ (1984, p. 772).

The above approaches rely on groups as a relevant level of analysis between the individual and society. Recourse to ethical variables in that context makes sense as the rejection of ethics from economics has long been encouraged by its focus on impersonal relationships in the market as opposed to interactions in close-knit groups, with frequency of interactions as the main factor constitutive of sense of belongingness. More recently, however, another factor has been considered. Sen (1985), for instance, studied the influence of identification with others in the determination of a person's own welfare (for an earlier attempt in that direction, see Boulding's, 1962, notion of empathy in relation to groups). Sen recognized that ‘[o]ne of the ways in which the sense of identity can operate is through making members of a community accept certain rules of conduct as part of obligatory behavior towards others in the community’ (1985, p. 349). Likewise, Herbert Simon (1992) allowed for loyalty in and identification with groups, and even accepted the working of these notions at the level of the city or nation.

In these approaches, one feels a growing uneasiness as economists move from close-knit groups, such as the family, to more informal groups, such as the country, society or humanity, in which the more obvious associations in terms of behavioural assumptions are with self-interest and not those ‘perceptions of a shared humanity’ which Kristen Monroe (1996) in The Heart of Altruism saw as central to unselfishness. There remains that in theory nothing prevents individuals from empathizing with strangers, feeling sympathy for them and behaving altruistically towards them. To date, however, this line of research has not attracted much attention.

The question may therefore be asked whether economists entertaining alternative views of unselfishness have really been able to get over the dichotomy, to be found in the mainstream view, between the family/altruism and the market/selfishness (see, for example, Becker, 1981). Considering the slight impact of Philip Wicksteed on modern economics, it can be argued that economists have yet to digest his crucial distinction between the nature of an economic relation – the fact that the agent enters it without expressing concern for the purposes of his or her partner (‘non-tuism’) – and the agent's motives, which are either selfish or altruistic depending on whether the economic relation is meant to further the agent's own welfare or that of a third party (Steedman, 1989; Fontaine, 2000). The lack of appreciation for that distinction in modern economic theories of unselfishness and the resulting derivation of motivation (selfishness or unselfishness) from the nature of economic relation itself (impersonal or personal), explain why economists find it so unnatural to explore seemingly unselfish behaviour outside families or groups even if a number of other social scientists have shown less reluctance in that respect (see, for example, some contributions in Mansbridge, 1990).

1993: annus mirabilis

Following attempts to investigate philanthropy in the early 1960s, unselfishness theories experienced a dramatic growth. When it is remembered that in the late 1950s economists complained about the lack of attention to love of humankind (philanthropy), Collard's (1992) late addition to the debate on unselfishness, ‘Love is Not Enough’, signalled a sea change. By early 1990, the weaknesses of research in that area could no longer be attributed to inadequate scrutiny of seemingly unselfish behaviour.
In striking contrast with the early 1960s, 1993 was a prolific year: it saw the publication of a session on the ‘Economics of Altruism’ in the *Papers and Proceedings* of the *American Economic Review* (Samuelson, 1993; Bergstrom and Stark, 1993; Simon, 1993); a collection of essays, *Beyond Economic Man*, edited by Marianne Ferber and Julie Nelson (1993), which challenged the masculine foundations of economics’ behavioural assumptions; and, outside economics, another collection including two essays by economists Sugden (1993) and Tyler Cowen (1993); and finally a special issue of the *Social Service Review* including interdisciplinary studies, among which was Dasgupta (1993), on the concept of ‘altruism’. And to crown this achievement, Becker (1993) published a revised version of his Nobel Lecture in which he tellingly observed: ‘Along with others, I have tried to pry economists away from narrow assumptions about self-interest [read: ‘selfishness’]. Behavior is driven by a much richer set of values and preferences’ (1993, p. 385).

This list is not meant to be comprehensive, though it reflects the increasing volume of publication in this area and explains in turn the addition of an ‘altruism’ heading to the JEL classification system for journal articles in December 1993. Since then, research on seemingly unselfish behaviour has not slowed down, giving more room to economic experiments. There have been a reader (Zamagni, 1995), several monographs and collections of essays (Stark, 1995; Gérard-Varet, Kolm and Mercier-Ythier, 2000) and a handbook investigating the foundations and applications of altruism research (Kolm and Mercier-Ythier, 2006). If this remarkable development speaks to something it is certainly for economics’ remarkable capacity to absorb and digest the most foreign subjects and notably those that present a serious challenge to its most central behavioural assumption. Whether this should be taken as a sign of strong intellectual identity is an open question.

Abstract

Experimental evidence strongly suggests that subjects facing a decision under uncertainty often find it difficult to assess the relative likelihood of certain events; decision theorists deem such events ‘ambiguous’. Furthermore, subjects generally dislike options (acts) whose final outcome depends upon the realization of such ambiguous events; that is, they are ‘ambiguity-averse’. This article surveys the main decision-theoretic models developed since the mid-1980s to accommodate ambiguity and ambiguity aversion, including Choquet-expected utility (Schmeidler, 1989) and maxmin expected utility (Gilboa and Schmeidler, 1989). More recent developments in the theory of ambiguity are also briefly summarized.

Keywords

ambiguity; ambiguity aversion; Bernoulli utility function; choice under uncertainty; Choquet-expected utility; decision theory; decision weights; Ellsberg paradox; Incomplete preferences; maximum likelihood; maxmin expected utility; multiple priors; preference reversals; probability; Savage, L.; second-order probabilities; subjective expected utility; sure-thing principle; von Neumann–Morgenstern utility function

Article

Consider the following choice problem, known as ‘Ellsberg's three-colour urn example’, or simply the ‘Ellsberg paradox’ (Ellsberg, 1961). An urn contains 30 red balls, and 60 green and blue balls, in unspecified proportions; subjects are asked to compare (a) a bet on a red draw with a bet on a green draw, and (b) a bet on a red or blue draw with a bet on a green or blue draw. If the subject wins a bet, she receives ten dollars; otherwise, she receives zero dollars. To model this situation as a problem of choice under uncertainty, let the state space be \( \{r, g, b\} \), in obvious notation, and consider the bets in Figure 1.

Figure 1
Ellsberg's three-colour urn
The modal preferences in this example are $f_r > f_g$ and $f_{rb} < f_{gb}$, where `$>'$ denotes strict preference. (Ellsberg did not conduct actual experiments, but similar patterns of behaviour have been reported in subsequent experimental studies; see Camerer and Weber, 1992, for an exhaustive survey.) A common rationalization runs as follows: betting on red is ‘safer’ than betting on green, because the urn may actually zero green balls; on the other hand, betting on green or blue is ‘safer’ than betting on red or blue, because the urn may contain zero blue balls. Equivalently, when one evaluates $f_r$ and $f_{gb}$, the fact that the relative likelihood of green as against blue balls is unspecified is irrelevant; on the other hand, this consideration looms large when one evaluates the acts $f_g$ and $f_{rb}$.

While these preferences seem plausible, they are inconsistent with subjective expected utility maximization (SEU). Indeed, they are inconsistent with the weaker assumption that the decision-maker’s (DM) qualitative beliefs, as revealed by her betting behaviour, can be numerically represented by a probability measure. Note that $f_r > f_g$ indicates that $r$ is deemed strictly more likely than $g$, so any probability $P$ that represents the individual’s likelihood ordering of events must satisfy $P(r) > P(g)$; on the other hand, $f_{rb} < f_{gb}$ indicates that $\{r, b\}$ is strictly less likely than $\{g, b\}$, which would require $P(r) + P(b) = P(\{r, b\}) < P(\{g, b\}) = P(g) + P(b)$, hence $P(r) < P(g)$.

The key to Ellsberg’s example is the fact that the composition of the urn is incompletely specified; in particular, the relative likelihood of a green as against a blue draw is
ambiguous’. More generally, in the words of Daniel Ellsberg, ambiguity is

a quality depending on the amount, type, reliability and ‘unanimity’ of information, and giving rise to one’s ‘degree of confidence’ in an estimate of relative likelihoods. (1961, p. 567).

To borrow Ellsberg’s terminology, the modal preferences \( f \rhd f g \) and \( f \rhd b \prec f gb \) indicate that the DM would rather have the ultimate outcome of her choices (that is, whether she receives 10 or 0) depend upon events about whose relative likelihood she is more confident. In other words, these preferences denote ambiguity aversion.

Since the mid-1980s, several decision models that can accommodate ambiguity and ambiguity aversion (or appeal) have been axiomatized; other contributions have addressed the behavioural manifestations and implications of ambiguity, as well as updating and dynamic choice. Furthermore, there is an ever-growing collection of applications to contract theory, auctions, finance, macroeconomics, political economy, insurance and other areas of economic inquiry.

The following section reviews two of the most influential models of ambiguity-sensitive preferences in a static setting, while the succeeding section briefly discusses additional models, updating, and dynamic choice.

‘Classical’ models of ambiguity-sensitive preferences

Preliminaries

Fix a finite or infinite state space \( S \) and an algebra \( \Sigma \) of its subsets. A probability charge is a set function \( P: \Sigma \rightarrow [0, 1] \) that satisfies \( P(S) = 1 \) and \( P(E \cup F) = P(E) + P(F) \) for all \( E, F \in \Sigma \) with \( E \cap F = \emptyset \); that is, \( P \) is normalized and finitely additive. The set of probability charges on \((S, \Sigma)\) is denoted \( \Delta(S, \Sigma) \).

The decision models discussed in this section were first axiomatized in the framework introduced by Anscombe and Aumann (1963); it is convenient to adopt the same set-up here. (Alternative axiomatizations that do not rely on lotteries have also been obtained: see, for example, Gilboa, 1987; Chew and Karni, 1994; Casadesus-Masanell, Klibanoff and Ozdenoren, 2000; Ghirardato et al., 2003). Fix a set of prizes \( X \) and let \( \Delta(X) \) be the collection of all lotteries (probability distributions) on \( X \) with finite support. An act is a \( \Sigma \)-measurable \( f: S \rightarrow \Delta(X) \). The set \( \Delta(X) \) is closed under mixtures, that is, convex combinations; mixtures of acts are then defined pointwise, so that the act \( g \) of all acts is also closed under mixtures (that is, for every \( \alpha \in [0, 1] \) and every pair of acts \( f, g \), \( \alpha f + (1 - \alpha) g \) is the act that yields the lottery \( \alpha f(s) + (1 - \alpha) g(s) \) in state \( s \in S \).

A preference is a binary relation \( \succ \) on \( \mathcal{G} \); its symmetric and asymmetric parts are denoted by \( \sim \) and \( \succ \) respectively. It is customary to identify every lottery \( p \in \Delta(X) \) with the constant act that yields \( p \) in every state.

A (von Neumann–Morgenstern, or Bernoulli) utility function is a map \( u: \Delta(X) \rightarrow \mathbb{R} \) that satisfies \( u(\alpha p + (1 - \alpha) q) = \alpha u(p) + (1 - \alpha) u(q) \) for all \( \alpha \in [0, 1] \) and \( p, q \in \Delta(X) \). All axiomatizations discussed below ensure that preferences over lotteries can be represented by a utility function.

A function \( \mathcal{G}: \Sigma \rightarrow \mathbb{R} \) is simple if its range is finite; write \( \mathcal{G} = (\mathcal{A}_1, \mathcal{E}_1; \ldots; \mathcal{A}_n, \mathcal{E}_n) \), where \( \mathcal{A}_1, \ldots, \mathcal{A}_n \in \mathcal{G} \) and \( \mathcal{E}_1, \ldots, \mathcal{E}_n \) is a partition of \( S \), to indicate that, for all \( n = 1, \ldots, N \), \( \mathcal{A}(s) = \mathcal{A}_n \) for all \( s \in \mathcal{E}_n \). An act is simple if its range can be partitioned into finitely many indifference classes. The set of simple \( \Sigma \)-measurable acts is denoted by \( \mathcal{G}_0 \).

Virtually all substantive decision-theoretic issues can be analysed by restricting attention to preferences over \( \mathcal{G}_0 \); the reader is urged to consult the references cited for a discussion of preferences over non-simple acts.

Capacities and Choquet-expected utility

The modal preferences in the three-colour urn example are inconsistent with a probabilistic representation of beliefs essentially because probabilities are finitely additive. Specifically, if the probability charge \( P \) represents the individual's qualitative beliefs, \( f r b \prec f gb \) requires that \( P((r, b)) < P((g, b)) \); since \( P \) is additive, this implies \( P((r)) < P((g)) \). However, \( f r b \prec f gb \) implies the reverse inequality. Thus, formally, the Ellsberg paradox can be ‘resolved’ if a weaker, non-additive representation of the individual's qualitative beliefs is allowed. This approach is pursued in Schmeidler (1986; 1989).

A capacity is a set function \( v: \Sigma \rightarrow [0, 1] \) such that \( v(S) = 1 \) and \( v(\mathcal{A}) \leq v(\mathcal{B}) \) for all events \( \mathcal{A}, \mathcal{B} \in \Sigma \) such that \( \mathcal{A} \subseteq \mathcal{B} \). Thus, a capacity is not required to be additive, although it must satisfy a monotonicity property that has a natural interpretation in terms of qualitative beliefs: ‘larger’ events are ‘more likely’.

To define expectation with respect to capacities, a suitable notion of integration is required. Consider a simple function \( a = (a_1, E_1; \ldots; a_n, E_n) \), where \( a_1 > a_2 > \ldots > a_n \). The Choquet integral of \( a \) with respect to a capacity \( v \) (Choquet, 1953) is the quantity
With the convention that $\bigcup_{m=1}^{0} E_m = \emptyset$, Eq. (1) can be rewritten as follows:

$$
\int a \, dP = \sum_{n=1}^{N-1} (a_n - a_{n+1}) v\left(\bigcup_{m=1}^{n} E_m \right) + a_N.
$$

(2)

Thus, Choquet integration performs a ‘weighted average’ of the values $a_1, \ldots, a_N$, with non-negative weights $v(E_1), v(E_1 \cup E_2) - v(E_1), \ldots, 1 - v(E_1 \cup \ldots \cup E_{N-1})$ that add up to one. If $v$ is additive, Eq. (1) reduces to $\int a \, dP = \sum_{n=1}^{N} a_n v(E_n)$. However, in general, the ordering of the values $a_1, \ldots, a_N$ affects the decision weights: for instance, suppose $a = (\alpha, E, \beta, S(E))$, with $\alpha \neq \beta$; then $\int a \, dv$ equals $\alpha v(E) + \beta[1 - v(E)]$ if $\alpha > \beta$, and $\beta v(S(E)) + \alpha[1 - v(S(E))]$ if $\beta > \alpha$. These expressions are different unless $v(E) + v(S(E)) = 1$.

A preference admits a Choquet-expected utility (CEU) representation if there exists a utility function $u$ and a capacity $v$ such that, for all simple acts $f$,

$$
v(f)_{\text{CEU}} = \int u(f(s)) \, dv = \int u(g(s)) \, dv,
$$

where the integrals are as in Eq. (1).

Preferences in the Ellsberg paradox are consistent with CEU. Let $u$ satisfy $u(10) > u(0)$, and observe that $f \succ f$ requires $v(\{r\}) > v(\{g\})$, whereas $f_{gb} \prec f_{gb}$ implies that $v(\{r, b\}) < v(\{g, b\})$; since $v$ is not required to be additive, these inequalities can be mutually consistent: for instance, let

$$
v(\{r\}) = v(\{r, b\}) = v(\{r, g\}) = \frac{1}{3}, v(\{g\}) = 0, \text{ and } v(\{b, g\}) = \frac{2}{3}.
$$

(3)

Recall that the key axiom in the Anscombe–Aumann axiomatization of SEU is Independence: for all triples of (simple) acts $f, g, h$, and all $\alpha \in (0, 1)$, $f \succ g$ implies $\alpha f + (1 - \alpha)h \succ g + (1 - \alpha) h$. Schmeidler (1989) shows that CEU preferences are instead characterized by a weaker independence property. Say that two acts $f$ and $g$ are comonotonic if there is no pair of states $s, s'$ such that $f(s) > f(s')$ and $g(s) < g(s')$; the key axiom in Schmeidler’s characterization of CEU preferences, Comonotonic Independence, requires that $f \succ g \iff f + (1 - \alpha)h \succ g + (1 - \alpha)h$ only if $f, g, h$ are pairwise comonotonic.

To illustrate the rationale behind this weakening of Independence, consider the acts $f_r$ and $f_g$ in the Ellsberg paradox, and define a third act $f_b$ by $f_b(r) = f_b(g) = 0$ and $f_b(b) = 10$.

For the CEU preferences defined above, $f_r \succ f_g$, but $\frac{1}{2} f_r + \frac{1}{2} f_b \prec \frac{1}{2} f_g + \frac{1}{2} f_b$. This is consistent with the notion that the DM dislikes ambiguity, and hence would rather have the ultimate outcome of her choices depend upon events about whose relative likelihood she is more confident; in particular, notice that the mixture $\frac{1}{2} f_g + \frac{1}{2} f_b$ yields the same outcome in states $g$ and $b$, so the DM need not worry about her lack of confidence in her assessment of their relative likelihood.

This example also suggests that mixtures of non-comonotonic acts can be appealing for an individual who might informally be described as ‘ambiguity-averse’. As was just noted, mixtures of $f_g$ and $f_b$ can reduce or eliminate the dependence of the final outcome upon the realization of $g$ rather than $b$, and hence provide a hedge against ambiguity. The DM under consideration finds this appealing: $\frac{1}{2} f_g + \frac{1}{2} f_b \succ \frac{1}{2} f_g \succ f_b$.

Schmeidler (1989) suggests that this ‘preference for mixtures’ may be taken as a behavioural definition of ambiguity aversion. Formally, say that an individual is ambiguity-averse if,
for all $f, g \in \mathcal{G}$, $f \succ g$ implies $\alpha f + (1 - \alpha) g \succneq g$. Schmeidler then shows that a CEU individual is ambiguity-averse if and only if the capacity representing her preferences is convex: that is, for all events $E, F \in \Sigma$, $\vee(E \cup F) + \vee(E \cap F) \geq \vee(E) + \vee(F)$. For instance, the capacity in Eq. (3) is convex.

Multiple priors and maxmin expected utility

Gilboa and Schmeidler (1989, p. 142) propose an alternative rationalization of the preferences $f_r > f_g$ and $f_r b < f_g b$ in the Ellsberg paradox:

One conceivable explanation of this phenomenon which we adopt here is as follows: ... the subject has too little information to form a prior. Hence (s)he considers a set of priors as possible. Being [ambiguity] averse, (s)he takes into account the minimal expected utility (over all priors in the set) while evaluating a bet. For an analysis of this interpretation of multiple priors, see Siniscalchi (2006).

Formally, preferences admit a maxmin expected utility (MEU) decision rule if, given a utility function $u$ and a weak* closed, convex set $C$ of probability charges on $S$, for all $f, g \in \mathcal{G}$, $f \succ g$ if and only if

$$\min_{P \in C} \int u(f) \ dP \geq \min_{P \in C} \int u(g) \ dP,$$

where integration has the usual meaning. For instance, the modal rankings in the Ellsberg paradox are consistent with MEU, with $u(10) > u(0)$ and

$$C = \left\{ P \in \Delta(S, \Sigma) : P(\{r\}) = \frac{1}{3} \right\}$$

(other choices of $C$ are possible).

Gilboa and Schmeidler's axiomatization of the MEU decision rule features two key axioms: C-Independence and Ambiguity Aversion. The latter was stated in the previous subsection; C-Independence requires that, for all acts $f, g \in \mathcal{G}$ and all constant acts, or lotteries, $P \in \Delta(S), f \succ g$ if and only if $\alpha f + (1 - \alpha) a \succ P + (1 - \alpha) a$. Thus, relative to the full Independence axiom, preference reversals are ruled out only for mixtures with constant acts.

Intuitively, mixing an act with a constant does not provide any hedging opportunities; rather, such mixtures change only the ‘scale and location’ of an act's utility profile. Thus, the requirement formalized by C-Independence is consistent with the discussion in the preceding subsection; indeed, CEU preferences satisfy C-Independence. On the other hand, C-Independence allows for violations of Comonotonic Independence (see Klibanoff, 2001, for an example and further discussion).

Ambiguity-averse CEU preferences satisfy both C-Independence and Ambiguity Aversion (in addition to other structural axioms); thus, they are MEU preferences. Schmeidler (1989) shows that, in particular, the convex capacity $v$ representing an ambiguity-averse CEU preference is the core of the set $C$ of priors in the MEU representation of the same preferences: that is, $C = \{ P \in \Delta(S, \Sigma) : \forall E \in \Sigma, P(E) \geq \vee(E) \}$. For instance, the capacity $v$ in Eq. (3) is the core of the set $C$ in Eq. (4).

Other models, updating, and dynamic choice

A generalization of the MEU model, related to Hurwicz’s $\alpha$-maxmin criterion (cf. Luce and Raiffa, 1957, p. 304), sometimes appears in applications; given a utility function $u$, a weak*-closed, convex set $C$ of priors, and a number $\alpha \in [0, 1]$, $f \succ g$ if and only if
thus, MEU corresponds to the case $\alpha = 1$. An axiomatization and further discussion can be found in Ghirardato, Maccheroni and Marinacci (2004).

Truman Bewley (2002) proposes an alternative approach to ambiguity. In both the CEU and MEU models, the DM responds to ambiguity by essentially evaluating different acts using different 'decision weights'. Bewley suggests that, alternatively, the DM may simply be unable to rank certain acts in the presence of ambiguity; in other words, preferences may be incomplete. He axiomatizes the following partial decision rule: for a given utility function $u$ and weak* closed, convex set $C$ of priors, $f \succ g$ if and only if

$$\forall p \in C, \int u(f) \, dp \geq \int u(g) \, dp.$$ 

For instance, in Ellsberg's three-colour-urn example, if the set $C$ is chosen as above, the DM is unable to rank the acts $f_r$ and $f_b$ as well as the acts $f_{rb}$ and $f_{gb}$. Notice that preferences satisfy the full Independence axiom in Bewley's model: ambiguity manifests itself solely through incompleteness.

Ambiguity can also be modelled by introducing second-order probabilities. For instance, Klibanoff, Marinacci and Mukerji (2005) axiomatize the following decision rule:

$$\forall f, g \in F, f \succ g \Leftrightarrow \int_{\Delta(S)} \phi \left( \int_S u(f) \, d\mu \right) d\mu \geq \int_{\Delta(S)} \phi \left( \int_S u(g) \, d\mu \right) d\mu,$$

where $\mu$ is a probability measure over the set $\Delta(S)$ of probability charges on the finite state space $S$, and $\phi$ is a 'second-order utility function'. A notion of ambiguity aversion is characterized by concavity of $\phi$. See also Ergin and Gul (2004).

Recent contributions aim at characterizing ambiguity without restricting attention to specific decision models, and without relying on functional-form considerations. Epstein and Zhang (2001) propose a definition of 'unambiguous event' that is based solely on preferences. Under suitable structural axioms, preferences over acts that are measurable with respect to such 'subjectively unambiguous' events are probabilistically sophisticated in the sense of Machina and Schmeidler (1992); this indicates that the proposed behavioural definition characterizes absence of ambiguity. See also Epstein (1999) for a related assessment of Schmeidler's definition of ambiguity aversion.

Ghirardato, Maccheroni and Marinacci (2004) note that, in models such as CEU and MEU, ambiguity manifests itself via violations of the Anscombe–Aumann Independence axiom. Thus, they propose to deem an act $f$ ‘unambiguously preferred’ to an act $g$ if $\forall f + (1 - \alpha) g + (1 - \alpha) h$ for all $\alpha \in (0, 1)$ and all $h \in \mathcal{G}$. They show that unambiguous preference admits a Bewley-style representation, characterized by a set $C$ of priors which is a singleton if and only if the original preference is SEU. In light of this result, they suggest that the DM perceives ambiguity whenever $C$ is not a singleton. See also Ghirardato and Marinacci (2002).

To highlight the differences between these definitions, consider a probabilistically sophisticated, non-SEU preference. According to the Epstein–Zhang definition, all events are subjectively unambiguous, whereas the Ghirardato–Maccheroni–Marinacci approach concludes that some ambiguity is perceived.

The modal preferences in the Ellsberg paradox constitute a violation of the sure-thing principle, which is arguably the centrepiece of Leonard Savage's (1954) axiomatization of SEU; indeed, this was a main focus of Ellsberg's seminal article. However, the sure-thing principle also plays a key role in ensuring that conditional preferences are well-defined and 'dynamically consistent'; finally, it provides a foundation for Bayesian updating. Thus, since ambiguity leads to violations of the sure-thing principle, defining updating and ensuring a suitable form of dynamic consistency for MEU, CEU and similar decision models presents some challenges.

All these updating rules may lead to ‘dynamic inconsistencies’, that is, preference reversals: the ranking of two acts may be different before and after learning than a (typically ambiguous) event has occurred. Epstein and Schmeider (2001) instead axiomatize a model of recursive MEU preferences by explicitly imposing dynamic consistency with respect to a
pre-specified filtration. The recursive formulation is especially convenient in applications; on the other hand, dynamic consistency imposes some restrictions on the set of MEU priors: see Epstein and Schneider (2001) for further discussion. Wang (2003) provides related results. Dynamic choice under ambiguity is currently an area of active research.

American Economic Association

Michael A. Bernstein

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Following its foundation, the American Economic Association (AEA) cultivated a unique professional visibility, struggling to establish its professional credentials and to demonstrate the usefulness of economists’ ostensible skills. While celebrating the virtues of ‘free markets’, the AEA was itself shaped by government and collective action. In the latter half of the 20th century, the AEA promoted a ‘New Economics’ focused on macroeconomic intervention and regulation. However, these developments fostered a new generation of specialists with different views of public purpose, the appropriate role of government, and how professional economists could participate in the formulation and implementation of public policy.

Article

The American Economic Association (AEA) was inaugurated by a miscellaneous group of scholars, university administrators and public figures, in September 1885, in the early stages of a sustained expansion in American academic life. Its original objectives of encouraging research, publications on economic subjects, and perfect freedom in economic discussions have been consistently maintained, sometimes not without difficulty given the disagreements among its members, and the persistent tension between the desire for scientific objectivity and non-partisanship on the one hand and the urge to make an impact on public policy on the other. This problem was especially acute during the AEA’s early years, when economic questions were at the forefront of public discussion. A number of prominent American economists were then under attack, and some were dismissed from or forced out of their university posts.
because of their opinions. However, under its first President, F.A. Walker, an internationally known figure who served for the first seven years, the AEA gradually lost some of its initial reformist tone and concentrated increasingly on more strictly scholarly issues. Unlike the British Royal Economic Society, which has frequently had a non-professional president, the AEA has invariably been dominated by academic economists, although in recent decades prominent government professional economists have occasionally held the office – for example, Alice Rivlin, the first woman President, in 1985.

Early challenges and strategies

While the AEA's contributions to economic knowledge through its periodicals – the American Economic Review (from 1911), the Journal of Economic Literature (from 1963), and the Journal of Economic Perspectives (from 1987) – and in various other ways are undeniable, its services to the profession have perhaps been unnecessarily restricted because of the heterogeneity of its constituency, which has always included a substantial proportion of non-academic members, and its commitment to non-partisanship. Thus, for example, the AEA's reactions to the conflicts and tensions in American society have been distinctly more cautious than those of some other learned societies, both within and outside the social sciences, with respect to academic freedom issues. However, in both world wars the AEA played a notable and constructive part by organizing professional expertise for government service, and by conducting open debates and issuing publications on the economic problems of war and peace. The Association has also since 1945 occupied a leading role in the internationalization of the economic profession. It has always been an ‘open’ society, with no significant membership restrictions, partly because of the objections to control by a limited elite or coterie. Consequently it has only occasionally had any direct influence on doctrinal developments in the field. Nevertheless, there have been periodic protests about the organization's unrepresentativeness and oligarchic management, a state of affairs reflecting the size, diversity, and geographical dispersion of its membership, which now stands at a little over 22,000 (including subscribers).

Under its charter of incorporation, the AEA committed itself to ‘the encouragement of economic research, especially the historical study of the actual conditions of industrial life’ as well as to ‘the encouragement of perfect freedom of economic discussion’. In particular, ‘the Association as such [took] no partisan attitude, nor commit[ed] its members to any position on practical economic questions’. While the formal organization was thus made distinct from the individual activities and convictions of its members, nevertheless the stresses and strains attendant upon the struggles over its initial establishment were, in its earliest years, never far from the surface. These anxieties in turn framed the process by which major decisions were ultimately made concerning AEA membership criteria, annual meetings, publications, and operational procedures; what is more, they made the Association's leadership particularly eager to seize upon whatever opportunities and circumstances within the public arena might enhance the prestige and sway of their field.

From its earliest days, the AEA faced certain difficulties associated with maintaining the separation between professional image and individual values. One of these involved continuing struggles over academic freedom issues, involving economists at certain educational institutions across the nation. The most celebrated of these, although by no means the only ones, were the cases of Richard Ely at the University of Wisconsin, Edward Bemis at the University of Chicago, and Edward Ross at Stanford. All three scholars had been accused in the 1890s, in different contexts and in various ways, of poisoning the
minds of their students with ideas and beliefs inimical to corporate interests and private wealth. Two of them, Ely and Ross, managed to bring their careers back from the brink of the abyss; Bemis was not as fortunate and, in the end, was condemned to oblivion. Whether in success or failure, however, the defence of colleagues placed in jeopardy for their political convictions and beliefs relied more on the individual support of powerful champions within the profession rather than on the collective imprimatur of the AEA.

Fretting over the size of their professional society was, for the early AEA leadership, one thing; firmly articulating the Association's raison d'être was something else. Declarations of purpose, no matter how frequently or even stridently made, served only to a point. It was in actual practice, and in the decisions that animated it, that the professional community of the AEA truly explained and revealed itself. No amount of enforcement of particular boundaries of expertise could substitute for the rigorous refinement of colleagues that would result from the inculcation of specific ways of doing the community's business. Whether self-consciously or not, Association members and officials were, from the earliest years of the 20th century, concerned to frame the interests, activities, and procedures of their group in ways that would, more powerfully and vividly than any set of membership standards might, decisively create and preserve the profession that it was their goal to foster.

Creating a professional journal was also quite challenging. With no debate among AEA secretariat colleagues, Davis Dewey, the founding editor of the American Economic Review, rejected a suggestion from the Theodora B. Cunningham in 1916 that the journal include ‘a Women's Department of household economics’. Dewey's decision in this regard was thoroughly consistent with not one but two strategies of professionalization in early-20th-century America. On the one hand, it furthered the conscious effort of AEA founders to secure a distinctive place for economics as a scientifically grounded enterprise that avoided the lesser prestige of feminized occupations like ‘home economics’. On the other, it actually dovetailed with efforts dating from 1900 to constitute home economics as a separate discipline in its own right. Women professionals eager to find in the home economics field the same authority and influence that their male counterparts struggled for in an array of other disciplines had worked assiduously to establish collegiate degree programmes, journals, and a national association – the American Home Economics Association (AHEA). Their very success made the ‘defeminization’ of economics, at the hands of professional communities like the AEA, rather easy.

In fact, the question of publication standards threatened to destabilize the general consensus about the desirability of creating the American Economic Review in the first place. Argument over the implementation of standards not only raised questions of intellectual freedom and openness but also drew attention back to the general and often delicate matter of the journal's purpose. Not simply value as to method and technique, but significance and appropriateness as to subject figured prominently in the deliberations of the AEA Executive Council regarding the new journal and the Association's annual meetings. These discussions continued for years and ultimately decades to come. They were, in fact, often intertwined, touching upon related concerns about professional status and prestige, scientific conduct and codes, and the boundaries (topical and methodological) of economics itself. Stoutly defining what economics was involved being clear-minded about what it was not. Prominent AEA members, at the very moment they were wrestling with the nature of a new publication for the Association, vigorously protested to President Seligman that sociologists be kept at bay from the annual meeting and even the quarterly itself. ‘We have heard [the sociologists] so many times’, Henry Carter Adams wrote Seligman in the spring of 1902, ‘that we know absolutely what each one of the[m] will say.
upon any subject’. When gathered in an annual convention, Thomas Carver argued, ‘Economists would prefer to stick to the subject of Economists. [One] should especially doubt whether the members of [the] association would easily find a common ground of discussion with Miss [Jane] Addams or Mr. Felix Adler, admirable as these persons are and valuable as their work is. [One] should be afraid that there would be difficulty in trying to think in the same language.’ The same, Carver believed, was true for the *Review*. He doubted very much if ‘it would be wise to include much sociology, except such as has a distinctly economic coloring’. (All quotations of AEA minutes and correspondence are from the AEA Archives, Northwestern University Library, Box 8.)

Enforcing disciplinary boundaries, in both publication strategies and convention planning, also involved making precise decisions about the relationship between scholarly research and contemporary policy debate. With apparently little discussion or debate, the AEA Executive Committee formally chose in 1915 to exclude from the pages of the *American Economic Review* a ‘department of current economic events’. Even if contemporary policy concerns found their way into the submissions to the Association’s quarterly, the editors were determined ‘that current economic questions…be treated by scholarly men and not left to the sensational magazine writer’. In some respects this was a curious position for the leadership to assume given the additional concern that the work of economists be made visible and influential in the world of public affairs. The notion that the *Review* should be ‘a craftsman's tool’ had, after all, animated a great deal of the effort of the editorial office from the earliest days. Maintaining a dispassionate, scholarly tone while encouraging a wide and even diverse readership was neither a simple nor an obvious task. Editor Davis Dewey put it well to the distinguished English theorist Francis Edgeworth in January 1911 when he wrote, ‘We are trying to appeal to a somewhat varied membership who are interested in current questions. We do not, however, wish to be popular in a commonplace way, but shall endeavor to have our articles prepared by men of scholarly standards.’ The problem of attracting ‘a somewhat varied membership’ while adhering to ‘scholarly standards’ that would guard against being ‘popular in a commonplace way’ was truly vexing.

**The impact of national mobilizations and emergencies**

The coming of the Great War stimulated the professionalization of AEA ranks. In the spring of 1914, the AEA secretariat fashioned a special opportunity to bring the potential benefits of professional economics expertise to the attention of federal officials. Not surprisingly, it involved concerns with the ways in which the United States Department of Agriculture (DOA) calculated and reported statistical data on the performance of the nation's farms. Cornell University Professor Allyn Young contacted the secretary of agriculture, David F. Houston, to express the fear of the AEA leadership that ‘much of the statistical work … issu[ed] from government offices [wa]s of disgracefully poor quality’. He noted that the failures of the DOA in this regard were by no means unique. Clearly, ‘many of the activities of [federal] government bureaus furnish[ed] statistical by-products that [c]ould be of the greatest usefulness’. There was a clear need, in Young's opinion, that these data be ‘properly tabulated and published’. By the interwar period, additional federal legislation also gave the AEA a unique opportunity to define itself. For example, passed by the Sixty-seventh Congress in 1923, the Classification Act provided for the categorization and grading of technical and professional employees in the civilian branches of the federal government. Like their counterparts in many other fields, the leaders of the American Economic Association succeeded in linking this particular federal effort to their own continuing pursuit of
professional cultivation. An early 1924 resolution of the AEA Executive Committee began steps to secure the classification of the technical economists in the professional and scientific services of the federal government. The findings of a committee tasked to collate the results of this survey were reported to the Personnel Classification Board (of the US Civil Service Commission), the Committees on the Civil Service of the two houses of the Congress, and to the Executive Office of the President. In many respects the classification survey powerfully resonated with what had begun a decade earlier as part of the effort to support national mobilization for war. Yet here, in peacetime, it extended beyond the confines of an emergency canvass and became instead the basis of a continuing and ever more specific detailing of economics subspecialties. Indeed, for some older members of the profession the steps taken to stipulate as precisely as possible the expertise of individual practitioners could at times appear to narrow, and thereby adulterate, what the discipline as a whole had to offer. For most colleagues, however, that governmental needs melded so well with professionalizing strategies was cause for satisfaction rather than regret.

By the late 1930s, a segment of the AEA membership dissatisfied with the Association's perceived lack of attention to financial issues worked to create the American Finance Association (AFA). At the 1939 AEA Annual Meeting, the formal steps were taken to create the AFA. Although the Second World War slowed the evolution of the new organization, by 1942 the new journal *American Finance* appeared. It ultimately evolved into the well-known *Journal of Finance* just after war's end. Over 1,000 members populated the AFA ranks by the early 1950s.

In so far as a desire to distil professional opinion dated back to the early years of the Association's founding, it is not surprising to find that renewed interest along these lines emerged as economists turned their attention to planning for another war and its aftermath, and anticipating the role of economists in government during peacetime. During the Second World War the AEA leadership began deliberations ‘to [consider ways of] making the informed opinion of our membership more effective in matters of public policy’. Because the Association, by the terms of its charter, could take no partisan positions, the trio nevertheless believed that the ‘technical competence’ of members could be expressed on ‘matters of public importance’. This would require of course that ‘all academically respectable views on any posed controversial question be represented’ on committees formed to pronounce on policy matters.

While striving to adhere to its strictures against partisan endorsements, a task made all the more difficult in the highly charged politics of the immediate post-war era, the leadership of the American Economic Association turned its attention to engagement with seemingly more ‘objective’ needs of the national security state. In these efforts, their work was paralleled by that of colleagues already assigned to some of Washington's highest echelons. Over the course of the 1950s, for example, government economists made frequent visits to the military service academies, and to such institutions as the War College of the Air Force and the Industrial College of the Armed Forces (of the National Defense University, Fort McNair, Washington, DC) to discuss (and participate in conferences on) such matters as ‘mobilization of the national economy in the face of atomic attack’, ‘economic stabilization after attack’ and ‘domestic economies and their relation to national power’.

AEA officials also worked closely with colleagues on government duty to assist the national service academies in fully integrating an increasingly rigorous and operational discipline within their curricula. On behalf of the Armed Forces Institute, Secretary-Treasurer James Washington Bell coordinated the efforts of several scholars to oversee textbook selections in the field for cadets and midshipmen, thus
‘providing] the Armed Forces of the United States with educational materials which [we]re in accord with the best civilian practices’ in economics as a whole. By the mid-1950s it had also become common for AEA functionaries to help designate particular professionals for work in special seminars on international organization and security convened by the transnational diplomatic and military alliance known as the North Atlantic Treaty Organization (NATO). It was a short step from these activities to involvement with the recruitment of undergraduate and graduate economics students for work within the now greatly expanded domain of the national security apparatus – including the Central Intelligence Agency (CIA).

The post-war and Cold War eras

Post-war reconstruction also brought the Association into the business of aiding professionals in devastated areas overseas. In addition to contributing free books and copies of the *American Economic Review* along with cash donations to scholarly libraries in Europe and East Asia, the AEA became involved in the revision of curricula and the rehabilitation and vetting of foreign faculties. American economists going overseas, on either official or personal tours, were asked by government authorities to check up on colleagues who had perhaps been imprisoned, wounded or otherwise victimized by German national socialism or Japanese imperialism. Letters to Association members from economists abroad often contained information regarding colleagues who either had or had not collaborated with the enemy. Efforts were made to raise money for the relief of those who had opposed fascism and militarism. A note from a German colleague to former AEA President Paul Douglas was forwarded to the Association offices because in it there was ‘a very valuable list of economists who either opposed Hitler or kept their honor clean’. American economists were now in a position not only to secure greater influence and prestige at home but also to reconstitute virtually from scratch the European and Asian branches of the guild.

The reconstruction of foreign scholarly libraries prompted the American Library Association (ALA) to ask professional societies to provide book lists in their fields to guide rebuilding efforts. AEA officials canvassed the membership for suggestions and ultimately provided such lists, with regard to economics, to the ALA. With such recommended titles as *Stalin, A Critical Survey of Bolshevism* and *Marxism: An Autopsy*, the ideological content of the library aid effort seems clear. This is of course hardly surprising. The point here is not that American economists would generally be loath to suggest books that extolled Marxism or Stalin – indeed, AEA members and the AEA leadership utterly failed to defend beleaguered colleagues victimized by the anti-communist hysteria stoked by McCarthyism – but that Allied victory had the added impact of giving them a great deal of influence on the future course of foreign scholarship in the field. If post-war reconstruction served to recast Europe and Asia in America's image, as some scholars have suggested, the representations of that process in the academic and intellectual world should not be overlooked.

Participation of the American economics profession in the emergent Pax Americana of the 1950s also expressed itself in a continuation and evolution of links between economists and the military–industrial establishment that had necessarily arisen in the 1940s. Economists of course participated both in the private sector and at the government level in the mobilization and allocation of resources for war. In addition, the profession became increasingly involved in establishing curricula at the nation's armed service academies on the economics of national security and defence. Defence-related research and
support of basic economics investigations by armed forces agencies became more and more common. Moreover, the emergence of wholly new aspects of the discipline – such as ‘linear programming’ and ‘input–output analysis’ – was inherent in the association of professional economics with the national security state. The AEA even helped the U.S. Information Agency in securing prominent and competent personnel to do radio broadcasts on economic subjects for the Voice of America.

Curriculum revision and reform was a project that lasted well into the 1950s. Two months before the opening of a second front in western Europe the Association Executive Committee asked that the new Committee on Undergraduate Teaching and the Training of Economists concern itself with ‘the long-run postwar period’. Ultimately, of particular interest to this committee with regard to the matter of undergraduate instruction were ‘problems of indoctrination [of students] as to social consciousness and professional responsibility’. Four months after the surrender of Japan, 160 college and university economics departments around the country received questionnaires from the AEA soliciting information on undergraduate instruction. By the autumn of 1950 the AEA secretariat initiated plans for a conference on social science teaching at the pre-collegiate and collegiate levels. At the same time, the Committee on Graduate Training in Economics began its work, seeking to formalize in detail the professional requirements for the Ph.D. degree. To this effort, the Rockefeller Foundation donated $16,000. When the committee transmitted its findings to university deans and presidents, return correspondence was grateful and enthusiastic. War-related agendas thus carried over into long-standing peacetime activities. Interestingly enough, and not surprisingly, concerns with the content and delivery of economics curricula emerged directly from Second World War experience. Wartime efforts on behalf of the National Roster of Scientific and Specialized Personnel (NRSSP) had made the leadership of the American Economic Association both particularly sensitive and responsive to requests for information about the discipline and its specialists. Moving from a focus on calculating the profession's numbers and activities, as the NRSSP had requested, to a self-conscious assessment of teaching methods, course content, and educational performance standards was altogether understandable and clear-cut. AEA initiatives in this regard were only further stimulated by the desire of the Veterans Administration and related agencies to facilitate the re-entry of armed forces personnel to civilian life after the Second World War and the Korean conflict.

Defining what an economist was, and what he or she did for a living, was one thing; stipulating how an economist was to be trained, not to mention evaluating his or her professional skills, was something else. In a series of studies, the first of which was launched in 1949, with follow-ups taking place throughout the 1950s, AEA task forces conducted wide-ranging surveys of undergraduate and graduate curricula throughout the country. Of particular importance to these committees were the ‘opinions of leaders in graduate training’ in the field at the nation's foremost research institutions. Recognizing that ‘[t]he Association ha[d] a definite professional responsibility in this [regard]’, the Ad Hoc Committee on Graduate Training in Economics made its first report to the AEA Executive Committee late in 1950. Determined to guide universities in the establishment and maintenance of ‘good graduate program[s] in economics at various levels’, the committee particularly encouraged institutions to improve standards for the selection of incoming students, articulate precise objectives for advanced study in the field, and vet subject matter and course content with a view towards the rigorous training of new colleagues. Specifically, the committee believed that the ‘important tools’ in all graduate economics instruction were ‘mathematics, accounting, statistics, history, logic, scientific method, and foreign language’. Not least of the historical forces that shaped the continuing evolution of the American economics
profession in the latter half of the 20th century was the unique prosperity the nation enjoyed throughout the 1950s and 1960s. If the application of a new learning to the management of a ‘mixed economy’ provided an exceptional opportunity for social scientific expertise to demonstrate its rigour and effectiveness, the context within which that display took place set the terms of both its practice and its success. Having proved its mettle in the extraordinary years of world wars, and having continued to do so in the early stages of what would be an even longer cold war, modern economic theory was now deployed in an altogether novel exercise: the pursuit and maintenance of full employment growth in peacetime. That, owing to history itself, the national economy was singularly well positioned for sustained expansion in the post-war period made that task all the more tractable.

Unlike any other industrialized nation in the world at the time, the United States met the 1950s with an economy not only physically intact but also organizationally and technologically robust. The demographic echoes of war set the stage for an acceleration in the rate of population growth, while the labour market effects of demobilization surprisingly sparked a rise in wages and incomes. Rapid and profitable conversion to domestic production was further stimulated by foreign demand – most vividly and poignantly emanating from those regions most devastated by the war itself – for the products of American industry and agriculture. As for international finance, the nation stood as creditor virtually to the entire world, and the dollar, both by default and by a multilateral agreement first reached by the Allied nations at Bretton Woods, had become a kind of numeraire to a newly emergent system of global commerce. With no small justification, the 1950s and 1960s came to be regarded as a golden age of American capitalism.

The era of the ‘New Economics’ and beyond

Macroeconomic management, demanding under any circumstances, was made substantially easier for a post-war generation that found itself the beneficiaries of historical circumstance. Farm from solving the cruel puzzle of idle capacity and widespread unemployment that had characterized the Great Depression, and unlike the challenge to rationalize allocation and maximize production in the emergency of war, the task that lay before American economists by the mid-1950s was both more straightforward and less difficult. More straightforward because, thanks to both the ‘Keynesian revolution’ in economic thought and the policy experience derived from mobilization and war, the relationship between individual market behaviour and aggregate outcomes was finally subject to systematic understanding. Less difficult because, given the sturdy rebound of the economy in the wake of the Second World War, there existed both the confidence (most especially exemplified by the moderate rates of return in the markets for Treasury bills and other government obligations) and the means (most vividly represented by rising income tax receipts) to realize fiscal spending targets with a minimum of redistributive implications. So optimistic were politicians and the vast majority of economists concerning the effectiveness of stabilization policy techniques that it became fashionable by the early 1960s to speak of the ‘end of the business cycle’ and of the ability of policymakers to ‘fine-tune’ macroeconomic performance. In the Economic Report of the President, 1965, President Lyndon Johnson made it clear that he ‘did not believe recessions were inevitable’ (Council of Economic Advisers, 1965, p. 10). Similarly, in what was arguably the most influential economics textbook ever published, Paul Samuelson (1972, p. 250) wrote that his colleagues ‘know how to use monetary and fiscal policy to keep any recessions that break out from snowballing into lasting chronic slumps’. He went on to claim that the business cycle was
thus a thing of the past. Expert knowledge buttressed by a healthy and resilient economy could now make the periodic deprivation and hardship once believed to be the inevitable consequence of the cycle truly a thing of the past.

Cultivating a politics of aggregate productivity and a discourse about sustained prosperity was not solely the result of professional self-assurance and self-promotion, nor was it simply the manifestation of a particular politician's (or a particular party's) strategy to procure votes. The focus on growth and accumulation so characteristic of the new economics of the post-war era represented as well a transformation in the nation's political culture that had been in the making for decades. For 19th-century convictions regarding the probity of thrift and self-improvement, mid-20th-century Americans had swapped a fascination with, and a virtual anxiety about, the individuation and comfort associated with consumption. Production was no longer an end in itself, nor could it alone provide meaning and dignity to one's life. Rather, it was the goods and services of the material world that afforded freedom and amenities, setting one's self off from others and liberating all from both the overt and the hidden injuries of class, ethnicity, and gender. What came to be known as the ‘economic growthmanship’ practised by a new social scientific elite was, on the one side, a particular aspect of a stage in the evolution of a professional community; on the other, it distilled, within a set of seemingly unassailable aspirations and beliefs, a society's unself-conscious embrace of an altogether new set of cultural ideals.

Within an economics of abundance and stability rested the ingredients of a prosperous commonwealth devoid of the class antagonisms and struggles over normative values that were a threat to both the legitimacy of social scientific policymaking and social tranquility and political cohesion. If an ‘emphasis on an ever-growing pie, rather than on slicing up a given pie in a new way, [wa]s well designed … to attract widespread support’ for particular policies (Tobin, 1966, p. 42), it was also true that the depiction of the economy as a kind of positive-sum game from which all could benefit independent of their relative shares in particular outcomes was an essential part of the political-economic ideology of post-war America from the time of Truman's Fair Deal through that of Lyndon Johnson's Great Society, up to and including the early stages of Richard Nixon's New Federalism. Their specific analytical differences aside, virtually all mainstream American economists both embraced and relied upon this ‘depoliticization’ of the marketplace in their determination to separate positive economic ‘science’ from normative assertions. So long as the profession could retain this image of its work as a calculation of optimal means to a given end rather than the comparison of different and possibly incompatible goals, its claims to the authority and influence devoutly sought since the late 1890s were secure. As soon as that archetype was jettisoned or challenged, modern economics would find itself in a world, not of rigour and logic, but rather of ideological belief and political power.

Indeed, in December 1968 the Union for Radical Political Economics (URPE) held its first national conference in Philadelphia. This was done in opposition to the AEA's Annual Meeting in Chicago, which URPE interpreted as an endorsement of that city's violent response to anti-war demonstrations that summer. The AEA Executive Committee, chaired by then AEA President Kenneth Boulding, concluded that moving the Meeting would have violated the Association's policy of political neutrality. A year later, an activist disrupted the AEA Annual Meeting by reading a statement, at a plenary session, denouncing the Association for ‘perpetuating professionalism, elitism, and petty irrelevance’. This led to a mass walk of ‘radical economists’. In partial response to these insurgencies from within the ranks, the AEA established a Committee on the Status of Minority Groups in the Economics Profession (CSMGEP) in 1968 – and, by 1971, a Committee on the Status of Women in the Economics Profession.
CSWEP) and a working group on the status of minorities. The social change and turmoil of American society in the Vietnam War era had come home to the AEA itself. In the mid-1980s, concerns regarding the training of new generations of economists came to the fore in AEA deliberations. At a National Science Foundation symposium held late in 1986, many participants argued that graduate curricula in economics had become exceedingly esoteric and abstract, of little use in the resolution of contemporary economic problems. A Commission on Graduate Education in Economics (COGEE) was subsequently charged to study the problem. It issued a report in 1991 that identified a number of problems in the profession such as a lack of focus on the inculcation of applied research skills, untoward emphasis on mathematics and axiomatic reasoning instead of analysing institutions and historical change, inadequate attention to the training with respect to communication and writing skills, an absence of creativity, and excessive emphasis on conformity and homogeneity in professional discourse. The COGEE report was so controversial that it was never accepted as an official AEA document.

Over a century ago American scholars eager to understand the economic world in which they lived embraced a project of both theoretical and social import. In doing so, they yoked the insights of an intellectual revolution in the ways social scientists understood human behaviour in commercial settings to a specific agenda of professional advancement. A late-19th-century transformation in economic thought afforded these investigators a powerful and versatile set of tools with which to situate human rationality at the centre of a remarkable and immensely influential human institution – the marketplace. A ‘science’ of individual behaviour and social organization was thus established, the implications of which played no small part in the creation of a respected and ultimately quite accomplished community of professional experts – as exemplified by the AEA.

But an authoritative community does not, precisely because it cannot, subsist on its own. American economists were most eager to place their skills at the service of the state. Here history proved both a blessing and a curse, for the profession's great achievements of the 20th century, especially but not solely during years of global conflict and war, were also paralleled by failures and betrayals emanating from the same source. Indeed, it would be these negative moments in the century-long progress of their self-realization that would drive economists and their discipline farther and farther from engagement with the affairs of state in favour of an increasingly introverted and surprisingly opaque discourse. At the same time, eager like most professionals to retain an influence and visibility in public affairs that would cultivate a continued appreciation of their virtues and skills, later generations of economists would make themselves – whether consciously or not – useful servants of those, in both the political and the commercial worlds, who had an altogether different view of public purpose and of the appropriate role of government.

American exceptionalism

Louise C. Keely
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

‘American exceptionalism’ refers to significant differences between the United States and Western Europe, first identified by European commentators in the 19th century, including the circumstances surrounding the founding and settlement of the United States, as well as a concept of nationhood based on immigration rather than a shared history. Economists have contributed in important ways to the documentation and evaluation of exceptionalism's economic effects. One important example of this research is on contemporary differences in social policy between the United States and Western Europe.

Keywords

American exceptionalism; crime; de Tocqueville, A.; equality of opportunity; fertility; higher education; individualism; inequality; international migration; productivity; racism; redistribution; religion; slavery; socialism; trade unions; voluntarism; Western Europe; workfare

Article

The term ‘American exceptionalism’, which has been current among scholars since Alexis de Tocqueville coined it, captures the idea that America is different in important ways from Western European countries. This exceptionalism is, at first glance, surprising given that the United States was initially settled and governed by persons from Europe and that in many ways the two regions appear relatively similar. The term suggests a set of reasons for the differences in institutions and individual choices in the realms of politics, economics, and social interactions. (For some insightful and broad discussions of American exceptionalism, see Lipset, 1996; Shafer, 1999.)

Comparing America with Western Europe is somewhat arbitrary. The attention paid to American exceptionalism does not suggest that other countries are not also exceptional. Indeed, other examples of exceptionalism have been studied by social scientists.

Interest in the United States is due in part to its economic and military power. Simply put, the US
government and economy exert a significant influence on all countries, including those of Western Europe. But there is an historical reason for the comparison with Western Europe. Europeans settled and governed the region that became the United States of America. It was Europeans who in the 19th century visited and wrote about the United States, comparing it with their native lands. De Toqueville is the best known, but he is only one of several Europeans who were interested in what they saw as a profound contrast between the United States and Western Europe.

It is useful to define American exceptionalism in terms of origins rather than consequences. Political, economic and cultural outcomes, whether observed today or in the 19th century, are endogenous. However, there may be circumstances distinguishing the United States from Western Europe that can be treated as fundamental, or exogenous, to the United States as a sovereign state. Those circumstances may have led to the differences in outcomes observed in the 19th century and today.

Before the American Revolution that began in 1776, the British governed the colonies that came to constitute the original United States. The constitution of the United States can be understood as a product of both the trauma of the revolution and the fact that 13 geographical areas, with distinct identities, were creating a single federal government. Moreover, the framers of the constitution were themselves diverse not only in place of origin but also in social and economic background (Mee, 1987). The constitution contains features reflecting a certain distrust of centralized public authority. The increase in popular political participation beyond that which existed under colonial administration, the checks and balances across the three branches of government, and the restrictions on the powers of the federal government are prominent indications of this concern.

Europeans, many with a specific religious agenda, initially settled the area that became the United States. They aimed to create a society directed by divine providence. These settlers faced unusual circumstances in modern history, having the opportunity not only to establish a government largely from scratch but also to settle a large geographic area that was either uninhabited or inhabited by people they could displace, albeit sometimes with difficulty.

The historical circumstance of the United States as a state whose citizens’ families came from other countries within recent memory led, in part, to a notion of nationality that was flexible from the beginning. What it is to be American has never, with the important exception of slaves who were not treated as full citizens, been dependent on ethnic background or common historical circumstances. This is not to deny that racism or ethnic prejudice have existed in the United States, but rather to say that what it is to be American has never been predicated on a particular origin or history.

This notion of nationality lent itself to the United States’ openness to immigrants from many countries, until recently mostly Europeans. Some immigrants came to the United States to escape political or religious persecution, such as the Jews during the pogroms of the late 19th century and during and after the fascist regimes that held sway in Europe in the first half of the 20th century. However, many more came in pursuit of economic opportunity. Some immigrants, such as the Irish in the mid-19th century, faced terrible economic circumstances in their home countries. Others chose to emigrate under less dire constraints.

Across these diverse circumstances of immigration, it is generally the case that immigrants to the United States were self-selected into this group. The important exception to this self-selection is the immigrants from Africa and the Caribbean who were brought as slaves to the United States. While self-selecting immigrants left their countries of origin for a variety of reasons, they would all have believed that in the United States their lives would be better in economic, political or religious terms. By
seizing the opportunity to become American, they could lead better lives (loosely defined). This possibility is attributable to exogenous circumstances: the physical expansiveness of the United States and the related expandable notion of American nationality. The populations who chose to move to the United States also did so in large part because they believed that self-determination was possible in the United States.

Such self-determination is part of the ideology on which (rather than on a common history) the United States was founded, and subscription to which makes one American. That ideology includes a set of values and institutions that are immediately familiar as distinctly American. Americans are viewed (and are thought to view themselves) as relatively distrustful of public authority and as embracing self-reliance. Broadly speaking, they subscribe to the ideals of equal socio-economic opportunity (as distinct from equality in outcomes), a classless society, and an inclusive democratic process. American institutions are relatively fragmented and public services are generally viewed to be less comprehensive than in countries with similar per capita incomes. Americans are more religious than Europeans. The concept of American nationality is relatively inclusive.

Why should American exceptionalism matter to economists? What role does economics have to play in understanding the consequences of American exceptionalism?

At least three distinct avenues of enquiry are of interest to economists. The first is positive: to document outcomes that may be attributable to American exceptionalism. The second is evaluative: to examine whether the exceptional circumstances under which the United States and its citizenry were constituted have led to differences between both the institutions and the values and beliefs (or culture) of Americans and those of Western Europeans. (A substantial political science literature debates the relative importance of institutional differences and cultural differences in defining American exceptionalism. The present author finds that discussion unclear, and thinks that it is more useful to view both types of differences as outcomes of exceptionalism rather than manifestations of it. That is, both types of differences may exist and are not mutually exclusive.) The third avenue of enquiry is normative: given evidence of exceptionalism, the task is to examine the context in which economic policies in the United States are to be designed and evaluated relative to Western Europe.

Existing research focuses on American-European differences in political, cultural, and economic outcomes, and asks questions including those in the following non-exhaustive list:

- Why was there not a socialist movement in the United States? (Jacoby, 1991; Lipset and Marks, 2000; Voss, 1993)
- Why have labour unions been weaker in the United States than in Western Europe? (Currie and Ferrie, 1995; Freeman, 1994; Jacoby, 1991; Voss, 1993)
- Why do Americans publicly redistribute income less than Europeans do? (Alesina and Glaeser, 2004; Benabou and Tirole, 2004; Shafer, 1991)
- Why do Americans perceive a higher probability of socio-economic mobility within and across generations than those in Western Europe? (Keely, 2005a)
- Why is the US higher education system larger than those in European countries? (Shafer, 1991)
- Why is there more violent crime in the United States? (Shafer, 1991)
- Why is productivity in the United States higher than in Western Europe? (Abramoviz and David, 1994; Gordon, 2002; Romano, 1993)
American exceptionalism: The New Palgrave Dictionary of Economics

- Why do Americans participate in volunteer activity more than Western Europeans? (Lipset in Shafer, 1991; Lipset, 1996)
- Why did the institution of slavery persist in the United States long after it disappeared from Western Europe? (Shafer, 1991)
- Why are Americans more religiously observant than Western Europeans? (Shafer, 1991)
- Why is fertility higher in the United States than in Western Europe? (Keely, 2004; 2005b)
- Why has the United States been able to assimilate immigrants at levels well beyond those of Western Europe? (Glazer, 1999)

Proposed answers to these questions have one common element: American exceptionalism. These issues are all directly or indirectly related to economic policy, and pose questions that economists’ tools can help to answer. Consider for example the question: Why do Americans publicly redistribute income less than Europeans do? Economists have recently tried to answer this question.

A first step is to document the differences in redistribution. OECD data indicate that, while public spending on social services amounted on average to 24 per cent of GDP in Western European countries, in the United States it amounted to 15 per cent. In the United States private social spending as a share of the total in 1995 is reported by the OECD to be 41 per cent, while for European Union countries it varied from 1.5 per cent (Spain) to 16.9 per cent (the United Kingdom) (OECD, 2005).

Second, how can this difference be attributed to American exceptionalism rather than to some other source? Identifying the effects of exceptionalism as such is extremely difficult. Competing hypotheses about the same outcome can be observationally equivalent. However, the models that lead to the same predicted outcome may also contain secondary predictions that do vary across models. That variation may be exploited to compare hypotheses. One suggested approach has been predicated on the higher level of ethnic heterogeneity in the United States than in Western Europe. The institution of slavery, which led to the existence of a minority of citizens of African origin, and the flow of ethnically varied immigrants into the United States have been attributed to American exceptionalism.

Heterogeneity itself doesn't explain why there is less income redistribution. Some authors have proposed that heterogeneity may matter in terms of its interaction with preferences. (This hypothesis has been proposed by Alesina, Baqir and Easterly, 1999, and Luttmer, 2001. See Keely and Tan, 2005, for related discussion.) The assumption regarding preferences is that agents experience disutility when they observe people who differ from them in some salient dimension such as race to be more likely recipients of public income redistribution. Such preferences capture a notion of racism.

Racism is not a feature or direct consequence of American exceptionalism as I have defined it. Nor are norms regarding interracial interactions exogenous or unchanging variables. Interactions between, and socio-economic outcomes across, racial and ethnic groups in the United States have changed enormously (though perhaps still not enough) over the past century. Therefore, this preference-based hypothesis regarding different levels of income redistribution in the United States and Europe is only partially based on an observation directly attributable to American exceptionalism.

An alternative hypothesis that relies more squarely on exceptionalism, rather than on other cultural or political assumptions, is as follows. People face uncertainty about future income and whether they will be net beneficiaries of income redistribution policies. In order to form the expectations that are necessary to determine preferred income redistribution policy, people may use information about others
who are similar to them in ways that are relevant to income determination. In a society where racial or ethnic characteristics are correlated with income, race and ethnicity can be a factor determining similarity. If the size of the minority group (in this case, blacks) is sufficiently large and/or the difference in the groups’ income distributions is sufficiently large (in some well-defined way), then it can be the case that whites, who have higher average income, are less likely to be in favour of income redistribution than are blacks.

This hypothesis relies on three factors that have been traced directly to American exceptionalism: (a) the ethnic heterogeneity of agents; (b) income inequality linked to the legacy of the institution of slavery (given the presence of relatively large amounts of arable land); and (c) the focus on individualism rather than communal obligation.

Both hypotheses lead to a prediction that the United States has lower levels of redistribution than Western European countries. How can competing hypotheses be evaluated? As suggested above, one strategy is to look for secondary and testable predictions that differ across hypotheses. While there is a history in the United States of racism connected to whites and blacks, there is also a history of racism against other ethnic groups such as Asians and Hispanics. Certainly there is a widely recognized ethnic distinction between those groups on the one hand and people of European descent on the other. If differences in income redistribution preferences are due to racism, then it should be the case that exposure to ethnic heterogeneity of these types should also lead to stronger opposition to redistribution overall.

In contrast, if differences in redistribution preferences stem from differences in income distributions conditional on ethnic group, then an effect of heterogeneity might not be uniform. For instance, if the conditional distribution of whites and Asians is not statistically significantly different, then income redistribution preferences are predicted to be lower in areas with more heterogeneity in the white-Asian dimension only under the first ‘racism’ hypothesis.

The third way in which American exceptionalism matters to economists is its impact on political economy parameters. Every public authority is policy constrained, for instance by cultural values and economic circumstances. America was founded on an ideology that, it has been argued, persists. While its details and interpretation may change, its essence is constant. Any normative statement regarding the political economy of the United States should, in the face of strong evidence of American exceptionalism, take account of those constraints. More specifically, one of the ways in which American exceptionalism manifests itself and has been summarized is the claim that individualism and anti-statism lead to a notion of egalitarianism based on opportunity rather than outcomes.

In this light, it is completely unsurprising that the United States has a smaller welfare state than those of Western Europe. Moreover, the types of welfare reform that have been instituted since 1995 and the rhetoric used to promote them are also consistent with American exceptionalism. Welfare is now sometimes called workfare; there is a push to move welfare towards a policy that provides opportunity through job training and work rather than providing a guaranteed outcome through direct transfers. Private involvement in a publicly administered welfare programme also seems more politically feasible than a purely public model as in Western Europe.

American exceptionalism is an old idea. In his now famous 1630 ‘City on a Hill’ speech, John Winthrop spoke thus of the newly settled land:

[W]ee shall finde that the God of Israell is among us, when tenn of us shall be able to
resist a thousand of our enemies, when hee shall make us a prayse and glory, that men
shall say of succeeding plantacions: the lord make it like that of New England: for wee
must Consider that wee shall be as a City upon a Hill, the eies of all people are uppon
us….

Economists have a perspective and set of skills to contribute towards understanding the extent to which
American exceptionalism exists and its implications for Americans and people in other countries.

Amoroso, Luigi (1886–1965)

Giancarlo Gandolfo
Edited by John Eatwell, Murray Milgate and Peter Newman

Keywords
Amoroso, Luigi; consumer equilibrium; Pareto efficiency

Article
A mathematician by training (at the Normale, Pisa), Amoroso was assistant professor of mathematics in Rome, then professor of financial mathematics in Bari, but soon turned to economics, which he taught from 1921 in Naples and then Rome. He was a fellow of the Econometric Society.
Leaving aside his contributions to pure mathematics (e.g. 1910), financial mathematics (e.g. 1921a), statistics (e.g. 1916), demography (e.g. 1929), four books (1921b, 1938, 1942, 1949) well summarize his contributions to economics, also contained in over 100 articles.
Inspired by Pareto, his mathematical background led him to develop the analogy between pure economics and classical mechanics: the principle of minimum (use of scarce) means is the equivalent of the principle of least action. He also saw analogies between Heisenberg's uncertainty principle and economic phenomena, but did not develop this idea. His existence and uniqueness proof (1928) of a meaningful solution to the system of equations defining consumers' equilibrium is the first modern treatment of existence and uniqueness problems in economics.
Amoroso stressed the need to analyse all optimum conditions in a dynamic context: for example, the consumer maximizes a function under the balance constraint expressed as a differential equation; the problem is solved by applying the calculus of variations. He thus derived the extension of Pareto's static optimum conditions to a dynamic context. By considering the market determination of prices and introducing relationships between inventories and prices, he obtained systems of integro-differential equations capable of causing cycles around a trend, thus giving an explanation for crises and secular movements.

amortization

Charles R. Hulten
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

amortization; balloon loan; depreciation; investment; asset value

Article

‘Amortization’ is an accounting term meaning the allocation of a cost to several time periods. The term is derived from the Latin word for ‘death’ and literally means to ‘kill off’ the liability. Debts which are paid off gradually are said to be amortized.
The term is also applied to the depreciation costs of the cost of certain assets which are used up in producing income. Amortization in this second sense is illustrated by the following example (Table 1).
A firm spends $10,000 to invent and patent a new product which is expected to yield revenue (net of operating expenses) of $5,000 in the first year of production, $2,000 in each of the next three years, and $1,500 in the fifth year (see column (3) of Table 1). The product is assumed to become obsolete at the end of five years and to generate no additional revenue. The patent thus becomes valueless at that time.

Amortization of hypothetical asset

*Present value of remaining net revenue calculated using discount rate of 9.992%.
The present value of the net revenue stream associated with the invention is initially $10,000 at an
approximate ten per cent rate of discount. However, the present value of the remaining net revenue falls to $6,000 at the end of the first year, to $4,599 at the end of the second year, to $3,058 and $1,364 at the end of the third and fourth years, and to zero at the end of the product’s useful life (see column (4)). This implies that the original $10,000 investment has been eroded by $4,000 at the end of the first year, $1,401 in the second year, and so on (see column (5)). In considering how much profit is earned in the first year, the loss in the value of the investment must be subtracted from revenue in order to keep the original value of the investment intact. Thus, profit in the first year is $1,000, or ten per cent of the original investment. Inspection of columns (4) and (6) reveals that the ratio of profit to remaining present value in the previous year is always ten per cent.

If, on the other hand, the reduction in value is not recognized as a cost, one would erroneously conclude that the investment yielded $12,500 over the life of the asset (the sum of column (3)) rather than $2,500 (the sum of column (6)). However, the value of the investment would have fallen from $10,000 to zero. To avoid a misstatement of profit for tax and financial accounting purposes, investors are allowed to amortize the cost of the asset over its useful life. A pattern of amortization that matches the actual yearly loss in asset value is usually termed ‘economic depreciation’, although this typically (but not always) applies to tangible capital like plant and equipment, while ‘amortization’ is often used in the context of intangible assets. The actual loss in value is often hard to measure and, in practice, reasonable assumptions about useful asset life and about the pattern of value loss are used (for example, the straight-line and declining-balance patterns).

The graduation write-off of a debt is another context in which the term ‘amortization’ is frequently used. The level-payment home mortgage is, for example, a common type of amortized loan. In the level-payment mortgage, the sum of the interest and principal payments is constant. During the early life of the loan, the bulk of this constant (or ‘level’) payment is for interest on the outstanding balance of the loan. The proportion of the level payment allocated to the repayment of principal gradually increases as time goes by, since interest is paid on the outstanding balance of the loan. In the fully amortized loan, the sum of the period-by-period repayments of principal over the life of the loan is equal to the original value of the debt.

This type of arrangement may be contrasted with the case of the ‘balloon’ loan, in which the entire principal is repaid at the termination date of the loan. Loans may be a mixture of the two types: amortization of part of the principal with a balloon payment equal to the unamortized balance.

analogy and metaphor

Rom Harré
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
analogy; metaphor; models; simile

Article

We say that something A is analogous to something B if, in some relevant respect, A is similar to but not identical with B. This is the basic relation upon which the use of analogy in various kinds of reasoning depends. We speak of reasoning by analogy when on the basis of some similarity which we discern between two things or processes or properties, or what you will, we infer some other similarity. Reasoning by analogy is a special case of inductive reasoning since we must be wary of the possibility that the further similarities which are presupposed in our inference may not actually obtain. Like all inductive inference reasoning by analogy is stepping from the known to the unknown. Clearly, then, analogical reasoning is not demonstrative or deductive.

A more refined analysis of the structure of the analogy can be made by distinguishing between those respects in which the analogues are similar, called the positive analogy, those respects in which they are different, called the negative analogy, and those respects in which we are unsure whether the property in question marks a similarity or a difference – the neutral analogy (Hesse, 1963). Once we have introduced the idea of neutral analogy the relation between the analogues is no longer symmetrical. If we think of analogy simply in terms of similarities and differences then if A is similar to B, B is similar to A, and if A is dissimilar to B, B is dissimilar to A. It does not matter which of A and B we say is analogous to which. But once we introduce the idea of neutral analogy we are obliged to decide which of the items under comparison is the one from which our reasoning will take a start and usually this decision is dependent on which of A or B we are confident we know. For example, if we argue that an illness is analogous to the invasion of a country by a hostile army, as van Helmont proposed in the 17th century, it seems reasonable to take the invasion by the hostile army as the term about which we can in principle know a great deal and the cause of illness as the term about whose properties we are less certain. In reasoning by analogy, then, about the cause of disease, the idea of an invasion is the given term and the illness is the unknown. We can then take the known properties of invasions and armies and
analogy and metaphor: The New Palgrave Dictionary of Economics

set out on an experimental programme to decide how many properties similar to them are to be found in the causes of disease. Thus: ‘Soldiers are organisms’, ‘Are the causes of disease micro-organisms?’ The logic of analogy then consists in picking out sets of properties and making comparisons between the members of the one set and of the other.

In judging the force of an analogy we must have some way of deciding which properties are important and which are not. If two things are similar only in unimportant or inessential ways and differ in other respects, then we generally take the analogy between them to be weak. Unlike deductive reasoning, analogy is, therefore, highly sensitive to context and to the interests of whoever is making use of it. It can hardly be said that there is anything intrinsic about a property which makes it important. Rather its importance depends upon the context and interests of the user. Furthermore, we need also to assume that we can make some sort of quantitative assessment of the degrees of similarities and differences between the analogues and this may be quite difficult to do in any principled way.

I have described the relation of analogy in terms of concrete relations of similarity and difference between the properties of analogous things. However, there are important linguistic phenomena which are in some ways like an analogy. The most obvious is simile. When we use that figure of speech we explicitly invite a comparison between the referents of the terms between which the simile is drawn by reference to likenesses. We tacitly assume that we draw a simile only where there are also differences. There are plenty of literary examples to illustrate this relationship.

The analogy relation seems to have another realization in language in metaphor. In a metaphorical use of a term an expression is employed in a novel context. Words which are customarily used for discussing one kind of subject matter, are used to describe some other. Some have said that in metaphor the sense of a word is displaced. In order for a metaphor to have any bite it must reflect some similarity. The metaphor ‘life's journey’ would hardly have had the currency that it enjoys in improving discourses, such as the speeches which accompany school prize-givings, had there been no way in which life could be seen as a journey. But unlike simile, metaphorical uses do not leave words unaffected. It has been pointed out by many students of metaphor that when a concept is displaced into a new domain it not only serves to highlight some hitherto unnoticed similarity between its old and new referents, but it changes its significance through coming to be used in a new domain. So the term ‘current’ was first used in the description of electricity, to highlight similarities between electricity and more easily observable fluids. The two centuries of use of this term in the electrical domain have certainly led to a change in its meaning (Martin and Harré, 1982).

Analogy and models

The recent trend in philosophy of science to look more closely at actual examples of scientific reasoning has disclosed the quite central role that analogical reasoning plays in both the physical sciences and the social sciences. A special terminology has grown up in the sciences by which the term ‘model’ is appropriated for concrete analogues (Bunge, 1973).

Scientific models are of two main kinds. There are heuristic or homoeomorph models and explanatory or paramorphic models. Each kind has a specific use.

Many phenomena are too complicated for ready examination. Salient features can be brought out by abstracting a simpler form from the original complexity and idealizing its properties. A homoeomorphic or heuristic model is a convenient representation of its subject. It may be a concrete thing, such as the
scale models used in engineering. But it may be an abstract conceptual representation embodied in something like the 'rational actor' assumption in economics. Heuristic models are conservative. In a sense they merely represent what we already know but in some useful or convenient form. Explanatory models (paramorphic analogues) are used creatively. They enable scientists to conceive of new kinds of beings and so far unobserved processes. Their main use is to complete theories by standing in for unobserved and so currently unknown causal processes. The kinetic theory depends on the idea of a swarm of molecules which are a model or analogue of the unknown constitution of real gases. The hypothetical behaviour of the molecular analogue must be like (analogous to) the behaviour of the real gas. Such models are of great interest to methodologists since they not only form the core of most scientific theories, but are also the vehicles for much creative scientific thinking. They are not devised at random. Their construction is always controlled by some implicit metaphysical assumptions (in the gas model case Newtonian atomism) which ensure their plausibility to the scientific community. This means that they are balanced between two analogy relations. They must behave analogously to the real thing they are a model for; and they are constructed by analogy with the real thing they are modelled on. For instance, the popular rule-following models in social psychology should replicate the behaviour of the unknown cognitive systems they are models for while they must lie within the constraints imposed by the real cases of rule-following, say in ceremonial action, which they are modelled on. Both analogy relations are usually open, that is, though they exhibit positive and negative aspects, similarities and differences, there is usually a degree of unexplored neutral analogy. Theories develop by the conceptual exploration and, in favourable cases, the empirical testing of the neutral analogy.

Explanatory and heuristic models can be neatly distinguished by reference to their constitutive analogies. For a heuristic model source and subject are identical. A model plane is a model of a plane. But for an explanatory model source and subject are distinct. The idea of an implicit rule is modelled on that of an explicit rule, but the former is an analogue of some unknown regulative cognitive process.

Anderson farmed from the age of 15, first at Hermiston near Edinburgh, then at Monkshill, Aberdeenshire. Aberdeen honoured him with an LL.D. in 1780. He settled in Leith (near Edinburgh) in 1783, and founded The Bee (1790–94), a miscellany weekly magazine including literary, political and economic topics. He moved to London in 1797 and set up the magazine Recreations … (1799–1802) along the same lines as The Bee. The most important primary and secondary sources are listed below. 

A contemporary of Adam Smith and James Steuart, James Anderson was second to none as a development economist. His writings lay great stress on the deadening effects of outmoded (feudal) institutions, adverse political and historic legacies, poor communications allied with sparse population, and repressive English-inspired taxation – especially the duties on salt and coal – on Scottish development. His proposals for improvement emphasized the gradualist approach – abstract economic models and grandiose schemes attracted his scorn – where the latent desire of man to improve his lot was freed from constraint and encouraged by state action and private self-interested philanthropy. Thus, though Anderson in general supported laissez-faire as being an essential requisite of optimal development, he believed the paternalistic encouragement of such development was frequently necessary, especially in the early stages. That he was no doctrinaire free-trader is seen in his espousal of the Corn Laws, on developmental grounds (see An Inquiry into the Nature of the Corn Laws …). He took issue with Smith on this, and also on Smith's notion that corn regulates the price of all commodities (see especially his ‘Postscript to Letter Thirteen’ in his Observations …). Smith never properly answered Anderson's criticisms (see Dow, 1984).

Anderson is regarded as an anticipator of Ricardo's rent theory (see, e.g., Schumpeter, 1954), but cannot in fact be cast in the narrowly abstract Ricardian mould. True, for Anderson an increase in corn price would have the differential effects on land rent as described by Ricardo; but this would be the first stage only of a development process. At the end of the process all land would have increased in fertility, and
what was previously the least fertile cultivated land could well be now as fertile as the previously most fertile land (see The Bee, vol. 6, 28 December 1791).

Anderson was convinced of the harm caused by the Poor Laws, and was responsible for a successful appeal against the introduction of the poor rate in Leith.

In addition to his writings on agriculture and economic development and his literary magazine pieces, Anderson also wrote on slavery, archaeology and greenhouse and chimney design!

Anderson was born on 2 August 1887 in Minsk, Russia, and died on 12 February 1960 in Munich, Federal Republic of Germany. As a disciple of Aleksandr A. Tschuprow the younger in St Petersburg, Anderson was a pioneer in statistics and econometrics. After leaving Russia in 1920 he became professor of statistics at the universities of Varna and Sofia in Bulgaria (until 1942), Kiel (until 1947) and Munich.

His oeuvre includes two textbooks and more than 150 articles in Russian, Bulgarian, English and German. Anderson participated during 1913–17 in the theoretical preparation and actual conduct of a sample on agricultural production in the Syr-Darja river area of Russia, one of the very earliest sample surveys. Later, he designed the sample plan for the processing of the Bulgarian Agricultural Census of 1926, with very good results which were decisive for further propagation and acceptance of sampling (1929; 1949).

Before and after the First World War Anderson developed, independently of W.S. Gossett, the variate difference method, a procedure to separate the smooth component (trend, business cycles) from the residual component, without making further assumptions about the underlying type of function (1929). Anderson wrote one of the first, much-noticed econometric papers, an effort to verify statistically the quantity theory of money, which was a very early analysis of causes by means of economic data (1931). Regarding index numbers, Anderson pointed particularly to the problem of chain index numbers, caused by error accumulation (1949; 1952).

Anderson was a charter member of the Econometric Society, a fellow or honorary member of numerous scientific associations, and held honorary doctorates from Vienna and Mannheim.

Article

Albert K. Ando was an eminent Japanese-born American economist who made many seminal contributions in a broad range of areas of economics. Born in Tokyo, Japan, on 15 November 1929, Ando went to the United States after the Second World War instead of joining the family business (ANDO Corporation, a major construction company). He received his BS in economics from the University of Seattle in 1951, his MA in economics from St Louis University in 1953, an MS in economics in 1956 and a Ph.D. in mathematical economics in 1959 from Carnegie Institute of Technology (now Carnegie Mellon University). After teaching at Carnegie and the Massachusetts Institute of Technology, Ando moved to the University of Pennsylvania in 1963 and remained there until his death from leukaemia on 19 September 2002, first as an associate professor of economics and finance, and from 1967 as a professor of economics and finance. Ando held visiting appointments at universities in Louvain, Bonn and Stockholm, and consulted with the International Monetary Fund, the Federal Reserve Board, the Bank of Italy, and the Economic Planning Agency of Japan.

During his long and productive career, Ando received many honours and awards. For example, he was named Fellow of the Econometric Society, Ford Foundation Faculty Research Fellow, Guggenheim Fellow, and Japan Foundation Fellow, and was given the Alexander von Humboldt Award for Senior American Scientists.

Ando made important contributions in such diverse fields as econometrics (theory and applications), stochastic optimal control, the theory of aggregation and partitions in dynamic systems, monetary economics, macroeconomic modelling, and policy design, with an emphasis on interactions between economic growth and cyclical fluctuations, investment behaviour, theoretical and empirical investigations of household saving and consumption behaviour, and demography. His geographic breadth was equally great, with particular focus on Italy, Japan, and the United States. Ando
collaborated, among others, with Nobel laureate Herbert Simon on questions regarding aggregation and causation in economic systems (see, for example, Simon and Ando, 1961, and Ando, Fisher, and Simon, 1963) and with another Nobel laureate, Franco Modigliani, on extending the life-cycle hypothesis of saving (see, for example, Ando and Modigliani, 1963), and constructing large-scale macroeconomic models (see, for example, Ando and Modigliani, 1969).

A common thread in much of Ando's work is the care with which he analysed data. He subjected all of the data he used (whether national accounts data, data from household surveys, or company data) to careful scrutiny, was constantly on the lookout for inconsistencies, conceptual deficiencies, and so on, in the data, and made the necessary adjustments to the data to correct for any inconsistencies and conceptual deficiencies. He then analysed the resulting data meticulously and creatively to shed light on important questions such as the causes of the decade-long recession in Japan in the 1990s (he found that it was due primarily to the massive capital losses on household holdings of corporate equities; see, for example, Ando, 2002a), whether aged households dissave (he found that they dissave relatively rapidly in Italy and the United States but moderately or not at all in Japan; see, for example, Ando and Kennickell, 1987; Hayashi, Ando and Ferris, 1988; and Ando and Nicoletti-Altimari, 2004), how the cost of capital compares in the United States and Japan (he found that it is considerably higher in the United States if individual company data are used but not if national accounts data are used; see, for example, Ando and Auerbach (1988; 1990) and Ando, Hancock and Sawchuk (1997).

Ando played a central role in the construction of the Massachusetts Institute of Technology, the University of Pennsylvania, and the Social Science Research Council (MPS) model, an early large-scale macroeconomic model of the US economy, as well of the Bank of Italy's macroeconomic model of the Italian economy (see, for example, Ando and Modigliani, 1969, and Ando, 1974), and in his later years he devoted considerable energy to constructing a dynamic micro-simulation model of demographic structure for Italy, Japan and the United States, which he used to project future trends in the saving rate (he projected that Japan's saving rate would increase slightly in the immediate future as the number of children per family declined sharply, then fall moderately as the proportion of older persons in the population increased; he projected similar trends in Italy as well: see, for example, Ando et al., 1995, and Ando and Nicoletti-Altimari, 2004).

animal spirits

Roger E. A. Farmer

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The term ‘animal spirits’ was used by Keynes to refer to the idea that business cycles might be caused by crowd psychology. Recent work, in the aftermath of rational expectations, has focused on incorporating this idea into general equilibrium theory by exploiting the fact that dynamic general equilibrium models often contain a continuum of indeterminate equilibria. In stochastic models, production may differ across states of nature solely because of differences in the rational self-fulfilling beliefs of investors. This dependence of outcomes on beliefs provides a modern interpretation of the idea that the business cycle may be driven by animal spirits.

Article

The term ‘animal spirits’ is closely associated with John Maynard Keynes, who used it in his 1936 book, The General Theory of Employment Interest and Money, to capture the idea that aggregate economic activity might be driven in part by waves of optimism or pessimism (although Robin Mathews, 1984, p. 212, points out that Keynes would have been aware of its use by David Hume, 1739, pp. 60–1).
Most, probably, of our decisions to do something positive, the full consequences of which will be drawn out over many days to come, can only be taken as the result of animal spirits – a spontaneous urge to action rather than inaction, and not as the outcome of a weighted average of quantitative benefits multiplied by quantitative probabilities. (Keynes, 1936, pp. 161–2).

The idea that waves of spontaneous optimism might drive business cycles was not new to Keynes and can be traced at least as far back as Henry Thornton, who attributed a central role in his theory of credit to ‘… that confidence which subsists among commercial men in respect to their mercantile affairs …’ (Thornton, 1802, p. 75).

The advent of rational expectations

The early writers, including Keynes, did not develop fully worked-out dynamic models in which expectations of agents are related to outcomes that are later realized. The development of complete artificial economies of this kind occurred first with the rational expectations revolution in the 1970s in which the static macroeconomic disequilibrium model of Keynes's *General Theory* was replaced by modern dynamic general equilibrium models rooted in Chapter 7 of Gerard Debreu's *Theory of Value* (1959). This development began with the work of Robert E. Lucas, Jr., and early examples of rational expectations models include Lucas and Leonard Rapping (1969) and Lucas (1972; 1973). Lucas's 1972 and 1973 papers were attempts to understand the business cycle as a monetary phenomenon. Monetary models gave way to exclusively real models of the business cycle following the publication of influential papers by Fynn Kydland and Edward C. Prescott (1982) and John B. Long and Charles Plosser (1983), and modern macroeconomics theories, based on these early contributions, are referred to as ‘dynamic stochastic general equilibrium (DSGE) models’.

Early DSGE models were restricted to examples in which there exists a finite number of agents (often only one) choosing consumption, investment and employment sequences in an economy with complete markets. Infinite horizon (IH) models of this kind have the same structure as the finite general equilibrium model studied by Kenneth Arrow and Gerard Debreu (1954) and Lionel McKenzie (1959), with the exception that the commodity space is infinite dimensional. Timothy Kehoe and David Levine (1985) showed that the competitive equilibria of IH exchange economies satisfy the first and second theorems of welfare economics; and from applying their methods to production economies it follows that consumption, investment and employment sequences can be treated ‘as if’ they were chosen by a social planner maximizing a concave objective function subject to a set of linear constraints. Social planning problems have a unique solution in which all fluctuations in investment must occur as a direct consequence of fluctuations in the fundamentals of the economy; typically taken to consist of preferences, endowments and technologies. It follows that, if expectations are rational, there is no room in these economies for animal spirits to exert an independent influence on economic activity.

The infinite horizon model under constant returns to scale

http://www.dictionaryofeconomics.com.proxy.library.csi...edu/article?id=pde2008_A.000105&goto=a&result_number=46[]2[]17[]2008-12-29 23:39:00
The modern use of DSGE models has followed two routes. One class of models, following the IH approach, assumes that all decisions are taken by a finite set of infinitely lived households each of which makes decisions for current and future family members. This class includes the real business cycle (RBC) model, currently dominant in the profession, which has a history dating back to Frank Ramsey (1928), David Cass (1965) and Tjalling Koopmans (1965).

In simple representations of the IH model, one assumes that a single representative agent allocates output, $Y_t$, between consumption, $C_t$, and next period's capital stock, $K_{t+1}$. Output is produced from capital, $K_t$, and labour $L_t$ using a constant returns to scale technology that is subject to a productivity shock which is modelled as a random variable $A_t$. The representative agent ranks alternative probability distributions over consumption and labour supply using an additively separable utility function. This problem can be represented as follows:

$$\max_{\{C_t, L_t, K_{t+1}\}} \sum_{k=1}^{\infty} \left( \frac{1}{1 + \rho} \right)^{t-1} \mathbb{E}_1 \left[ U(C_t, L_t) \right],$$

(1)

$$Y_t = A_t K_t^a L_t^b,$$

(2)

$$K_{t+1} = K_t (1 - \delta) + Y_t - C_t, K_1 = \bar{K}_1.$$

(3)

Here, $\delta > 0$ is the agent's discount rate and $0 \leq \delta < 1$ represents depreciation. The parameters $a$ and $b$ represent the elasticities of capital and labour in production and the assumption of constant returns to scale implies that

$$a + b = 1.$$ 

(4)
$E_1[\cdot]$ is the expectations operator, and the interpretation of this problem is that the agent chooses sequences $\{C_t(A^t), L_t(A^t)K_{t+1}(A^t)\}_{t=1}^{\infty}$ where $A^t = \{A_1, A_2, \ldots, A_t\}$ is the history of shocks from date 1 to date $t$. $A_t$ is a random variable, generated by an autocorrelated stochastic process.

In standard IH models one assumes that $U(x, y)$ is increasing in $x$, decreasing in $y$, strictly concave and twice continuously differentiable, and under these assumptions the programming problem defined in eq. (1) is concave and has a unique solution. Under the commonly assumed functional form,

$$U(C, L) = \log(C) - \frac{1}{1 + \gamma} \frac{1}{L},$$

this solution is characterized by the first order conditions:

$$C_t L_t \gamma = b \frac{Y_t}{L_t},$$

(5)

$$\frac{1}{C_t} = E_t \left( \frac{1}{(1 + \rho) C_{t+1}} \left( 1 - \delta + a \frac{Y_{t+1}}{K_{t+1}} \right) \right),$$

(6)

$$\lim_{\tau \to \infty} \left( \frac{1}{1 + \rho} \right)^\tau E_1 \left[ \frac{K_{\tau+1}}{C_{\tau}} \right] = 0.$$
For the real business cycle programme it is critical to assume that the production function is linearly homogenous and preferences are strictly concave, since these assumptions imply that the problem of the representative agent has a unique solution. More generally, if there are multiple agents one can write down the problem of a social planner who maximizes a social welfare function, defined as a weighted sum of individual utilities.

**The OLG model and how it differs**

In contrast to the IH model, in overlapping generations (OLG) economies one assumes that the set of agents is infinite and that each agent lives for a finite number of periods; this model was developed first in English by Paul Samuelson (1958), although Maurice Allais’ book (1948), written in French, predates Samuelson’s contribution.

In OLG models, unlike in the IH model with concave preferences and technologies, there may exist equilibria that are dynamically inefficient. In equilibria of this kind the economy has ‘too much capital’, and a benevolent social planner could improve social welfare for all generations by consuming part of the capital stock (thereby raising consumption for the current generation) and diverting future output from investment to consumption (thereby raising consumption for all future generations).

After the publication of Samuelson's article in 1958, a considerable literature developed discussing the source of dynamic inefficiency. The question was finally settled with the publication of Shell's (1971) paper, ‘Notes on the Economics of Infinity’. Shell argued that both IH and OLG models are special cases of Debreu's (1959) formulation of general equilibrium. In both cases the commodity space is infinite dimensional. In the IH model the number of agents is finite; in the OLG model it is infinite. This apparently innocuous difference is the key to understanding why there may be inefficient equilibria in the OLG model since, in an inefficient equilibrium, no single agent can make a welfare-improving trade. In contrast, dynamic inefficiency in an IH economy would imply the existence of an agent with infinite wealth at equilibrium prices.

Both IH and OLG models have been used as vehicles to develop the idea that animal spirits may independently influence economic activity. Since the IH model with concave preferences and technologies leads to equilibria that are efficient, it was the OLG model that was first exploited to develop the modern version of the ‘animal spirits hypothesis’. However, since the period length of the two-period OLG model is typically interpreted as 25 or 30 years, and since the average period of a business cycle is six to eight years, it was easy to dismiss the early work, based on the OLG structure, on the grounds that the equilibria that it led to were theoretical curiosities that are not relevant in the real world. This criticism was addressed by a second generation of animal spirits economies, in which the OLG model was replaced by an IH framework that relaxed the assumption that the technology is subject to constant returns to scale.

**Animal spirits, sunspots and incomplete participation**

In DSGE models the term ‘animal spirits’ (Azariadis, 1981; Howitt and McAfee, 1992; Farmer and Guo, 1994) is used interchangeably with ‘sunspots’ (Cass and Shell, 1983), ‘self-fulfilling
Animal spirits: The New Palgrave Dictionary of Economics

prophecies’ (Azariadis, 1981; Farmer, 1993) and most recently ‘irrational exuberance’ by Alan Greenspan (1996) at an after-dinner speech.

Jevons (1884) used the term ‘sunspots’ to refer to the literal possibility that astronomical events could influence the trade cycle through the intermediating effect of the weather on agriculture. In their 1983 article, Cass and Shell meant something different. They constructed a two-period general equilibrium model with complete markets in which some agents are unable to enter into insurance contracts. They referred to this restriction as ‘incomplete participation’ to distinguish it from a potentially more serious market breakdown in which some kinds of insurance contracts cannot be entered into by anyone. Cass and Shell distinguished between intrinsic uncertainty, which can influence fundamentals of the economy, and extrinsic uncertainty, under which the fundamentals are unchanged across alternative extrinsic events. They showed that the inability of a subset of agents to enter into insurance contracts is a sufficient departure from standard general equilibrium assumptions to permit the existence of equilibria in which allocations differ across states of the world in which all uncertainty is extrinsic. When this occurs, they said that sunspots matter.

In an economy with a complete set of insurance markets and risk-averse agents, all of whom can participate in these markets, sunspots cannot matter. Since agents are risk averse, they would prefer the mean of a random allocation to the allocation itself. But if all uncertainty is extrinsic then the mean allocation is feasible; hence a sunspot allocation cannot be an equilibrium of a complete markets economy with complete participation. Sunspot equilibria are Pareto-inefficient, but for a different reason from the dynamic inefficiency associated with over-accumulation of capital in deterministic OLG models. Sunspot inefficiency arises from the addition of unnecessary randomness to an economy in which agents prefer to avoid fluctuations in their consumption allocations.

Animal spirits in an OLG model

The first application of sunspots to a DSGE model is due to Azariadis (1981). He constructed a two-period overlapping generations model with no intrinsic uncertainty. This model possesses a unique steady state in which money has value. Under typical assumptions about preferences, the linearized dynamics of equilibrium price sequences in the neighbourhood of the steady state obey a functional equation of the form

\[ p_t = \alpha E_t [ p_{t+1} ] + \varepsilon, \quad |\alpha| < 1. \]

Azariadis looked for equilibria that follow a two-state Markov process: that is, equilibria of the form
where $s_t \in \{1, 2\}$ is the state at date $t$ and $\pi_{ij}$ is the probability that $s_t = i$ conditional on $s_{t-1} = j$. For the linearized model, the fact that $|\alpha| < 1$ implies that the only equilibrium in this class is one for which

$$\rho(s_t = i) = \frac{c}{1 - \alpha}, i = 1, 2,$$

(10)

that is, the price is constant and independent of the non-fundamental uncertainty. But in the nonlinear model the equation that defines equilibrium price sequences takes the form

$$\rho_t(s_t) = E_t[ g(\rho_{t+1}(s_{t+1}) | s_t) ],$$

(11)

where the function $g(\cdot)$ depends on assumptions about the form of the utility function. The equation defining a two-state Markov equilibrium takes the more general form

$$\begin{bmatrix} \rho_t(s_t = 1) \\ \rho_t(s_t = 2) \end{bmatrix} = \begin{bmatrix} \pi_{11} & \pi_{12} \\ \pi_{21} & \pi_{22} \end{bmatrix} \begin{bmatrix} \alpha \rho_{t+1}(s_t = 1) \\ \alpha \rho_{t+1}(s_t = 2) \end{bmatrix} + \begin{bmatrix} c \\ c \end{bmatrix}$$

(12)

In this case, Azariadis showed that, as long as consumption and leisure are not gross substitutes, it is possible to find positive numbers $p_1, p_2$ such that $\rho_1 \neq \rho_2$ and positive probabilities $\pi_{11}, \pi_{12}, \pi_{21}$ and $\pi_{22}$ such that
In other words, prices (and implicitly employment, consumption and GDP) in this economy fluctuate between two different levels based purely on the occurrence of self-fulfilling expectations or, in Keynes's terminology, ‘animal spirits’. As with the Cass–Shell example of sunspots, however, the Azariadis example could easily be dismissed as a model of a real economy since it required the assumption that consumption and leisure are gross complements – an assumption that was widely believed to be implausible and inconsistent with other evidence. The challenge was to develop a quantitative model of the business cycle in which aggregate fluctuations are driven by animal spirits, expectations are rational, and the model can capture the observed volatilities of output, consumption, GDP and hours.

Animal spirits and indeterminacy

The example of sunspots provided in the Cass–Shell (1982) paper relied on constructing an economy in which there are multiple equilibria. They showed that, when some agents are unable to participate in the insurance markets that occur before they are born, randomizations across deterministic allocations can also be sustained as equilibria. In the presence of complete participation in insurance markets these randomized equilibria would be ruled out since they are associated with unnecessary uncertainty that risk-averse agents would prefer to avoid.

In addition to the fact that an OLG equilibrium can be dynamically inefficient, there is a second key way in which OLG and IH models differ. In the IH model the set of equilibria is generically finite whereas OLG economies can contain a continuum of equilibria. (Roughly speaking, ‘generically finite’ means that for almost all IH economies there is a finite number of equilibria, and ‘almost all’ means that this statement is true for an open dense set of parameters in a parameterized family of economies.) The fact that there is a finite number of equilibria implies that each equilibrium of the IH model is locally unique, that is, there is no other equilibrium that is arbitrarily close to it.

A locally unique equilibrium is also called ‘determinate’. Determinacy of equilibrium is an important property since, if one is interested in comparative statics, it is important that small changes in exogenous variables lead to predictable small changes in endogenous variables. If the equilibrium is one of a continuous set of equilibria (as would happen if the equilibrium were indeterminate) then the model does not make a clear prediction as to how prices and quantities would be expected to change in response to a change in policy or in some other fundamental of the economy.

Under some assumptions about preferences (a sufficient condition is that the endowment of the agents is sufficiently tilted towards youth), the one-good two-period OLG model possesses two steady states. Each of these steady states is a stationary equilibrium with a constant real rate of interest; in one stationary equilibrium money has positive value and in the other it does not. David Gale (1973) refers to economies that possess a monetary steady state as ‘Samuelson’ to distinguish them from those that do
not (he calls these ‘Classical’). In a Samuelson economy the two steady states are respectively ‘generationally autarkic’ (money has no value) and ‘golden rule’ (the real rate of interest equals the population growth rate). In Samuelson economies there exists a continuum of non-stationary equilibria and, when consumptions in adjacent periods are gross substitutes, each of these non-stationary equilibria converges to the autarkic steady state.

The non-stationary equilibria in the OLG model provide a rich source of equilibria over which to randomize; however, they all converge to an autarkic equilibrium in which money has no value. This property makes it difficult to construct stationary stochastic equilibria around the autarkic steady state since there are no non-stationary paths that approach the steady state from below. To get around this difficulty, Farmer and Woodford (1984) showed that, by adding government spending to the OLG model, one can construct randomizations over a set of non-stationary equilibria that converge to a stationary state in which money has value. The addition of positive inflation-financed government expenditure shifts the set of stationary equilibria, and the indeterminate non-monetary equilibrium of the OLG model becomes a second monetary equilibrium. By adding a zero mean random variable to the model, Farmer and Woodford were able to construct a new set of stationary sunspot equilibria. Locally, these equilibria obey a difference equation of the form of eq. (8), but the parameter \( \alpha \) is greater than 1 in absolute value. It follows that one can construct equilibria in this model of the form:

\[
p_{t+1} = \frac{1}{\alpha} p_t - \frac{c}{\alpha} + u_{t+1},
\]

where \( u_{t+1} \) is any random variable with zero conditional mean. Further, the unconditional probability distribution of the price level can be shown to converge to an invariant probability measure that depends on the distribution of the sequence of sunspot shocks, \( \{u_t\} \). This is an important property of a rational expectations equilibrium since, arguably, stationarity is necessary for agents to learn about the world in which they live and to find ways of making unbiased forecasts of the moments of future prices.

**Real business cycles and the animal spirits hypothesis**

The examples of stationary sunspot rational expectations equilibria, originally constructed in the OLG model, did not have much impact on mainstream macroeconomics. Although the first rational expectations models were constructed as monetary examples within the two-period OLG structure (for example, Lucas's seminal 1972 paper), the profession soon moved on to real models based on IH economies. The IH structure is more amenable to confrontation with data since the period of the model can easily be mapped into the period of data collection. Further, the examples of Azariadis and Farmer–Woodford were constructed in models that relied on assumptions widely believed to be unrealistic; these included the assumption of gross complements and two-period lives (in the case of the Azariadis model) and the assumption that sunspots exist close to a dynamically inefficient steady state in the Farmer–Woodford model (this assumption can be shown to generate counter-intuitive responses of inflation to...
To confront these criticisms, Howitt and McAfee (1992), Benhabib and Farmer (1994) and Farmer and Guo (1994) constructed examples of animal spirits equilibria within the IH paradigm by dropping the assumption that the technology is subject to constant returns to scale. At the time that this work was published, a number of authors (Caballero and Lyons, 1993, are prominent examples) had estimated the degree of increasing returns to scale in US manufacturing industries and found it to be large. In their 1994 paper, Benhabib and Farmer took a relatively standard IH model and added externalities and increasing returns to scale. Farmer and Guo (1994) constructed a discrete time version of the Benhabib–Farmer model and showed that it can be used to generate business cycle fluctuations driven by animal spirits. They argued that the animal spirits-driven model is more successful than the real business cycle model at capturing the observed dynamics of output, employment, investment and consumption because it can replicate the hump-shaped response of output and investment to shocks that is observed in US data.

The Benhabib–Farmer–Guo (BFG) model has the same form as the IH model described in eqs. (11) to (17) but it distinguishes between the private technology and the social technology. BFG assume that the economy contains a large number of identical firms, each of which produces output using the production function

$$\gamma_t = A_t K_t^\alpha L_t^\beta.$$  
(15)

In BFG, the term $A_t$ is not exogenous. Instead, it represents an input externality of the form

$$A_t = \bar{K}_t^{\alpha - a} \bar{L}_t^{\beta - b},$$  
(16)

where $\bar{K}_t$ and $\bar{L}_t$ represent the economy-wide average use of capital and labour. Replacing (1.16) in (1.15) and imposing the assumption that the economy is in a symmetric equilibrium in which $\bar{K}_t = K_t$ and $\bar{L}_t = L_t$ leads to the social technology

$$\gamma_t = K_t^\alpha L_t^\beta.$$  
(17)
BFG assumed that

\[ \alpha + \beta > 1, \quad a + b = 1, \]  
(18)

which implies that there are increasing returns to scale in the social technology but constant returns to scale at the level of the individual firm. Since increasing returns enter the economy as an external effect, each firm maximizes a concave profit function, and the equilibrium of the competitive economy is well defined. BFG showed that equilibria in their IH economy with increasing returns are characterized by the following system of equations.

\[ y_t = \alpha_k K_t^\alpha L_t^\beta, \]  
(19)

\[ K_{t+1} = K_t (1 - \delta) + Y_t - C_t, \]  
(20)

\[ C_t L_t \frac{y_t}{L_t} = b \frac{y_t}{L_t}, \]  
(21)

\[ \frac{1}{C_t} = E_t \left\{ \frac{1}{(1 + \rho) C_{t+1}} \left( 1 - \delta + a \frac{y_{t+1}}{K_{t+1}} \right) \right\}, \]  
(22)
When $\alpha = \beta$ and $\beta = \beta$, this model collapses to the real business cycle version of the IH economy. But if $\alpha > \alpha$, $\beta > \beta$ and $\alpha + \beta$ is greater than 1 and ‘large enough’, Benhabib and Farmer showed that the dynamics of the IH model change character, and the model contains a continuum of indeterminate equilibria, just as the OLG model does. Farmer and Guo calibrated the model to US data and, by choosing parameters that appeared consistent with contemporary estimates of returns to scale, they showed that the model exhibits business cycles driven by self-fulfilling waves of optimism and pessimism.

To provide a degree of discipline to the calibration exercise, real business cycle economists estimate the volatility of real productivity shocks by constructing an estimate of total factor productivity (TFP). This is an accurate measure of TFP under the maintained assumptions of competitive markets and constant returns to scale. Farmer–Guo provided discipline to their calibration exercise by constructing the measure of TFP that would be estimated from data generated by an animal spirits economy by an econometrician who assumed incorrectly that the technology was driven by technology shocks, and imposed the incorrect identifying assumption of constant returns to scale. They showed that this measure has very similar properties to that of the TFP estimates from US data.

**Animal spirits, business cycles and welfare**

Much recent business cycle research assumes that business cycles are driven by technology shocks; but we do not have a very good explanation of what these shocks represent. The BFG model represents a plausible alternative to the real business cycle model. It recaptures an old idea and recasts it in modern language.

Why should we care if shocks arise in the productivity of the technology or in the minds of entrepreneurs? The answer is connected to the efficiency question. If business cycles arise as the consequence of the optimal allocation of resources in the face of unavoidable fluctuations in the technology, then there is not much that government can or should do about them. But, if they arise as the consequence of avoidable fluctuations in the animal spirits of investors, then the fluctuations that result are avoidable and the allocations are Pareto-suboptimal. Animal spirit-driven business cycles provide a reason for countercyclical stabilization policy, and the cause of cycles is therefore an important question. In 1996 Takashi Kamihigashi showed that the RBC economy (driven by TFP shocks) and the Benhabib–Farmer model (driven by animal spirits) are observationally equivalent when estimated on aggregate...
data and that, if one uses aggregate evidence alone, constant returns to scale is an identifying assumption. The empirical literature since the publication of volume 63 of the *Journal of Economic Theory* in 1994 suggests that early estimates of the degree of returns to scale were overstated, and more recent estimates (for example, Basu and Fernald, 1997) are more modest. This has led to renewed developments by theorists who have constructed modifications of the basic animal spirits model that are able to bring down the required degree of returns to scale to well within the tolerance of the best econometric estimates. Innovations to this literature include the construction of multi-sector models (Benhabib and Farmer, 1996; Weder, 1998; Benhabib, Nishimura and Meng, 2000; Harrison, 2001), externalities in preferences (Farmer and Bennett, 2000; Hintermaier, 2003), capital–labour substitution (Grandmont, Pintus and de Vilder, 1998), stabilization policy (Schmitt-Grohé and Uribe, 1997; Guo and Lansing, 1998; Lloyd Braga, 2003), alternative explanations of the Great Depression (Harrison and Weder, 2006) and variable capacity utilization (Wen, 1998; Benhabib and Wen, 2004). Benhabib and Farmer (1999) provide a survey of this literature and references to additional related papers. Recent examples of animal spirits-driven models are able to explain a wide range of phenomena and, when supplemented by the assumption of variable capacity utilization, the animal-spirits explanation of business cycles outperforms the RBC model in most dimensions. Since the two models have very different policy conclusions, research that addresses the question of whether business cycles are driven by animal spirits is likely to remain a lively and important focus of research for some time to come.

Anthropometric history is the study of human size as an indicator of how well the human organism fared during childhood and adolescents in its socio-economic and epidemiological environment. The development of this field has opened up new windows on the ways in which economic processes affected the populations experiencing it, such as the hidden costs of industrialization and urbanization.

Keywords
antebellum puzzle; anthropometric history; biology; cliometrics; gross national product; height; biological welfare; Human Development Index; labour productivity; longevity; an indicator of biological welfare; nutrition; population density; Sen, A.; slaves; weight

Anthropometric history is the study of human size, primarily physical stature, weight, and the body mass index \[
\frac{\text{weight(kg)}}{\text{height(m)}^2}
\] in order to ascertain how well the human organism thrived in its socio-economic and epidemiological environment.

As early as 1829 scholars recognized that the economy had a profound influence on human physical growth. In the 1960s French historians resurrected this tradition and explored the socio-economic correlates of height (Le Roy Ladurie, Bernageau and Pasquet, 1969), but the true expansion of the field began simultaneously in the mid-1970s among development economists and cliometricians. The former were interested in measuring malnutrition and its synergistic effect on economic performance in the Third World (Scrimshaw, 2003). In cooperation with the United Nations, they expanded the work of nutritionists in combating poverty (Strauss and Thomas, 1998) and measuring the impact of nutrition on labour productivity. Their effort culminated in the United Nation's formulation of the Human Development Index (HDI), which incorporates income, mortality, and schooling, in a superior measure of welfare (Sen, 1987). In contrast, cliometricians analyse secular changes and cross-sectional patterns in biological welfare as well as the effect of economic development on the growth of the human organism. Initial research in this vein was influenced by the controversial finding that American slaves were relatively well nourished (Fogel and Engerman, 1974), and was followed up by investigations of the height of slaves as an indicator of their nutritional status (Engerman, 1976). The results implied that slaves were indeed well-nourished once they reached working age, as they were markedly taller than the European lower classes (Figure 1) as well as their brethren in Africa (Steckel, 1979). This astounding discovery prompted further research along these lines at a time when there was increased dissatisfaction with relying exclusively on gross national product (GNP) per capita as a welfare indicator, as it is not adjusted for income distribution or for externalities such as pollution; moreover, it pertains only indirectly to children and others not in the labour market, such as self-sufficient peasants and women for much of human history. Hence, GNP is only a rough indicator of well-being in a society.

Figure 1
The average height of a birth cohort – until adulthood is given approximately by:

\[
H(x)_t = H_{\text{min}}(x) + \int_{\text{age}=0}^{x} s_t \cdot Y_t \left( \frac{P_t}{P_{\text{avg}}(t)} \right), W_t, D_t, \sigma_t, \theta_t, M_t, T_t, E_t \, dt < H_{\text{max}}(x),
\]

where \(H(x)_t\) is the physical stature at age=x for a particular birth cohort, for \(x < 25\), \(Y_t\) is real disposable family income; \(s_t\) is the share of income dedicated to children; \(P_f\) is the price of nutrients;
Diminishing returns to income imply that higher income volatility results in shorter stature for a given amount of average income over time. In practice, the analysis frequently pertains to the changes in height over time of adjacent cohorts of adults or of sub-adults of the same age in order to eliminate possible genetic components relevant to $H_{\min}(x)$ and $H_{\max}(x)$. Thereby one analyses how height is affected by the variables inside the integral over time (Komlos 1985; WHO, 1995). Thus, adult height of a cohort reflects the history of its net-nutritional status during the growing years.

This innovative perspective opened new windows to understanding of the impact of economic processes on the human organism and vice versa. According to archaeological evidence it is now evident that health of the natives of the New World ‘…was on a downward trajectory long before Columbus arrived’ (Steckel and Rose, 2002, p. 578). There were cycles in physical stature of about a generation long, brought about by demographic growth, urbanization, or changes in relative prices, market structure, income, inequality, and climate (Baten, 2002; Baten and Murray, 2000; Komlos, 1998). There were also shorter cycles in height associated with business cycles (Woitek, 2003); only in the 20th century were these cycles attenuated due to improvements in medicine, increases in labour productivity, and the substantial decline in the relative price of nutrients. The socio-economic crisis of the 17th century is evident in the height of the French population, as men measured about 162 cm on average (Komlos, 2003). Europeans were never as short thereafter. The rapid population growth during the demographic revolution of the late 18th century brought about a decline in height everywhere in Europe as technological change in the agricultural sector did not suffice to maintain the nutritional status of the populations. The French Revolution was preceded by a decline in nutritional status, but no worse than in other parts of Europe, and not to the previous trough of the 17th century. Malthusian crisis generally began with a decline in heights even before mortality rates increased, as human organisms attempted to adjust their size to the available nutrition before the onset of subsistence crisis.

Social status has been related positively to height everywhere and at all times without exception. This generalization holds for 18th-century Germany as well as for the German Democratic Republic in the 20th century. The greatest social gradient in height ever recorded was found in early industrial England, where the difference between upper and lower class 15-year-olds reached 20 cm (Figure 1). Height was related negatively to population density, as denser populations tended to have a higher disease load, as well as higher prices of nutrients. Urban populations tended to be shorter because of higher food prices and because of the higher incidence of diseases until the turn of the 20th century, when perishables became transportable longer distances due to refrigeration, and improvements in urban sanitation improved the epidemiological environment of towns. The degree of commercialization of the economy had an effect on human growth, as propinquity to nutrients invariably conferred considerable nutritional advantages in the early industrial period in so far as self-sufficient consumers did not have to pay for transportation costs of nutrients. Hence, self-sufficient (protein-producing) farmers tended to be tall. This was true in such widely separated places Tennessee, Japan or Bavaria (Cuff, 1998; Craig and Weiss, 1998; Haines, 1998). Americans were the tallest in the world until the middle of the 20th century as resource abundance translated into higher wages, lower food prices, and a more equal distribution of income than prevailed elsewhere.

A transformation in the economic system put a hitherto unknown stress on the human organism. This was the case not only during the neolithic agricultural revolution but also during the Industrial Revolution, during the onset of modern economic growth as well as during the transition from socialism to capitalism. Thus, height declined (in the 1830s) at the onset of modern economic growth even in the resource-abundant United States, a phenomenon that has come to be known as the ‘antebellum puzzle’. Average heights declined although real incomes increased (at a rate of 1.4 per cent per annum) because the relative price of nutrients and the degree of inequality were increasing and because self-sufficiency in agriculture was declining (Figure 2).

Figure 2

Anthropometric history: The New Palgrave Dictionary of Economics

Slaves were well nourished relative to the European lower classes (Figure 1), even if they were not particularly tall in the US context (Figure 3). Income was protective of nutritional status, as one would expect. High-status Americans did not experience a decline in height at the onset of modern economic growth, and the height of aristocrats did not decline during the Industrial Revolution. As Kuznets (1966) demonstrated, the anthropometric record also shows an increase in inequality with industrialization. Heights did not begin to improve substantially and reach their 18th-century levels until the end of the 19th century. Heights tended to correlate positively with wages except in the presence of countervailing forces. Height was associated positively with life expectancy up to about 185 cm; underweight and overweight individuals tended to have lower life expectancy; populations were underweight prior to the mid-20th century as food was relatively expensive and there was a lot of physical activity associated with daily life. Much of the increase in life expectancy in the 20th century is associated with an increase in body size; however, for the first time in its existence, because of technological and cultural changes the human specie is facing an obesity epidemic that threatens to slow down the rate of increase of life expectancy.

Figure 3
The citizens of the western and northern European welfare states are the tallest in the world now, having overtaken the Americans about a generation ago. That implies that these welfare states provide a higher biological standard of living than the more free-market-oriented American society (Komlos and Baur, 2004).

With the development of the concept of the ‘biological standard of living’ as distinct from conventional indicators of well-being, and with the founding of the new journal *Economics and Human Biology* in 2003, biology became integrated into mainstream economics. Height and weight are components and relatively easily measured indicators of biological welfare. In addition, we gain new insights of the effect of economic processes on the human organism. Hence, anthropometric history emphasizes that well-being encompasses more than the command over goods and services. Rather, it is multidimensional, and height, weight, health in general, and longevity all contribute to it – independently of purchasing power. In many ways, such indexes provide a more nuanced view of the impact of dynamic economic processes on the quality of life than income or GNP per capita alone. Anthropometric indicators are not meant to be substitutes for, but complements to, such conventional measures of living standards as income per capita.

anti-discrimination law

John J. Donohue III
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article reviews the major legislative initiatives outlawing discrimination, discusses the theoretical arguments for and against such initiatives, and assesses the impact of these laws on the groups they try to protect. The significant effects of federal law in the first decade after passage of the 1964 Civil Rights Act are contrasted with the less optimistic findings from subsequent anti-discrimination interventions. Insights about the social benefits and the costs of the unintended consequences of employment discrimination law apply equally to other types of anti-discrimination legislation, such as mortgage lending and policing.

Keywords

anti-discrimination law; Becker, G.; black–white labour market inequality in the United States; efficient capital markets hypothesis; Friedman, M.; human capital; insider–outsider problems; Jim Crow South; labour market discrimination; sex discrimination; statistical discrimination

Article

In the aftermath of the Second World War, New York and New Jersey became the first in a series of non-Southern states to pass laws prohibiting racial discrimination in employment. Almost two decades later Congress passed, over strong Southern opposition, the momentous Civil Rights Act of 1964, which banned discrimination on the basis of race, sex, religion and national origin in employment and public accommodations. Over the ensuing 40 years, the reach of federal and state anti-discrimination law has extended beyond intentional discrimination (disparate-treatment discrimination) to ostensibly neutral practices that have an adverse impact on selected groups (disparate-impact law), and to protect those over age 40 (the Age Discrimination in Employment Act) and those with disabilities (the Americans with Disabilities Act). Anti-discrimination law has come to play an increasingly important role in employment, government contracting, policing and criminal justice, mortgage lending, retail and
marketing practices, and education.

The Becker model, federal anti-discrimination law, and the end of the Jim Crow era

In 1957, Gary Becker launched the serious economic evaluation of discrimination when he developed a model based on individual animus towards a certain class of workers (see Becker, 1957). The analysis had a number of shortcomings when applied to the real world, not least of which was that it assumed that the psychological burden of discrimination fell only on the *discriminators* (they were the ones who suffered the distaste), and the only cost borne by the victims of discrimination was any resulting decrease in wages or employment. In the early 1960s, Milton Friedman, in part influenced by Becker's work, argued against employment discrimination law on the grounds that it was unnecessary since competitive markets would protect workers from discrimination, and undesirable since government should not interfere with the personal preferences of discriminating employers. Although it is now clear that Friedman's position was incomplete, both arguments carry some weight.

First, frictionless competitive markets should offer protection from discriminatory employers. This means that, even in the presence of substantial employer animus, highly competitive markets reduce the need for law if a sufficient number of non-discriminators are available to bid up the wages of, say, black labour. The efficient capital markets hypothesis assumes that prices of financial assets will always tend to be close to their underlying value. Workers are also valuable assets, so Friedman believed that competitive markets would similarly push wages towards underlying productivity ('true value') in the labour market as well. But, even under the best of circumstances, one would not expect labour markets to be as efficient as capital markets with their homogeneous products, low transaction costs, ability to sell short and hordes of analysts whose job it is to identify the true value of certain securities. The resulting trades will tend to push these stock prices towards their true value (Donohue, 1994). In the labour market, workers are not homogeneous, transaction costs associated with hiring and dealing with labour are high, there is no ability to sell short, and the value in ascertaining the true productivity of a modal worker is relatively small. If one adds in labour market imperfections posed by unions, minimum wage laws, high information costs and the racist and segregationist Jim Crow laws – laws requiring strict racial segregation in many aspects of public life including schooling and accommodations that led to inferior treatment of blacks despite the supposed legal requirement of equality under the 'separate but equal' doctrine – it is not hard to imagine that, in the absence of anti-discrimination legislation, blacks would be unfairly excluded from a range of good jobs or paid less than their marginal product. Moreover, while competitive markets would be hostile to employer discrimination, they would actually encourage an employer to discriminate if that is the preference of fellow workers or customers.

Second, under the Becker model, net utility will be decreased by an employment discrimination law if...
one gives weight to the preferences of discriminators, as Friedman and Becker were wont to do. But Donohue (1986; 1989) argued that driving the discriminators out of business could actually enhance welfare by eliminating the Beckerian social cost. Moreover, while Becker conceived of discrimination as a stable taste, the evidence again suggests that the federal prohibition ultimately changed the attitudes (tastes) of millions of Americans. Rather than relentlessly and constantly imposing the burdens of inefficient interactions on unwilling discriminators, the Civil Rights Act aided a social process of integration that ultimately reduced the prior Beckerian taste for discrimination. While short-run costs were undoubtedly high, in the long run an entire region of the country was energized by the disruption of previously regimented views of racial inferiority – to the benefit of both blacks and whites. Since the Beckerian discriminatory tastes represented social costs, the reduction in the magnitude of these social costs constituted a major social benefit.

Did federal law improve the economic status of blacks and others?

Perhaps the most important question concerning federal anti-discrimination law is whether it has aided its primary intended beneficiaries – black Americans (particularly in the South). James Smith and Finis Welch (1989) argued that the Civil Rights Act of 1964 was not responsible for substantial gains in black economic welfare. They conceded that black economic welfare improved at about the time of the federal initiatives in the 1960s, but they contended that the gains were the result of human capital enhancement, not of demand-side policies addressed to ameliorate the impact of discrimination. To buttress their view that Title VII – the section in the Civil Rights Act prohibiting employment discrimination based on, inter alia, race or colour – generated no benefits for black workers, Smith and Welch argued that the economic gains of blacks during the period 1940–60 were the same as those in the 1960–80 period (thereby suggesting that the Civil Rights Act of 1964 had been unimportant). The major response to Smith and Welch came from Donohue and Heckman (1991), who argued that Title VII did indeed generate a decade of economic gains for blacks:

...the evidence of sustained economic advance for blacks over the period 1965–1975 is not inconsistent with the fact that the racial wage gap declined by similar amounts in the two decades following 1940 as in the two decades following 1960. The long-term picture from at least 1920–1990 has been one of black relative stagnation with the exception of two periods – that around World War II and that following the passage of the 1964 Civil Rights Act. (Donohue and Heckman, 1991, p. 1614)

It is now widely accepted that, in helping to break down the extreme discriminatory patterns of the Jim Crow South, Title VII considerably increased the demand for black labour, leading to both greater levels of employment and higher wages in the decade after its adoption (see also, Freeman et al., 1973; Conroy, 1994; and Orfield and Ashkinaze, 1991). Chay (1998) shows that, when the reach of the 1964 Civil Rights Act was expanded in 1972, the demand for black labour was further stimulated. But the good news in terms of law-induced efforts to improve the economic status of blacks through anti-discrimination policy has probably run its course. A series of papers by Oyer and Schaefer (2000; 2002a; 2002b) offers little support for the view that the strengthening of federal anti-discrimination law in 1991
stimulated black or female employment, as occurred with the federal laws passed in 1964 and 1972. (The CRA actually changed race discrimination law in a relatively minor way – restoring the standards that had existed in June 1989 with respect to discriminatory discharge and the standards for employer justification of practices with disparate racial impacts. For non-race cases, however, the 1991 Act expanded the damages available and authorized punitive damage awards for intentional discrimination.) Moreover, papers by Acemoglu and Angrist (2001), and DeLiere (2000) hold that another piece of anti-discrimination legislation, the Americans with Disabilities Act (ADA), actually harms employment. This very pessimistic conclusion may be too strong. Attributing the poorer employment experience of the disabled in a short period after the federal law passed in 1990 turns out to be a tricky proposition, given the downturn in the economy and the substantial growth in those collecting disability benefits at roughly the same time. Burkhauser, Houtenville and Rovba (2006) extend the time period of Acemoglu and Angrist's analysis, and conclude that the decline in relative employment of the disabled actually began in the mid-1980s, roughly the time at which rules for disability benefits eligibility were loosened. But even if the ADA did not hurt, there is no strong evidence that it helped on the macro level, even if it did assist in securing small micro-level accommodations for the disabled. Jolls and Prescott (2004) argue that disability laws having a reasonable accommodation requirement may generate an insider–outsider problem. Those who gain the accommodation are better off, but at the expense of some disabled workers who end up out of the labour force.

Is employment discrimination a first-order problem for US blacks today?

Is the black–white earnings differential fully explained?

Heckman (1998) contends that labour market discrimination no longer substantially contributes to the black–white wage gap (as it once clearly did), and therefore he doubts that four decades after the Civil Rights Act racial discrimination in the labour market is a first-order problem in the United States. Rather, Heckman looks to other factors (namely, those that promote skill formation) to explain the black–white earnings gap – a theme that he builds on in Carneiro, Heckman, and Masterov (2005).

An important paper that informs Heckman's analysis of the current reasons for the black–white wage gap is Neal and Johnson (1996). If factors that exist prior to workers' entry into the labour market largely explain the black–white wage gap, then the contribution of racial discrimination to this wage gap is presumably small. Neal and Johnson note that many studies have examined the black–white wage gap and found that it could not be explained with standard measures such as age, years of education, marital status and so forth, implying that the contribution of discrimination was sizable. Neal and Johnson note that years of education may exaggerate the true skill level attained by blacks, given the poorer-quality schools that many blacks attend. They argue that scores on the Armed Forces Qualification Test (AFQT) are a better measure than innate ability of acquired skill brought to the labour market.

The authors begin by showing that the unadjusted wage gap between blacks and whites is minus 24.4 per cent for black men and minus 8.5 per cent for black women. Using National Longitudinal Surveys of Youth (NLSY) data, Neal and Johnson found that the unexplained wage gap fell to minus 7.2 per cent for black men and plus 3.5 per cent (although insignificant) for black women, once they controlled for race, age and AFQT score. In other words, the AFQT test score can explain a very large portion of the
black–white wage gap for men, and the entire gap for women. One source of continuing debate in the literature is whether these wage regressions should include controls for years of education as well as AFQT score. Neal and Johnson say it should not since the test better captures ability, and so they exclude the education measure from their regressions. Others have included years of education and find that the unexplained wage gap re-emerges when this control is added.

A potential problem with their approach is the possibility of black underinvestment in human capital due to the presence of statistical discrimination. Neal and Johnson reject this concern, finding that the return to higher AFQT scores is significantly higher for black men (although not for black women), so that blacks seem to have adequate incentive to invest in developing human capital.

Evidence of racial discrimination in entry level hiring from audit-pair studies

The view that racial discrimination seems to have largely been wrung from the labour market is in apparent conflict with a number of audit studies that document differential treatment of blacks and whites. For example, a recent study by Devah Pager concludes that the degree of discrimination in employment is so great that blacks without criminal records are treated as badly as whites with criminal records (Pager, 2003). Pager's audit experiment involved four male participants, two blacks and two whites, applying for entry-level job openings. The auditors formed two teams so that the members of each team were of the same race (the only difference in the application was that one of the testers in each team was assigned a criminal record, a felony drug conviction, and 18 months of prison). The teams applied for 15 jobs per week and the final data included 150 applications by the white pair and 200 by the black pair. The auditors applied for the jobs and advanced as far as they could during the first visit. The application was considered a success only if the auditors were called back for a second interview or hired.

The results showed that 34 per cent of whites with no criminal record were called back, compared with only 17 per cent of those with a criminal record; 14 per cent of blacks without a criminal record were called back, compared to only 5 per cent with a criminal record. Notably, the black auditor without a criminal record received a smaller percentage of callbacks than the white auditor with a criminal record, suggesting the presence of substantial discrimination against blacks in general. Note that Pager found a greater disparity than that found in other audit pair studies in the employment realm. Pager's approach has one notable advantage: the black pair and the white pair were able to use identical sets of résumés, which would not have been possible had they been visiting the same employers (the résumés of test partners were similar but not identical). Some have also raised concerns about whether experimenters might have been influenced by the goals of the study to ‘find discrimination’. (This is the ‘experimenter’ effect that Heckman and Siegelman, 1993, discuss in the context of the Urban Institute audit studies and that social psychologists have long recognized.)

Bertrand and Mullainathan (2004) also try to measure the extent of race-based labour market discrimination using a slightly different audit strategy that avoids some of the potential pitfalls of direct applicant auditing. Employing a so-called correspondence test methodology, they submitted about 5,000 fictitious résumés in response to employment advertisements appearing in Boston and Chicago newspapers. Their experiment was designed to estimate the racial gap in response rates, measured by phone calls or e-mails requesting an interview. Random application of traditional black or white names to résumés ensures (a) that race remains the only component that varies for a given résumé and (b) that
heterogeneous responses to behaviour or appearance do not affect outcomes (as often occurs with human auditors). The Bertrand and Mullainathan paper differs from Pager's audit study in that no personal contact with the potential employer takes place in their experiment, so perceived problems with auditor behaviour are eliminated. Bertrand and Mullainathan find significant differences in callback rates for whites and blacks: ‘applicants with White names need to send about 10 résumés to get one callback whereas applicants with African–American names need to send about 15 résumés’ (Bertrand and Mullainathan, 2004, p. 3). Put differently, the advantage of having a distinctly white name translates into roughly eight additional years of experience in the eyes of a potential employer. Whites also appear to benefit much more than blacks from possessing the skills and attributes of a high-quality applicant and from living in a wealthier or whiter neighbourhood. (The difference in callback rates between high and low quality whites is 2.3 percentage points, while for blacks the difference is a meagre one half a percentage point.) Although these results represent compelling evidence of unlawful discriminatory conduct by employers, the question remains whether the markets are robust enough to reduce or eliminate the apparent disadvantage in the initial hiring process. Fryer and Levitt (2004) indicate that distinctive names do not disadvantage blacks for a variety of adult outcomes. They offer some potential arguments for reconciling their findings with those of Bertrand and Mullainathan (2004). First, if names are considered a noisy initial indicator of race, then they should have no effect once a candidate arrives for the interview. Second, if distinctively black names damage labour market prospects, one might observe more name changes than appear to occur. Finally, with only about ten per cent of jobs being secured through formal résumé-submission processes, the disadvantage of being screened out by certain employers may not be high when other employers and other job search paths remain open.

The combination of the audit studies and the better regression studies seems to tell us that (a) there are enough discriminators around for blacks to have to search harder to find employment, (b) there are enough non-discriminators around for the resulting unexplained earnings shortfall to be not very high, and (c) the unexplained earnings shortfall will overstate discrimination if other legitimate factors are omitted, but will understate the cost of discrimination to blacks because they bear the added search costs of the higher level of employer rejection and any attendant psychological burden that it imposes. To eliminate discrimination would narrow the unexplained earnings gap and remove the added search costs, but this would still leave a substantial unadjusted disparity in black and white earnings.

Statistical discrimination

A number of theoretical articles have explored whether statistical discrimination contributes to the black–white earnings gap (Arrow, 1973; Phelps, 1972). This seems unlikely. If, say, blacks are on average treated as their productivity would warrant, then as a class there should be no earnings shortfall, apart from the issue of underinvestment that was discussed above with reference to the Neal and Johnson paper. David Autor and David Scarborough (2004) explore the impact on the hiring and productivity of minority workers, using data from a large nationwide retail firm that changed from an informal worker selection process to one based on standardized testing in 1999. Given that minorities and underprivileged groups on average score lower on such standardized tests, one would expect that this change in the firm's hiring scheme would disadvantage minority workers.
The company originally used informal, paper applications to select candidates for entry level positions. Starting in June 1999, the firm began instituting a computer-based application system that included a personality test for selecting compatible and potentially productive candidates. Autor and Scarborough's sample contains information on test scores, worker demographics, termination date and termination reason (if applicable) for hires made between January 1999 and May 2000 in all the firm's outlets; their sample consists of 34,257 observations. The question they address is how the introduction of testing and the ensuing improvement in the firms’ applicant selection procedure affected minority hiring and productivity.

Autor and Scarborough show that if employers statistically discriminate before the test is introduced – that is, if they already use demographic characteristics as a signal for expected productivity of the candidate – then adding testing to the model does not hurt minority hiring but still increases the average productivity of both minority and non-minority workers. The empirical evidence supports this last scenario, revealing uniform increased productivity across demographic groups along with no negative effects on minority hiring.

While we must be careful not to extrapolate the Autor and Scarborough results too far from their context of entry level, near-minimum wage jobs, the paper suggests that before testing was implemented the retail firm either selected workers based on (a) some non-race proxy that was correlated (imperfectly) with productivity, or (b) statistically discriminated on the basis of race (in violation of federal law), which was itself (imperfectly) correlated with productivity. The evidence from this one firm confirms the intuition of many economists that statistical discrimination should not be unlawful since on average it should not disadvantage minority workers. One should query, though, whether the legal regime is nuanced enough to legitimize statistical discrimination while prohibiting intentional, animus-based discrimination. Judicial and jury determinations of such issues would presumably be subject to high levels of Type I (incorrectly finding discrimination) and Type II (incorrectly failing to find discrimination) errors.

**Sex discrimination in employment**

Many of the issues discussed above with respect to race discrimination are also relevant to other types of discrimination, including sex discrimination. First, there are questions about whether anti-discrimination law has helped the protected worker. Second, there are issues about whether discrimination can be accurately established. Almost all the groups that seek the aid of anti-discrimination law – minorities, women, the disabled, the elderly – have attributes that non-discriminatory employers might be legitimately concerned about. Under such circumstances, it is difficult to prove that under-representation of any of these groups is caused by discrimination rather than some legitimate factor. The original goal of employment discrimination law in the United States was to eliminate any gap between a worker's productivity and pay caused by discrimination. Today, some argue that the goal of mimicking the outcome of perfectly competitive labour markets is insufficient and that employment discrimination law should more aggressively pursue broader goals of social fairness that will enhance the economic status of disadvantaged groups beyond what a perfect market would provide. According to this view, women should be treated differently to ensure that their role in child-bearing does not disadvantage them in the labour market even if it imposes costs on employers.

Claudia Goldin and Cecelia Rouse (2000) offer an interesting illustration of establishing labour market
discrimination in the context of auditions and hiring of musicians for the major US orchestras. To test for sex discrimination in the hiring process, they exploit the changes in the audition process introduced by all major US orchestras in the 1970s and 1980s. Of particular interest for their study was the change to ‘blind’ auditions, which effectively hid the identity and gender of the applicant from the hiring committee for certain rounds of the audition process. Using audition and roster data spanning several decades and employing an individual fixed effect strategy, they found that the likelihood of female hiring and advancement was increased by the introduction of blind auditions.

More specifically, using audition data from the late 1950s to 1995, Goldin and Rouse found that in blind audition rounds women were as much as 50 per cent more likely to advance from preliminary to final rounds. Furthermore, the likelihood of women winning the finals increased by 33 percentage points if the final round was blind. Using official roster data from 1970 to 1996, they found that completely blind auditions – defined as auditions in which all rounds are conducted with a screen hiding the gender of the applicant – increased the likelihood of a women being hired by 25 per cent. Based on the roster data, blind auditions explain 30 per cent of the increase in female hiring and 25 per cent of the increase in overall female representation in the orchestras. There are, however, some caveats with respect to these findings: first, some estimates have relatively large standard errors that render them statistically insignificant; second, in one scenario – auditions with blind semi-finals – the effect on females is persistently strongly negative.

The issue of gender differences in aptitude, specifically aptitude in competitive environments, is explored in an article by Uri Gneezy, Muriel Niederle, and Aldo Rustichini (2003). Unlike previous studies that tried to explain the gender gap either through occupational self-selection due to differences in abilities and preference or through employer discrimination, Gneezy, Niederle and Rustichini explore the possibility of gender-differentiated performance in competition, which could ‘reduce the chance of success for women when they compete for new jobs, promotions, etc’. In a series of controlled experiments the authors examine the performance of men and women in a computerized maze game as they vary the incentive schemes and group composition for different treatments. They find that, while men receive a significant performance boost in competitive environments such as tournaments, the response of women in competitive environments is more nuanced: they do not significantly change their performance in mixed-sex tournaments, but they do increase their performance in single-sex competitions.

The authors find that under a piece-rate payment scheme men perform only slightly (and not significantly) better than women on average in terms of number of mazes solved. However, when the authors introduce their main competitive treatment of mixed-sex tournaments, they find that men increase their performance significantly, while women's performance remains relatively unchanged. While women do not seem to receive a performance boost in mixed competitive environments, Gneezy, Niederle and Rustichini also use single-sex tournaments to show that there are competitive situations where women increase their performance in response to competition. Both women and men significantly increase their performance in single-sex tournaments, suggesting that women do not dislike competition in general; rather, they dislike competing against men. To explain this, the authors also test for varying feelings of competence across gender. Indeed, once they allow men and women to choose the level of difficulty of the mazes that they are to solve, men choose a higher level of difficulty on average than women do. Whether such factors could explain different pay levels between male and female workers operating under merit pay systems – such as, the lower pay of female stockbrokers, which has been a
subject of sex discrimination litigation – is a question that will probably be further explored in the courtroom as well as in the academy.

Conclusion

Anti-discrimination law has generated a number of important social benefits. The elimination of the oppressive race code of the South has been a major benefit of law and policy, opening up all jobs to the most highly qualified candidates. The development of a strong anti-discrimination norm has been an important social asset, and one that merits preservation. To the extent that employers find it natural to be fair to all applicants and workers, the burdens on workers, courts, and employers will be lessened, to the benefit of all.

At the same time, anti-discrimination law has generated some unfortunate unintended consequences, some of which may even threaten the important anti-discrimination norm by undermining its widespread acceptance. I have already alluded to the perverse effects of the situation where an employer might avoid hiring a particular protected worker because of the presence of a governing anti-discrimination law, as some have argued with respect to the protections mandated by the Americans with Disabilities Act. In a regime where the difficulties in ascertaining the existence of discrimination lead to Type I error, firms might find that they are being compelled to hire and compensate certain workers at wages above their levels of productivity. Similarly, as with any negligence-type standard where being adjudicated to have been below a certain level of care can lead to substantial damage awards (including punitive damages), firms have an incentive to take costly measures to be above the threshold that might lead to a finding of discrimination. Tests that may be useful in selecting a high-quality workforce may be avoided if they have, or are thought to have, a disparate impact on certain protected workers that could provide the basis for costly litigation. Note that all these employer adjustments involve costs, but they would appear to involve the benefit of enhancing the employment of groups that are relatively disadvantaged. One might argue that this is a positive development in terms of distributive justice even if it is not actually furthering a corrective justice rationale of eliminating discrimination.

But of course if costs are being imposed on businesses, they will have an incentive to avoid them in the cheapest way possible, which might be through compliance with the legal mandates but could also involve efforts to circumvent the legal mandates. Indeed, because movements in either direction from the ‘non-discriminatory equilibrium’ can lead to litigation by whites or blacks or males or females, firms may at times take measures to avoid the litigation risks by using temporary help or by sending their jobs offshore. If these issues were to arise in a racial discrimination context, firms might decide to move offices out to suburban areas or locate where the requirements for hiring black workers would be lessened by the smaller minority benchmark percentages in the relevant labour markets.

As Donohue and Siegelman (1991) noted, the nature of employment discrimination litigation has changed very dramatically in a way that was not anticipated and which may not be entirely desirable. Specifically, most early cases of discrimination complained of failure to hire. These suits tended to open up whole industries or occupations to formerly excluded workers, thereby furthering the objectives of the law. Over time, however, there has been a massive shift in the direction of discharge lawsuits where protected workers claim that they were discriminated against when they were fired. This change sometimes means that low productivity workers can threaten Title VII litigation to hold up an employer for a higher severance package when they are fired for cause. Even worse, firms may find that, at the
margin, it is safer not to hire additional protected workers because, at the margin, firms face greater risks from possible, future wrongful discharge discrimination lawsuits than from failure to hire cases. An overall assessment of the impact of anti-discrimination law needs to examine not only the obvious benefits in the form of better treatment of workers through greater professionalization in hiring and human resource management and the productivity enhancements from selecting workers in non-discriminatory ways, but also the array of costs in terms of non-optimal employee selection and retention and firm location decisions, more costly selection processes, and greater litigation costs and legal consulting fees. When every discharge carries the potential for an award of punitive damages, the costs of getting rid of even quite poor workers becomes high. Thus, it may not be surprising that, once the extreme forms of discriminatory conduct were eliminated in the wake of the initial passage of the 1964 Act, further efforts at ratcheting up enforcement of anti-discrimination law seem not to have generated added benefits. Similar arguments about the costs of unintended consequences apply to anti-discrimination enforcement in the realms of mortgage lending, consumer purchases, policing and fighting terrorists.

**How to cite this article**

Antidumping refers to a legal statute that allows for a remedy (typically an import duty) to offset the effects of dumped imports. Under the General Agreement on Trade and Tariffs/World Trade Organization (GATT/WTO) rules, two tests must be satisfied before a country may impose an antidumping duty on subject imports. First, the imports must be shown to be sold at price that is ‘less than fair value’. Second, the dumped imports must be shown to have caused or threaten to cause ‘material’ injury to a domestic industry.
all AD activity was confined to four major countries/regions – the United States, the European Union, Australia and Canada (Finger, 1993). By the early 1990s countries with newly adopted antidumping statutes accounted for almost one-quarter of AD cases and, since the mid-1990s, new antidumping countries have accounted for well over half of AD complaints (Miranda, Torres and Ruiz, 1998; Prusa, 2001). These new antidumping countries are also far more likely to make an affirmative determination and, consequently, now account for far more than half of all measures in place. Since 1980 GATT/WTO members have filed more complaints under the AD statute than under all other trade laws combined. Worldwide, more AD duties are now levied in any one year than were levied in the entire period from 1947 to 1970.

An antidumping investigation generally proceeds as follows, though there are differences across countries. First, an investigation is initiated when an interested party (often a domestic industry that competes with the imported product) files a petition with the appropriate government agency contending dumping of a particular product(s) from certain import-source countries. The administering government agency (or agencies) then collects data from petitioners and foreign firms that are alleged to be the source of dumped imports and calculates the extent to which imports have been dumped and have injured the domestic industry. Findings of dumping and material injury lead to the imposition of an antidumping duty, which is often equal to the per cent difference between the price of the dumped imports and fair value (that is, the dumping margin). Under WTO statutes, antidumping cases must be reviewed at least every five years to determine whether an antidumping remedy is still appropriate given recent import activity in the subject product.

It is important to understand that antidumping arises from legal concepts. Thus, the meaning of ‘less-than-fair-value’, causation, and material injury are examined from a legal perspective where previous rulings establish precedence in interpreting the legal definitions. Legal bodies have been active in adjusting these statutes over time. The GATT/WTO antidumping code has undergone significant revisions in nearly every negotiating round, and most countries with these statutes also make periodic legislative changes to their antidumping codes. Many economists have noted that the increase in antidumping activity after these legislative changes is not coincidental. For example, the Tokyo GATT Round contained numerous amendments to the antidumping statute. Of particular importance was the broadening of the definition of the ‘less-than-fair-value’ concept to capture not only price discrimination, but also sales below cost. Cost-based allegations now account for between one-half and two-thirds of US AD cases (Clarida, 1996); an even greater share of EU cases is prosecuted using cost-based methodology (Messerlin, 1989).

Given its legal foundation, perhaps it is not surprising that the economic rationale for antidumping statutes is far from clear. A possible rationale is to address predatory pricing practices, where foreign firms are pricing low to induce exit by the domestic firms, allowing monopoly prices in future periods. Economists generally agree that predatory pricing will lead to a welfare loss for a country, but they are sceptical about how often such a strategy is feasible or successful. More importantly, antidumping statutes and practices do not apply the stringent standard used by antitrust (or competition) agencies to determine if pricing is predatory, that is, pricing below marginal cost. Instead, depending on the typical definitions of fair value used by agencies, simple price discrimination across markets or pricing below a level that would return a significant profit to the foreign firm will lead to findings of dumped imports. Such practices are not generally seen as anticompetitive and, in fact, there is often clear tension between antidumping and competition policy. For example, Staiger and Wolak (1992) have shown that domestic
firms can use AD actions to punish foreign firms for refusing to join in collusive actions to raise prices, including the enforcement of price-fixing cartels; examples of price-fixing behaviour in conjunction with AD activity include Ferrovandium and DRAMS. Thus, economists generally believe there is little connection between national welfare considerations and antidumping protection (Stiglitz, 1997). Instead, most economists find evidence that antidumping activity is motivated by the same political economy considerations that lead to other forms of trade protection. While the studies documenting this vary in what proxies they construct to measure political pressure, all find that such non-statutory factors are significant in ultimate antidumping decisions. These studies include Moore (1992), DeVault (1993) and Hansen and Prusa (1996; 1997). Industries with production facilities in politically important districts fare better. There is also some evidence that financial contributions to politicians by industries seeking antidumping protection improve the chance of an affirmative determination. In a related vein, these studies find that antidumping duties are more likely to be levied against particular trading partners. Blonigen and Bown (2003) argue that this finding does not so much reflect a bias against certain countries, but rather reflects that the inability of certain countries to effectively use the threat of retaliation to deter others from using antidumping against it.

In addition, studies of US antidumping activity have found that changes in legal statutes and agency discretion have led to ever greater dumping margins and the likelihood of determining material injury. For example, Hansen and Prusa (1996) show that the US legal change to allow government agencies to consider the all import sources named in an investigation cumulatively (not individually) makes a material injury decision much more likely. This US legal change was later adopted by WTO antidumping statutes in the Uruguay Round and led to both a dramatic increase in the incidence of multi-country cases and also a sharp increase in affirmative determinations (Hansen and Prusa, 1996; Tharakan, Greenway and Tharakan, 1998; Irwin, 2005). Another example is the documentation by various studies of how the antidumping statutes allow substantial latitude to agencies in how they practically determine dumping margins. Blonigen's (2006) statistical analysis finds that changes in agency discretionary practices is the primary factor behind the rise in average US dumping margins from around 15 per cent in the early 1980s to 60 per cent by 2000.

**Direct economic effects of antidumping statutes and remedies**

The direct economic result of antidumping remedies is to reduce import flows. Such import declines can happen once an investigation is begun and when antidumping remedies are uncertain. In addition, Staiger and Wolak (1994) emphasize that about half the trade impact occurs before the final determination. They argue that trade impact is sufficiently large for the benefits accruing during the investigation to often exceed the costs of filing the petition. Ethier and Fischer (1987), Fischer (1992), Reitzes (1993), and Prusa (1994) also emphasize the dampening impact on trade created by the threat of AD investigation.

From a welfare perspective, a number of studies have documented that domestic firms can gain from such trade-dampening effects, including Hartigan, Kamma and Perry (1989), Blonigen, Tomlin and Wilson (2004), and Konings and Vandenbussche (2005). However, the latter paper shows that such positive gains are eliminated when foreign firms locate production of the investigated product in country
and, thus, avoid the antidumping duties. Prusa (1997) also documents the substantial trade diversion effects that can take place from investigated import sources to non-investigated sources, which provides another reason why such antidumping remedies may not benefit the domestic industry. Other studies have used computable equilibrium analysis to examine the total welfare consequences of antidumping remedies for a country. As is typical of trade policy welfare analysis, such losses to consumers are typically estimated to outweigh the gains to the protected producers for antidumping protection. For example, using a computable general equilibrium model, Gallaway, Blonigen and Flynn (1999) estimate that the cumulative effect of all antidumping duties in place leads to an annual four billion dollar welfare loss for the United States. This figure places this form of trade protection as second only to the restrictive and comprehensive quotas on textiles and apparel (Multifiber Arrangement) in terms of welfare costs.

Indirect economic effects of antidumping statutes and remedies

Beyond these typical trade and welfare considerations, economists have pointed to a number of features of antidumping programmes that may cause a greater range of ancillary (or indirect) effects that are often unique to this form of trade protection. In fact, this is where the bulk of recent economic literature has centred its attention, and insights often come from thinking about strategic considerations applying game theoretic techniques.

Such issues are pervasive in analysing the decision to file an antidumping case and its likely chance of success. A foreign industry can almost guarantee it will not be subject to antidumping duties if it charges sufficiently high prices in its export markets. On the other hand, a domestic industry has incentives to look ‘weak’ to make an injury determination more likely, which could lead it to charge higher prices (produce less) than optimal, or lay off more workers than it otherwise would. Ethier and Fischer (1987), Fischer (1992), Reitzes (1993), and Prusa (1994) are examples of applied game theory pieces that document these possible strategic decisions by domestic and foreign firms to influence future antidumping outcomes. Anderson (1992; 1993) examines the potential interdependence of antidumping with another form of trade protection: voluntary export restraints (VERs). The artificial scarcity created by the VERs generates rents for foreign firms that are typically divided up by their market shares. This perversely gives the foreign firms incentives to ‘dump’ their products to garner larger market shares, which makes antidumping investigations and remedies more likely.

The strategic interactions described above are non-cooperative in nature, but a number of papers have examined how antidumping can elicit various forms of cooperative strategic behaviour. These studies primarily provide theoretical analysis, showing how antidumping law can facilitate or sustain collusive cartel pricing by foreign and domestic firms; such studies include Staiger and Wolak (1989), Prusa (1992), and Veugelers and Vandenbussche (1999). Taylor (2004) and Zanardi (2004) provide empirical examinations of collusive behaviour in antidumping activity using US data.

Strategic interactions surrounding antidumping petitions may also occur amongst domestic firms. Cassing and To (2004) show that the decision by a domestic firm to join an antidumping petition can signal its efficiency to other firms in the market. Thus, for example, some domestic firms may not join a petition to signal to others that they have low costs.

Once antidumping remedies are in place, other strategic reactions are possible too. As mentioned above,
antidumping: The New Palgrave Dictionary of Economics

A foreign firm can ‘jump’ the antidumping duties and relocate its production to either the domestic market or to a third country that is not subject to the duties. Belderbos (1997) and Blonigen (2002) document significant tariff-jumping of antidumping duties in Europe and the United States. Interestingly, if foreign firms differ in their ability to make such investments, then antidumping might particularly burden firms who cannot make such adjustments. Ironically, this means the foreign firms who are most able to ‘jump’ the AD duty potentially have an incentive to encourage antidumping actions (Blonigen and Ohno, 1998).

The ability of firms to reduce their antidumping duties in subsequent administrative reviews also provides interesting incentives to firms. Such reviews examine recent data to recalculate antidumping duties, which creates a dynamic environment for price setting by the foreign firm. Blonigen and Park (2004) develop a model of dynamic pricing decisions by foreign firms facing the possibility of antidumping duties and subsequent recalculations in future periods. They first show that, if antidumping duties are a certainty when a foreign firm dumps, then the only firms that will dump care very little about the future (high discount rates). Over time the punitive antidumping duties will cause them to dump even more. However, if antidumping remedies are uncertain, foreign firms that have ex ante low expectations of antidumping remedies will quickly reduce their dumping once, to their surprise, they become subject to antidumping duties. Blonigen and Park confirm these hypotheses using data on US antidumping investigations. In a related paper, Blonigen and Haynes (2002) find that foreign firms subject to antidumping duties alter their behaviour to fully pass through exchange rate changes and also pass through greater than 100 per cent of the antidumping duty onto the prices in their export market. Blonigen and Prusa (2003) provide a detailed review of the economics literature on antidumping and also point towards what they consider fruitful areas for future research. These include the treatment of antidumping in competition policy, effects on downstream industries and import/export companies, and comparisons of antidumping statutes across various WTO member countries. The U.S. Antidumping and Countervailing Duty Database and the Global Antidumping Database should play an important role in facilitating future research in antidumping.

Anti-poverty programmes in the United States have received much attention from the economics profession since the 1970s. Economists have studied their effectiveness in reducing poverty and increasing well-being among the poor, their rationale and goals, and trends in their caseloads and expenditures. Scholars have also extensively studied the effects of anti-poverty programmes on a wide range of individual and family behaviours.

Rationale and design issues

Economic theory suggests that the extent of redistribution should be constrained by its direct and indirect costs, including disincentive effects. The emphasis in the United States has been on programmes that emphasize employment as well as in-kind rather than cash redistribution, and that provide benefits to populations with special needs. Research on their effects has shown them to decrease poverty rates and the poverty gap but to have labour-supply disincentives as well. Reforms to the main cash programme in the 1990s have increased earnings and employment.

Anti-poverty programmes are generally considered to arise from altruism on the part of non-poor voters, who wish to transfer resources, for charitable reasons, to those who have low incomes or assets. Such charitable support is generally considered to be suboptimally provided if left to the private sector because of the free-riding problem that arises when one individual's contribution to the poor makes other givers better off, so individuals have an incentive to let others contribute rather than contribute themselves.

However, the exact nature of the preferences of the non-poor – let us call them voters, since the United States is a democracy – are not well understood. In the classic utilitarian model, the social welfare function equals the sum of individual utilities and the marginal utility of income is assumed to decline with income, so that a dollar redistributed from a high-income person to a low-income person raises social utility. One issue with this framework is whether the ‘weights’ that the voters assign to the poor are the same as marginal utility of income weights, and today most analysts assume those weights to deviate in an arbitrary way and to simply reflect voter preferences that will vary from group to group and from country to country. Another important distinction is whether the voters desire to increase the utility of the poor per se, as the utilitarian model implies, or to increase their consumption of specific goods like food, housing, and medical care. Redistributing in the latter fashion, resulting in what are termed ‘in-kind’ transfers, is quite common in practice, and economists have often assumed that it implies that voters are paternalistic in the sense that they wish to override the spending preferences of the poor themselves. Redistributing purely in the form of income, for example, would allow recipients to allocate the transfer in a way that maximizes their utility as they see it. Another rationale for in-kind transfers is that they induce only those with the highest marginal utility of consumption of those goods to accept such transfers, which induces a desirable (from the voter's point of view) selection from the low-income population to those who need it most (Nichols and Zeckhauser, 1982; Blackorby and Donaldson, 1988), and yet another is that they reduce the incentive of the recipient to alter behaviour to increase later transfers (Bruce and Waldman, 1991).

Whatever the preferences of the voters, the main issue in models of optimal provision of anti-poverty benefits to the poor is the trade-off between the benefits of redistribution and the direct and indirect costs of the transfer. The direct costs arise because taxation has its own resource cost and the indirect costs arise because the transfer distorts the behaviour of the recipients. As in the classic models of taxation, lump-sum transfers are not possible and so transfers alter the prices of various goods in the utility function. In the well-known Mirrlees (1971) model, the main margin examined is work effort, which is reduced by transfers, and optimal redistribution proceeds up to the point where the marginal benefits of additional redistribution are counterbalanced by the marginal losses arising from reductions in work effort. However, one of the main areas of research on anti-poverty programmes, particularly those that are empirical in nature, has been on other possible margins of adjustment by programme recipients. Transfers may reduce incentives to invest in human capital, reduce incentives to save if assets are taxed by the programme, increase incentives to have additional children if benefits are tied to family size, change incentives to marry if marital status affects benefits, or increase incentives to migrate from one jurisdiction to another to obtain higher benefits if benefits vary within a country. For in-kind programmes, there is also potential ‘leakage’ in the consumption effects. For example, giving a family either a lump-sum amount of food or a subsidy to the price of food may lead them to reduce their own expenditures on food in order to spend more on other consumption items.

The prototype of a transfer programme that aims to balance redistribution and disincentives is the
negative income tax (NIT) (Watts, 1987). In an NIT, recipients who have no income receive a maximal benefit but the size of the transfer declines as income rises. Thus those with lower incomes receive greater benefits than those with higher incomes, as most models imply should occur, but the rate at which benefits are reduced as income rises is generally taken to be less than 100 per cent. This provides some incentive to work, and work disincentives are therefore controlled by the rate of benefit reduction. A transfer system with a 100 per cent reduction rate, particularly one that extends relatively high into the income distribution, is said to create a ‘poverty trap’ because individuals cannot escape poverty through modest increases in income. The first formal demonstration of the optimality of an NIT was provided again by Mirrlees (1971), who showed that such a programme results from an optimal utilitarian model. This general paradigm applies to the other margins mentioned above as well, for in each case a programme can be designed to provide the highest benefits to those with the lowest resources while paying attention to the effect of the programme on the price of changing behaviour (undertaking human capital investment, saving, and so on). An important modification of the Mirrlees models appears in Diamond (1980) and Saez (2002), who showed that consideration of the ‘extensive’ margin of work – namely, the decision to work at all rather than the decision of how many hours to work, which was the focus in the Mirrlees model – can lead to earnings subsidies, where the marginal ‘tax rate’ on earnings at the bottom of the income distribution is negative rather than positive for some range. The Earned Income Tax Credit in the United States and the Working Families Tax Credit in the United Kingdom are important examples of such earnings subsidies.

Finally, a benefit-provision issue that economists have studied is the relative merits of redistribution by a central government versus local governments within a country. For many years it was assumed that the utility of the poor in all jurisdictions should affect the utility of voters in all jurisdictions equally, which leads to a central government programme. But Pauly (1973) and others have argued that local voters care more about the poor in their own jurisdictions, making redistribution partly a local public good, although they may care to some extent about the poor in other jurisdictions as well. This leads to a mixed central–local system in which the central government subsidizes local governments because of the limited interest of all voters but allows localities to spend on redistribution out of their own resources as well. This leads to subsidy mechanisms such as block grants, matching grant programmes and related funding mechanisms. This structure is found in the United States but also in some European countries.

Anti-poverty programmes

There are a large number of anti-poverty programmes in the United States whose structure and expenditure have changed over time (Moffitt, 2003). We shall ignore Social Security, which has a major impact on poverty rates of the elderly but which is generally considered to be a social insurance programme rather than a means-tested transfer programme. The most well-known and heavily studied programme, and that which historically most resembled an NIT, is the Temporary Assistance for Needy Families (TANF) programme, which was called the Aid to Families with Dependent Children (AFDC) programme prior to 1996. The TANF programme provides monthly cash benefits to families with low income and assets, but primarily to those headed by a single parent (mostly single mothers). The benefit-reduction rate in the programme varies across states but is most often around 50 per cent. However, the TANF programme also has some non-NIT features – specifically, it has work requirements that mandate
that most able-bodied parents work at least some minimum number of hours per week as a condition of receiving benefits, and time limits, which stipulate that parents can receive benefits for only a limited number of years over their lifetimes. These latter provisions were enacted in 1996. While the AFDC programme was one of the leading US anti-poverty programmes in the 1960s and 1970s, when its caseloads and expenditures were among the largest of US programmes, in 2007 it ranked only sixth in terms of expenditure and fifth in terms of caseload (Moffitt, 2007). It is smaller than the Medicaid programme, which provides medical subsidies to the poor; the Supplemental Security Income (SSI) programme, which provides benefits to poor families with aged adults and disabled adults and children; the Earned Income Tax Credit (EITC), which provides tax credits to working families; Food Stamps, which provides food subsidies to the poor; and housing programmes for the poor. Per capita expenditures on AFDC–TANF have steadily declined since the late 1970s, whereas those on the other programmes have grown by amounts much greater in magnitude. In 2007, total real per capita expenditures in the largest means-tested transfer programmes in the United States had more than quadrupled since 1968 and had grown by 60 per cent just since 1990 as a result of the growth in many of these programmes.

The Medicaid programme, the largest programme in the United States, is a diverse programme covering several different populations. The four primary groups served are low-income single mothers and their children; the low-income elderly; the low-income disabled; and individuals in nursing homes or long-term care with low income and assets. Expenditures and caseloads in the programme grew rapidly in the late 1980s and early 1990s as a result of expansions of eligibility for low-income mothers and children and growth of disabled recipients, and have continued to grow secularly because of growth in the demands for long-term care of the elderly. The United States does not have national health insurance and the size and growth of the Medicaid programme partially reflects that fact. With a few exceptions in certain parts of the programme, there is no benefit-reduction rate in the programme; either the full package of benefits is provided or none at all.

The SSI programme pays cash benefits to low-income individuals who are blind or disabled, and to the low-income elderly. The programme also saw very rapid growth in the early 1990s as a result of increases in disabled, child, and non-citizen recipients. The definition of disability for adults is quite stringent; 60 per cent of applications are denied. The disability definition for children is more elastic and has fluctuated in stringency over time. The programme has a nominal 50 per cent benefit-reduction rate. The EITC also grew rapidly in the late 1980s and early 1990s, while the Food Stamp programme grew most rapidly after its introduction in the late 1960s and early 1970s, but also most recently (since 2000). The EITC has a subsidy rate of up to 40 per cent and a maximum clawback rate of 21 per cent, while the Food Stamp programme has a nominal 30 per cent benefit-reduction rate.

Other important programmes include those covering housing, child care and training programmes. Housing programmes, which have a typical benefit-reduction rate of 30 per cent, grew most rapidly in the late 1970s and early 1980s, and have seen only modest growth since that time. Child care subsidies in the United States are spread over several different programmes serving overlapping populations, including the welfare poor but also the ‘working’ poor. Expenditures have grown modestly since 2000 as the need for employment support has become increasingly recognized. Included in the child care framework is the Head Start programme, whose goal is to assist child development in pre-school children of low-income families but which also serves a child care function. The United States spends relatively little on training programmes, and has changed the name and nature of its programme for
adults several times since the 1970s in an attempt to make the programmes more effective. Perhaps the most popular programme is the Job Corps, a high-cost residential-based programme for disadvantaged young men and women.

Several patterns can be discerned in the US transfer programme system. First, in-kind transfers are preferred to cash transfers. The only programme that is a pure cash transfer programme is the AFDC–TANF programme, which has declined in importance because of its unpopularity and is now coupled with work requirements in any case. The most popular programmes are those that subsidize medical and food expenditures; those which subsidize housing and child care expenditures are large as well. Second, subsidies that serve specialized populations with specific identifiable needs are preferred to subsidies based on low income per se. The SSI programme, which is cash in nature, is the best example of this preference. However, even the EITC could be argued to fit this category, for it provides cash but only to a specific population viewed as meritorious, namely, low-wage workers. Third, an increasing emphasis on employment is apparent. The EITC reflects this emphasis as do the recent reforms in the AFDC–TANF programme and increases in child care subsidies. Fourth, US voters dislike providing subsidies to low-income single-mother families, who are viewed unfavourably because of US views towards marriage. All four of these features are in explicit conflict with the original idea of an NIT as espoused by Milton Friedman, Robert Lampman, James Tobin, and others, who saw the ideal transfer programme as one that provided only cash benefits, on the basis of income only, and without preference for family structure or type.

Research findings on the effects of US anti-poverty programmes

One overriding issue of interest in research on US anti-poverty programmes is whether such programmes have, in fact, reduced poverty. The evidence indicates that they have (Scholz and Levine, 2001). In 1997, the system of means-tested transfer programmes in the United States reduced the poverty rate of families from 29 per cent to 26 per cent, a modest amount. However, the programmes also raised the incomes of many poor families even if not by enough to cross the poverty line, for the programmes filled in 27 per cent of the poverty gap (defined as the total dollar gap between the poverty line and the incomes of poor families). The most important programme in reducing poverty was Medicaid; SSI and the EITC were also important. It is often noted that these estimates should be considered to be an upper bound for the true effect of transfer programmes on poverty because the work disincentives of the programmes themselves cause a reduction in income, which widens the poverty gap and increases the poverty rate to some offsetting extent.

In addition to this issue, there has been a very large amount of research on the behavioural effects of US anti-poverty programmes. By far the most research has been conducted on the AFDC–TANF programme, where the primary focus prior to 1996 was on its effects on labour supply, marriage and fertility, and a few other behaviours (Moffitt, 1992). Most research on labour supply indicated, as economic theory would predict, negative effects of the programme as a whole. However, the effects of reducing the benefit-reduction rate have been shown to be mostly zero or negligible, with the general interpretation being that such changes bring in new recipients who experience labour-supply reductions that offset the labour supply increases of those initially on the programme. Research on marriage and fertility effects of AFDC has shown mostly small but non-zero effects in reducing marriage and
increasing childbearing. Research conducted on the effects of the 1996 reform of the programme (Blank, 2002; Moffitt, 2003; Grogger and Karoly, 2005) has shown the reform, whose major elements were work requirements and time limits, to have had positive effects on average employment, earnings, and family income and negative effects on welfare usage. However, some research also suggests that there is a group of very disadvantaged families who were made worse off by the reform. The research also has shown the reform to have had little if any effect on marriage and fertility behaviour and to have had modest effects, if any, on children in low-income families.

There has been a fair amount of research on other programmes as well. The Medicaid programme appears to have modest negative effects on labour supply and expansions in the programme have led to ‘crowdout’ of private health insurance, but the programme has also been shown to have had many favourable effects on health, particularly that of children (Gruber, 2003). Research on the SSI programme has focused particularly on reasons for fluctuations in the size of the caseload, but has also concerned work incentives, where both benefit-reduction rates and other employment-incentive programmes have been shown to have had little effect (Daly and Burkhauser, 2003). Research on child care programmes have shown them to have had positive effects on female employment, and Head Start has been shown to have some positive effects on child outcomes, but which fade out over time (Blau, 2003). Work on training programmes has shown them to have different effectiveness for different groups, with several low-cost programmes found to be effective in increasing earnings for single mothers and with the high-cost Job Corps programme found to be effective for disadvantaged youth, but with no type of programme having been found to have a significantly positive rate of return for adult men (Lalonde, 2003).

doi:10.1057/9780230226203.0047
Antitrust enforcement is the process whereby a more competitive environment is created through the prohibition of certain practices deemed illegal by antitrust laws. Restraints of trade such as price-fixing and bid-rigging are prohibited in the United States under section 1 of the Sherman Act of 1890 and in the European Union under article 81 of the Treaty of the European Communities of 1999. Practices designed to create monopolies (such as predatory pricing and tying) are prohibited in the United States under section 2 and in the European Union under article 82. Mergers that are harmful to competition are prohibited in the United States under section 7 of the Clayton Act of 1914 and in the European Union under article 2(3) of the Merger Regulation. Although this article adopts a US focus, much of what is described is applicable to many OECD countries. (For a more general treatment on antitrust policy, see Motta, 2004, for the European Union and Viscusi, Harrington and Vernon, 2005, for the United States.)

Detection of antitrust offences
Enforcement can involve three stages: (a) discovery and evaluation of a possible antitrust violation; (b) prosecution when it is deemed there is a violation; and (c) levying of penalties and enacting of remedies when prosecution is successful. Antitrust cases can arise in a variety of ways. With a recent exception noted below, cartels are generally discovered not by the antitrust authorities but rather by customers, employees, and even competitors. Though not yet widely used, economic and econometric methods for detecting collusion include determining whether: (a) firm behaviour is inconsistent with competition; (b) there is a structural break in behaviour; (c) the behaviour of suspected colluding firms differs from that of some benchmark competitive firms; and (d) a collusive model fits the data better than a competitive model (Harrington, 2006). In contrast, prospective merger cases are brought by the participants themselves to the antitrust authorities, as mandated by the Hart–Scott–Rodino Act of 1976. In evaluating a proposed merger, the primary considerations are the extent to which it would raise price and whether there are offsetting cost savings.

Antitrust penalties

In the case of price-fixing, the government levies fines at the corporate level which, as a result of the Sentencing Reform Act of 1984, can be as high as twice the gross pecuniary gain of the defendant or twice the pecuniary loss of the victims (though a Supreme Court decision in 2005 has since put these guidelines into jeopardy). The most significant financial penalty comes from private damages which, due to the Clayton Act, allow direct buyers to receive compensation equal to three times the damages. At the individual level, the government imposes fines and prison sentences; since 1970, 53 per cent of convicted individuals have been imprisoned (Gallo et al., 2000). The use of government fines is common in many other countries, although prison sentences and civil damages are unique to the United States and Canada.

Are these penalties optimal? An optimal penalty is one that deters only those activities that are welfare-reducing. If the gain to the offenders is $g$, the loss to other agents is $l$, the probability of being penalized is $p$, and the penalty is $f$ then optimality requires: $g - pf \geq 0$ if and only if $g \geq l$ (Polinsky and Shavell, 2000). Therefore, the optimal penalty is $f = l/p$. In practice, private damages are calculated as $(P_c - P_{bf})Q_c$ where $P_c$ is the observed (collusive) price, $Q_c$ is the number of units sold, and $P_{bf}$ is the ‘but for’ price, that is, the price that would have been charged but for collusion. $P_c - P_{bf}$ is referred to as the ‘overcharge’. A major source of contention in many price-fixing cases is the determination of $P_{bf}$, for which reduced-form estimation methods are largely deployed with the use of data encompassing both the cartel and non-cartel regimes. The ‘before and after’ approach is quite common and entails estimating: $P(t) = \delta + \beta X(t) + \gamma V(t) + \epsilon(t)$ where $P(t)$ is price, $X(t)$ is a vector of demand and cost shifters, and $V(t)$ is a dummy variable that equals one in those periods that firms were colluding (Page, 1996). If $\hat{\delta}$ and $\hat{\beta}$ are the parameter estimates, then $P_{bf}(t) = \hat{\delta} + \hat{\beta} X(t)$. Since damages, as calculated in practice, ignore deadweight loss, penalties are neither optimally punitive nor compensatory: $g < (P_c - P_{bf})Q_c < l$. Government fines also suffer from this deficiency as they tend to be proportional to sales, $P_cQ_c$.

Of course, if collusion serves only to reduce supply, then $l > g$ and thus we should prevent all collusion.
in which case \( f \geq g / p \) is desired. As cartels continue to form, penalties clearly fall short. But how far away are they from being an effective deterrent? In practice, cases are largely settled out of court and single (not treble) damages are typical (Lande, 1993). For international cartels over 1990–2003, Connor (2004) calculates private and public recovery in the United States was only 115 per cent of damages. Bryant and Eckard (1991) infer from observed cartel lengths that the chances of a price-fixing cartel being indicted in a 12-month period is 11–15 per cent. Though that estimate relies on a properly specified functional form for the distribution on cartel lifetimes, it is safe to say that the probability of a cartel being discovered and paying penalties is well below one, so that financial penalties are woefully inadequate. What may be more effective is the use of prison sentences (Werden and Simon, 1987).

Although remedies have been used in price-fixing cases (for example, a ten-year consent decree in 1994 placed restrictions on announcements of future price changes by airlines), they are typically more important in merger and monopolization cases. Some proposed mergers receive government approval only after restructuring, such as the selling of assets that, if retained by the newly merged firm, would significantly harm competition. In rare cases, the authorities seek to prevent the merger entirely. In the case of monopolization, remedies may be either behavioural or structural. Behavioural remedies could, for example, require a firm to license intellectual property to competitors (as with Xerox) or prohibit certain contractual arrangements (as with Microsoft). Structural remedies are typically quite draconian and accordingly rare. Notable examples include the break-up of Standard Oil in 1911 and AT&T in 1984. A lower court initially ordered Microsoft to be broken into two companies – one with the operating system and the other with applications – though it was later remanded by the US Court of Appeals, and the Department of Justice (DOJ) stopped pursuing it as a remedy.

Corporate leniency program

One of the most significant innovations in antitrust enforcement in recent years is the 1993 revision of the DOJ's Corporate Leniency Program and the institution of a similar programme by the European Commission in 1996. The first member of a cartel to come forward and cooperate receives full amnesty with respect to government penalties and liability for only single damages. As a condition of entering the programme, company representatives must answer an ‘omnibus question’ which asks them whether they know of any collusion in other markets. Failure to truthfully answer that question results in the loss of all amnesty. This policy has proven useful for both the discovery and the prosecution of cartels. Under the standard repeated game framework, a leniency programme affects the stability of collusion through the usual equilibrium condition: the expected payoff from continuing to collude must be at least as great as the payoff to a firm from (optimally) cheating on the cartel. (The discussion here is based on Harrington, 2005; see also Motta and Polo, 2003, and Spagnolo, 2003.) More leniency enhances the payoff to cheating because a firm that does so can simultaneously apply for amnesty and thereby reduce expected penalties. However, leniency also affects the expected collusive payoff because firms anticipate the possibility of using the programme in the future. More leniency lowers penalties in the event that leniency is received and thus can raise the payoff from continuing to collude. But it is also possible that waiving a higher fraction of penalties increases future expected penalties. The reason is that there can be two equilibria: one in which all firms apply for amnesty and one in which none does. The latter can Pareto-dominate because only one firm can receive amnesty and use of the programme...
results in certain conviction. More leniency can destabilize the Pareto-preferred equilibrium in which all firms refrain from using the programme because it becomes too attractive for a firm to apply (given that other firms do not). Although there are then several countervailing forces, it is generally optimal to provide some leniency, and conditions are not too restrictive for it to be optimal to waive all penalties.

**Intensity of antitrust enforcement**

An enforcement policy is described not just by the types of cases pursued but also by its intensity. One might expect the socially optimal level of enforcement to vary with economic activity as, for example, there are more merger notifications during booms and possibly more cartels during periods of weak demand. Furthermore, government preferences regarding the level and focus of enforcement may vary with the incumbent presidential administration.

The budgets of the DOJ and the Federal Trade Commission are indeed increasing in GDP (Kwoka, 1999) but antitrust case activity is counter-cyclical (Ghosal and Gallo, 2001). Although most studies do not find case activity to be related to the administration's political party, Ghosal (2004) shows that this is due to aggregation and mis-specification. He disaggregated data for 1958–2002 into criminal and civil cases and allowed there to be a structural break in the relationship between the usual independent variables – such as GDP, the DOJ's budget, and the president's political party – and the number of DOJ cases. Reasons for a break comprise the growing influence among economists and judges of the Chicago School – which argued that a number of previously considered antitrust offences may be profitable for firms to pursue for competitive reasons – and the fact that the Supreme Court had a two-thirds majority of Republican-nominated justices starting in 1972. Both of these forces would give less credence to certain practices – such as vertical restraints and monopolization practices – being treated as antitrust violations. A break in the number of civil cases (such as mergers and vertical restraints) occurred around the mid-1970s, which resulted in a significant decline, while a significant rise in the number of criminal cases (collusion) occurred around the late 1970s. There is also a post-regime rise in polarization between Republican and Democratic presidential administrations with Republicans pursuing more (less) criminal (civil) cases.

**Impact of antitrust enforcement**

Is enforcement having an effect? This is a difficult question for which hard facts are lacking, and sharply divergent views have been expressed. (See Baker, 2003, and Crandall and Winston, 2003; the latter should be read with caution as their review of some literatures is seriously deficient – Kwoka, 2003, and Werden, 2004, provide a critique.) With respect to the most egregious offence – namely, collusion – we pose three questions. Do cartels actually charge higher prices? Does prosecution lower prices? And, does successful prosecution have a deterrent effect?

The evidence is overwhelming that cartels raise prices. Connor and Lande (2005) have provided an exhaustive survey and found the median overcharge is 25 per cent. The evidence on how prices respond after indictment and conviction is mixed. A price decline was found in the break-up of cartels in white pan bread (Block, Nold and Sidak, 1981); and Feinberg (1984) found that, for four of five cartels, the Producer Price Index for the cartelized market fell by 6.6–11.4 per cent relative to a broader industry
Even if prices do rebound from a conviction, prosecution and penalties are still useful because they reduce the profitability of collusion and thus may deter some cartels from forming. Indeed, there is some evidence of deterrence. The general method of testing for it is to have a reduced form equation explaining markups over time and to include a dummy variable when an action has been filed for collusion in a related market. In the case of white pan bread, markups fell for cities in a region for which the DOJ had filed an action that year in some other city in that region (Block, Nold and Sidak, 1981). Similar evidence of deterrence holds for highway construction procurement auctions, which are notorious for bid-rigging (Block and Feinstein, 1986).

In sum, the evidence is that cartels exist, they substantially raise price, and the indictment and conviction of firms may result in lower prices and may have a deterrent effect. Finally, financial penalties fall significantly short of making collusion unprofitable.

Antonelli, Giovanni Battista (1858–1944)

A.P. Kirman

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
Antonelli, G. B.; Engel curves; indirect demand function; integrability problem

Article

Antonelli was born near Pisa in 1858. He studied mathematics and then went on to qualify as an engineer. Although his life was devoted to civil engineering, he made an important contribution to early mathematical economics. His *Sulla teoria matematica dell’economia politica* (1886), intended to be the first part of a book, is remarkable, in particular for the conditions he gives for the ‘integrability problem’. This asks under what conditions single valued demand functions are generated by the maximization of a utility function. Antonelli studied the ‘local’ aspects of this problem. He started from what is now called the indirect demand function:

$$ p = M \left[ q \right] $$

where $q$ is the vector of goods and $p$ the vector of prices. He gave the symmetry of the matrix of the price substitution terms $\frac{\partial p_i}{\partial q_j}$ as a condition for the recoverability of the utility function but should have also required the negative semi-definiteness of this matrix. The importance of this work has been recognized by Samuelson (1950) and later authors, but passed unappreciated if not unnoticed at the time. In the same work Antonelli derives a condition for a market demand function to be derivable from a market utility function, that is, that individuals have linear parallel Engel curves. This condition was found much later by Gorman (1953) and Eisenberg (1961). Antonelli had an active and productive career in engineering and what would now be called ‘operations research’ but never came back to theoretical economics. He died in 1944.

approximate solutions to dynamic models (linear methods)

Harald Uhlig
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article explains how to obtain an approximate solution to dynamic stochastic discrete-time (DSGE) models by first log-linearizing the relevant equations and then obtaining a recursive law of motion, by using the method of undetermined coefficients. Calculations are provided based on both an eigenvector decomposition and the QZ or Schur decomposition. The role of sunspots and the relationship to the method of Blanchard and Kahn are discussed. The base example is a generic real business cycle model, for which log-linearization is described generally and in detail. The method described should be easily implemented. Further literature references and software sources are provided.

Keywords

approximate solutions to dynamic models (linear methods); dynamic stochastic general equilibrium (DSGE) models; linearization; log-linearization; QZ decomposition; real business cycles; representative agent; recursive law of motion; sunspots

Article

Linear methods are often used to compute approximate solutions to dynamic models, as these models often cannot be solved analytically. While a plethora of advanced numerical methods exist, the most popular 'bread-and-butter' method for solving them is linearization. It is described here first with the example of a simple real business cycle model, but is applicable generally to dynamic stochastic general equilibrium (DSGE) models. It is shown how to easily generate the log-linearized equations needed. The linear system is then solved for the recursive law of motion, by using the method of undetermined coefficients. The classic reference for solving linear difference models under rational expectations is Blanchard and Kahn (1980), while Kydland and Prescott (1982) is the origin of the modern approach of calculating numerically approximate solutions to dynamic stochastic models in order to obtain quantitative results. Much of the material here is taken from Uhlig (1999), which builds on the method of undetermined coefficients in King, Plosser and Rebelo (2002).

A basic example

As a basic example, consider a version of the real business cycle model of Hansen (1985). A social planner or representative agent chooses $c_t$, $k_t$, $y_t$, $l_t$ and $n_t$ to maximize the utility function $U = E \sum_{t=0}^{\infty} \beta^t u(c_t, l_t)$ for some twice differentiable utility function $u(\cdot)$, satisfying the usual conditions, subject to the constraints

$$c_t + k_t = y_t + (1 - \delta)k_{t-1}y_{t-1} - \gamma_t f(k_{t-1}, n_{t-1}) - n_t + l_t$$

as well as a given initial capital stock $k_{t-1}$,where $c_t$ denotes consumption, $k_t$ denotes capital, $y_t$ denotes output, $l_t$ denotes leisure, $n_t$ denotes labour, $f(k,n)$ denotes a twice differentiable production function, typically assumed to obey constant returns to scale, $\beta$ is the discount factor and $\gamma_t$ is total factor productivity, with $2\gamma_t = \log(y_t) - \log(y_{t-1})$ evolving according to $\gamma_{t+1} = \rho \gamma_t + \xi_t$ where $E_t[\xi_{t+1}] = 0$ for some values $\gamma^* \text{ and } \rho$, with $-1 < \rho < 1$. A solution is a stochastic sequence $(c_t, k_t, y_t, l_t, n_t)$, $t > 0$ where all variables dated $t$ are independent of all $\varepsilon$ s for $s > t$ and satisfies all constraints, and which maximizes the utility function given above within the set of all such sequences.

The necessary first-order conditions for this problem are given by

$$u'(c_t, l_t) = \lambda_t u'(c_t, l_t) = f'_{n}(k_{t-1}, n_{t-1})\lambda_t = \beta E_t [\lambda_{t+1} k_t + 1] \lambda_t = f_{k}(k_{t-1}, n_{t-1}) + 1 - \delta$$

Linearization

The first step towards solving the model by linear approximation is to linearize all the constraints and necessary equations (possibly after substituting out some variables, if so desired). Linearization amounts to finding a first-order approximation to all equations. Formally, linearization amounts to replacing a set of equations $0 = g(x_t)$ in a vector $x_t$ of variables with its linearized counterpart around some point of approximation $x^*$, $0 = g'(x^*) (x_t - x^*)$, where $x_t = x_{t-1} - x^*$ is the deviation of $x_t$ from the approximation point $x^*$ and where $G' (x^*)$ is the matrix of first derivatives of $G(x)$. As point of approximation $x^*$, the nonstochastic steady state is often chosen, that is, one solves the equations $0 = g'(x^*)$ under the assumption that all exogenous stochastic variables are constant (here: $\gamma_t = \gamma^*$ and all $\epsilon_t = 0$). Then, the remaining linearized system consists of $0 = g'(x^*) (x_t - x^*)$.

Since many economic variables are constrained to be positive, it is often more attractive to log-linearize the equations rather than to linearize them. The difference between linearization and log-linearization is that in entries in $x_t$ denote the original variable (for example, consumption $c_t$) in the case of linearization and the log of these variables (for example, log($c_t$)) in the case of log-linearization. There is no need to choose either linearization or log-linearization for all entries in $x_t$. One may choose to linearize some and log-linearize others or take other transformations. Indeed, for variables such as trade balances it is better to use linearization rather than log-linearization, if they can take negative values. Also, tax rates, for example, are often more appropriately linearized than log-linearized to provide a more useful interpretation.

This makes no difference as far as the linearized solution is concerned. More generally, differentiable and differentiable invertible transformations (that is, homeomorphisms) of the variables (for example, taking ratios of variables) make no difference to the properties of the linearized solution. The differences always lie only in the recalculation of the nonlinearities originally inherent in the model. To see, more generally, that any homeomorphism (that is, differentiable and differentiable invertible transformation) $x_t = h(x_t)$ of the variables makes no difference to remaining calculations, note that the equations can be restated as $0 = g(h^{-1}(x_t))$. The linearized version is now $0 = g(h^{-1}(y^*)') + g'(y^*) (y_t - y^*)$, which coincides with the previous linearization if $y^* = f(x^*)$.

While linearization can be performed numerically or with the usual rules of calculus, one can often ‘read’ the log-linearized version of an equation from its original form, exploiting $x_t = \exp(y_t) = x^* + x^* y_t$ where now $y_t = \log(x_t)$. Write $\tilde{y}_t$ instead of $Y_t$ for the loglinear deviation.

For log-linearization, the following useful ‘rules’ can easily be derived. Let $a_t, b_t, c_t$ be three variables, with $c_t = h(x_t)$ for some monotone and differentiable function $h(\cdot)$, and let $B$ be some constant. Then,

$$a_t + Bc_t = (a^* + Bb^*) + (a^* \delta \bar{h} + Bb^* \delta \bar{h}) \delta \bar{h} + (Bb^* b^*) (\delta \bar{h} + \delta \bar{h}) \delta \bar{h} = \frac{h'(a^*) x^*}{h'(B)} \delta \bar{h}$$

Either with these rules or directly, the equations in the example log-linearize to

$$e^y Y_t + k^y \delta \bar{h}_t - \gamma Y_t + (1-B)k^y \delta \bar{h}_{t-1} Y_t = z_t + \frac{f^y k^y}{f} (\delta \bar{h}_t) + \frac{f^y g^y}{f} \delta \bar{h}_t + \left(1-h^y\right) \delta \bar{h}_{t-1} = \frac{b^y}{1} x^* \delta \bar{h}_t + \frac{b^y}{u^y} \delta \bar{h}_t + \frac{b^y}{v^y} \delta \bar{h}_t - \frac{f^y k^y}{f} \delta \bar{h}_{t-1} - \frac{f^y g^y}{f} \delta \bar{h}_{t-1}$$

Solving for the recursive law of motion

With some further algebra, one can turn this system into a second-order one-dimensional difference equation, $0 = E_t [x_{t+1} + Lz_{t+1}] + C x_t + M z_t + H x_{t-1}$ plus the evolution of the exogenous state, $z_t = N z_{t-1} + D \epsilon_t$, where $x_t = k_{it}$ is the capital stock, and $F, L, G, M, H$ and $O$ are real numbers (here, with $K = D$ and $O = 1$). Alternatively, use the system of equations above directly (or with some variables substituted out) and stack all variables into a vector $x_t$, to reformulate it in this form, where now $F, L, G, M$ and $H$ are matrices of coefficients. Indeed, if there is only one predetermined variable like $k_{it-1}$ in the system of equations, one will need to use such a matrix restatement of the equations anyways. More generally, $c_t$ may also be a vector, and $N$ matrices. Anderson et al (1996) as well as Binder and Pesaran (1997) contain detailed and general results for solving linearized systems. In most cases, the system has a solution in the form of a recursive law of motion, $x_t = P x_{t-1} + Q z_t$, for some coefficient matrices $P$ and $Q$. Most models require the solution to be stable, that is, all eigenvalues of $P$ to be less than unity in absolute value. Often, one also allows for roots equal to unity in absolute value, as this arises easily in, for example, models of international trade or with multiple agents: one may then want to think of the linear approximation as a local solution. In many models, this uniquely determines the matrix $P$ and usually also $Q$.

The solutions can be found by substituting the recursive law of motion in for $x_{t+1}$ and again for all $x_t$ into the second-order difference equation above, exploiting $N z_t = E_t [z_{t+1}]$ so that only $k_{t-1}$ and $z_t$ and some coefficient matrices remain.

Examine first the equation by matching coefficients on $x_{t-1}$. One obtains the equation $0 = F P^2 + Q P + H$ for $P$. In case of a one-dimensional difference equation (as can be obtained for the example above and $x_t = k_{it}$), this is a quadratic equation in the feedback coefficient $P$, which has two solutions. The system is said to be saddle-path stable if only one of the two roots is smaller than unity in absolute value. Thus, if a stable solution is desired, this is the unique solution for $P$.

Generally, the equation above is a matrix quadratic equation, which can be solved per computing generalized eigenvalues or by QZ decomposition as follows. Let $m$ be the dimensionality of $x_t$. Define the matrices

$$A = \begin{bmatrix} -G & -H \\ L_m & Q_m \end{bmatrix}$$

$$B = \begin{bmatrix} F \\ O_m \end{bmatrix}$$

$$C = \begin{bmatrix} Q_m \\ L_m \end{bmatrix}$$

$$D = \begin{bmatrix} \frac{1}{2} P \\ \frac{1}{2} P \end{bmatrix}$$

$$E = \begin{bmatrix} H \\ N \end{bmatrix}$$

$$F = \begin{bmatrix} D \\ E \end{bmatrix}$$

$$G = \begin{bmatrix} B \\ C \end{bmatrix}$$

$$H = \begin{bmatrix} F \\ E \end{bmatrix}$$

$$I_m = \begin{bmatrix} 1_m \end{bmatrix}$$

$$J_m = \begin{bmatrix} 1_m \\ 1_m \end{bmatrix}$$

$$K_m = \begin{bmatrix} 1_m \\ 0_m \end{bmatrix}$$

$$L_m = \begin{bmatrix} 0_m \end{bmatrix}$$

$$M_m = \begin{bmatrix} 0_m \\ 1_m \end{bmatrix}$$

Where

$$1_m = \begin{bmatrix} 1 \end{bmatrix}$$

$$0_m = \begin{bmatrix} 0 \end{bmatrix}$$

$$m$$ is the dimensionality of $x_t$.
where $I_m$ is the m-by-m identity matrix and $0_m$ the m-by-m matrices of only zeros. Recall that a generalized eigenvector $s$ with eigenvalue $\lambda$ for the matrices $A$ and $B$ is defined as satisfying $\lambda B s = A s$. The generalized eigenvector problem reduces to the standard eigenvector problem of $B^{-1} A$, if $B$ is invertible. If $s$ is a generalized eigenvector with eigenvalue $\lambda$ for the matrices $A$ and $B$ above, it can be written as $s' = [\lambda^n s', s']$ for some m-dimensional vector $x$. If there are $m$ generalized eigenvalues $\lambda_1, \ldots, \lambda_m$ together with generalized eigenvectors $s_i = [\lambda_i^n s_i', s_i']$ such that $\mathcal{E} = [s_1, \ldots, s_m]$ is of full rank, then $P = \mathcal{E} \mathcal{E}^{-1}$ is a solution to the matrix quadratic equation, where

$$
\Lambda = \begin{bmatrix}
\lambda_1 & 0 & \ldots & 0 \\
0 & \lambda_2 & \ldots & 0 \\
\vdots & \ddots & \ddots & \vdots \\
0 & \ldots & 0 & \lambda_m
\end{bmatrix}
$$

is the diagonal matrix of the generalized eigenvectors $\lambda_1, \ldots, \lambda_m$ together with generalized eigenvectors $s_i = [\lambda_i^n s_i', s_i']$ such that $\mathcal{E} = [s_1, \ldots, s_m]$ is of full rank, then $P = \mathcal{E} \mathcal{E}^{-1}$ is a solution to the matrix quadratic equation, where

If $B$ is invertible, the solutions can now be characterized in terms of the eigenvalues and eigenvectors of $B^{-1} A$. This is the approach taken in the classic reference of Blanchard and Kahn (1980). Alternatively, find the QZ decomposition (or generalized Schur decomposition) of $A$ and $B$ (see Sims, 2002), that is, find unitary matrices $U$ and $V$ as well as upper triangular matrices $K$ and $L$ such that

$$
\mathcal{E} = U^I \mathcal{E} V = U^I K \nu
$$

(and recall that a matrix is unitary, if the product with its complex conjugate transpose is the identity matrix). Such a Schur decomposition always exists, although it may not be unique. Partition $U$ and $V$ into m-by-m submatrices,

$$
U = \begin{bmatrix} U_{11} & U_{12} \\ U_{21} & U_{22} \end{bmatrix}, \quad V = \begin{bmatrix} V_{11} & V_{12} \\ V_{21} & V_{22} \end{bmatrix}
$$

If $U_{21}$ and $V_{21}$ are invertible, then $P = -V_{21}^{-1} U_{21}$ solves the matrix quadratic equation. Suppose furthermore, that the QZ decomposition has been chosen so that the ratios $|K_{mn}| / |K_{mp}|$ are in ascending order. Furthermore, suppose $|L_{mm}| / |K_{mm}| < 1$. Then $P$ is stable.

To solve for $Q$, given a solution to $P$, compare the coefficients on $z_i$ to find $\nu \vec{z}(Q) = -\nu \vec{z}(L N + \mu)$ where $\vec{z}(\cdot)$ denotes columnwise vectorization and where $\nu = \nu' + i \epsilon \phi (EP + Q)$ with $k$ the dimensionality of $z_i$. If $V$ is invertible, the solution is unique.

St Thomas Aquinas is generally acknowledged as the outstanding theologian of the high Middle Ages. A member of the Dominican order and a pupil of Albertus Magnus (1206–80), St Thomas taught at a number of centres including Paris, Anagni, Orvieto, Rome, Viterbo and Naples. In his research he drew on an extensive range of sources, from the Christian tradition (based on the Scriptures, the Fathers and the Roman writers) to Greek philosophy including the thought of the newly ‘rediscovered’ Aristotle. The writings of Aquinas are also wide-ranging, including commentaries on Aristotle's *Politics* and *Ethics*. Most celebrated among his major works is the *Summa Theologica*, which was set down between 1265 and 1273.

For St Thomas, economic reasoning is integrated with moral philosophy and the establishment of legal precepts. Analysis of economic activity is undertaken for the sake of determining appropriate standards in dealings between citizen and citizen, and so is an aspect of the inquiry into justice. The category of justice which Aquinas finds most relevant to economic life is commutative justice (from *commutatio*, that is, transaction). Hence the focal points for his economic reasoning are value and price, money and interest.

On money, St Thomas stresses its roles as a medium for the exchange of commodities and as a unit of account, that is, a standard of value or measuring rod for comparing the relative worths of exchangeable things. In his treatments of compensation for delay in repayment of a money loan and of restitution of stolen money Aquinas also recognizes that money may have economic significance when held in balance (especially when held by businessmen). The stress on money as a medium of exchange and unit of account leads to a condemnation of most forms of interest-taking as usury, hence unjust. However, the analysis of restitution and compensation help pave the way for the later acceptance by theologians of *lucrum cessans* and *damnum emergens* as phenomena offering bases for a legitimate positive rate of
The just price of any commodity for St Thomas is its current market price, established in the absence of fraud or monopolistic trading practices. It is a price established by *communitier venditur*, the price generally charged in the community concerned, rather than the price dictated by the preferences or needs of any one individual in that community. The value of a commodity will depend on subjective estimates of the utility of the good in question. It will also depend, in part, on cost of production, in that the latter influences supply conditions in any particular market. Aquinas does not achieve an effective synthesis of the utility and cost elements in his analysis of value, nor does he extend the analysis into a theory of distribution. These latter problems, however, were addressed by some of his Scholastic successors, often with reference to the analytical framework devised by St Thomas.

The arbitrage pricing theory (APT) was developed primarily by Ross (1976a; 1976b). It is a one-period model in which every investor believes that the stochastic properties of returns of capital assets are consistent with a factor structure. Ross argues that, if equilibrium prices offer no arbitrage opportunities over static portfolios of the assets, then the expected returns on the assets are approximately linearly related to the factor loadings. (The factor loadings, or betas, are proportional to the returns’ covariances with the factors.) The result is stated in section 1.

Ross's (1976a) heuristic argument for the theory is based on the preclusion of arbitrage. This intuition is sketched in Section 2. Ross's formal proof shows that the linear pricing relation is a necessary condition for equilibrium in a market where agents maximize certain types of utility. The subsequent work, which
is surveyed below, derives either from the assumption of the preclusion of arbitrage or the equilibrium of utility maximization. A linear relation between the expected returns and the betas is tantamount to an identification of the stochastic discount factor (SDF). Sections 3 and 4, respectively, review this literature.

The APT is a substitute for the capital asset pricing model (CAPM) in that both assert a linear relation between assets’ expected returns and their covariance with other random variables. (In the CAPM, the covariance is with the market portfolio’s return.) The covariance is interpreted as a measure of risk that investors cannot avoid by diversification. The slope coefficient in the linear relation between the expected returns and the covariance is interpreted as a risk premium. Such a relation is closely tied to mean-variance efficiency, which is reviewed in section 5.

Section 5 also points out that an empirical test of the APT entails a procedure to identify at least some features of the underlying factor structure. Merely stating that some collection of portfolios (or even a single portfolio) is mean-variance efficient relative to the mean-variance frontier spanned by the existing assets does not constitute a test of the APT, because one can always find a mean-variance efficient portfolio. Consequently, as a test of the APT it is not sufficient to merely show that a set of factor portfolios satisfies the linear relation between the expected return and its covariance with the factors portfolios.

A sketch of the empirical approaches to the APT is offered in section 6, while section 7 describes various procedures to identify the underlying factors. The large number of factors proposed in the literature and the variety of statistical or ad hoc procedures to find them indicate that a definitive insight on the topic is still missing.

Finally, section 8 surveys the applications of the APT, the most prominent being the evaluation of the performance of money managers who actively change their portfolios. Unfortunately, the APT does not necessarily preclude arbitrage opportunities over dynamic portfolios of the existing assets. Therefore, the applications of the APT in the evaluation of managed portfolios contradict at least the spirit of the APT, which obtains price restrictions by assuming the absence of arbitrage.

1 A formal statement

The APT assumes that investors believe that the $n \times 1$ vector, $r$, of the single-period random returns on capital assets satisfies the factor model

$$r = \mu + \beta f + \varepsilon,$$

(1)

where $e$ is an $n \times 1$ vector of random variables, $f$ is a $k \times 1$ vector of random variables (factors), $\mu$ is an $n \times 1$ vector and $\beta$ is an $n \times k$ matrix. With no loss of generality, normalize (1) to make $E[f] = 0$ and $E[\varepsilon] = 0$, where $E[\cdot]$ denotes expectation and 0 denotes the matrix of zeros with the required dimension. The factor model (1) implies $E[r] = \mu$. 

http://www.dictionaryofeconomics.com.proxy.library.csi...edu/article?id=pde2008_A000119&goto=a&result_number=56
The mathematical proof of the APT requires restrictions on $\beta$ and the covariance matrix $\Omega = E[ee']$. An additional customary assumption is that $E[ef] = 0$, but this assumption is not necessary in some of the APT's developments. The number of assets, $n$, is assumed to be much larger than the number of factors, $k$. In some models, $n$ is infinity or approaches infinity. In this case, representation (1) applies to a sequence of capital markets; the first $n$ assets in the $(n+1)$st market are the same as the assets in the $n$th market and the first $n$ rows of the matrix $\beta$ in the $(n+1)$st market constitute the matrix $\beta$ in the $n$th market. The APT asserts the existence of a constant $a$ such that, for each $n$, the inequality

$$\langle \mu - X\lambda \rangle Z^{-1} (\mu - X\lambda) \leq a$$

(2)

holds for a $(k + 1) \times 1$ vector $\lambda$, and an $n \times n$ positive definite matrix $Z$. Here, $X = (1, \beta)$, in which $1$ is an $n \times 1$ vector of ones. Let $\lambda_0$ be the first component of $\lambda$ and $\lambda_1$ consists of the rest of the components. If some portfolio of the assets is risk-free, then $\lambda_0$ is the return on the risk-free portfolio. The positive definite matrix $Z$ is often the covariance matrix $E[ee']$. Exact arbitrage pricing obtains if (2) is replaced by

$$\mu = X\lambda = 1\lambda_0 + \beta\lambda_1.$$  

(3)

The vector $\lambda_1$ is referred to as the risk premium, and the matrix $\beta$ is referred to as the beta or loading on factor risk. The interpretation of (2) is that each component of $\mu$ depends approximately linearly on the corresponding row of $\beta$. This linear relation is the same across assets. The approximation is better, the smaller the constant $a$; if $a = 0$, the linear relation is exact and (3) obtains.

2 Intuition

The intuition behind the model draws from the intuition behind Arrow–Debreu security pricing. A set of $k$ fundamental securities spans all possible future states of nature in an Arrow–Debreu model. Each asset's payoff can be described as the payoff on a portfolio of the fundamental $k$ assets. In other words, an asset's payoff is a weighted average of the fundamental assets' payoffs. If market clearing prices allow no arbitrage opportunities, then the current price of each asset must equal the weighted average of the current prices of the fundamental assets.
The Arrow–Debreu intuition can be couched in terms of returns and expected returns rather than payoffs and prices. If the unexpected part of each asset's return is a linear combination of the unexpected parts of the returns on the \( k \) fundamental securities, then the expected return of each asset is the same linear combination of the expected returns on the \( k \) fundamental assets.

To see how the Arrow–Debreu intuition leads from the factor structure (1) to exact arbitrage pricing (3), set the idiosyncratic term \( e \) on the right-hand side of (1) equal to zero. Translate the \( k \) factors on the right-hand side of (1) into the \( k \) fundamental securities in the Arrow–Debreu model. Then (3) follows immediately.

The presence of the idiosyncratic term \( e \) in the factor structure (1) makes the model more general and realistic. It also makes the relation between (1) and (3) more tenuous. Indeed, ‘no arbitrage’ arguments typically prove the weaker (2). Moreover, they require a weaker definition of arbitrage (and therefore a stronger definition of no arbitrage) in order to get from (1) to (2).

The proofs of (2) augment the Arrow–Debreu intuition with a version of the law of large numbers. That law is used to argue that the average effect of the idiosyncratic terms is negligible. In this argument, the independence among the components of \( e \) is used. Indeed, the more one assumes about the (absence of) contemporaneous correlations among the component of \( e \), the tighter the bound on the deviation from exact APT.

### 3 No-arbitrage models

Huberman (1982) formalizes Ross's (1976a) heuristic argument. A portfolio \( v \) is an \( n \times 1 \) vector. The cost of the portfolio \( v \) is \( v'1 \), the income from it is \( v'r \), and its return is \( v'r / v'1 \) (if its cost is not zero). Huberman defines arbitrage as the existence of zero-cost portfolios such that a subsequence \( \{ w \} \) satisfies

\[
\lim_{n \to \infty} E[w'r] = \infty \quad \text{and} \quad \lim_{n \to \infty} \text{var}[w'r] = 0,
\]

where \( \text{var}[ \cdot ] \) denotes variance. The first requirement in (4) is that the expected income associated with \( w \) becomes large as the number of assets increases. The second requirement in (4) is that the risk (as measured by the income's variance) vanishes as the number of assets increases. Accordingly, a sequence of capital markets offers no arbitrage if there is no subsequence \( \{ w \} \) of zero-cost portfolios that satisfy (4).

Huberman shows that, if the factor model (1) holds and if the covariance matrix \( E[e'e'] \) is diagonal for all \( n \) and uniformly bounded, then the absence of arbitrage implies (2) with \( Z = 1 \) and a finite bound \( a \).

The idea of his proof is as follows. Consider the orthogonal projection of the vector \( \mu \) on the linear space spanned by the columns of \( X \):
\[ \mu = X\hat{\lambda} + \alpha, \]

(5)

where \( \alpha'X = 0 \) and \( \hat{\lambda} \) is a \( k \times 1 \) vector. The projection implies

\[ \alpha'\alpha = \min_{\lambda} (\mu - X\lambda)'(\mu - X\lambda). \]

(6)

A violation of (2) is the existence of a subsequence of \( \{\alpha'\alpha\} \) that approaches infinity. The vector \( \alpha \) is often referred to as a pricing error and it can be used to construct arbitrage. For any scalar \( h \), the portfolio \( w = h\alpha \) has zero cost because the first column of \( X \) is 1. The factor model (1) and the projection (5) imply

\[ \sigma^2 \leq \text{var}(w'r) \leq \frac{1}{3} \sigma^2 \]

and

\[ \text{var}(w'e) \leq \frac{1}{3} \sigma^2, \]

which imply that (4) is satisfied by a subsequence of the zero-cost portfolios \( \{\alpha'\alpha\}^{-2/3} \).

Using the no-arbitrage argument, the exact APT can be proven to hold in the limit for well-diversified portfolios. A portfolio \( w \) is well diversified if \( w'1 = 1 \) and \( \text{var}(w'e) = 0 \), that is, if the portfolio's return contains only factor variance. A sequence of portfolios, \( \{w\} \), is well diversified if \( w'1 = 1 \) and \( \lim_{n \to \infty} \text{var}(w'e) = 0 \). Suppose there are \( m \) sequences of well-diversified portfolios and \( m \) is a fixed number larger than \( k + 1 \). For each \( n \), let \( W \) be an \( n \times m \) matrix, in which each column is one of the well-diversified portfolios. The exact APT holds in the limit for the well-diversified portfolios if and only if there exists a sequence of \( k \times 1 \) vectors, \( \{\lambda\} \), such that

\[ \lim_{n \to \infty} (W'm - \tilde{X}\lambda)'(W'm - \tilde{X}\lambda) = 0, \]

(7)

where \( \tilde{X} = (j, W'\beta) \) and \( j \) is an \( m \times 1 \) vector of ones. The projection of \( W'm \) on the columns of \( \tilde{X} \) gives

\[ W'm = \tilde{X}\hat{\lambda} + \alpha, \]

in which \( \alpha'\tilde{X} = 0 \). If eq. (7) does not hold, a subsequence of \( \alpha \) satisfies \( \alpha'\alpha > \delta \) for some
positive constant $\delta$. This sequence of $\alpha$ can be used to construct arbitrage as follows. For any scalar $h$, define a portfolio as $\nu = hW\alpha$, which is then costless because $\nu'1 = h\alpha'W'1 = h\alpha'j = 0$. It follows from $\nu'\tilde{X} = 0$ that $\mathbb{E}[\nu'\nu] = h\alpha'\alpha$ and $\operatorname{var}[\nu'\nu] = h^2\alpha'W'\mathbb{E}[ee']W\alpha$. If $h$ is chosen to be $\left(\alpha'W'\mathbb{E}[ee']W\alpha\right)^{-1/3}$, then $\operatorname{var}[\nu'\nu] = h^{-1}$. Since $\{W\}$ is well-diversified and $\mathbb{E}[ee']$ is diagonal and uniformly bounded, it follows that $\lim_{n \to \infty} h_n = \infty$. This implies that portfolio sequence $\{\nu\}$ is arbitrage because it satisfies (4).

Ingersoll (1984) generalizes Huberman's result, showing that the factor model, uniform boundedness of the elements of $\beta$ and no arbitrage imply (2) with $Z = \mathbb{E}[ee']$, which is not necessarily diagonal. A variant of Ingersoll's argument is as follows. Write the positive definite matrix $Z$ as the product $Z = UU'$, where $U$ is an $n \times n$ non-singular matrix. Then, consider the orthogonal projection of the vector $U^{-1}\mu$ on the column space of $U^{-1}X$:

$$U^{-1}\mu = U^{-1}X\lambda + \alpha,$$

(8)

where $\alpha'U^{-1}X = 0$. The rest of the argument is similar to those presented earlier.

Chamberlain and Rothschild (1983) employ Hilbert space techniques to study capital markets with (possibly infinitely) many assets. The preclusion of arbitrage implies the continuity of the cost functional in the Hilbert space. Let $L$ equal the maximum eigenvalue of the limit covariance matrix $\mathbb{E}[ee']$ and $d$ equal the supremum of all the ratios of expectation to standard deviation of the incomes on all costless portfolios with a non-zero weight on at least one asset. Chamberlain and Rothschild demonstrate that (2) holds with $\alpha = Ld^2Z$ and $Z = I$ if asset prices allow no arbitrage.

With two additional assumptions, Chamberlain (1983) provides explicit lower and upper bounds on the left-hand side of (2). He further shows that exact arbitrage pricing obtains if and only if there is a well-diversified portfolio on the mean-variance frontier. The first of his additional assumptions is that all the factors can be represented as limits of traded assets. The second additional assumption is that the variances of incomes on any sequence of portfolios that are well diversified in the limit and that are uncorrelated with the factors converge to zero.

4 Utility-based arguments

In utility-based arguments, investors are assumed to solve the following problem:

$$\max_{\epsilon_0, \epsilon_T} \mathbb{E}[u(\epsilon_0, \epsilon_T)] \text{subject to } \epsilon_0 \leq b - w'1 \text{ and } \epsilon_T \leq w'r,$$
where $b$ is the initial wealth, and $u(c_0, c_T)$ is a utility function of initial and terminal consumption $c_0$ and $c_T$. The utility function is assumed to increase with initial and with terminal consumption. The first order condition is

$$E[rM] = 1,$$

(10)

where $M = (\partial u / \partial c_T) / (\partial u / \partial c_0)$. The random variable $M$ satisfying (10) is referred to as the stochastic discount factor (SDF) by Hansen and Jagannathan (1991; 1997). Substitution of the factor model (1) into the first order condition gives

$$\mu = \lambda_0 + \beta \lambda_1 + \alpha,$$

(11)

where $\lambda_0 = 1 / E[M]$, $\lambda_1 = -E[\mu M] / E[M]$ and $\alpha = -E[eM] / E[M]$. It follows from (11) that

$$(\mu - X\lambda)'(\mu - X\lambda) = \alpha'\alpha,$$

(12)

where $X = (1, \beta)$ and $\lambda = (\lambda_0, \lambda_1)$. Clearly, the APT (2) holds for $Z = I$ and $a$ if $\alpha'\alpha$ is uniformly bounded by $a$. Ross (1976a) is the first to set up an economy in which $\alpha'\alpha$ is uniformly bounded. The exact APT (3) holds if and only if

$$E[eM] = 0.$$

(13)
If the SDF is a linear function of the factors, then eq. (13) holds. Conversely, if eq. (13) holds, there exists an SDF, which is a linear function of factors, such that eq. (10) is satisfied. However, the SDF does not have to be a linear function of factors for the purpose of obtaining the exact APT. A nonlinear function, $M = g(f)$, of factors for the SDF would also imply (13) under the assumption $E[\epsilon f] = 0$. Connor (1984) shows that, if the market portfolio is well diversified, then every investor holds a well-diversified portfolio (that is, a $k + 1$ fund separation obtains; the funds are associated with the factors and with the risk-free asset, which Connor assumes to exist). With this, the first order condition of any investor implies exact arbitrage pricing in a competitive equilibrium. Connor and Korajczyk (1986) extend Connor's previous work to a model with investors who have better information about returns than most other investors. The former class of investors is sufficiently small, so the pricing result remains intact and it is used to derive a test of the superiority of information of the allegedly better informed investors. Connor and Korajczyk (1988) extend Connor's single-period model to a multi-period model. They assume that the capital assets are the same in all periods, that each period's cash payoffs from these assets obey a factor structure, and that competitive equilibrium prices are set as if the economy had a representative investor who maximizes exponential utility. They show that exact arbitrage pricing obtains with time-varying risk premium (but, similar to Stambaugh, 1983, with constant factor loadings.) Chen and Ingersoll (1983) argue that, if a well-diversified portfolio exists and it is the optimal portfolio of some utility-maximizing investor, then the first order condition of that investor implies exact arbitrage pricing. Dybvig (1983) and Grinblatt and Titman (1983) consider the case of finite assets and provide explicit bounds on the deviations from exact arbitrage pricing. These bounds are functions of the per capita asset supplies, individual bounds on absolute risk aversion, variance of the idiosyncratic risk, and the interest rate. To derive his bound, Dybvig assumes that the support of the distribution of the idiosyncratic term $e$ is bounded below, that each investor's coefficient of absolute risk aversion is non-increasing and that the competitive equilibrium allocation is unconstrained Pareto optimal. To derive their bound, Grinblatt and Titman require a bound on a quantity related to investors' coefficients of absolute risk aversion and the existence of $k$ independent, costless and well diversified portfolios.

5 Mean-variance efficiency

The APT was developed as a generalization of the CAPM, which asserts that the expectations of assets' returns are linearly related to their covariances (or betas, which in turn are proportional to the covariances) with the market portfolio's return. Equivalently, the CAPM says that the market portfolio is mean-variance efficient in the investment universe containing all possible assets. If the factors in (1) can be identified with traded assets, then exact arbitrage pricing (3) says that a portfolio of these factors is mean-variance efficient in the investment universe consisting of the assets $r$. Huberman and Kandel (1985b), Jobson and Korkie (1982; 1985) and Jobson (1982) note the relation between the APT and mean-variance efficiency. They propose likelihood-ratio tests of the joint hypothesis that a given set of random variables are factors in model (1) and that exact arbitrage pricing (3) obtains. Kan and Zhou (2001) point out a crucial typographical error in Huberman and Kandel
arbitrage pricing theory: The New Palgrave Dictionary of Economics

Peñaranda and Sentana (2004) study the close relation between the Huberman and Kandel's spanning approach and the celebrated volatility bounds in Hansen and Jagannathan (1991). Even when the factors are not traded assets, (3) is a statement about mean-variance efficiency: Grinblatt and Titman (1987) assume that the factor structure (1) holds and that a risk-free asset is available. They identify \( k \) traded assets such that a portfolio of them is mean-variance efficient if and only if (3) holds. Huberman, Kandel and Stambaugh (1987) extend the work of Grinblatt and Titman by characterizing the sets of \( k \) traded assets with that property and show that these assets can be described as portfolios if and only if the global minimum variance portfolio has non-zero systematic risk. To find these sets of assets, one must know the matrices \( \mathbf{BB}' \) and \( \mathbb{E}[\mathbf{e}\mathbf{e}'] \). If the latter matrix is diagonal, factor analysis produces an estimate of it, as well as an estimate of \( \mathbf{BB}' \).

The interpretation of (3) as a statement about mean-variance efficiency contributes to the debate about the testability of the APT. (Shanken, 1982; 1985, and Dybvig and Ross, 1985, however, discuss the APT's testability without mentioning that (3) is a statement about mean-variance efficiency.) The theory's silence about the factors' identities renders any test of the APT a joint test of the pricing relation and the correctness of the factors. As a mean-variance efficient portfolio always exists, one can always find 'factors' with respect to which (3) holds. In fact, any single portfolio on the frontier can serve as a 'factor'. Thus, finding portfolios which are mean-variance efficient – or failure to find them – neither supports nor contradicts the APT. It is the factor structure (1) which, combined with (3), provides refutable hypotheses about assets' returns. The factor structure (1) imposes restrictions which, combined with (3), provide refutable hypotheses about assets' returns. The factor structure suggests looking for factors with two properties: (a) their time-series movements explain a substantial fraction of the time-series movements of the returns on the priced assets, and (b) the unexplained parts of the time series movements of the returns on the priced assets are approximately uncorrelated across the priced assets.

6 Empirical tests

Empirical work inspired by the APT typically ignores (2) and instead studies exact arbitrage pricing (3). This type of work usually consists of two steps: an estimation of factors (or at least of the matrix \( \mathbf{B} \)) and then a check to see whether exact arbitrage pricing holds. In the first step, researchers typically use the following regression model to estimate the parameters in the factor model:

\[
r_t = \alpha + \beta f_t + \varepsilon_t,
\]

(14)

where \( r_t, f_t \) and \( \varepsilon_t \) are the realization of the variables in period \( t \). The factors observed in empirical studies often have a non-zero mean, denoted by \( \delta \). Let \( T \) be the total number of periods and \( \sum \) the summation over \( t = 1, \ldots, T \). The ordinary least-square (OLS) estimates are
These are also maximum-likelihood estimators if the returns and factors are independent across time and have a multivariate normal distribution.

In the second step, researchers may use the exact pricing (3) and (14) to obtain the following restricted version of the regression model,

\[ \hat{r}_t = \lambda_0 + \beta (f_t + \lambda_1) + \epsilon_t. \]  

(19)
Under the assumption that returns and factors follow identical and independent normal distributions, the maximum-likelihood estimators are

\[
\bar{\beta} = \left( \sum (r_t - \bar{\lambda}_0)(f_t + \bar{\lambda}_1)' \right) \left( \sum (f_t + \bar{\lambda}_1)(f_t + \bar{\lambda}_1)' \right)^{-1}
\]

(20)

\[
\bar{\Omega} = \frac{1}{T} \sum \bar{e}_t \bar{e}_t' \text{where } \bar{e}_t = r_t - \bar{\lambda}_0 - \bar{\beta}(f_t + \bar{\lambda}_1)
\]

(21)

\[
\bar{\lambda} = (\bar{\chi}' \bar{\Omega}^{-1} \bar{\chi})^{-1} \bar{\chi}' \bar{\Omega}^{-1} (\hat{\mu} - \bar{\beta} \hat{\delta}) \text{where } \bar{\chi} = (1, \bar{\beta}).
\]

(22)

These estimators need to be solved simultaneously from the above three equations. Notice that \(\bar{\beta}\) and \(\bar{\Omega}\) are the OLS estimators in (19) for a given \(\bar{\lambda}\). The last equation shows that \(\bar{\lambda}\) is the generalized least-square estimator in the cross-sectional regression of \(\hat{\mu} - \bar{\beta} \hat{\delta}\) on \(\bar{\chi}\) with \(\bar{\Omega}\) being the weighting matrix. To test the restriction imposed by the exact APT, researchers use the likelihood-ratio statistic,

\[
LR = T \left( \log |\bar{\Omega}| - \log |\hat{\Omega}| \right),
\]

(23)

which follows a \(\chi^2\) distribution with \(n - k - 1\) degrees of freedom when the number of observations, \(T\), is very large. When factors are payoffs of traded assets or a risk-free asset exists, the exact APT imposes more restrictions. For these cases, Campbell, Lo and MacKinley (1997, ch. 6) provide an overview. If the observations of returns and factors do not follow independent normal distribution, similar tests can be carried out using the generalized method of moments (GMM). Jagannathan and Wang (2002) and
Jagannathan, Skoulakis and Wang (2002) provide an overview of the application of the GMM for testing asset pricing models including the APT. Interest is sometimes focused only on whether a set of specified factors are priced or on whether their loadings help explain the cross section of expected asset returns. For this purpose, most researchers study the cross-sectional regression model

\[
\hat{\mu} = \hat{X}\lambda + \nu \Rightarrow \hat{\lambda} = \hat{X}\lambda + \hat{\beta}\lambda_1 + \nu,
\]

(24)

where \(\hat{X} = (1, \hat{\beta})\) and \(\nu\) is an \(n \times 1\) vector of errors for this equation. The OLS estimator of \(\lambda\) in this regression is tested to see whether it is different from zero. To test this specification, asset characteristics \(z\), such as firm size, that are correlated with mean asset returns are added to the regression:

\[
\hat{\mu} = \lambda_0 + \hat{\beta}\lambda_1 + z\lambda_2 + \nu.
\]

(25)

A significant \(\lambda_1\) and insignificant \(\lambda_2\) are viewed as evidence in support of the specified factors being part of the exact APT. Black, Jensen and Scholes (1972) and Fama and MacBeth (1973) pioneered this cross-sectional approach to test the CAPM. Chen, Roll and Ross (1986) used it to test the exact APT. Shanken (1992) and Jagannathan and Wang (1998) developed the statistical foundations of the cross-sectional tests. The cross-sectional approach is now a popular tool for analysing risk premiums on the loadings of proposed factors.

7 Specification of factors

The tests outlined above are joint tests that the matrix \(\beta\) is correctly estimated and that exact arbitrage pricing holds. Estimation of the factor loading matrix \(\hat{\beta}\) entails at least an implicit identification of the factors. The three approaches listed below have been used to identify factors. The first consists of an algorithmic analysis of the estimated covariance matrix of asset returns. For instance, Roll and Ross (1980), Chen (1983) and Lehman and Modest (1988) use factor analysis, and Chamberlain and Rothschild (1983) and Connor and Korajczyk (1986; 1988) recommend using principal component analysis.

The second approach is one in which a researcher starts at the estimated covariance matrix of asset returns and uses his judgement to choose factors and subsequently estimate the matrix \(\hat{\beta}\). Huberman and Kandel (1985a) note that the correlations of stock returns of firms of different sizes increase with a
similarity in size. Therefore, they choose an index of small firms, one of medium-size firms and one of large firms to serve as factors. In a similar vein, Fama and French (1993) use the spread between the stock returns of small and large firms as one of their factors. Echoing the findings of Rosenberg, Reid and Lanstein (1984), Chan, Hamao and Lakonishok (1991) and Fama and French (1992) observe that expected stock returns and their correlations are also related to the ratio of book-to-market equity. Based on these observations, Fama and French (1993) add the spread between stock returns of value and growth firms as another factor.

The third approach is purely judgemental in that it is one in which the researcher primarily uses his intuition to pick factors and then estimates the factor loadings and checks whether they explain the cross-sectional variations in estimated expected returns (that is, he checks (3)). Chan, Chen and Hsieh (1985) and Chen, Roll and Ross (1986) select financial and macroeconomic variables to serve as factors. They include the following variables: the return on an equity index, the spread of short- and long-term interest rates, a measure of the private sector's default premium, the inflation rate, the growth rates of industrial production and the aggregate consumption. Based on economic intuition, researchers continue to add new factors, which are too many to enumerate here.

The first two approaches are implemented to conform to the factor structure underlying the APT: the first approach by the algorithmic design and the second because researchers check that the factors they use indeed leave the unexplained parts of asset returns almost uncorrelated. The third approach is implemented without regard to the factor structure. Its attempt to relate the assets’ expected returns to the covariance of the assets’ returns with other variables is more in the spirit of Merton's (1973) inter-temporal CAPM than in the spirit of the APT.

The empirical work cited above examines the extent to which the exact APT (with whatever factors are chosen) explains the cross-sectional variation in assets’ mean returns better than the CAPM. It also examines the extent to which other variables – usually those that include various firm characteristics – have marginal explanatory power beyond the factor loadings to explain the cross section of assets’ mean returns. The results usually suggest that the APT is a useful model in comparison with the CAPM. (Otherwise, they would probably have gone unpublished.) However, the results are mixed when the alternative is firm characteristics. Researchers who introduce factors tend to report results supporting the APT with their factors and test portfolios. Nevertheless, different tests and construction of portfolios often reject the proposed APT. For example, Fama and French (1993) demonstrate that exact APT using their factors holds for portfolios constructed by sorting stocks on firm size and book-to-market ratio, whereas Daniel and Titman (1997) demonstrate that the same APT does not hold for portfolios that are constructed by sorting stocks further on the estimated loadings with respect to Fama and French's factors. The APT often seems to describe the data better than competing models. It is wise to recall, however, that the purported empirical success of the APT may well be due to the weakness of the tests employed. Some questions come to our mind: which factors capture the data best; what is the economic interpretation of the factors; what are the relations among the factors that different researchers have reported? As any test of the APT is a joint test that the factors are correctly identified and that the linear pricing relation holds, a host of competing theories exist side by side under the APT's umbrella. Each fails to reject the APT but has its own factor identification procedure. The number of factors, as well as the methods of factor construction, is exploding. The multiplicity of competing factor models indicates ignorance of the true factor structure of asset returns and suggests a rich and challenging research
8 Applications

The APT lends itself to various practical applications due to its simplicity and flexibility. The three areas of applications critically reviewed here are: asset allocation, the computation of the cost of capital, and the performance evaluation of managed funds.

The application of the APT in asset allocation is motivated by the link between the factor structure (1) and mean-variance efficiency. Since the structure with \( k \) factors implies the existence of \( k \) assets that span the efficient frontier, an investor can construct a mean-variance efficient portfolio with only \( k \) assets. The task is especially straightforward when the \( k \) factors are the payoffs of traded securities. When \( k \) is a small number, the model reduces the dimension of the optimization problem. The use of the APT in the construction of an optimal portfolio is equivalent to imposing the restriction of the APT in the estimation of the mean and covariance matrix involved in the mean-variance analysis. Such a restriction increases the reliability of the estimates because it reduces the number of unknown parameters.

If the factor structure specified in the APT is incorrect, however, the optimal portfolio constructed from the APT will not be mean-variance efficient. This uncertainty calls for adjusting, rather than restricting, the estimates of mean and covariance matrix by the APT. The degree of this adjustment should depend on investors’ prior belief in the model. Pastor and Stambaugh (2000) introduce the Bayesian approach to achieve this adjustment. Wang (2005) further shows that the Bayesian estimation of the return distribution results in a weighted average of the distribution restricted by the APT and the unrestricted distribution matched to the historical data.

The proliferation of APT-based models challenges an investor engaging in asset allocation. In fact, Wang (2005) argues that investors averse to model uncertainty may choose an asset allocation that is not mean-variance efficient for any probability distributions estimated from the prior beliefs in the model. Being an asset pricing model, the APT should lend itself to the calculation of the cost of capital. Elton, Gruber and Mei (1994) and Bower and Schink (1994) used the APT to derive the cost of capital for electric utilities for the New York State Utility Commission. Elton, Gruber and Mei specify the factors as unanticipated changes in the term structure of interest rates, the level of interest rates, the inflation rate, the GDP growth rate, changes in foreign exchange rates, and a composite measure they devise to measure changes in other macro factors. In the meantime, Bower and Schink use the factors suggested by Fama and French (1993) to calculate the cost of capital for the Utility Commission. However, the Commission did not adopt any of the above-mentioned multi-factor models but used the CAPM instead (see DiValentino, 1994).

Other attempts to apply the APT to compute the cost of capital include Bower, Bower and Logue (1984), Goldenberg and Robin (1991) who use the APT to study the cost of capital for utility stocks, and Antoniou, Garrett and Priestley (1998) who use the APT to calculate the cost of equity capital when examining the impact of the European exchange rate mechanism. Different studies use different factors and consequently obtain different results, a reflection of the main drawback of the APT – the theory does not specify what factors to use. According to Green, Lopez and Wang (2003), this drawback is one
of the main reasons that the US Federal Reserve Board has decided not to use the APT to formulate the imputed cost of equity capital for priced services at Federal Reserve Banks.

The application of asset pricing models to the evaluation of money managers was pioneered by Jensen (1968). When using the APT to evaluate money managers, the managed funds’ returns are regressed on the factors, and the intercepts are compared with the returns on benchmark securities such as Treasury bills. Examples of this application of the APT include Busse (1999), Carhart (1997), Chan, Chen and Lakonishok (2002), Cai, Chan and Yamada (1997), Elton, Gruber and Blake (1996), Mitchell and Pulvino (2001), and Pastor and Stambaugh (2002).

The APT is a one-period model that delivers arbitrage-free pricing of existing assets (and portfolios of these assets), given the factor structure of their returns. Applying it to price derivatives on existing assets or to price trading strategies is problematic, because its stochastic discount factor is a random variable which may be negative. Negativity of the SDF in an environment which permits derivatives leads to a pricing contradiction, or arbitrage. Consider, for instance, the price of an option that pays its holder whenever the SDF is negative. Being a limited liability security, such an option should have a positive price, but applying the SDF to its payoff pattern delivers a negative price. (The observation that the stochastic discount factor of the CAPM may be negative is in to Dybvig and Ingersoll, 1982, who also studied some of the implications of this observation.)

Trading and derivatives on existing assets are closely related. Famously, Black and Scholes (1973) show that dynamic trading of existing securities can replicate the payoffs of options on these existing securities. Therefore, one should be careful in interpreting APT-based excess returns of actively managed funds because such funds trade rather than hold on to the same portfolios. Examples of interpretations of asset management techniques as derivative securities include Merton (1981) who argues that market-timing strategy is an option, Fung and Hsieh (2001) who show that hedge funds using trend-following strategies behave like a look-back straddle, and Mitchell and Pulvino (2001) who demonstrate that merger arbitrage funds behave like an uncovered put.

Motivated by the challenge of evaluating dynamic trading strategies, Glosten and Jagannathan (1994) suggest replacing the linear factor models with the Black–Scholes model. Wang and Zhang (2005) study the problem extensively and develop an econometric methodology to identify the problem in factor-based asset pricing models. They show that the APT with many factors is likely to have large pricing errors over actively managed funds, because empirically these models deliver SDFs which allow for arbitrage over derivative-like payoffs.

It is ironic that some of the applications of the APT require extensions of the basic model which violate its basic tenet – that assets are priced as if markets offer no arbitrage opportunities.

arbitrage

Philip H. Dybvig and Stephen A. Ross
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The absence of arbitrage is the unifying concept for much of finance. Absence of arbitrage is more general than equilibrium because it does not require all agents to be rational. The Fundamental Theorem of Asset Pricing asserts the equivalence of absence of arbitrage, existence of a positive linear pricing rule, and existence of some hypothetical agent who prefers more to less and has an optimum. Equivalent representations of the pricing rule are the martingale measure (risk-neutral pricing), and a positive state price density. Applications of no arbitrage and these representations include Modigliani–Miller theory, option pricing, investments, and forward exchange parity.

Article

An arbitrage opportunity is an investment strategy that guarantees a positive payoff in some contingency with no possibility of a negative payoff and with no net investment. By assumption, it is possible to run the arbitrage possibility at arbitrary scale; in other words, an arbitrage opportunity represents a money pump. A simple example of arbitrage is the opportunity to borrow and lend costlessly at two different fixed rates of interest. Such a disparity between the two rates cannot persist: arbitrageurs will drive the rate together.

The modern study of arbitrage is the study of the implications of assuming that no arbitrage opportunities are available. Assuming no arbitrage is compelling because the presence of arbitrage is inconsistent with equilibrium when preferences increase with quantity. More fundamentally, the presence of arbitrage is inconsistent with the existence of an optimal portfolio strategy for any competitive agent who prefers more to less, because there is no limit to the scale at which an individual would want to hold the arbitrage position. Therefore, in principle, absence of arbitrage follows from individual rationality of a single agent. One appeal of results based on the absence of arbitrage is the intuition that absence of arbitrage is more primitive than equilibrium, since only relatively few rational agents are needed to bid away arbitrage opportunities, even in the presence of a sea of agents driven by ‘animal spirits’.

The absence of arbitrage is very similar to the zero economic profit condition for a firm with constant returns to scale (and no fixed factors). If such a firm had an activity which yielded positive profits, there would be no limit to the scale at which the firm would want to run the activity, and no optimum would exist. The theoretical distinction between a zero profit condition and the absence of arbitrage is the distinction between commerce, which requires production, and trading under the price system, which does not. In practice, the distinction blurs. For example, if gold is sold at different prices in two markets, there is an arbitrage opportunity but it requires production (transportation of the gold) to take advantage of the opportunity. Furthermore, there are almost always costs to trading in markets (for example, brokerage fees), and therefore a form of costly production is required to convert cash into a security. For the purposes of this article, we will tend to ignore production. In practical applications the necessity of production will weaken the implications of absence of arbitrage and may drive a wedge between what the pure absence of arbitrage would predict and what actually occurs.

The assertion that two perfect substitutes (for example, two shares of stock in the same company) must trade at the same price is an implication of no arbitrage that goes under the name of the law of one price. While the law of one price is an immediate consequence of the absence of arbitrage, it is not equivalent to the absence of arbitrage. An early use of a no-arbitrage condition employed the law of one price to help explain the pattern of prices in the foreign exchange and commodities markets.

Many economic arguments use the absence of arbitrage implicitly. In discussions of purchasing power parity in international trade, for
example, presumably it is an arbitrage possibility that forces the spot exchange rate between currencies to equal the relative prices of common baskets of (traded) goods. Similarly, the statement that the possibility of repackaging implies linear prices in competitive product markets is essentially a no-arbitrage argument.

**Early uses of the law of one price**

The parity theory of forward exchange based on the law of one price was first formulated by Keynes (1923) and developed further by Einzig (1937). Let $s$ denote the current spot price of, say, euros, in terms of dollars, and let $f$ denote the forward price of euros one year in the future. The forward price is the price at which agreements can be struck currently for the future delivery of euros with no money changing hands today. Also, let $r_s$ and $r_m$ denote the one year dollar and euro interest rates, respectively. To prevent an arbitrage possibility from developing, these four prices must stand in a particular relation.

To see this, consider the choices facing a holder of dollars. The holder can lend the dollars in the domestic market and realize a return of $r_s$ one year from now. Alternatively, the investor can purchase euros on the spot market, lend for one year in the German market, and convert the euros back into dollars one year from now at the fixed forward rate. By undertaking the conversion back into dollars in the forward market, the investor locks in the prevailing forward rate, $f$. The results of this latter path are a return of

$$f (1 + r_m) / s$$

dollars one year from now. If this exceeds $1 + r_s$, then the foreign route offers a sure higher return than domestic lending. By borrowing dollars at the domestic rate $r_s$ and lending them in the foreign market, a sure profit at the rate

$$f (1 + r_m) / s - (1 + r_s)$$

can be made with no net investment of funds. Alternatively, if

$$f (1 + r_m) / s - (1 + r_s) < 0,$$

the arbitrage works in reverse. By borrowing in euros, investing in dollars, and buying euros forward, a sure profit at the rate

$$(1 + r_s) - f (1 + r_m) / s$$

can be made with no investment in funds.

Thus, the prevention of arbitrage will enforce the forward parity result,

$$(1 + r_s) / (1 + r_m) = f / s.$$

This result takes on many different forms as we look across different markets. In a commodity market with costless storage, for example, an arbitrage opportunity will arise if the following relation does not hold:

$$f \leq s (1 + r).$$
In this equation, \( f \) is the currently quoted forward rate for the purchase of the commodity – for example, silver, one year from now – \( s \) is the current spot price, and \( r \) is the interest rate. More generally, if \( c \) is the up-front proportional carrying cost, including such items as storage costs, spoilage and insurance, absence of arbitrage ensures that

\[
f \leq s(1 + c)(1 + r).
\]

(We normally would expect these relations to hold with equality in a market in which positive stocks are held at all points in time, and perhaps with inequality in a market which may not have positive stocks just before a harvest. However, proving equality is based on equilibrium arguments, not on the absence of arbitrage, since to short the physical commodity one must first own a positive amount.)

The above applications of the absence of arbitrage (via the law of one price) share the common characteristic of the absence of risk. The law of one price is less restrictive than the absence of arbitrage because it deals only with the case in which two assets are identical but have different prices. It does not cover cases in which one asset dominates another but may do so by different amounts in different states. The most interesting applications of the absence of arbitrage are to be found in uncertain situations, where this distinction may be important.

The fundamental theorem of asset pricing

The absence of arbitrage is implied by the existence of an optimum for any agent who prefers more to less. The most important implication of the absence of arbitrage is the existence of a positive linear pricing rule, which in many spaces including finite state spaces is the same as the existence of positive state prices that correctly price all assets. Taken together with their converses, we refer collectively to these results as the Fundamental Theorem of Asset Pricing. Traditionally, the emphasis has been on the linear pricing rule as an implication of the absence of arbitrage. Including the existence of an optimum (introduced in the version of this article in the first edition of The New Palgrave) is useful both because it reminds us why we are interested in arbitrage, and because the converse tells us that, absent other restrictions, consistency with equilibrium is equivalent to the absence of arbitrage. We state the theorem verbally here; the formal meanings of the words and the proof are given later in this section.

**Theorem: (Fundamental Theorem of Asset Pricing)** The following are equivalent:

1. (i) absence of arbitrage;
2. (ii) existence of a positive linear pricing rule;
3. (iii) existence of an optimal demand for some agent who prefers more to less.

Beja (1971) was one of the first to emphasize explicitly the linearity of the asset pricing function, but he did not link it to the absence of arbitrage. Beja simply assumed that equilibrium prices existed and observed ‘that equilibrium properties require that the functional \( q \) be linear’, where \( q \) is a functional that assigns a price or value to a risky cash flow. The first statement and proof that the absence of arbitrage implied the existence of non-negative state space prices and, more generally, of a positive linear operator that could be used to value risky assets appeared in Ross (1976a; 1978). Besides providing a formal analysis, Ross showed that there was a pricing rule that prices all assets and not just those actually marketed. (In other words, the linear pricing rule could be extended from the marketed assets to all hypothetical assets defined over the same set of states.) The advantage of this extension is that the domain of the pricing function does not depend on the set of marketed assets. We will largely follow Ross’s analysis with some modern improvements.

Linearity for pricing means that the price functional or operator \( q \) satisfies the ordinary linear condition of algebra. If we let \( x \) and \( y \) be two random payoffs and we let \( q \) be the operator that assigns values to prospects, then we require that

\[
q(\alpha x + \beta y) = \alpha q(x) + \beta q(y),
\]

where \( \alpha \) and \( \beta \) are arbitrary constants. Of course, for many spaces (including a finite state space), any linear functional can be represented as a sum or integral across states of state prices times quantities.

To simplify proofs in this article, we will make the assumption that there are finitely many states, each of which occurs with positive probability, and that all claims purchased today pay off at a single future date. Let \( \Theta \) denote the state space,

\[
\Theta = \{1, \ldots, m\},
\]
where there are \( m \) states and the state of nature \( \Theta \) occurs with probability \( \pi_{\Theta} \). Applying \( q \) to the ‘indicator’ asset \( e_{\Theta} \) whose payoff is 1 in state \( \Theta \) and 0 otherwise, we can define a price \( q_{\Theta} \) for each state \( \Theta \) as the value of \( e_{\Theta} \):

\[
q_{\Theta} = q(e_{\Theta}).
\]

Now, if there were linearity, the value of any payoff, \( x \), could be written as

\[
q(x) = \sum_{\Theta} q_{\Theta} x_{\Theta}.
\]

Of course, this argument presupposes that \( q(e_{\Theta}) \) is well defined, which is a strong assumption if \( e_{\Theta} \) is not marketed.

We want to make a statement about the conditions under which all marketed assets can be priced by such a linear pricing rule \( q \). We assume that there is a set of \( n \) marketed assets with a corresponding price vector, \( p \). Asset \( i \) has a terminal payoff \( X_{\Theta_i} \) (inclusive of dividends, and so on) in state of nature \( \Theta_i \). The matrix \( X = [X_{\Theta_i}] \) denotes the state space tableau whose columns correspond to assets and whose rows correspond to states. Lower-case \( x \) represents the random vector of terminal payoffs to the various securities. An arbitrage opportunity is a portfolio (vector) \( \eta \) with two properties. It does not cost anything today or in a state in the future. And, it has a positive payoff either today or in some state in the future (or both). We can express the first property as a pair of vector inequalities. The initial cost is not greater than zero, which is to say that it uses no wealth and may actually generate some,

\[
p\eta \leq 0,
\]

(1)

and its random payoff later is never negative,

\[
X\eta \geq 0.
\]

(2)

(We use the notation that \( \geq \) denotes greater or equal in each component, \( > \) denotes \( \geq \) and greater in some component, and \( \bullet \) denotes greater in all components. Note that writing the price of \( X\eta \) as \( p\eta \) for arbitrary \( \eta \) embodies an assumption that investment in marketed assets is divisible.) The second property says that the arbitrage portfolio \( \eta \) has a strict inequality, either in (1) or in some component of (2). We can express both properties together as

\[
X \bullet \eta = \begin{bmatrix} -p \\ X \end{bmatrix} \eta > 0.
\]

(3)

Here, we have stacked the net payoff today on top of the vector of payoffs at the future date. This is in the spirit of the Arrow–Debreu model in which consumption in different states, commodities, points of time and so forth, are all considered components of one large consumption vector.

The absence of arbitrage is simply the condition that no \( \eta \) satisfies (3). A consistent positive linear pricing rule is a vector of state prices \( q \) that correctly prices all marketed assets, that is, such that

\[
p = qX.
\]
We have now collected enough definitions to prove the first half (that \( i \Leftrightarrow ii \)) of the Fundamental Theorem of Asset Pricing.

**Theorem:** (first half of the Fundamental Theorem of Asset Pricing) There is no arbitrage if and only if there exists a consistent positive linear pricing rule.

**Proof:** The proof that having a consistent positive linear pricing rule precludes arbitrage is simple, since any arbitrage opportunity gives a direct violation of (4). Let \( \eta \) be an arbitrage opportunity. By (4),

\[
p\eta = q\mathcal{X}\eta,
\]

or equivalently

\[
0 = -p\eta + q\mathcal{X}\eta = [1q]X\eta.
\]

By definition of an arbitrage opportunity (3) and positivity of \( q \), we have a contradiction.

The proof that the absence of arbitrage implies the existence of a consistent positive linear pricing rule is more subtle and requires a separation theorem. The mathematical problem is equivalent to Farkas' Lemma of the alternative and to the basic duality theorem of linear programming. We will adopt an approach that is analogous to the proof of the second theorem of welfare economics that asserts the existence of a price vector which supports any efficient allocation, by separating the aggregate Pareto optimal allocation from all aggregate allocations corresponding to Pareto preferable allocations. Here we will find a price vector that 'supports' an arbitrage-free allocation by separating the net trades from the set of free lunches (the positive orthant).

The absence of arbitrage is equivalent to the requirement that the linear space of net trades defined by

\[
S \equiv \{ \forall \text{for some } \eta, \mathcal{X}\eta \}
\]

(5)

does not intersect the positive orthant \( \mathbb{R}_{+}^{m+1} \equiv \{ v \mid v \geq 0 \} \) except at the origin, that is \( S \cap \mathbb{R}_{+}^{m+1} = \{0\} \).

Since \( S \) is a subspace (and is therefore a convex closed cone), a simple separation theorem (Karlin, 1959, Theorem B3.5) implies that there exists a nonzero vector \( q^* \) such that for all \( \forall \in S \) and all \( z \in \mathbb{R}_{+}^{m+1}, z \neq 0 \), we must have

\[
q^*z \geq 0, \quad q^*\forall \geq q^*\forall \quad (6)
\]

Letting \( \epsilon \) be each of the unit vectors in turn, the first inequality in (6) implies that \( q^* \) is a strictly positive vector.

Since \( S \) is a subspace, the second inequality in (6) must hold with equality for all \( \forall \in S \) Define

\[
q \equiv (q^*\epsilon_2, q^*\epsilon_3, \ldots, q^*\epsilon_n) / q^*\epsilon_1.
\]

Since \( q^*\epsilon_0 \), likewise \( q^*\epsilon_0 \).

Dividing the second equality in (6) (which we now know to be an equality) by \( q^*\epsilon_1 \) and expanding using the definition of \( X^* \) [from (3)], we
have that

$$0 = -p + qX,$$

or

$$p = qX,$$

which shows that $q$ is a consistent positive linear pricing rule.

Before we can prove the second half of the pricing theorem, we need to define the maximization problem faced by a typical investor. In this problem, all we really need to assume is that more is preferred (strictly) to less, that is, that increasing initial consumption or random consumption later in one or more states always leads to a preferred outcome. In fact, this is literally all we need: we do not need completeness or even transitivity of preferences, let alone a utility function representation or any restriction to a functional form. However, for concreteness, we will write down preferences using a state-dependent utility function of consumption now and in the future. The assumption that the investor prefers more to less is satisfied if the utility function in each state is increasing in consumption at both dates.

The state-dependent restriction implies that the maximization problem faced by a particular agent is the maximization of the expectation of the state-dependent utility function $u_0(\cdot, \cdot)$ of initial wealth and terminal wealth, given initial wealth $w_0$ and the possibility of trading in the security market. Then the maximization problem faced by a typical agent is the unconstrained choice of a vector $\alpha$ of portfolio weights to maximize

$$\sum_0 \pi_0 u_0 [w_0 - p\alpha, (X\alpha)_0].$$

The quantity $p\alpha$ is the price of the portfolio, and therefore $w_0 - p\alpha$ is the residual amount of the initial wealth available for initial consumption. The preferences of the agent are said to be increasing if each $u_0(\cdot, \cdot)$ is (strictly) increasing in both arguments. Saying the agent prefers more to less is just another way of saying that preferences are increasing.

Here is the rest of the proof of the Fundamental Theorem of Asset Pricing.

**Theorem:** (second half of the Fundamental Theorem of Asset Pricing) There is no arbitrage if and only if there exists some (at least hypothetical) agent with increasing preferences whose choice problem has a maximum.

**Proof:** If there is an arbitrage opportunity, $\eta$, then clearly the choice problem for an agent with increasing preferences cannot have a maximum, since for every $\alpha$,

$$\sum_0 \pi_0 u_0 [w_0 - p(\alpha + k\eta), (X(\alpha + k\eta)] \theta)$$

increases as $k$ increases.

Conversely, if there is no arbitrage, by the first half of the Fundamental Theorem of Asset Pricing (proven earlier), there exist a consistent positive linear pricing rule $q$. Let $w_0 = 0$ and $\alpha = 0$. Consider the particular utility function

$$u_\theta(\epsilon_0, \epsilon_1) = -\exp[-(\epsilon_0 - w_0)] - (q\theta / \pi_0)\exp(-\epsilon_1).$$

Each function $u_\theta$ is strictly increasing and also happens to be strictly concave, infinitely differentiable, and additively separable over time. Using $p = qX$, it is easy to show that this utility function satisfies the first-order conditions for a maximum, which are necessary and sufficient
by concavity. (Note: by a more complicated argument, it can be shown that the von Neumann–Morgenstern ‘state independent’ utility function \(- \exp (-c_0) - \exp (-c_1)\) has a maximum, but the maximum will not necessarily be achieved at \(\alpha = 0\).

As should be clear from the proof, it is not really important what class of preference we use, so long as all agents having preferences in the class prefer more to less and the class includes the particular preferences used in the proof (which are additive over states and time, increasing, concave, and infinitely differentiable).

Recent research on arbitrage, starting with Ross (1978) and Harrison and Kreps (1979), has focused on extending these results to more general state spaces in which there are many time periods and, more importantly, infinitely many states. In these spaces, deriving a positive linear pricing rule for marketed claims is still straightforward (one can prove the algebraic linearity condition and positivity directly from the no-arbitrage condition), but extending the pricing rule from the priced claims to all non-marketed claims requires some sort of extension theorem, such as a Hahn–Banach theorem. Obtaining a truly general result is complicated by the fact that the positive orthant is not typically an open set in these general spaces, and openness is a condition of the Hahn–Banach theorems. One part of the result that goes through in general is the implication that existence of an optimum implies existence of a linear pricing rule: so long as preferences are continuous in our topology, the preferred set will be open, and the linear pricing rule will be a hyperplane that separates the optimum from the preferred set.

Alternative representations of linear pricing rules

There are many equivalent ways of representing a linear pricing rule. Which representation is simplest depends on the context. In one representation, the price is the expected value under artificial ‘risk-neutral’ probabilities discounted at the riskless rate. (The risk-neutral probability measure is also referred to as an equivalent martingale measure.) In another representation, the price is the expectation of the quantity times the state price density, which is the state price per unit probability. In yet another representation, the price is the expected value discounted at a risk-adjusted rate. The purpose of this section is to show the fundamental equivalence of these representations.

The motive for using a particular representation is usually found in the study of intertemporal models or models with a continuum of states. Nonetheless, we will continue our formal analysis of the single-period model with finitely many states, leaving the more general discussion of the merits of the various approaches until afterwards. Now, we have already seen the basic linear pricing rule representation. For any portfolio \(\alpha\),

\[
\rho \alpha = q^T \alpha = \sum_{\theta} q_\theta (\alpha_\theta) \theta,
\]

that is, the sum across states of state price times the payoff.

The risk-neutral or martingale representation asserts the existence of a vector \(\Pi\) of artificial probabilities and a shadow riskless rate \(r\) such that

\[
\rho \alpha = (1 + r)^{-1} \Pi^T \alpha = (1 + r)^{-1} E_R(\alpha),
\]

that is, the expectation \(E_{\Pi}\) of the payoff under the risk-neutral (martingale) probabilities \(\Pi\), discounted at the riskless rate. It is easy to see the shadow riskless rate is equal to the riskless rate if one exists. The risk neutral approach is trivially equivalent to the positive linear pricing rule approach. Simply let

\[
\Pi = q / \sum_{\theta} q_\theta
\]

and

\[
(1 + r)^{-1} = \sum_{\theta} q_\theta
\]
For the converse, let

$$q = (1 + r)^{-1} = \sum_{B} q_{B}$$

(12)

Therefore, the existence of a positive linear pricing rule is the same as the existence of positive risk-neutral probabilities. (The risk-neutral measure is equivalent to the original probability measure, that is, $\Pi$ has the same null sets as $\alpha$. Here, that is simply the requirement that the list of states with positive probability is the same for both measures.)

A third approach emphasizes the role of the state price density, $\rho$. In this case, the price is given by

$$\rho \alpha = \sum_{B} \Pi_B \rho_B (\alpha) \beta = E(\rho \alpha).$$

(13)

To see that this is equivalent to the linear pricing rule, simply let

$$\rho_{B} = q_{B} / \Pi_{B},$$

(14)

or, conversely, let

$$q_{B} = \rho_{B} \Pi_{B}.$$  

(15)

Clearly, $p$ is positive in all states if and only if $q$ is.

We have shown the equivalence of these three approaches. This equivalence is stated in the following theorem.

**Theorem:** (*Pricing Rule Representation Theorem*) The following are equivalent:

- existence of a positive linear pricing rule;
- existence of positive risk-neutral probabilities and an associated riskless rate (the martingale property);
- existence of a positive state price density.

The remaining representation is that the value is equal to the terminal value discounted at a risk-adjusted interest rate $r_a$.

$$\rho \alpha = (1 + r_{a})^{-1} E(\rho \alpha)$$

(16)

While this might at first appear to be inconsistent with the other representations, the risk-adjusted rate $r_{a}$ is typically proportional to the covariance of return ($=\alpha \rho \alpha$) with some random variable, and consequently solving this equation for $\rho \alpha$ yields a linear rule. (See Beja, 1971, and Rubinstein, 1976, for general results concerning pricing rules using covariances.) For example, in the capital asset pricing model,
where \( r_m \) is the random return on the market and \( \lambda \) is the market price of risk. Solving these two equations for \( p\alpha \), we obtain

\[
p\alpha = (1 + r)^{-1}E[\alpha (1 - \lambda [r_m - E(r_m)])],
\]

which is certainly linear in \( x\alpha \). The subtle question is whether or not this is positive, and this hinges on whether the market return can get larger than \( E(r_m) + 1 / \lambda \) (Dybvig and Ingersoll, 1982). In any case, the important observation is that the basic form of the representation is linear even if verification of positivity depends on the exact form of the risk premium.

Now we return to the question of the comparative advantages of the various representations. The risk-neutral or martingale representation was first employed by Cox and Ross (1976a) for use in option pricing problems and was later developed more formally by Harrison and Kreps (1979) and a number of others. The risk-neutral representation is particularly useful for problems of valuation or optimization without reference to individual preferences, since under the martingale probabilities we can ignore risk altogether and maximize discounted expected value. In fact, for some problems this approach tells us that risk-neutral results generalize immediately to worlds where risk is priced.

However, this approach tends to be complicated when preferences are introduced, since von Neumann–Morgenstern (state independent) preferences under ordinary probabilities become state dependent under the martingale probabilities. As an aside, we note that, in intertemporal contexts in which the interest rate is stochastic, the price is the risk-neutral expectation of the future value discounted by the rolled-over spot rate (which is stochastic).

The state price density representation (Cox and Leland, 2000; Dybvig, 1980; 1988) is most useful when we want to look at choice problems. Samuelson (1947) emphasized the value of deriving equilibrium conditions from first- and second-order conditions for optimization. In asset pricing the first-order condition for an agent with von Neumann–Morgenstern preferences is that the agent's marginal utility of consumption is proportional to a consistent state price density (not necessarily unique) for the security market (Dybvig and Ross, 1982). (Note that if there is a non-atomic continuum of states, the state price density will typically be well-defined even though all primitive states have probability zero and state price zero.) For the CAPM, this fact was used implicitly by Sharpe (1964) and Lintner (1965), and was made explicit by Dybvig and Ingersoll (1983).

The representation of discounting expected returns using a risk-adjusted discount rate is most useful when we can get some independent assessment of the risk premium involved. Otherwise, it is needlessly complicated, since the price appears not only on the left-hand side of the equation but also in the denominator on the right-hand side. Discounting using a risk-adjusted rate is usually the method of choice for capital budgeting, since the risk adjustment is usually determined from comparables (for example, from past returns on assets in similar firms). For capital budgeting, there may also be a pedagogical advantage that (so far) it has been easier to communicate to practitioners than the other methods. Furthermore, focusing on the risk-adjusted discount rate sharpens the comparison of competing approaches (such as the capital asset pricing model and the dividend discount model).

It is useful to note how the various representations evolve over time. State prices are simply the product of state prices over sub-periods. For example, for \( r_s T \), the state price of a state at \( T \) given the state at \( t \) is equal to the state price of the state at \( T \) given the state at \( s \) times the state price of the state at \( s \) given the state at \( t \). (The state at \( s \) is determined by the state at \( T \) given the pervasive assumption of perfect recall, that is, the assumption that the family of sigma-algebras is increasing. If we use some reduced specification of the state – as when looking at Markov processes – the state price is the product of the two, summed over all possible intermediate states.)

The martingale representation yields a price equal to the expected value under the martingale measure of the product of the terminal value time a discount factor that corresponds to rolling over shortest maturity default-free bonds. This representation makes particularly clear the interaction between term structure effects and other effects. If there is a significant term structure, the discount factor is random, and we cannot ignore the interplay between term structure risk and random terminal value unless the terminal value of the asset under consideration is independent of interest rates (under the martingale measure). If the terminal value is independent of interest rate movements, then the value of the asset today is the risk-neutral expected terminal value of the asset discounted at the riskless discount factor (which equals the risk-neutral expected discount factor from rolling over shorts).

The state price density has an evolution over time similar to that of the state price, namely, the state price density over a long interval is the product of the state price density over short intervals. Since the state price density equals the state price divided by the probability, the ratio of the two evolutions gives us a relation involving only probabilities, which is Bayes’ law.

Finally, the discounted expected value approach is more complicated than the others. The exact evolution over time depends on whether uncertainty is multiplicative, linear, a distributed lag, or whatever. This difficulty is usually overlooked in capital budgeting applications.
which is probably not so bad in practice, given the imprecision of our estimates of risk premia and future cash flows.

Modern results based on the absence of arbitrage

Most of modern finance is based on either the intuitive or the actual theory of the absence of arbitrage. In fact, it is possible to view absence of arbitrage as the one concept that unifies all of finance (Ross, 1978). In this section, we will try to provide a sample of how arbitrage arguments are used in diverse areas in finance. We will touch on applications in option pricing, corporate finance, asset pricing and efficient markets. The efficient market hypothesis says that the price of an asset should fully reflect all available information. The intuition behind this hypothesis is that, if the price does not fully reflect available information, then there is a profit opportunity available from buying the asset if the asset is underpriced or from selling it if it is overpriced. Clearly this is consistent with the intuition of the absence of arbitrage, even if what we have here is only an approximate arbitrage possibility, that is, a large profit at little risk. Approximate arbitrage is always profitable to a risk-neutral investor. More generally, the issue is clouded somewhat by questions of risk tolerance and what is the appropriate risk premium. Happily, empirical violation of efficiency of the market (for example, in event studies) is not significantly affected by the procedure for measuring the risk premium (Brown and Warner, 1980; 1985). Therefore, an empirical violation of efficiency is an approximate arbitrage opportunity that presumably would be attractive at large scale to many investors.

The Modigliani–Miller propositions tell us that, in perfect capital markets, changing capital structure or dividend policy without changing investment is a matter of irrelevance to the shareholders. The original proofs of the Modigliani–Miller propositions used the law of one price and assumed the presence of a perfect substitute for the firm that was altering its capital structure. As an illustration of the Fundamental Theorem of Asset Pricing, Ross (1978) demonstrated that these propositions could be derived directly from the existence of a positive linear pricing rule.

To illustrate this argument, consider the proposition that the total value of the firm does not depend on the capital structure. The original argument assumed that there is another identical firm. If we change the financing of our firm, then the value of holding a portfolio of all the parts will give a final payoff equal to that of the identical firm, and must therefore have the same value under the law of one price. Alternatively, suppose that there exists a positive linear pricing rule \( q \). Let \( x \) represent the total terminal value of a firm in a one-period model and \( x_i \) the payoff to financial claim \( i \) on the assets of the firm. Then the sum of all the payoffs must add up to the total terminal value.

\[
\sum_{i} x_i = x
\]

(19)

Using the positive linear operator, \( q \), which values assets, we have that the value of the firm,

\[
\nu = \sum_{i} q(x_i) = q(\sum_{i} x_i) = q(x),
\]

(20)

which is independent of the number of structure of the financial claims.

Note that both proofs make an implicit assumption that goes beyond what absence of arbitrage promises, namely, that changing the capital structure of the firm does not change the way in which prices are formed in the economy. In the original proof this is the assumption that the other firm’s price will not change when the firm changes its capital structure. In the linear pricing rule proof this is the assumption that the state price vector \( q \) does not change.

Another application of the absence of arbitrage is to asset pricing. The most obvious application is the derivation of the arbitrage pricing theory (Ross, 1976a; 1976b). We will consider the special case without asset-specific noise. Assume that the mechanism generating the per dollar investment rates of return for a set of assets is given by

\[
R_i = E_i + \beta_1 f_1 + \ldots + \beta_k f_k, \quad i = 1, \ldots, n
\]

(21)

where \( E_i \) is the expected rate of return on asset \( i \) per dollar invested and \( f_i \) is an exogenous factor. This form is an exact factor generating mechanism (as opposed to an approximate one with an additional asset specific mean zero term).
Applying the pricing operator, \( q \), to equation (21) we have that

\[
1 = q(1 + R) = q(1 + E_i + \beta_1 q(f_1) + \ldots + \beta_k q(f_k)) = q(1 + E_i) + \beta_1 q(f_1) + \ldots + \beta_k q(f_k) = (1 + E_i) / (1 + r) + \beta_1 q(f_1) + \ldots + \beta_k q(f_k),
\]

which implies that

\[
E_i - r = \lambda_1 \beta_1 + \ldots + \lambda_k \beta_k \tag{22}
\]

where \( \lambda_j = -(1 + r) q(f_j) \) is the risk premium associated with factor \( j \). Equation (22) is the basic equation of the arbitrage pricing theory. We have derived it using absence of exact arbitrage in the absence of asset-specific noise. More general derivations account for asset-specific noise and use absence of approximate arbitrage.

The most important paper in option pricing, Black and Scholes (1973), is based on the absence of arbitrage, as is the whole literature it has generated. At any point in time, the option is priced by duplicating the value one period later using a portfolio of other assets, and assigning a value using the law of one price. We will illustrate this procedure using the binomial process studies by Cox, Ross and Rubinstein (1979).

During each period, the stock price either goes up by 20 per cent or it goes down by 10 per cent, and for simplicity we take the riskless rate to be zero. Assume that we are one period from the maturity of a call option with an exercise price of $100, and that the stock price is now $100 (the call is at the money).

How much is the option worth? To figure this out, we must find a portfolio of the stock and the bond that gives the same terminal value. This is the solution of two linear equations (one for each state) in two unknowns (the two portfolio weights). Explicitly, the terminal call value is the larger of 0 and the stock price less 100. In the good state, the stock value will be $120 and the option will be worth $20. In the bad state, the stock price will be $90 and the option will be worthless. If \( \alpha_S \) is the amount of stock and \( \alpha_B \) the amount of $100 face bond to hold in the duplicating portfolio, then we have that

\[
20 = 120 \alpha_S + 100 \alpha_B
\]

to duplicate the option value in the good state, and

\[
0 = 90 \alpha_S + 100 \alpha_B
\]

to duplicate the option value in the bad state. The solution to the two equations is given by

\[
\alpha_S = 2 / 3 \alpha_B = -3 / 5.
\]

Therefore, each option is equivalent to holding 2/3 shares of stock and shorting (borrowing) 3/5 bonds. By the law of one price, the option value is the value of this portfolio, or \( 100 \alpha_S + 100 \alpha_B = 60 / 3 \). In this context, we used arbitrage to value the option exactly. More generally, if less is known about the form of the stock price process, absence of arbitrage still places useful restrictions on the option price (Merton, 1973; Cox and Ross, 1976b). For example, the price of a call option is less than the current stock price, and the price of a European put option is no smaller than the present value of the stock price less the current stock price.

Absence of arbitrage also implies a surprising feature of the behaviour of long interest rates in the limit as maturity increases. Let \( V(t,T) \) denote the zero-coupon bond price, namely, the price at \( t \) of a riskless claim for $1 at \( T \). Equivalently, we can describe bond prices in terms of the zero-coupon rate \( z(t,T) \) where \( V(t,T) = 1 / (1 + z(t,T)) T - t \). Defining the long zero-coupon rate, \( z_L(t) \equiv \lim_{\mathcal{T} \rightarrow \infty} z(t, \mathcal{T}) \), absence of arbitrage implies that the probability is zero that this rate will ever fall. This is because the bond price today is an average of bond prices tomorrow weighted by (positive) state prices, and the bond price in any state declines asymptotically at the rate \( z_L(t) \) in that state tomorrow. Thus, the weighted
average of prices today declines at a rate equal to the smallest rate under our maintained assumption of finitely many states (and perhaps more slowly given infinitely many states). As a consequence, $z_L(t)$ at time $t$ is always less than or equal to its value $z_L(t)$ at any future date, $s > t$, in every realization (with probability one). For details see Dybvig, Ingersoll and Ross (1996).

Dominance is a useful concept to combine with the absence of arbitrage. A dominance argument gives features of a strategy that are optimal independent of preferences and, often, independent of distributions as well. For example, when we write the payoff on a call as $\max(S-X, 0)$, we are implicitly assuming it is a chosen strategy to exercise the option when it is in the money and not to exercise it when it is out of the money. Absent frictions, this is a dominant strategy and the assumption is without loss of generality. A more subtle dominance argument, relying on the absence of frictions and on a non-negative riskless rate, gives the classical result that an American call option (which can be exercised at or before maturity) has the same value as the corresponding European call option (which can only be exercised at maturity), because waiting to exercise is a dominant strategy (Merton, 1973; Cox and Ross, 1976b). Another dominance argument can be used to show that it is optimal to exercise certain reload options used in executive compensation again and again, whenever they are in the money (Dybvig and Loewenstein, 2003).

An alternative to option pricing by arbitrage is to use a ‘preference-based’ model and price options using the first-order conditions of an agent (Rubinstein, 1976). While using this alternative approach is very convenient in some contexts, the Fundamental Theorem of Asset Pricing tells us that we are not really doing anything different, and that the two approaches are simply two different ways of making the same assumption. The same point is true of the distinction some authors have made between the ‘equilibrium’ derivations of the arbitrage pricing theory and the ‘arbitrage’ derivations: there is no substance in this distinction. One derivation may give a tighter approximation than another, but all derivations require similar assumptions in one form or another.

ARCH models

Oliver B. Linton
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The ARCH model and its many generalizations are very important in analysing discrete time financial data. We review the properties of the original model and discuss many of the subsequent developments.

Keywords

ARCH models; ARMA models; estimation; exponentially weighted moving average model; factor models; GARCH models; generalized error distribution; heteroskedasticity; IGARCH models; linear models; long memory models; multivariate models; news impact curve; nonparametric models; semiparametric models; stationarity; time series analysis; unit roots

Article

Introduction of model and basic properties

The key properties of financial time series appear to be that: \((a)\) marginal distributions have heavy tails and thin centres (leptokurtosis); \((b)\) the scale appears to change over time; \((c)\) return series appear to be almost uncorrelated over time but to be dependent through higher moments (see Mandelbrot, 1963; Fama, 1965). Linear models like the autoregressive moving average (ARMA) class cannot capture well all these phenomena, since they only really address the conditional mean \(\mu_t = E(y_t | y_{t-1}, \ldots)\) and in a rather limited way. This motivates the consideration of nonlinear models. For a discrete time stochastic process \(y_t\), the conditional variance \(\sigma^2_t = \text{var}(y_t | y_{t-1}, \ldots)\) of the process is a natural measure of risk for an investor at time \(t-1\). Empirically it appears to change over time and so it is important to have a model for it. Engle (1982) introduced the autoregressive conditional heteroskedasticity (ARCH) model
where for simplicity we rewrite $V_t \mapsto V_t - \mu_t$ and suppose that the process started in the infinite past. This model makes $\sigma_t^2$ vary over time depending on the realization of past squared returns. For $\sigma_t^2$ to be a valid conditional variance it is necessary that $\omega > 0$ and $\gamma \geq 0$, in which case $\sigma_t^2 > 0$ for all $t$. Suppose also that $V_t = \epsilon_t \sigma_t$ with $\epsilon_t$ i.i.d. mean zero and variance one. Provided $\gamma < 1$, the process $y_t$ is weakly (covariance) stationary and has finite unconditional variance $\sigma^2 = E(\sigma_t^2) = E(V_t^2) = \omega / (1 - \gamma)$. This can be proven rigorously under a variety of assumptions on the initialization of the process (see Nelson, 1990). The meaning of this is that the process fluctuates about the long-run value $\sigma^2$ and forecasts converge to this value as the forecast horizon lengthens.

The ARCH process is dynamic like ARMA models and indeed we can write the process as an AR(1) in $V_t^2$, that is,

$$V_t^2 = \omega + \gamma V_{t-1}^2 + \eta_t,$$

where $\eta_t = V_t^2 - \sigma_t^2 = \sigma_t^2 (\epsilon_t^2 - 1)$ is a mean zero, uncorrelated sequence, that is heteroskedastic. Therefore, we generally have dependence in $\sigma_t^2$, $V_t^2$, and because of the parameter restrictions, positive dependence that is, $\text{cov}(\sigma_t^2, \sigma_{t-j}^2) > 0$ and $\text{cov}(V_t^2, V_{t-j}^2) > 0$. As far as the second order properties (that is, the covariance function) of the process $V_t^2$, this is identical to that of an AR(1) process.

However, it should be remembered that $V_t^2$ is heteroskedastic itself and that the form of the heteroskedasticity has to be particularly extreme since $V_t^2$ is kept non-negative.

One feature of linear models like the ARMA class is that the marginal distribution of the variable is normally distributed whenever the shocks are i.i.d. normally distributed. This is not the case for the ARCH class of processes. Specifically, the marginal distribution of $y_t$ will be heavy tailed even if $\epsilon_t = (V_t - \mu_t) / \sigma_t$ is standard normal. Suppose $\epsilon_t$ is standard normal (and the process is weakly stationary), then the excess kurtosis of $y_t$ is $\kappa_4 = 6\gamma^2 / (1 - 3\gamma^2) \geq 0$ provided $\gamma^2 < 1 / 3$. If $\gamma \geq 1 / 3^{1/2}$, then $E(V_t^4) = \infty$. For leptokurtic $\epsilon_t$, the restriction on $\gamma$ for finite fourth moment is even more severe. Although the ARCH(1) model implies heavy tails and volatility clustering, it does not in practice generate enough of either. The constraint on $\gamma$ for finite fourth moment severely restricts the amount of persistence; it is an undesirable feature that the same parameter controls both persistence and heavy tailedness, although if one allows non-normal distributions for $\epsilon_t$, this link is broken on one side.
The extension to the ARCH(\(p\)) process with \(p\) lags, while more flexible, becomes very complicated to estimate without restrictions on the coefficients. Bollerslev (1986) introduced the GARCH(\(p,q\)) process

\[
\sigma_t^2 = \omega + \sum_{k=1}^{p} \beta_k \sigma_{t-k}^2 + \sum_{j=1}^{q} \gamma_j (y_{t-j} - \mu_{t-j})^2,
\]

whose \(p=1, q=1\) GARCH(1,1) special case contains only three parameters and usually does a better job than an unrestricted ARCH(12), say, according to a variety of statistical criteria. The GARCH(1,1) process is probably still the most widely used model. As with the ARCH process one needs restrictions on the parameters to make sure that \(\sigma_t^2\) is positive with probability one. For the GARCH(1,1) it is necessary that \(\gamma, \beta \geq 0\) and \(\omega > 0\). Interestingly, for higher order processes it is not necessary that \(\omega, \gamma_j, \beta_j \geq 0\) for all \(j\): see Nelson and Cao (1992). For example, in GARCH(1,2) the conditions are that \(\beta, \gamma_1 \geq 0\) and \(\beta \gamma_1 + \gamma_2 \geq 0\). Provided \(\sum_{k=1}^{p} \beta_k + \sum_{j=1}^{q} \gamma_j < 1\), the process \(y_t\) is weakly stationary and has finite unconditional variance

\[
\sigma^2 = E(\sigma_t^2) = \frac{\omega}{1 - \sum_{k=1}^{p} \beta_k - \sum_{j=1}^{q} \gamma_j}.
\]

As for the ARCH process, the series \(y_t\) has higher kurtosis than \(\varepsilon_t\).

Drost and Nijman (1993) provide an important classification of ARCH models according to the precise properties required of the error terms. The strong GARCH process is where

\[
\varepsilon_t = \frac{y_t - \mu_t}{\sigma_t} \text{ i.i.d.} \quad E(\varepsilon_t) = 0 \text{ and } E(\varepsilon_t^2) = 1.
\]

It is generally this case that has been investigated in the literature. It is a very strong assumption by the standards of most modern econometrics, where usually only conditional moment restrictions are imposed, but is a complete specification that is useful for deriving properties like stationarity. The strong Gaussian case is where \(\varepsilon_t\) is additionally normally distributed. The semi-strong GARCH process is where
ARCH models: The New Palgrave Dictionary of Economics

These assumptions are weaker and turn out to be sufficient in many cases for consistent estimation. They are quite weak assumptions and restrict only the conditional mean and conditional variance of the process, allowing a variety of behaviour in the potentially time varying distribution of $\varepsilon_t$. Drost and Nijman (1993) show that conventional strong and semi-strong GARCH processes are not closed under temporal aggregation, meaning that if a process is GARCH at the daily frequency that the weakly or monthly data may not be GARCH, either weak or strong.

**Strong stationarity and mixing**

Consider the GARCH(1,1) process

$$\gamma_t = \sigma_t \varepsilon_t, \quad \sigma_t^2 = \omega + \beta \sigma_{t-1}^2 + \gamma \gamma_{t-1}^2$$

with $\varepsilon_t$ i.i.d. and $\omega > 0$ and $\beta, \gamma \geq 0$. A sufficient condition for strong stationarity is that

$E[\ln (\beta + \gamma \varepsilon_t^2)] < 0$ (see Nelson, 1990). If additionally, $E(\varepsilon_t)=0$ and $\text{var}(\varepsilon_t)=1$, then the necessary and sufficient condition for weak stationarity is that $\beta + \gamma < 1$. By Jensen's inequality

$E[\ln (\beta + \gamma \varepsilon_t^2)] < \ln E[(\beta + \gamma \varepsilon_t^2)] = \ln (\beta + \gamma)$, so it can be that $E[\ln (\beta + \gamma \varepsilon_t^2)] < 0$ even when $\beta + \gamma \geq 1$, that is, there are strongly stationary processes that are not weakly stationary.

There are many measures of dependence in time series. Mixingness is the property that dependence dies out with horizon. It can be measured in different ways: covariance mixing, strong mixing, and beta mixing are the main concepts. A stationary sequence $\{X_t, t=0, \pm1, \ldots\}$ is said to be covariance mixing if

$\text{cov}(X_t, X_{t+k}) \to 0$ as $k \to \infty$. A stationary sequence $\{X_t, t=0, \pm1, \ldots\}$ is said to be strong mixing ($\alpha$-mixing) if

$$\alpha(k) = \sup_{A \in \mathcal{F}_{-n}, B \in \mathcal{F}_{n+k}} |P(AB) - P(A)P(B)| \to 0$$

as $k \to \infty$, where $\mathcal{F}_{-n}$ and $\mathcal{F}_{n+k}$ are two $\sigma$-fields generated by $\{X_t, t \leq n\}$ and $\{X_t, t \geq n+k\}$.
ARCH models: The New Palgrave Dictionary of Economics

respectively. We call $\alpha(\cdot)$ the mixing coefficient. A stationary sequence $\{X_t, t=0, \pm 1, \ldots\}$ is said to be $\beta$-mixing if

$$\beta(k) = \sup_{A \in \mathcal{F}_{-\infty}, B \in \mathcal{F}_{\infty}} |P(A|B) - P(A)| \to 0$$

as $k \to \infty$. We call $\beta(\cdot)$ the mixing coefficient. We have $2\alpha(k) \leq \beta(k)$. The covariance mixing property is only well defined for weakly stationary processes, so it is natural here to work with the more general notions of $\alpha$ and $\beta$ mixing. A sufficient condition that a GARCH(1,1) process is $\beta$-mixing with exponential decay is that it is weakly stationary, Carrasco and Chen (2002), but this is not necessary. More recently it has been shown that IGARCH is strong mixing under some conditions (see Meitz and Saikkonen, 2004). One problem is that when you combine a GARCH process with other processes for the mean, the mixingness is not preserved and has still to be established. The weaker concept of near epoch dependence can be established, though in quite a general class of models (Hansen, 1991). Why does mixing matter? It is a key property that allows one to learn from the data through the law of large numbers and central limit theorems.

IGARCH models

In practice, estimated GARCH parameters lie close to the boundary of the weakly stationary region. This prompts consideration of the process where $\sum_{k=1}^{p} \beta_k + \sum_{j=1}^{q} \gamma_j = 1$, which is called the integrated GARCH or IGARCH. In this case, the process $y_t$ with i.i.d. Gaussian innovations is strongly stationary but not covariance stationary, since the unconditional variance is infinite (although the conditional variance is finite with probability 1). This is in contrast to linear unit root processes in which the process is neither weakly nor strongly stationary and these two notions coincide. Also, in contrast to the linear case, differencing does not induce weak stationarity, that is, $V_t^2 - V_{t-1}^2$ is not weakly stationary (although its mean is constant over time).

The exponentially weighted moving average model (sometimes called the J.P. Morgan model) is a variant on the IGARCH model in which there is no intercept $\omega$ and a unit root:

$$y_t = \sigma_t \varepsilon_t, \quad \sigma_t^2 = \beta \sigma_{t-1}^2 + (1 - \beta) y_{t-1}^2.$$

It is a very simple process with only one parameter and is widely used by practitioners, with particular values of the parameter $\beta$. Write $\sigma_t^2 = \sigma_{t-1}^2 [\beta + (1 - \beta) \varepsilon_{t-1}^2]$, so that $\ln \sigma_t^2$ is a random walk, that is,
\[ \ln \sigma_t^2 = \ln \sigma_{t-1}^2 + \eta_{t-1}, \quad \eta_{t-1} = \ln (\beta + (1 - \beta)\varepsilon_{t-1}^2), \]

and hence is not strongly stationary. On the other hand, the process \( y_t \) is informally weakly stationary since 
\[ E[y_t^2 | \sigma_0^2] = E[\sigma_t^2 | \sigma_0^2] = \prod_{s=1}^t E[\beta + (1 - \beta)\varepsilon_s^2] \sigma_0^2 = \sigma_0^2 \]
for all \( t \). The properties of this process depend on the moments of \( \eta_{t-1} \). If \( E[\eta_{t-1}] > 0 \), then \( \sigma_t^2 \to \infty \) with probability 1. If \( E[\eta_{t-1}] < 0 \), then \( \ln \sigma_t^2 \to -\infty \) with probability 1 as \( t \to \infty \) and so \( \sigma_t^2 \to 0 \) with probability 1. If \( E[\eta_{t-1}] = 0 \), then \( \ln \sigma_t^2 \) is a driftless random walk and the process just wanders everywhere. If we assume \( E[\varepsilon_t^2] = 1 \), then by Jensen's inequality \( E[\eta_{t-1}] < 0 \), and the process \( \sigma_t^2 \to 0 \) with probability 1 as \( t \to \infty \) whatever the initialization. Thus the process is essentially degenerate and is not plausible, despite being widely used.

**Functional form**

The news impact curve is the relationship between \( \sigma_t^2 \) and \( y_{t-1} = y \) holding past values \( \sigma_{t-1}^2 \) constant at some level \( \sigma^2 \). This is an important relationship that describes how new information affects volatility. For the GARCH process, the news impact curve is

\[ m(y, \sigma^2) = \omega + \gamma y^2 + \beta \sigma^2. \]

It is separable in \( \sigma^2 \), it is an even function of news \( y \), \( m(y, \sigma^2) = m(-y, \sigma^2) \), and it is a quadratic function of \( y \). The symmetry property implies that \( \text{cov}(\varepsilon_t^2, y_{t-j}) = 0 \) for symmetric about zero \( \varepsilon_t \).

The GARCH process does not allow 'leverage effects' or asymmetric news impact curves. Because of limited liability, we might expect that negative and positive shocks have different effects on volatility.

Nelson (1991) introduced the exponential GARCH model. Let \( h_t = \log \sigma_t^2 \) and let

\[ h_t = \omega + \sum_{j=1}^p \gamma_j [\theta \varepsilon_{t-j} + \delta \varepsilon_{t-j}] + \sum_{k=1}^q \beta_k h_{t-k} \]
where $\varepsilon_t = (y_t - \mu_t) / \sigma_t$ is i.i.d. with mean zero and variance one. Nelson's paper contains four innovations. First, it models the log, not the level. Therefore there are no parameter restrictions to ensure that $\sigma_t^2 \geq 0$. Second, it allows asymmetric effect of past shocks $\varepsilon_{t-j}$ on current volatility, that is, the news impact curve is allowed to be asymmetric. For example, $\text{cov}(\varepsilon_t^2, \varepsilon_t) \neq 0$ even when $\varepsilon_t$ is symmetric about zero. Third, it makes the innovations $\varepsilon_t$ i.i.d. It follows that $h_t$ is a linear process so that strong and weak stationarity coincide where they ought to (for $h_t$ anyway). On the other hand estimation and forecasting is quite tricky because of the repeated exponential/logarithmic transformations involved. The final innovation was to allow heavy tailed innovations based on the so-called generalized error distribution (GED) that nests the Gaussian as a special case.

An alternative approach to allowing asymmetric news impact curve is the Glosten, Jagannathan and Runkle (1993) model

$$\sigma_t^2 = \omega + \beta \sigma_{t-1}^2 + \gamma y_{t-1}^2 + \delta y_{t-1}^2 1(y_{t-1} < 0).$$

In this case, the news impact curve is asymmetric but still has quadratic tails. It is a simple enough modification, that it has similar probabilistic properties to the GARCH(1,1) process. There are many other variations on the basic GARCH model, too many to list here, but the interested reader can find a fuller description in the survey paper of Bollerslev, Engle and Nelson (1994).

One might expect that risk and return should be related: see Merton (1973) for an example. The GARCH-in-Mean process captures this idea. This process is

$$y_t = g(\sigma_t^2; b) + \varepsilon_t \sigma_t,$$

for various functional forms of $g$, for example, linear and log-linear and for some given GARCH specification of $\sigma_t^2$. Engle, Lilien and Robins (1987) used this model on interest rate data (see also Pagan and Hong, 1991). Here, $b$ are parameters to be estimated along with the parameters of the error variance. Some authors find small but significant effects.

**Estimation**

The standard approach to estimation of these models has been through estimation of the (conditional) Gaussian quasi-likelihood criterion
$L_T(\theta) = \sum_{t=1}^{T} \mathcal{L}_t(\theta) = - \sum_{t=1}^{T} \log \sigma_t^2(\theta) - \frac{1}{2} \sum_{t=1}^{T} \left( \frac{\nu_t - \mu_t(\theta)}{\sigma_t(\theta)} \right)^2,$

where $\sigma_t^2(\theta)$ and perhaps $\mu_t(\theta)$ are built up by recursions from some starting values. There are several possibilities regarding starting values: (a) $\sigma_0^2(\theta) = \omega / (1 - \beta - \gamma)$, (b) $\sigma_0^2(\theta) = T^{-1} \sum_{t=1}^{T} \nu_t^2$, and (c) $\sigma_0^2(\theta) = \nu_1^2$. Approach (a) imposes weak stationarity and would not be appropriate were IGARCH to be thought plausible, while value (b) sort of requires weak stationarity for the asymptotic properties to follow through. The likelihood function is maximized with respect to the parameter values usually using some derivative-based algorithm like BHHH and sometimes imposing inequality restrictions (like those required for $\sigma_t^2 \geq 0$ with probability 1 or for $\sigma_t^2$ to be weakly stationary) and sometimes not.

The (quasi) MLE (QMLE) can be expected to be consistent provided only the conditional mean and the conditional variance are correctly specified (Bollerslev and Wooldridge, 1992), that is, semi-strong not strong GARCH is required and conditional normality is certainly not required. This is true because the score function $\partial \mathcal{L}_t(\theta)/\partial \theta$ is a martingale difference sequence. Robust standard errors can be constructed in the usual way

$$
\left[ \frac{\partial \mathcal{L}_T(\hat{\theta})}{\partial \theta} \frac{\partial \mathcal{L}_T(\hat{\theta})}{\partial \theta}^\top \right]^{-1} \left[ \sum_{t=1}^{T} \frac{\partial \mathcal{L}_t}{\partial \theta} \frac{\partial \mathcal{L}_t}{\partial \theta}^\top (\hat{\theta}) \right] \left[ \frac{\partial \mathcal{L}_T(\hat{\theta})}{\partial \theta} \frac{\partial \mathcal{L}_T(\hat{\theta})}{\partial \theta}^\top \right]^{-1},
$$

although the default option in many software packages is to compute standard errors as if Gaussianity held.

The distribution theory is difficult to establish from primitive conditions even for simple models. There is one important point about these asymptotics – that one does not need moments on $y_t$ (for example, one does not need weak stationarity). Lumsdaine (1996) established consistency and asymptotic normality allowing the IGARCH case but under strong stationarity and symmetric unimodal i.i.d. $\varepsilon_t$ with $E[\varepsilon_t^3] < \infty$. Lee and Hansen (1994) proved the same result under weaker conditional moment conditions and allows for semi-strong processes with some higher-level assumptions. Jensen and Rahbek (2004) established consistency and asymptotic normality of the QMLE in strong GARCH model without strict stationarity. Hall and Yao (2003) assume weak stationarity and show that if $E(\varepsilon_t^4) < \infty$ the asymptotic normality holds, but also establish limiting behaviour (non-normal) under weaker moment conditions. No results have yet been published for consistent and asymptotically normality of EGARCH.
ARCH models: The New Palgrave Dictionary of Economics

from primitive conditions, although simulation evidence does suggest normality is a good approximation in large samples.

Typically, one finds small intercepts and a large parameter on the lagged dependent volatility; see Lumsdaine (1995) and Brooks, Burke and Persand (2001) for simulation evidence. These two parameter estimates are often highly correlated. Engle and Sheppard (2001) suggested a method they called target variance to obviate the computational difficulties sometimes encountered in estimating GARCH models.

For a weakly stationary GARCH(1,1) process we have $E(y_t^2) = \omega / (1 - \beta - \gamma)$ so that $\omega = E(y_t^2) (1 - \beta - \gamma)$. They suggest replacing $E(y_t^2)$ by $\sum_{t=1}^{T} y_t^2 / T$ in the likelihood so that one only has two parameters to chose. This results in a much more stable performance of most algorithms. The downside with this approach is that distribution theory is much more complicated due to the lack of martingale property, and in particular one needs to use Newey–West standard errors.

It is quite common now to estimate GARCH models using different objective functions suggested by alternative specifications of the error distribution like the $t$ or the GED distribution that Nelson (1991) favoured. These objective functions often have additional parameters such as the degrees of freedom that have to be computed. They lead to greater efficiency when the chosen specification is correct, but otherwise can lead to inconsistency, as was shown by Newey and Steigerwald (1997).

Long memory

The GARCH(1,1) process $\sigma_t^2 = \omega + \beta \sigma_{t-1}^2 + \gamma y_{t-1}^2$ is of the form

$$\sigma_t^2 = c_0 + \sum_{j=1}^{\infty} c_j y_{t-j}^2$$

(2)

for constants $c_j$ satisfying $c_j = \gamma \beta^{j-1}$, provided the process is weakly stationary, which requires $\gamma + \beta < 1$. These coefficients decay very rapidly so the actual amount of memory is quite limited. There is some empirical evidence on the autocorrelation function of $y_t^2$ for high frequency data that suggests a slower decay rate than would be implied by these coefficients. Long memory models essentially are of the form (2) but with slower decay rates. For example, suppose that $c_j = j^{-\theta}$ for some $\theta > 0$. The coefficients satisfy $\sum_{j=1}^{\infty} c_j < \infty$ provided $\theta > 1 / 2$. Fractional integration (FIGARCH) leads to such an expansion. There is a single parameter called $d$ that determines the memory properties of the series, and
ARCH models: The New Palgrave Dictionary of Economics

(1 − L)^d \sigma_t^2 = \omega + \gamma \sigma_{t-1}^2 (\varepsilon_{t-1}^2 - 1),

where (1−L)^d denotes the fractional differencing operator. When d=1 we have the standard IGARCH model. For d≠ 1 we can define the binomial expansion of (1−L)^−d in the form given above. See Robinson (1991) and Bollerslev and Mikkelson (1996) for models and evidence of long memory. The evidence for long memory is often based on sample autocovariances of \nabla_t^2, and this may be questionable due to a paper of Mikosch and St•ric• (2000).

Multivariate models

In practice we observe many closely related series, and so it may be important to model their behaviour jointly. Define the conditional covariance matrix

$$
\Sigma_t = \mathbb{E}(y_t y_t^T | \mathcal{F}_{t-1})
$$

for some n×1 vector of mean zero series y_t. Bollerslev, Engle and Wooldridge (1988) introduced the most general generalization of the univariate GARCH(1,1) process

$$
h_t = \text{vech} (\Sigma_t) = A + Bh_{t-1} + C\text{vech} (y_{t-1} y_{t-1}^T),
$$

where A is an n(n+1)/2×1 vector, while B, C are n(n+1)/2×n(n+1)/2 matrices. In practice, there are too many parameters. Also, the restrictions on the parameters to ensure that \Sigma_t is positive definite are very complicated in this formulation. For weak stationarity one requires that the matrix \( I - B - C \) is nonsingular and positive definite in which case the unconditional variance matrix is \text{unvech}( (I - B - C)^{-1} A ). The conditions for strong stationarity are rather complicated to state.

The so-called BEKK model is a special case that addresses these issues. It is of the form

$$
\Sigma_t = AA^T + B\Sigma_{t-1} B^T + C y_{t-1} y_{t-1}^T C^T
$$

for n×n matrices A, B, C. This gives a big reduction in number of parameters and imposes symmetry and
positive definiteness automatically. There are still many parameters that have to be estimated simultaneously, of the order \( n^2 \), and this limits the applicability and interpretability of this model. Bollerslev (1990) introduced the constant conditional covariance (CCC) model, which greatly reduces the parameter explosion issue. This involves standard univariate dynamic models for each of the conditional variances and a constant correlation assumption, that is,

\[
\Sigma_t = D_t R D_t, \quad D_t = \text{diag}\{\sigma_{it}\}
\]

(3)

and

\[
\sigma_{it}^2 = \omega_i + \beta_i \sigma_{i,t-1}^2 + \gamma_i \tau_{i,t-1}^2
\]

(4)

and \( R = (R_{ij}) \) is a time invariant matrix.

\[
R_{\hat{ij}} = \frac{E[\varepsilon_{it}\varepsilon_{jt}]}{\left(E[\varepsilon_{it}^2]E[\varepsilon_{jt}^2]\right)^{1/2}} = E[\varepsilon_{it}\varepsilon_{jt}],
\]

where \( \varepsilon_{it} = \gamma_{it}/\sigma_{it} \). The values \( R_{ij} \) are restricted to lie in \([-1,1]\] and the matrix \( R \) is symmetric and positive definite but otherwise unrestricted. This model generates time varying conditional covariances, but the dynamics are all driven by the conditional variances as the correlations are constant. The estimation of \( R \) is quite straightforward: use the sample correlation matrix of the standardized residuals \( \varepsilon_{it} = \gamma_{it}/\hat{\sigma}_{it} \). The estimated matrix \( R \) is guaranteed to be symmetric and positive definite because it is a correlation matrix and consequently the estimated \( \Sigma_t \) shares these properties.

Engle and Sheppard (2001) introduced the dynamic conditional covariance (DCC) model where we replace in (3) and (4)

\[
R_{i,j,t} = \frac{q_{ij,t}}{(q_{ii,t}q_{jj,t})^{1/2}}
\]
If we assume also that $a_{ij}=a$, $b_{ij}=b$, and $c_{ij}=c$ for all $i \neq j$ one can show that the resulting covariance matrix $\Sigma_t$ is guaranteed to be symmetric and positive definite. This model allows slightly more flexibility in allowing the correlations to vary over time, but because of the need to impose positive definiteness it still imposes common dynamics on the correlations, which may be too restrictive.

The approach that brings the most flexible dimensionality reduction is based on the ideas of factor analysis. Suppose that for $\forall t \in \mathbb{R}^n$, $f_t \in \mathbb{R}^k$:

$$
\begin{align*}
Y_t &= \mathcal{C} f_t + \epsilon_t \\
\left( f_t \right)' l_{t-1} &\sim 0, \left( \begin{array}{c}
\Lambda_t \\
0
\end{array} \right), \left( \begin{array}{c}
0 \\
\Gamma
\end{array} \right),
\end{align*}
$$

where $Y_{t-1}=\{y_{t-1}, \ldots\}$ is the observed information and $l_t = \{Y_t, f_t, Y_{t-1}, f_{t-1}, \ldots\}$ contains both observed series and the latent factors $F_{t-1} = \{f_{t-1}, f_{t-1}, \ldots\}$. Suppose that $\text{rank}(\mathcal{C})=k$ and that $\Lambda_t$ is a $k \times k$ positive definite time varying matrix. It follows that $Y_{t-1} l_{t-1} \sim 0$, $\mathcal{C} \Lambda_t C^T + \Gamma$ (Sentana, 1998). The implied $\Sigma_t$ is of reduced rank and depends on only order $nK$ (time-varying associated) parameters so there is a big reduction in dimensionality. This model includes as a special case the Diebold and Nerlove (1989) model where $\Gamma$, $\Lambda_t$ are diagonal and

$$
\lambda_{jjt} = \text{var}[f_j l_{t-1}] = \omega_j + \beta_j \lambda_{jj,t-1} + \gamma_j f_j z_{j,t-1},
$$

in which case $\lambda_{jjt} \notin \mathcal{Y}_{t-1}$. This process is closed under block marginalization – that is, subsets of $y_t$ do not have the same structure. Estimation is complicated by the latent variables. This framework also includes the Engle, Ng and Rothschild (1990) factor GARCH model $\Sigma_t = \Sigma_0 + \sum_{k=1}^K \delta_k \delta_k^T \sigma_{kt}^2$, where $K<n$, and
ARCH models:
The New Palgrave Dictionary of Economics

\[ \sigma^2_{kt} \] is the conditional variance of a certain portfolio \( k \), with time invariant weights \( \alpha_k \), that is,

\[ \gamma^2_{kt} = \alpha_k^T \gamma_t \] with \( \alpha_k^T \gamma_t = 1 \). They assume also that \( \sigma^2_{kt} \) are standard univariate GARCH(1,1) processes, that is, for some parameters \( (\omega_k, \beta_k, \gamma_k) \),

\[ \sigma^2_{kt} = \omega_k + \beta_k \sigma^2_{k,t-1} + \gamma_k (\gamma^T_{kt} \gamma_{t-1})^2. \]

This model is written in terms of observables and consequently its estimation is somewhat easier, but it suffers from the fact that it is not closed under block marginalization – that is, subsets of \( y_t \) do not have the same structure. Sentana (1998) shows how it is nested in the general model (5) and (6).

Nonparametric and semiparametric models

There have been a number of contributions to ARCH modelling from the nonparametric or semiparametric point of view; see Hafner (1998) for an overview. Engle and González-Rivera (1991) suggested treating the error distribution in a GARCH process nonparametrically, that is,

\[ \gamma_t = \mu_t + \varepsilon_t \sigma_t^2 = \omega + \beta \sigma^2_{t-1} + \gamma (\gamma_{t-1} - \mu_{t-1})^2, \]

where \( \mu_t \) depends on observed covariates and parameters, while \( \varepsilon_t \) is i.i.d. with density \( f \) that is not restricted in shape. This is motivated by the great deal of evidence that the density of the standardized residuals \( \varepsilon_t = (\gamma_t - \mu_t) / \sigma_t \) is non-Gaussian. They proposed an estimation algorithm that involved estimating \( f \) from the data. Linton (1993) and Drost and Klaassen (1997) have shown that one can achieve significant efficiency improvements depending on the shape of the error density.

An alternative line of research has been to treat the functional form of \( \sigma^2_t (\gamma_{t-1}, \gamma_{t-2}, \ldots) \) nonparametrically. In particular, suppose that

\[ \sigma^2_t = g(\gamma_{t-1}, \ldots, \gamma_{t-p}) \]

for some unknown function \( g \) and fixed lag length \( p \). This allows for a general shape to the news impact curve and nests all the usual parametric ARCH processes. See Pagan and Hong (1991) and Härdle and Tsybakov (1997) for some applications. This model is somewhat limited in the dependence it allows in comparison with the GARCH(1,1) process, which is a function of all past \( y_t \) s. Also, the curse of dimensionality means that the usual estimation methods do not work well in practice for large \( p \), that is, \( p > 4 \).

One compromise approach to avoiding the curse of dimensionality is to use additive models, whence
ARCH models: The New Palgrave Dictionary of Economics

\[ \sigma_t^2 = \sum_{j=1}^{p} g_j(\gamma_{t-j}) \]  

(7)

for some unknown functions \( g_j \). The functions \( g_j \) are allowed to be of general functional form but only depend on \( \gamma_{t-j} \). This class of processes nests many parametric ARCH models. The functions \( g_j \) can be estimated by kernel regression techniques (see Masry and Tjøstheim, 1995). Yang, Härdle and Nielsen (1999) proposed an alternative nonlinear ARCH model in which the conditional mean is again additive, but the volatility is multiplicative \( \sigma_t^2 = \epsilon \prod_{j=1}^{d} \sigma_j^2(\gamma_{t-j}) \). Kim and Linton (2004) generalize this model to allow for arbitrary, but known, transformations, that is, \( G(\sigma_t^2) = \epsilon + \sum_{j=1}^{d} \sigma_j^2(\gamma_{t-j}) \), where \( G(.) \) is known function like log or level. Linton and Mammen (2005) considered the case where \( \sigma_t^2 = \sum_{j=0}^{\infty} \beta_j g(\gamma_{t-j}) \), which nests the GARCH(1,1) process when \( g(\gamma) = \omega + \gamma \gamma^2 \).

One final semiparametric approach has been to model the coefficients of a GARCH process as changing over time, thus

\[ \sigma_t^2 = \omega(x_{tT}) + \beta(x_{tT}) \sigma_{t-1}^2 + \gamma(x_{tT})(\gamma_{t-1} - \mu_{t-1})^2, \]

where \( \omega \), \( \beta \), and \( \gamma \) are smooth functions of a variable \( x_{tT} \), for example, \( x_{tT}=t/T \). This class of processes is non-stationary but can be viewed as locally stationary along the lines of Dahlhaus (1997).

ARCH models: The New Palgrave Dictionary of Economics

SFB 373. Berlin: Humboldt-Universität.

The traditional literature on arms races starts with the Richardson model (named after Lewis Fry Richardson, 1881–1953, British polymath who made fundamental contributions to the mathematical analysis of war, to weather forecasting, and to measuring the length of coastlines and borders). The Richardson model is a descriptive model of the dynamic processes of interaction in an arms race. The model is summarized by two differential equations describing the rate of change over time of weapon stocks in each of two countries, 1 and 2. Let $w_1(t)$ represent the stock of weapons for country 1 and $w_2(t)$ represent the stock of weapons for country 2 at time $t$. In the Richardson model the rate of change of weapon stocks at time $t$ is given by

\begin{align}
\dot{w}_1(t) &= a_1 w_2(t) + b_1 w_1(t) + c_1 \\
\dot{w}_2(t) &= a_2 w_1(t) + b_2 w_2(t) + c_2
\end{align}

According to these coupled differential equations, the accumulation of weapons in country 1 can be described as the sum of three separate influences. First is the ‘defence term’, $a_1$, where the accumulation of weapons is influenced positively by the stock of weapons of the opponent, $w_2(t)$, representing the need to defend oneself against the opponent. Second is the ‘fatigue term’, $b_1$, where the accumulation of weapons is influenced negatively by one’s own stock of weapons, representing the economic and administrative burden of...
conducting the arms race. Third is the ‘grievance term’, $c_1$, representing all other factors influencing the arms race, whether historical, institutional, cultural, or derived from some other source. The dynamics of the arms accumulation equation for country 2 are symmetrical.

During the Cold War, Richardson's equations attracted much interest among political scientists, economists and others interested in the arms race. One of the questions of interest was the stability of the arms race. There are three schools of thought about the stability of armament races. One is that armaments races have a stable equilibrium. A second belief is that armaments races are unstable, a belief often seen in the popular press, which holds that unless some agreement is reached weapon stocks will increase in an ever-accelerating spiral that must ultimately lead to bankruptcy or nuclear holocaust. A third view is that a stable equilibrium may exist, but that the stability may only be a local property, so that a large disturbance of the system, such as the introduction of a new weapons system, which may set off an armaments race, either positive (leading to larger and larger weapons stocks) or negative (leading to major decreases in weapons).

The first two questions could be addressed by using the parameters of the model to calculate the roots and check for stability. The third question requires that the underlying process that led to these differential equations be modelled. Much of the theoretical work on the arms race is in the Richardson tradition of explaining the arms race was attempt to estimate these parameters empirically or to find theoretical reasons for constraining the magnitudes (as discussed in the Intriligator, 1982, survey paper). The third question was addressed by research that derived the dynamics of arms accumulation in a model based on the axioms of rational choice, on the assumption that each country can be modelled as a single rational actor. Brito (1972) and Intriligator (1975) each obtained a general set of equations describing an arms race, of which the Richardson model is one special case.

In Figure 1, $\hat{x}_1$ and $\hat{x}_2$ are the stable equilibrium.

Figure 1
The Richardson paradigm was the central focus of research on arms races. During the Cold War, the build-up of bombers and then missiles by the United States and the Soviet Union was, or should have been, the most important concern as it had the potential of destroying civilization as we know it, if not mankind. This danger was reduced with the end of the Cold War and the later dissolution of the Soviet Union, which ended the US–Soviet arms race. The new environment may not be well characterized by the Richardson paradigm; this article describes the changes and suggests a new approach to the formulation of a model of arms races.

The changing nature of arms races

There have been several major changes in the nature of the arms race since the early 1990s. The most important has clearly been the end of the Cold War. This epochal change began with the demise of the Warsaw Pact in 1989 and ended with the dissolution of the Soviet Union in December 1991. The result has been the end of the global East–West arms race of the Cold War period, when it dominated global politics. Among the implications of this profound change have been drastic reductions in arms expenditures by the member states of the former Soviet Union and its former allies, accompanied by relatively smaller reductions in arms expenditures by the United States prior to the Afghanistan and Iraq wars and by its allies in NATO. As a result, the United States is currently by far the world leader in expenditures on arms, spending almost as much as the rest of the world combined. Another major change since the mid-1990s has been the substantial increases in arms expenditures by China and its neighbouring states in east and south-east Asia. In China, the reforms that started as a result of Deng Xiaoping’s four modernizations of 1978 profoundly changed the course of the country and its economy and society. The last of these four
modernizations was that of the military, which led to the rapid modernization of the Chinese People's Liberation Army (PLA), involving the deployment of newer weapons and major expenditures on arms. The neighbouring nations of east and south-east Asia have reacted to these developments in China by increasing their own arms expenditures. As a result, this region is witnessing major increases in arms, including substantial arms imports.

The India–Pakistan arms race also continues with both qualitative and quantitative arms developments, both nations having demonstrated their nuclear weapons capabilities in tests conducted in May 1998. In both cases, third parties have played an important role. China has shared nuclear and missile technology with Pakistan, and Pakistan, in turn, has been a major actor in the proliferation to nuclear technology to North Korea and Iran.

In the Middle East, the United States has provided Saudi Arabia with weapons, given financial and military assistance to both Israel and Egypt, and has shared anti-missile defence technology with Israel. While Russia can no longer afford to support the former client states of Soviet Union, it appears to be willing to sell weapons technology to any country that can afford it for purely commercial, as opposed to diplomatic or military, purposes.

An important change of recent years has been the appearance of certain newer or evolving regional arms races or arms build-ups. One is the important arms race is that involving the nations of the Gulf, including Iraq, Iran, Syria, Saudi Arabia, Kuwait and the Gulf States, that both was stimulated by and resulted in wars in the region, including the Iran–Iraq war and the Iraqi invasion and annexation of Kuwait, resulting in a war to liberate it and the subsequent US-led invasion and occupation of Iraq. The major suppliers of weapons to all parties in the region except Iran are the United States and its European allies. Second, there have also also been arms build-ups among the states of the former Soviet Union that are seeking to preserve their independence through their military capabilities. A third type of arms build-up is that in the former Warsaw Pact states of central and eastern Europe that have joined NATO, or hope to do so, and that have to upgrade their weapons capabilities to become members of the alliance.

The major weapons states have played an important role in fuelling these and other regional arms races through arms exports, including the disposal of surplus weapons in the post-cold war period. The United States, Russia, Germany, Britain and France are the leading suppliers of surplus weapons, while Turkey, Greece, Pakistan, Morocco and a number of Middle East countries are the main recipients of such weapons.

**Impacts of recent changes on stability**

These changes in arms races since the mid-1990s have had important impacts on the stability of both the regional and global systems. As a result of these changes, we believe that there are probably greater instabilities today than those of the earlier Cold War period.

Consider first the principal antagonists of the Cold War. Where there had earlier been two ‘superpowers’, now there is only one as measured by arms expenditures and military capabilities, namely, the United States. Russia has assumed most of the Soviet weapons of mass destruction and the associated responsibilities involved with such weapons. The continued presence of nuclear weapons in Russia and the United States, albeit at lower levels, is probably adequate for mutual deterrence, but there are great dangers inherent in the current unstable political, economic, and social situation in Russia. The result could be a loss of effective control of weapons of mass destruction, with the possibility of an accidental or inadvertent launch of such weapons. The disquieting similarities between Russia today and Germany in the Weimar Republic period between the wars, including loss of empire, inflation, depression and the destruction of the middle class, suggest the possibility of the emergence of a new authoritarian leader in Russia, which would create additional instabilities.

Another major threat to stability at both global and regional levels is the proliferation of weapons of mass destruction. There is now much greater worldwide access to technology and the required material for nuclear, chemical, and biological weapons stemming, in part, from the collapse of the Soviet Union and the desperate situation of its military and scientific establishment. There are also the chains of proliferation that started with the United States and continued with the Soviet Union, the United Kingdom, France, China, India, and Pakistan, and that could continue to other nations, including Iran and other nations of the Gulf region.

Yet another threat to stability in the post-Cold War world is that of terrorists using various weapons of mass destruction. Sub-national groups, motivated by extreme ideologies, religious fanaticism, or other causes, have much greater access to such weapons on world markets. Large urban centres and freedoms of speech, travel, assembly, and the press have made modern societies highly vulnerable to possible terrorist attack. This was clearly demonstrated on September 11, 2001.

**Beyond the Richardson paradigm**

Until the East–West arms race of the Cold War period, most arms races were naval. Until the 20th century, armies were highly labour-intensive institutions with relatively little capital. Roman soldiers furnished their own equipment until the late Republic. Feudal armies also furnished their own equipment, where the obligation of a fief holder under military tenure was to furnish a certain number of knights and men at arms for a given number of days a year and to provide arms and horses for these men. The key element in deploying military power at that time was the organization of the state and its ability to raise revenue. The possibility of organizing and disciplining free men to serve as heavy infantry was the key to the Greek and Republican Roman armies. Heavy infantry required a body of free men willing to serve. It is very difficult to find examples of heavy infantry manned by professional soldiers except in circumstances where the state had the ability to tax effectively, such as the early Roman Empire and European states after the 16th century.
In hindsight, however, the Richardson paradigm of competitive accumulation of weapons, though important, was limited. The Anglo–German naval race that first attracted Richardson's attention played a very minor role in the First World War. After the indecisive battle of Jutland in 1916, both battle fleets were inactive and the important naval element was the German use of U-boats.

The other important arms race of the 20th century that fits the Richardson paradigm was the nuclear arms race between the United States and the Soviet Union. Fortunately, because of mutual assured destruction, these weapons were never used and the downfall of the Soviet Union was largely the result of the failure of its institutions.

Arms races did not play a major role in the Second World War. British aircraft manufacturers increased the stock of fighter planes during the Battle of Britain. The United States did not fully gear up for a war economy until after Pearl Harbor, and Soviet war production came from factories they moved east of the Urals. Even German production was increasing until the very end of the war.

In recent years technological change has also called into question the Richardson paradigm. Constant or increasing returns to scale have always created difficulties for economic theory. An economy with constant returns to scale is indeterminate with respect to the scale size of firms, and it is necessary to appeal to some fixed factor to determine the size of the economy. Increasing returns to scale leads to monopolies constrained only by demand. Firm behaviour then becomes strategic and none of the standard welfare theorems that hold in competitive markets apply. Thus, it is not surprising that increasing returns to scale in an arms race can lead to very different results than constant or decreasing returns to scale. Increasing returns to scale in the technology of arms production is more likely to occur with newer types of ‘smart’ weapons that rely heavily on electronics, computers, software, and so forth. In producing weapons with such a large informational component, it is likely that increasing the scale of the production process will make production more efficient. Nations producing arms may sell weapons even when these sales may be contrary to their foreign policy. The drive to lower weapons unit costs through greater sales gives momentum to foreign arms sales that can even conflict with diplomatic or political goals. An example may be the decision of the United States to lift its embargo on arms sales to Latin America at the urging of weapons producers.

Another consequence of technological change is that new technologies have made nuclear weapons and missiles feasible for most nation states, and some of these technologies have valid non-military applications. North Korea with an annual GDP of US$40 billion has acquired nuclear weapons and is ready to test the Taeposong-2, a missile that can reach the United States or, as the North Koreans claim, put a satellite in orbit. Iran is developing the capability of enriching uranium, a capability that can be used to produce fuel or bombs. As of 2006, the developed world is trying to prevent the test of the missile by North Korea and the acquisition of the capability of enriching uranium by Iran. Technological change has forced the developed world into the position of trying to deny countries in the developing world technologies that the developed world possesses and that have plausible non-military use.

As discussed above, social capital has been a very important element in the ability of a state to mobilize its resources and project power. Social capital includes not only the tangible institutions that the state has to tax, to conscript and to mobilize resources, but also less tangible institutions such as the relations of the members of the state to each other and to the state. States with sharp class, ethnic or caste distinctions may find it difficult to mobilize effectively to project force. During the American Civil War, the institution of slavery kept the South from mobilizing the members of its population that were black, and gave President Lincoln the political advantage of defining the war to be against the institution of slavery. In present day Iraq, ethnic differences have made it very difficult to organize an Iraqi national army.

Among the components of social capital are the common values of the society and its institutions. One important element of social capital familiar to most economists, but largely neglected in the arms race literature, is the attitude of the society towards risk and uncertainty. One very important question is how a society views a lottery that will cost a specific member of society his or her life with certainty to be equivalent to a lottery in which 1,000 individuals face one chance in a thousand of dying. It has long been noted by scholars in such fields as public finance, law, and economics that people in the United States are willing to spend more resources to save a specific individual than an individual who is a statistical abstraction. This element of social capital is reflected in how the United States conducts war, but it is not shared by other cultures.

There is widespread use of suicide bombers in current conflicts in Palestine and Iraq. Although this is a new phenomenon in recent history, most of the elements are not new. In the Second World War Japan sent young pilots on kamikaze suicide missions while the United States was willing to send bomber crews over Germany knowing that few would survive and there would be civilian casualties. The probability that a bomber crew would survive a full tour of duty was small. There may be some substantive difference between the Palestinians being willing to send a young man to kill himself to induce terror among the Israelis and the Doolittle raid where 16 bombers attacked the Japanese home islands in 1942 for psychological purposes; but it seems that the difference is that, whereas Western cultures are willing to sacrifice individuals for the common good as long as the sacrifice is a lottery, some other cultures are willing to sacrifice specific individuals. This difference changes the war-making potential of the different cultures.

To illustrate with another example, the Japanese supply of trained pilots was seriously depleted during the battle of Midway in 1942 and subsequent naval engagements. The Japanese were not able to compete with the Americans in training new pilots. By the Marianas campaign the Japanese were no match for the Americans, and the Japanese resorted to using untrained pilots as kamikazes to attack the American fleet. This example illustrates the role of various forms of social capital in war. The more open and egalitarian American society allowed the United States to train pilots as it had a larger pool to draw from than the more structured and hierarchical Japanese society. However, the advantage of this type of American social capital was offset in part by the fact that Japanese society was willing to sacrifice specific individuals. American pilots were better trained and had more human capital; the willingness of Japanese society to sacrifice specific Japanese pilots was a different form of social capital.

Richardson’s world was one in which dreadnoughts and battlecruisers would steam into battle planned by admirals who had studied Admiral Thayer Mahan (1840–1914, US naval officer and geostrategist who was influential on the US building a modern naval fleet, acquiring overseas naval bases, and building the Panama Canal) and other theorists. The US–
Soviet arms race was also a very intellectual process that was based on very sophisticated doctrines and involved weapons systems that were highly quantifiable. The conflicts we now face, by contrast, are very different. They involve state and non-state entities, and the means of deploying force are highly asymmetrical. Fighter planes carrying GPS guided bombs are used against terrorists who employ suicide bombers and can use the internet to transmit pictures of the decapitation of prisoners. Modelling such phenomena is the task for the next generation. What we propose to do is offer a conjecture as to the nature of such processes.

A conjecture on arms race theory

Assume that the war-making potential of the $i$-th country can be described by a vector of physical, human, intellectual and social capital, $k_i$ and a vector of strategies $v_i$. Its war-making potential, $x_i$, is given by

$$x_i = \max_{v_i} \theta(k_i, v_i)$$

where the cost of the strategies and other tradeoffs is reflected in the social capital. We conjecture that the intertemporal optimization results in a differential equation of the form

$$\dot{x}_1 = a_1(x_1) + b_1(x_2) + c_1(x_1, x_2)$$

$$\dot{x}_2 = a_2(x_2) + b_2(x_1) + c_2(x_1, x_2)$$

The first term $a_i(x_i)$ reflects the role of the $i$-th country's war-making potential on the rate of growth of $i$-th country's war-making potential. In the Richardson model the derivative of this term is negative as it represents the fatigue term. In this model it could well be positive as many of the components of the war-making potential – social, intellectual and human capital – are productive. The second term $b_i(x_i)$ reflects the role of the $j$-th country's war-making potential on the rate of growth of $i$-th country's war-making potential. This is analogous to the defence term in the Richardson model. As in the Richardson model, this term is positive. In this model such an assumption is made for two reasons. First, as in the Richardson model, an increase in the war-making potential of the $j$-th country will be viewed as a threat. Second, and perhaps more important, some of the inputs in the production of $x_j$, particularly intellectual capital and social capital, are public goods and can be transferred to the competing country. Meiji Japan acquired from the West the technology to build warships and organize a modern navy, and at the present time the technology the North Koreans are using to build nuclear bombs can be traced from the United States through various intermediaries to China, to Pakistan and then to North Korea. The problem of technological transfer is more difficult to control when it is dual use, that is, could be used for civilian as well as military purposes. After all, the Taepdong-2 could be used to launch weather satellites. The term, $c_i(x_i, x_j)$ is different from the grievance term in the Richardson model in that it represents the competition of the parties for resources or perhaps even ecological space, and is assumed to be quadratic in order. The derivative is assumed to be positive. If we consider the equation

$$\dot{x}_1 = a_1(x_1) + b_1(0) + c_1(x_1, 0)$$

and if $a_1(0) = 0$ and $b_1(0) = 0$, we would assume that eq. (4) would behave in a way similar to a biological population growth equation (Figure 2).
\(x_1\) is the maximum potential size of Country 1 in the absence of competition. A linear approximation of eq. (3) is given by

\[
\begin{align*}
\dot{x}_1 &= a_1 x_1 + b_1 x_2 + c_1 (x_1 + x_2)^2 \\
\dot{x}_2 &= a_2 x_2 + b_2 x_1 + c_2 (x_1 + x_2)^2
\end{align*}
\]

This is similar to the Richardson equation except for the quadratic term of the common resource constraint. If we assume that \(a_i\), the ‘fatigue term’, is negative, \(b_i\), the ‘defence term’, is positive and \(c_i\), the ‘resource term’, is negative, then we can represent the dynamics of this nonlinear system in the phase diagram in Figure 3.
Although on the surface this appears to be very similar to the Richardson equation, the variable $x_i$ is war-making potential that is the result of a prior optimization. One of the elements of the prior optimization is social capital, which includes among its elements moral values.

The differential equation system has four equilibria, of which two are stable and two are unstable. The two that are stable, $(\bar{x}_1, 0)$ and $(0, \bar{x}_2)$, involve the elimination of one of the parties. Whether this is good or bad depends on the process of the optimizations underlying the dynamical system. Recall that one of the important components of the process is social capital. One realization could be that the social capital of the competing parties would evolve in such a fashion as to eliminate conflict. An example is the transformation of the nation states of Europe, with a thousand-year history of wars, into the European Union. A second, less optimistic, scenario is the complete destruction of the weaker party. Again, the crucial element is social capital. Initially, the weaker power may threaten the stronger power by using tactics that are not acceptable to the values of the stronger power — for example, the use of suicide bombers. However, civilization has a thin veneer. Historically, if a country feels that its survival or vital interests are at stake, it will quickly shed its inhibitions. The tactics the British used to suppress the sepoy mutiny were brutal. At Peshawar, 40 sepoys were stood before cannons and blown apart in a public execution. The countries that condemned the German bombing of Guernica in the Spanish Civil War (fewer than 2,000 casualties) firebombed Hamburg (50,000 casualties), Dresden (25,000–35,000 casualties).
and Tokyo (100,000 casualties) in the Second World War, and ultimately used atomic weapons on Japanese cities. Before the start of the Gulf War of 1991, US Secretary of State James A. Baker III warned Iraq that the use of weapons of mass destruction by Iraq would result the destruction of Iraq as a modern state.

The third alternative is decoupling. This results in a stable equilibrium (see Figure 4). The French in Algeria, the United States in Vietnam and the Soviet Union in Afghanistan withdrew because the game was not worth the candle. The partition that appears to be imminent in Palestine, where Israel is building a wall to minimize its interaction with the Palestinians, may be an omen of things to come. If interaction with the developing world becomes too costly, the developed world has the alternative of disengaging. Without oil, the Middle East would be no more important than Africa, and conflicts between the Sunnis and Sh’ias would receive the same attention as conflict between the various African tribes. At prices greater than US$45.00 a barrel, technologies exist for the developed world to be self-sufficient in oil. History could repeat itself. An argument can be made that the Muslim world started to decline in the 16th century partly because the opening of alternative trade routes to Asia destroyed the Muslim monopoly on such trade.

Figure 4
Conclusions

The arms race as described by the Richardson paradigm, where nation states arm in a competitive fashion, is a phenomenon that starts with the naval arms race at the end of the 19th century and may have ended along with the US–Soviet arms race after the dissolution of the Soviet Union. Before that time, warfare was not very capital-intensive, and the most important elements in the projection of military power were the human capital of the population and the social capital that enabled countries to mobilize their resources in war. Richardsonian arms races reflect competition that is constrained by economic resources. Recent developments in technology have broken that link. Technological change has made it possible for a country like North Korea, with an annual GNP of US$40 billion, to acquire nuclear weapons and a missile that may be capable of attacking the United States. The link between economic power and the ability to project military power has been broken. The Richardson paradigm no longer applies. We conjecture the structure of an alternative model. This model suggests three alternatives: cultural convergence, destruction of the weaker party, and decoupling of the conflict. It should be clear that the model is a conjecture based on our intuition, and much work is needed to develop the theoretical foundations of the next arms race paradigm.

Arms trade is the transfer of weapons systems, components, technologies, and services across national and territorial borders. Contemporary arms trade occurs in three product categories: major conventional weapons (MCW), such as fighter aircraft and destroyers; small arms and light weapons (SALW), such as assault rifles, machine guns and improvised explosive devices; and weapons of mass destruction (WMD), such as nuclear, biological and chemical weapons technologies and long-range missile systems. MCW are the dominant form of weapons in interstate wars, while SALW are used intensively by non-state actors in intra-state wars (for example, civil wars) and extra-state conflicts (for example, transnational terrorism). WMD components and technologies proliferate by spreading to states or possibly non-state actors via trade or indigenous production.

Major sources of arms trade data include the US Congressional Research Service for all categories of weapons and arms-related services to developing nations; the Stockholm International Peace Research Institute for MCW; the Norwegian Initiative on Small Arms Transfers and the Graduate Institute of International Studies (Geneva) Small Arms Survey for SALW; and the Monterey Institute's Center for Nonproliferation Studies for WMD proliferation. These sources indicate that, of the world's total arms
exports, more than one-half originates in the United States and Russia, and close to two-thirds goes to developing nations (Brauer, 2007).

Theories of arms trade have shifted in emphasis over time. Pre-Cold War literature emphasized economic motives, often from a condemnatory ‘merchants of death’ perspective (see, for example, Engelbrecht and Hanighen, 1934). During the Cold War, classic texts focused on domestic and international politics, with some coverage of economic incentives (see, for example, Pierre, 1982). Post-Cold War models of arms trade highlight both commercial and security concerns. For example, in Levine and Smith's (1995) model, a few suppliers export weapons to a large number of price-taking buyers who are involved in dyadic arms rivalries. Suppliers’ utility depends on security and producers’ profits, while recipients’ utility depends on security and consumption. Under certain conditions, commercial gains to arms exporters are offset by security losses because the arms exports create a greater risk of war among recipients. Under other conditions, arms exports reduce war risk, implying both commercial and security gains to suppliers from weapons exports.

Theoretical models of international trade and industrial organization often apply to arms trade (see, for example, Anderton, 1996). Competitive models are useful for the study of SALW trade because such weapons are relatively homogeneous and the number of buyers and sellers is large. For MCW and WMD, the number of suppliers is relatively small and products within weapons classes are differentiated. For these weapons, models incorporating economies of scale, technological differences, intermediate products and strategic behaviour are more appropriate.

Some empirical studies investigate the determinants of arms trade (for example, Smith and Tasiran, 2005), but most focus on economic and political effects, including the impact on employment, growth and development, arms rivalries, and human rights (see, for example, Grober, Stern and Deardorff, 1990; Yakovlev, 2005; Sanjjan, 1999; and Blanton, 1999). Perhaps the most important empirical relationship considered is the effect of arms trade on the risk of war. Craft and Smaldone (2003) report that arms imports significantly increase the risk of interstate or intrastate conflict for sub-Saharan African nations. Krause (2004) finds that arms transfers that occur outside of defence pacts increase the risk that recipients will become involved in militarized interstate disputes. Most other studies likewise find that arms exports increase the risk of conflict, but there are exceptions (see Anderton, 1995).

Arms exports are typically subject to extensive government influence. Arms trade offsets require an exporting firm to use some of the revenue from arms sales to invest in activities in the importing nation. Brauer and Dunne (2004) report that there is little empirical or case study evidence that arms trade offsets enhance economic development. Some interventions, like subsidies and diplomatic lobbying on behalf of weapons firms, enhance arms exports. Virtually all governments limit arms exports to particular recipients, and various multilateral arms export limitation regimes exist including the Wassenaar Arrangement, the EU Code of Conduct on Arms Exports, the Nuclear Suppliers Group, the Missile Technology Control Regime, and the Australia Group. Brzoska (2004) argues in favour of a multilateral arms export tax in order to reduce arms exports.

Because production and trade are jointly determined economic activities, arms export restraints cannot be understood in isolation from arms production (Brauer, 2000). In a competitive market model, reduction of weapons supply through production or export controls can raise the equilibrium world price, creating an incentive for new arms suppliers to enter the market or existing suppliers to
Arms trade involves many direct and indirect economic and political costs and benefits, which suggest a number of broad research themes going forward. First, for the sake of tractability, partial equilibrium analyses of arms trade determinants and effects will continue to dominate the literature. Second, general equilibrium perspectives are beginning to emerge which promise a richer assessment of the nature and effects of arms trade and arms export restraints (see, for example, Levine, Sen and Smith, 2000). Third, efforts by governments, NGOs, and multilateral organizations to implement Pareto-improving arms trade policies require collective action solutions (Sandler, 2000).

Arndt, Heinz Wolfgang (1915–2002)

R.D. Freeman
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
Arndt, H. W.; Indonesia; Keynesianism; planning

Article

Born February 1915 in Breslau, Germany (now Wroclaw, Poland), Arndt was educated at Oxford University (1933–8) and London School of Economics (1938–41). After two years as a research assistant at the Royal Institute of International Affairs, Arndt was Assistant Lecturer in Economics, University of Manchester (1943–6), Senior Lecturer, University of Sydney (1946–50) and then Professor of Economics in the School of General Studies and Research School of Pacific Studies, Australian National University (1951–80). He became Emeritus Professor of Economics, Australian National University, in 1981. His many prestigious appointments include Member, Governing Council, United Nations Asian Institute for Economic Development and Planning (1969–75); Deputy Director, OECD (1972) and Chairman, Expert Group on Structural Change and Economic Growth Commonwealth Secretariat (1980).

Arndt first came to prominence in 1944 with his analytical economic analysis of the interwar period in which he argued the structuralist thesis that market forces could not correct the existing major disequilibria in the world economy. He recommended cooperative planning in the post-war period, involving controls on the volume and directions of international trade and investment and international cooperation if not supranational economic authorities.

His major contributions were in policy-oriented economic research with particular reference to developing countries in the Pacific Basin. A leading authority on the Indonesian economy as well as other Asian economies, led Arndt to start the Bulletin of Indonesian Economic Studies in 1965; he was also instrumental in the establishment in the Australian National University of a major research school on Asian economic development.

A prolific writer, Arndt was an important influence in Australian academic and policy circles in developing post-war understanding and acceptance of Keynesian macroeconomic analysis.

Arrears, in both common and general economic parlance, are overdue payments of any sort. The comparative economics literature has focused on the large-scale arrears of all sorts that emerged when central and eastern Europe and the former USSR began the transition to market economies. Soft budget constraints have been invoked in explanations of the growth of overdue trade credit or ‘inter-enterprise arrears’ in early transition, and in analyses of arrears to banks and tax arrears; studies of wage arrears in transition economies have focused on differential impacts across workers and firms and on weak institutions.

arrears; inter-enterprise arrears; soft budget constraint; tax arrears; trade credit arrears; transition economies; wage arrears

Article

Arrears, in both common and typical economic parlance, are overdue payments of any sort. In its last previous appearance in this dictionary, *Palgrave’s Dictionary of Political Economy*, the term is defined simply as ‘sums remaining unpaid after they are due’ (Higgs, 1925, p. 58). The context is usually one in which a payment is required by a contract or by law; hence the cross-references in the 1925 *Palgrave* entry to ‘law of contract’ and ‘wages’. The same is true of contemporary usage: Internet search engines at the time of writing indicate the most commonly used term by far is ‘mortgage arrears’, followed by ‘wage arrears’ and ‘tax arrears’. In most of economic science, arrears are generated by some behaviour or event, and it is the latter which is typically the focus of analysis. The analytical framework varies hugely with the object of analysis, and there is no theme that unites, for example, the analysis of consumer debt arrears and that of sovereign debt arrears.

The main exception to this, and the reason ‘arrears’ has reappeared in the *New Palgrave*, is the arrears
The arrears phenomenon in transition economies arose when firms accumulated non-payments of obligations to various creditors, often on a very large scale. The natural way to analyse this phenomenon is to distinguish between the main categories of creditors to the firms that have accumulated arrears—other firms, banks, the state and employees—and between stocks and flows, late payments and non-payments.

In the comparative and transition economics literature, overdue debts of firms to other firms has often been termed ‘inter-enterprise arrears’, though a more standard term from mainstream economics would be ‘trade credit arrears’. The rapid emergence of large volumes of overdue trade credit in many formerly socialist countries in the early phase of the transition (1989–93) took many economists in both the policy and academic communities by surprise. In retrospect, this surprise partly reflects the fact that trade credit is an understudied phenomenon in general. After early, rapid growth, the volumes of both total trade credit and overdue trade credit in the transition economies stabilized at levels similar to those found in developed market economies—the equivalent of roughly 20–40 per cent and 10–20 per cent of GDP, respectively (Schaffer, 1998). The eventual stabilization at levels found in normal market economies implies an approximate matching of inflows and outflows, and follows partly from the fact that late payment of trade credit is an endemic problem in market economies generally, as a reading of the business press and reports by factoring agencies will confirm. It also implies that firms in transition economies, including state-owned firms that had previously been unexposed to market forces, learned fairly rapidly to impose hard budget constraints on each other.

The early phase of rapid growth of trade credit arrears is a somewhat different matter. First, the payment systems that were used in socialist economies were typically very inflexible. Ickes and Ryterman (1992) argue that in Russia, the most studied country case of trade credit arrears, the combination of a lack of liquidity following price liberalization in January 1992 and a first-in-first-out (FIFO) queuing system for clearing payments generated ‘payments gridlock’ and thus rapid growth in arrears on payments to suppliers. The government’s response in mid-1992 was to abandon the payment queuing system and, separately, to try to clear the accumulated backlog of payments with an accompanying injection of credit, amounting to a bail-out of the enterprise sector. Second, the model of Perotti (1998) suggests that collusive non-payment by the enterprise sector can force a government bail-out via a ‘too-big-to-fail’ mechanism. Both explanations are examples of soft-budget constraints in action. This early phase of rapid growth also took place in the moderate- to high-inflation environments that followed price liberalization in these countries. The effective interest rate subsidy that accompanied trade credit thus involved a substantial discount to buyers, though it has also been suggested that sellers anticipated both inflation and payment delays, and incorporated a corresponding markup in their prices.

Arrears of firms to banks in transition economies is the phenomenon that is least specific to the transition experience. The large bad-debt problems that emerged following the start of transition have been analysed in the literature using the standard frameworks and tools for analysing systemic banking-sector problems. The limited evidence from these economies suggests that connected lending and directed state credits became a primary mechanism in the slower reformers for bailing out firms and softening budget constraints into the 1990s and beyond. Large-scale tax arrears of firms, by contrast, are peculiar to the transition experience. In developed market economies, tax arrears of firms are a phenomenon largely associated with exit of insolvent firms, and the scale is relatively small; New York...
Zealand has been cited as an example, with a stock of tax arrears amounting to one or two percentage points of GDP, and annual write-offs of uncollectible taxes coming to less than one-half of one percentage point of GDP. In the first five or ten years of transition, however, available evidence suggests that government toleration of non-payment of taxes was common even in the more rapidly reforming countries. Rough estimates of the scale of tax arrears range from two to 12 percentage points of GDP for the stock, and one to seven percentage points for the annual flow (Schaffer, 1998), and the empirical evidence suggests they were one of the main mechanisms governments used to soften the budget constraints of firms.

Lastly, large-scale and persistent wage arrears are also peculiar to transition economies, though in this case mostly limited to the countries of the former USSR. The scale of the wage arrears of firms at their peak – in aggregate, several percentage points of GDP – was typically smaller than trade credit and even tax arrears, but substantial in comparison with monthly wages. Payment of wages to employees several months in arrears was commonplace, and the absence of indexation imposed an extra cost in the high-inflation period of the early 1990s and following the burst of inflation that accompanied the collapse of the rouble in mid-1998. Wage arrears have sometimes been an important adjustment mechanism for labour markets in transition economies, partially absorbing negative shocks that would otherwise be fully reflected in actual wages or employment levels. The empirical evidence suggests that most wage arrears were late payments rather than non-payments, and with important distributional impacts with respect to household income. The social consequences of uncertainty and irregularity of wage payments were substantial, since workers in these countries had limited savings to fall back on and even less access to consumer credit markets, and thus faced great difficulties in smoothing income. Patterns across firms and workers in wage arrears have been related to firm, worker, and economy-wide characteristics (state-owned, poorly performing firms; workers in rural areas, outside options; tight credit policies; workers in sectors such as health and education, funded by the government budget), and to weak institutional environments that made it possible for firms to violate wage contracts at relatively low cost (see, for example, Lehmann, Wadsworth and Acquisti, 1999; Earle and Sabirianova, 2002).

Abstract

Kenneth Arrow is the author of key post-Second World War innovations in economics that have made economic theory a mathematical science. The Arrow Possibility Theorem created the field of social choice theory. Arrow extended and proved the relationship of Pareto efficiency with economic general equilibrium to include corner solutions and non-differentiable production and utility functions. With Gerard Debreu, he created the Arrow–Debreu mathematical model of economic general competitive equilibrium including sufficient conditions for the existence of market-clearing prices. Arrow securities and contingent commodities extend the model to cover uncertainty and provide a cornerstone of the modern theory of finance.

Kenneth Arrow is a legendary figure, with an enormous range of contributions to 20th-century economics, responsible for the key post-Second World War innovations in economic theory that allowed economics to become a mathematical science. His impact is suggested by the number of major ideas that bear his name: Arrow's Theorem, the Arrow–Debreu model, the Arrow–Pratt index of risk aversion, and Arrow securities.

Four of his most distinctive achievements, all published in the brief period 1951–54, are as follows: 

**Arrow Possibility Theorem. Social Choice and Individual Values** (1951a) created the field of social choice theory, a fundamental construct in theoretical welfare economics and theoretical political science. 

**Fundamental Theorems of Welfare Economics.** ‘An extension of the basic theorems of classical welfare economics’ (1951b) presents the First and Second Fundamental Theorems of Welfare Economics and their proofs without requiring differentiability of utility, consumption, or technology, and including corner solutions (zeroes in quantities of inputs or outputs).

**The Arrow–Debreu model of general economic equilibrium.** ‘Existence of equilibrium for a competitive economy’ (with Gerard Debreu, 1954) creates the mathematical model of a competitive economy. The article formalizes the cross-effects between markets (effect of one market's price on another's demand and supply) and provides sufficient conditions for the existence of prices allowing decentralized market-clearing general equilibrium of a market economy. This model is central to the study of markets and welfare economics; it is now a standard of the field.

**Securities markets and risk-bearing.** ‘Le rôle des valeurs boursières pour la répartition la meilleure des risques’ (1953) introduces the concept of a ‘contingent commodity’. The article formalizes the role of markets, including financial markets, insurance and the stock market, in resource allocation; it is a cornerstone of the modern theory of finance.

**Personal and intellectual history**

Kenneth Arrow was born in New York City on 23 August 1921. He describes his family circumstances as financially comfortable during the 1920s, but ‘my father lost everything in the great depression and we were very poor for about ten years … When it came to college, my family's poverty constrained me to attend the City College’ (Breit and Spencer, 1986, p. 45). Free tuition at City College of New York (CCNY) gave a generation of New Yorkers their start on success.

The searing experience of the Depression affected career ambitions. Arrow thought he should pursue the safe career of a high-school mathematics teacher. He took education courses and he had a very successful period of practice teaching in mathematics, preparing students for the New York State Regents examination. However, the roster of applicants for New York City teachers’ positions was already filled.

Arrow graduated from CCNY in 1940 with the unusual combination of a mathematics major and a Bachelor of Science in Social Science. While at CCNY he studied with Alfred Tarski in a course on the calculus of relations. Arrow was a proofreader for Tarski's *Introduction to Logic* (1941). He entered Columbia University for graduate study and received an MA in mathematics in June 1941. Harold Hotelling, a statistician with an appointment in the economics department, was the decisive influence.
Arrow notes, ‘When I took [Hotelling’s] course in mathematical economics, I realized I had found my niche’ (Breit and Spencer, 1986, p. 45). With the inducement of a fellowship in economics, Arrow transferred to the economics department for the rest of his graduate study.

Arrow’s graduate work at Columbia was interrupted by the Second World War. During the war Arrow was a weather officer in the US Army Air Corps achieving the rank of Captain, working in the Long Range Forecasting Group. Arrow's first published paper comes from that period, ‘On the Use of Winds in Flight Planning’ (1949a). The group's principal task was to forecast the number of rainy days in air combat areas – a month in advance. The young statisticians in the Weather Division subjected the prediction techniques in use to statistical test against a simple null hypothesis based on historical data. Finding that prevailing techniques were not significantly more reliable than the null, the junior officers sent a memo to the General of the Air Corps suggesting that the group be disbanded. Six months later, the General's secretary replied on his behalf: ‘The general is well aware that your forecasts are no good. However, they are required for planning purposes.’ The group remained intact.

In 1946 Arrow returned to graduate study at Columbia. Harold Hotelling had by then left for the University of North Carolina’s newly formed statistics department. The concern about making a living persisted. Arrow considered a non-academic career as a life insurance actuary. Tjalling Koopmans (at a Cowles Commission meeting in Ithaca, New York) advised him that actuarial statistics would prove unrewarding, saying, with characteristic reticence, ‘There is no music in it.’ Fortunately for economic science, Arrow followed this advice and decided to continue a research career.

In 1947 Arrow joined the (now legendary – then fledgling) research group at the Cowles Commission for Research in Economics at the University of Chicago. It seemed a golden age – all the ideas of mathematical economic theory and econometrics were being newly discovered. The close friendships and collaborations among colleagues of the Cowles Commission lasted a lifetime. Arrow describes the setting as a ‘brilliant intellectual atmosphere … with eager young econometricians and mathematically inclined economists under the guidance of Tjalling Koopmans and Jacob Marschak’ (Lindbeck, 1992, p. 107).

Jacob Marschak, the Cowles Commission Research Director, arranged for the Commission to administer the Sarah Frances Hutchinson Cowles Fellowship for women pursuing quantitative work in the social sciences (the Fellowship had originally specified a preference that fellows be women of the Episcopal Church of Seneca Falls, New York [reported in conversation with Jacob Marschak]). The fellows were Sonia Adelson (subsequently married to Lawrence Klein) and Selma Schweitzer. Kenneth Arrow and Selma Schweitzer were married in 1947.

Graduate study 1946–50, through Columbia, Chicago, Cowles, RAND and Stanford, included a daunting search for a worthy dissertation topic. Prospects considered and rejected included revising and restating the Tinbergen model (Tinbergen, 1939), and revising and restating Hicks's *Value and Capital* (1939). No topic seemed worthy. Then lightning struck: Arrow invented an entire field of economics with his dissertation ‘Social Choice and Individual Values’. The Columbia Ph.D., with Professor Albert Hart as dissertation advisor, was granted in 1951. As an econometrician, T. W. Anderson of Columbia (subsequently Arrow’s colleague at Stanford) was called upon to pass judgement on a draft thesis unrecognizable as economics to Ken’s advisors; Anderson pronounced the work sound.

The summer of 1948 and several summers thereafter were spent at the recently formed RAND Corporation in Santa Monica, California, a major centre of the newly emerging specialities of game theory and mathematical programming. In 1949 Arrow was appointed Acting Assistant Professor of
Economics and Statistics at Stanford University, and rapidly became Professor of Economics, and of Statistics, with the eventual additional title of Professor of Operations Research. He moved to Harvard in 1968 (returning regularly to Stanford for summer workshops), and rejoined the Stanford faculty in 1979. He retired in 1991.

In the 1950s and 1960s at Stanford, economic theory and econometrics faculty and graduate students were located in Serra House (converted from the retirement residence of the first president of the university) under the auspices of the Institute for Mathematical Studies in the Social Sciences (IMSSS) organized under the leadership of Patrick Suppes. In his memorial remarks for his student, Walter P. Heller (1942–2001), Arrow describes the *esprit de corps*: ‘Economic theory backed by serious mathematical reasoning was just beginning to be recognized. Our group of faculty and students in economic theory at Serra House felt ourselves a community. Not an oppressed minority, but rather a vanguard. We were taking over!’

Stanford and UC Berkeley were centres of research in statistics and economic theory. The joint Berkeley–Stanford Mathematical Economics Seminar met biweekly at alternate campuses. The Berkeley group included Gerard Debreu, Roy Radner, Peter Diamond and Dan McFadden. Stanford's included Herbert Scarf and Hirofumi Uzawa. Uzawa came to Stanford on fellowship arranged by Arrow. Working on his own in Japan, he had written the manuscript eventually published as ‘Gradient method for concave programming, II: Global stability in the strictly convex case’ (Arrow, Hurwicz and Uzawa, 1958a, ch. 7). It was a successful global stability analysis of gradient adjustment, following Arrow and Hurwicz's local analysis (available to Uzawa in manuscript, published in the same volume). Arrow read the manuscript and enthusiastically invited Uzawa to accept a fellowship at Stanford.

Although the profession is now used to mathematical expression, in the 1950s and 1960s the mathematical complexity of Arrow's work was regarded as forbidding. Although Arrow was the pre-eminent economic theorist at Stanford, he was not designated to teach in the required first-year graduate microeconomic theory course; it was presumed that the treatment would be excessively abstract for this general audience. His reputation for mathematical abstraction provided the excuse for a jest when Arrow received the 1957 John Bates Clark Award of the American Economic Association (presented to a leading economist under the age of 40). At the presentation ceremony, introductory remarks were made by George Stigler, who reportedly advised Arrow, in a stage whisper, ‘You should probably say, “Symbols fail me”.’

Under the administration of President J.F. Kennedy, Arrow and Robert Solow served on the research staff of the Council of Economic Advisers. That was a remarkable group: Walter W. Heller, chair, Kermit Gordon and James Tobin. The Council and its staff then included three future Nobel laureates: Arrow, Solow and Tobin.

To no one's surprise, Arrow received the 1972 Nobel Prize in Economic Sciences (jointly with the distinguished British economic theorist, John Hicks of Oxford). Aged 51 at the time of the award, he is (at this writing) by far the youngest recipient of the Nobel Prize in Economics. Testimony to Arrow's qualities as a dissertation advisor, a teacher of the next generation of economists, is abundant. The flurry of former students volunteering to contribute to the Festschrift by Heller, Starr and Starrett (1986) was overwhelming. The most personal tribute is the number of leading colleagues...
whose children have studied with Arrow. Jacob Marschak’s son Thomas Marschak and Walter W.
Heller's son Walter P. Heller wrote their doctoral dissertations with Arrow as principal advisor. Any list
of Arrow's students (dissertation advisees, postdocs, and so forth) is a partial listing. They are numerous
and are enthusiastically devoted to him, playing leading roles in academic and research economics. A
selection includes: Theodore Bergstrom (UC Santa Barbara), David Bradford (Princeton University),
Michael Bruno (Hebrew University, Bank of Israel), Graciela Chichilnisky (Columbia University), Peter
Coughlin (University of Maryland), John Geanakoplos (Yale University), Louis Gevers (Université de
Namur, Belgium), John Harsanyi (UC Berkeley), Walter P. Heller (UC San Diego), Peter Huang
(University of Minnesota Law School), Takatoshi Ito (University of Tokyo), Jean-Jacques Laffont
(Université des Sciences Sociales, Toulouse, France), Robert Lind (Cornell University), Thomas
Marschak (UC Berkeley), Eric Maskin (Institute for Advanced Study, Princeton), Roger Myerson
(University of Chicago), Hajime Oniki (Osaka-Gakuin University, Osaka, Japan), Heraklis
Polemarchakis (Brown University), Karl Shell (Cornell University), Ross Starr (UC San Diego), David
Starrett (Stanford University), Nancy Stokey (University of Chicago), Laurence Weiss (Goldman Sachs
Corp.), Ho-Mou Wu (National Taiwan University), and Menahem Yaari (Hebrew University, Jerusalem).
A range of stories depict Arrow as a legendary larger-than-life figure:
‘Arrow is personally accessible and unpretentious, addressed as “Ken” by students, colleagues, and
staff… Arrow thinks faster than he – or anyone else – can talk. Conversation takes place at such a rapid
pace that no sentence is ever actually completed’ (Heller, Starr and Starrett, 1986, v. 1, p. xvii). The
breadth of Arrow’s knowledge is repeatedly a surprise, encompassing Chinese art, English history and
the works of Shakespeare. At the 80th birthday celebration, Eric Maskin related the following example:

On almost any subject arising in conversation, Arrow turns out to know a lot more than
you do. Tired of being repeatedly shown up by their senior colleague, a group of junior
faculty once concocted a plan. They first read up thoroughly on the most arcane topic they
could think of – the breeding habits of gray whales. On the appointed day they gathered in
the coffee room and waited for Ken to come in. Then they started talking about whales,
concentrating on the elaborate theory of a marine biologist named Turner on how gray
whales found their way back to the same breeding spot year after year. Ken was silent …
they had him at last! With a sense of delicious triumph, they continued to discuss whales,
and Ken looked more and more perplexed. Finally, he couldn't hold back: ‘But I thought
that Turner's theory was entirely discredited by Spencer, who showed that the
hypothesized homing mechanism couldn't possibly work.’

 Arrow's presence in seminars is distinctive. He may open his (copious) mail, juggle a pencil, seem
inattentive. He will then make a comment demonstrating that he is several steps ahead of the speaker. He
will make clear that the history of economic thought includes abundant antecedents (which he can
readily cite from memory) for the issues under discussion.

Social Choice and Individual Values: The General Possibility Theorem

Social Choice and Individual Values was Arrow's doctoral dissertation, published as a Cowles
Commission monograph. There are very few new ideas in economics. Arrow's General Possibility Theorem is as novel and fundamental as they come. The paradox of voting (cyclic majorities) appears to have been well-known, though not well formalized; Arrow (1951a) and Duncan Black (1948) both take it as understood. A review of the literature shows that it is attributable to Condorcet (1785). The paradox – intransitivity of choice from majority vote based on voters with transitive preferences – can be stated simply.

Think of three voters trying to decide by majority vote among three possibilities, A, B and C. Each of the individual voters has transitive (rational) preferences. Voter 1 prefers A to B and prefers B to C. Voter 2 prefers B to C and C to A. Voter 3 prefers C to A and A to B. Then there is a majority of voters preferring A to B (voters 1 and 3), and a majority preferring B to C (voters 1 and 2). If group decision-making is also transitive (rational), then the group should prefer A to C. But just the opposite occurs; there is a majority preferring C to A (voters 2 and 3). Despite the transitivity of individual preferences, the group preference on pairs of alternatives, as expressed by majority vote, is intransitive (irrational). Arrow's General Possibility Theorem (also known as 'Arrow's Theorem', the 'Arrow Possibility Theorem' or the 'Arrow Impossibility Theorem') shows that the paradox is not merely an anomaly but intrinsic to group decision-making. The theorem has been a focus of vigorous study for generations. An elegant proof in Sen (1986) is particularly striking since it is framed as a generalization of the Condorcet paradox.

The Possibility Theorem suggests four reasonable criteria for a group decision-making mechanism, all of which are fulfilled by majority voting (assume at least three possible choices and at least three voters):

1. **Unrestricted Domain.** The decision-making mechanism can accommodate all logically possible preferences on the available choices.
2. **Pareto Principle.** If everyone prefers one alternative over another, the group decision should have that preference as well.
3. **Independence of Irrelevant Alternatives.** In choosing between any two alternatives, group decision-making takes account only of individual preferences on those alternatives; preferences on a third possibility do not enter the choice between those two.
4. **Non-dictatorship.** There is no single person whose preferences will always be followed by the group decision-making mechanism.

The Possibility Theorem says that no decision-making mechanism that fulfils all four of the above conditions results in transitive (rational) group choices based on transitive (rational) individual preferences. The Condorcet paradox is not merely an anomaly. It is unavoidable. It represents a fundamental defect in group decision-making. Each of the four above conditions is essential to the theorem; there are examples of transitive group decision-making mechanisms that fulfil any three but not four. Of the four, the most controversial is Independence of Irrelevant Alternatives; it prevents voluntary misstatement by a voter of his preferences from being an attractive strategy (overstating dislike of a third option to make a preferred one of two succeed in a weighted voting scheme).

At the time *Social Choice and Individual Values* was published, the logic of group decision-making was
not even recognized as an economic issue. Since then there has been an overwhelming blossoming of the ‘social choice’ field. It is a topic for the *Handbook of Mathematical Economics* (Sen, 1986); thousands of journal articles deal with it; every graduate student in economics is introduced to it. Kenneth Arrow created the field by formalizing a result that says the object of the field is unachievable. The book also had a significant impact in a second direction: treating economic theory as an axiomatic logical field rather than as a sphere of calculation. *Social Choice* was one of the first essays, certainly the first monograph, to treat economics with the same generality and logical rigour as classical geometry. This approach was to be repeated in the next of Arrow's several major works in general equilibrium theory and classical welfare economics.

How did Arrow come to develop this structure? It was during the first summer, in 1948, at RAND that several strands of thought came together. The Condorcet paradox of cyclic majorities was common knowledge (though not the attribution to Condorcet). Independently of Duncan Black (1948), Arrow developed the restriction of individual preferences to the single-peaked format as a solution, but then realized that he'd been scooped when he read Black's result in the *Journal of Political Economy*. He was aware of the ambiguity in describing the optimizing policy of a business firm under uncertainty: profit maximization is no longer well-defined and majority voting of shares is subject to the Condorcet paradox. Arrow's techniques of logical formalization were ready. As a high-school student he had read Russell's *Introduction to Mathematical Philosophy* (1920); at CCNY he became familiar with Tarski's *Introduction to Logic* (1941) and the calculus of relations. With that preparation, it was obvious that the indifference curve approach used by economists was a form of a logical ordering. Axiomatic treatment came naturally.

RAND was the centre of the developing field of game theory, which was being used to formalize discussions of strategic behaviour in international relations. During a coffee break the logician Olaf Helmer posed the following problem. Game theory supposes rational strategic behaviour among optimizing agents. The maximand of an individual may be well-defined, perhaps as a utility function; but what is the maximand of a country? Arrow replied that a Bergson social welfare function should represent a country's maximand. That set him to work. Demonstrating that his answer to Helmer was fundamentally and necessarily inadequate is the meaning of the Possibility Theorem. Arrow started the inquiry by looking at a variety of group decision-making mechanisms. They all looked wrong; either they led to intransitivity or they violated the Independence of Irrelevant Alternatives, so that preferences for an alternative that was out of the running nevertheless entered the group's decision. He was led to formalize the conditions of group decision-making, reflecting a long-standing interest in axiomatic reasoning. ‘The development of the theorems and their proofs then required only about three weeks, although writing them as a monograph took many months’ (1983a, p. 4).

**Extension of the fundamental theorems of welfare economics**

In the 1940s welfare economics in mathematical form (the relationship of market equilibrium to economically efficient allocation) was very much a matter of the calculus (Samuelson, 1947). Marginal rates of substitution (ratios of marginal utilities) were equated to marginal rates of transformation (ratios of marginal products of factors) which were equated to price ratios. This is a sound viewpoint so long as the underlying functions are differentiable and the quantities of goods and factors are in a range where
they can be varied. Arrow's view was that there is a fundamental weakness to this approach in the presence of non-negativity constraints on quantities. It works only when quantities are strictly positive. That is, the calculus doesn't treat corner solutions. But almost every practical economic solution is a corner solution: it is rare to find that all quantities of all possible goods and all possible inputs are used in strictly positive quantities. This is particularly true when differing qualities or varieties of similar goods are treated distinctly (white, sourdough and rye breads are distinct commodities, as are luxury and efficiency apartments). There must be a welfare economics that includes corner solutions; it must be possible to present welfare economics without the calculus.

Arrow attributes his insight to a seminar presentation on the fundamental theorems of welfare economics given by Paul Samuelson at the University of Chicago, in Samuelson's style using the calculus (1983b, p. 14). The diagrams that illustrated the equations depicted a separating hyperplane. Arrow had learned of the fundamental role of convexity and the separating hyperplane theorem at RAND in the summer of 1948. The result of these reflections is ‘An extension of the basic theorems of classical welfare economics’ appearing in *Proceedings of the Second Berkeley Symposium on Mathematical Statistics and Probability*. The conference was held in the summer of 1950 in Berkeley, and the proceedings appeared a year later. There, the First and Second Fundamental Theorems of Welfare Economics are stated in terms of real analysis and convex sets, without the use of the calculus and including corner solutions.

At the level of the firm and the household, characterizing optimizing behaviour at corner solutions is the job of the Kuhn–Tucker Theorem. In a case of simultaneous discovery of related ideas, that theorem was first publicly presented at the same Berkeley Symposium (Kuhn and Tucker, 1951).

**First Fundamental Theorem of Welfare Economics:** Every competitive equilibrium allocation is Pareto efficient. This result does not require convexity of tastes or technology, though convexity may be useful in establishing the existence of equilibrium prices.

**Second Fundamental Theorem of Welfare Economics:** In an economy with convex technology and preferences, every Pareto-efficient allocation can be sustained as a competitive equilibrium with appropriate prices subject to a redistribution of ownership shares in firms and redistribution of endowment (except that some low-income households may be expenditure minimizers subject to utility constraint, rather than utility maximizers subject to budget).

Neither of these results depends on positivity of quantities or on differentiability of the functions or relations. The generality of the results, the use of a formal mathematical structure of assumptions, theorems and proofs was again novel. It meant that economics was becoming closer to formal mathematics.

**General equilibrium theory**

In the early 1950s, Arrow (at Stanford) pursued, largely by correspondence, joint work on general equilibrium theory with Gerard Debreu, who was then at the Cowles Commission in Chicago. The theory of general economic equilibrium recognizes that the economy is an interactive system. Decisions and prices in one market have a direct impact on supply and demand in other markets. The question Arrow and Debreu treated is: under what (sufficiently general and formalized) conditions can there be prices so that all markets simultaneously clear? This issue is known as ‘the existence of economic general equilibrium’. The term ‘general’ equilibrium refers to the many markets simultaneously clearing, as opposed to ‘partial’ equilibrium where a single market is considered in isolation. Moreover,
the theory allows – or forces – the theorist to formulate relatively complete models of the economy. The result of these inquiries has been an intellectual revolution and an intellectual foundation for market economics. A half-century after it was introduced to economics, the Arrow–Debreu model is the cornerstone and workhorse of our theory of markets and resource allocation.

Abraham Wald, with whom Arrow had studied at Columbia, had written several papers in the field (while in Vienna in the 1930s before emigrating to avoid the Nazi takeover) but had run up against fundamental mathematical difficulties (Wald, 1934–35, 1936). He explained to Arrow that the problem was ‘very difficult’, advice that was enough to discourage the young economic theorist for some years. It was the recognition by Arrow and Debreu of the importance of using a fixed point theorem that led to major progress in this area. (Credit for independent discovery of the importance of fixed point theorems in this context is due to Lionel McKenzie, 1954. The use of a fixed point theorem for demonstrating the existence of an equilibrium [of a game] was pioneered by John Nash, 1950. See Debreu, 1983).

Arrow describes his early thoughts on the subject and the interaction with ideas current at the time (particularly the Nash equilibrium of N-person games) thus:

My original approach, for what it is worth, was to formulate competitive equilibrium as the equilibrium of a suitably chosen game. The players of this fictitious game were the consumers, a set of ‘anticonsumers’ (one for each consumer), producers, and a price chooser. Each consumer chose a consumption vector, each anticonsumer a nonnegative number (interpretable as the marginal utility of income), each firm a production vector, and the price chooser a price vector on the unit simplex. The payoff to a consumer was the utility of his consumption vector plus the budgetary surplus (possibly negative, of course) multiplied by the anticonsumer's chosen number. The payoff to an anticonsumer was the negative of the payoff to the corresponding consumer. The payoff to the firm was profit and to the price chooser the value of excess demand at the chosen prices. This is a well-defined game. The existence of equilibrium does not follow mechanically from Nash's theorem, since some of the strategy domains are unbounded.

Debreu and I sent our manuscripts to each other and so discovered our common purpose. We also detected the same flaw in each other's work; we had ignored the possibility of discontinuity when prices vary in such a way that some consumers’ incomes approach zero. [The possibility of discontinuity in demand at incomes where household consumption is on the boundary of the possible consumption set is known as the ‘Arrow corner’]. We then collaborated, mostly by correspondence, until we had come to some resolution of this problem. In the main body of the work we followed more closely Debreu's more elegant formulabased on the concept of generalized games, which eliminated the need for ‘anticonsumers.’ (1983b, pp. 58–9)

The papers of Arrow and Debreu (1954) and McKenzie (1954) were presented to the 1952 meeting of the Econometric Society. Publication of ‘Existence of equilibrium for a competitive economy’ represents a fundamental step in the revision of economic analysis and modelling, demonstrating the power of a formal axiomatic approach with relatively advanced mathematical techniques. The approach of the field is revolutionary: it fundamentally changes our way of thinking. Once we see things this way,
it is hard to conceive of them otherwise.

Sufficient conditions for the existence of market-clearing prices – consistent with one-another – for N distinct commodities are: (a) demand and supply are continuous as a function of prices, and (b) Walras's Law. These properties are derived from fundamental assumptions on the structure of preferences and endowments of households and the technology of firms. The theory is general enough to include point-valued and (convex) set-valued demand and supply.

Debreu's *Theory of Value* (1959) made the Arrow–Debreu general equilibrium model accessible to the wider profession. The implications for economic theory as a discipline were multifaceted: *general* equilibrium, treating all markets as interacting together, became systematic; the axiomatic method was set firmly in place as part of economic theory. Economic theory could be as precise and logically demanding as geometry. The potential of formal theory to generalize could be brought to bear. The Arrow–Debreu treatment proved, with full mathematical rigour, that any economy fulfilling the model's clearly and generally specified assumptions would produce its specified results.

A number of articles (principally co-authored with Leonid Hurwicz, 1958b, 1959) treat the stability of general equilibrium. Though Arrow and Debreu (1954) establishes the existence of market clearing prices, it does not derive ‘equilibrium’ as the rest point of a dynamic system. The stability question focuses on how a price adjustment system will lead to market clearing prices. Since prices in each market (at least potentially) enter into the excess demands of all markets, there is plenty of room for price adjustments to go awry. This body of literature sorts out and proves sufficient conditions for adjustment to be successful. Bottom line: a sufficient condition is that other markets do not excessively interfere with excess demands on any single market; if the principal determinant of excess demands for each good is the price of that good, then price adjustment to market clearing will be successful.

The effect of the introduction of the Arrow–Debreu model on economic theory has been overwhelming. Every graduate-level textbook in microeconomic theory discusses it. Whole classes of economic theorists describe their speciality as ‘general equilibrium theory’. In the 15 years following publication of *Theory of Value*, a major focus of pure theory was understanding and extending the model. This included its relationship to bargaining (Debreu and Scarf, 1963), to large economies (Aumann, 1966) and to computing general equilibrium prices (Scarf and Hansen, 1973). It was further elaborated by Arrow and Hahn (1971a).

**Contingent commodities**

Part of the power of mathematics is generalization. If you've solved a problem once, you don't have to solve it again – even in different circumstances if you can show that the previous treatment applies. This was the brilliantly simple insight in the creation of the concept of ‘contingent commodity’.

Arrow's thought had been influenced by Hicks's *Value and Capital*, including understanding the power of defining a commodity to include specification of time and location, and by L.J. Savage's lectures on mathematical statistics at Chicago, including a notion of the ‘state of the world’ as defining a random variable. (The ‘state of the world’ concept for defining a random variable is attributable to Kolmogorov [1933]). It was a fundamental step to combine these notions so that a commodity might be defined by what it is, where and when deliverable, *and by the ‘state of the world’ in which it is deliverable.* By redefining a ‘commodity’ in this way as a ‘contingent commodity’, the complete structure of the
Arrow–Debreu model of general equilibrium and economic efficiency could be applied. This is now typically described in the literature as ‘a full set of Arrow–Debreu futures contracts’. The concept of an efficient (or ‘optimal’) allocation of risk-bearing is immediately evident as a consequence of the modelling structure. The next step is to suggest a security contract contingent on the state of the world payable in money – to economize on the number of actively traded commodities – now known as an ‘Arrow security’ or ‘Arrow insurance contract’. This has been an extremely powerful concept, allowing researchers to formulate their ideas clearly; the Arrow security is a staple of 21st century theoretical finance.

The paper ‘Le rôle des valeurs boursières pour la répartition la meilleure des risques’, originally written in English, was translated into French for a conference at Centre National de Recherche Scientifique, Paris, in June 1952. Other conference participants included Jacob Marschak, Maurice Allais, L.J. Savage, Milton Friedman and Pierre Massé. It was published in French in Econométrie and the original English version appeared (as a ‘translation’) a decade later in Review of Economic Studies, after the notions had been introduced to English-speaking readers in Theory of Value.

**Individual behaviour towards risk, economics of medical care, learning by doing**

Treatment of uninsurable risk (where contingent commodities and Arrow securities are not available or correctly priced) has been a focus of Arrow’s work for decades. It appears in the Collected Papers, the Aspects of the Theory of Risk Bearing (Yrjo Jahnsson lectures) (1965a), and in Essays in the Theory of Risk Bearing (1971b). These essays provide for many readers the most systematic treatment available of the statement and proof of the Expected Utility Theorem, derivation of the Arrow–Pratt risk aversion index, and a systematic framework for considering decision-making in an uncertain world.

Several papers (1963, 1965b) treat the economics of medical care, a setting where uncertainty, information as a scarce resource, and insurance all play a part. An element of the contribution is to state the issues in an abstract analytic economic framework. This reminds economists of why these problems are not textbook economics, and reminds non-economists that the economics textbook is useful. The historical setting in which these articles were written is pre-1990, that is, before health maintenance organizations (HMOs) became popular, when the principal form of medical insurance available was fee for service. They contain several insights (probably not unique to or first from Arrow, but effectively presented). For example, medical needs are uncertain so medical insurance is not merely a form of payment but is a response to risk. Again, medical insurance reduces the marginal cost of care as seen by the patient below actual cost, encouraging increased use (moral hazard consequence of insurance).

Finally, medical care is distinct (but not unique) among commodities in that the decisions to incur care and the form that it should take are made to a large extent by the provider (the medical doctor) who is paid for providing care rather than by the buyer (patient). There is a resulting conflict of interest and reliance on professional norms. Arrow’s treatment of the doctor-patient relationship as a seller-buyer interaction is an early appearance in the literature of the conflict we now recognize as the ‘principal-agent problem’ with an attendant family of issues.

In the 18th century Adam Smith noted that one of the benefits of specialization in production was that workers at specialized tasks learned how most effectively to perform them. Arrow’s ‘The economic implications of learning by doing’ (1962) reflects in part the temper of the time – economic growth and growth models were a principal focus of theory and policy. In addition, it is a leap several decades ahead.
in growth theory. In contrast to growth models in the 1960s, it presents endogenous growth, a research topic that became an active focus decades later (Romer, 1994). The study brings together two apparently disparate strands of economic modelling: technical change and the theory of external effects. The benefits of production in a particular line of work include not only output but the greater experience of the firm and the workforce in production. Through production, workers and firms learn how to produce more with fewer inputs. To the extent that this knowledge is inappropriable or non-marketable, it provides an external benefit to the economy. This on-the-job experience will typically be under-provided relative to an economically efficient allocation.

**Optimal programming, control theory, mathematical statistics, racial discrimination, and the CES production function**

In 16 books (not including the *Collected Papers*) and 250 technical articles, there are significant contributions to a breadth of issues in economics, mathematical programming and public policy. There’s even some mathematical statistics (with Blackwell and Girshick, 1949b).

One of the most useful – to other economists – is ‘Capital-labor substitution and economic efficiency’ by Arrow, Chenery, Minhas and Solow (1961). It introduced the constant-elasticity-of-substitution (CES) production function, spawning an immense empirical literature.

*Public Investment, the Rate of Return, and Optimal Fiscal Policy* and several papers with Mordecai Kurz (1970) introduced control theory to the theory of the firm, to the theory of the household, and to public finance. A variety of books and articles treat mathematical programming and optimal inventory policy.

Several papers formally model racial discrimination in employment (1973). This is a tricky problem, and not merely because it is politically controversial. Pure microeconomic theory would suggest that there should be no racial discrimination by rational profit-maximizing employers; significant discrimination should result in below-market wage rates for the discriminated-against workers with resultant extra incentive for employers to hire them. How then can an economic model of optimizing behaviour explain the prevalence of racial discrimination? The answers (based on the racial views of employers, employees, customers) provide clues to locating the points of leverage that may lead to amelioration or policy.

**What we have learned?**

Arrow, along with Debreu, was a decisive figure in introducing the axiomatic method to economic theory. *Social Choice and Individual Values* and ‘Existence of equilibrium for a competitive economy’ fundamentally changed the agenda of economic theory. Formal logical reasoning and formal statement of assumptions and conclusions became the standard of pure theory (Suppes, 2005). The axiomatic method need not be a straitjacket. Arrow's less formal work demonstrates the role of insight: observing actual economic activity and asking ‘why?’, where the acceptable class of answers reflects underlying principles of economic analysis. The result is a rich understanding of the nuance and power of economics.
Celebrations

Dedicated colleagues and students have done their best to show adulation and gratitude to Arrow. There has been a succession of public celebrations.

On Arrow's 65th birthday in August 1986, an immense birthday conference and party, known as the ‘Arrowfest’, took place at Stanford. It reunited colleagues and students from all over the world. There were two days of conference papers and testimonial remarks. A three-volume Festschrift was presented (on time) (Heller, Starr and Starrett, 1986), including papers by 35 of Arrow's students and colleagues. Among the contributing authors were three (eventual) Nobel laureates: John Harsanyi, Amartya Sen and Robert Solow. The observance included a gala dinner with testimonial remarks and an expression of thanks from Arrow.

To observe his 70th birthday, the celebration was at the doctoral alma mater, a conference and social gathering in October 1991 titled ‘Columbia Celebrates Arrow's Contributions’. The Festschrift volume (Chichilnisky, 1999) included papers by 22 colleagues and students. The 70th birthday was also the occasion of formal retirement from active faculty status at Stanford. That rite of passage was observed with a reception, including testimonials from colleagues, among them the senior colleagues who had been clever enough to recruit Arrow to Stanford two generations earlier. Stanford's Arrow Lecture Series was initiated, annually inviting distinguished speakers in economic theory in Arrow's honour.

A 40th anniversary party for general equilibrium theory was held in June 1993 at Center for Operations Research and Econometrics (CORE) of the Université Catholique de Louvain in Louvain-la-Neuve, Belgium. For several days and nights hundreds of professors, researchers and students from around the world presented papers, discussions and reminiscences of the speciality they had pursued for years. At the centre of the celebration were the 20th-century founders of the field, Kenneth Arrow, Gerard Debreu and Lionel McKenzie.

There was a happy coincidence in 2001, when the 50th anniversary of *Social Choice and Individual Values* approximately coincided with Arrow's 80th birthday. A panel discussed the book's impact over the previous half century: Pat Suppes (Stanford University) on philosophy, John Ferejohn (Stanford University) on political science, and Eric Maskin (Institute for Advanced Study) on economics. The gathering included Professor Ted Anderson, who was at Columbia when *Social Choice* was submitted as Arrow's dissertation.

A dinner that evening featured moving toasts of appreciation by colleagues from around the world and presentations by Arrow's sons, Andy and David. The conclusion – sending the audience out singing into the evening – was the ad hoc musical group, the Economy Singers, singing advice to rising young economists: ‘Brush Up Your Arrow, Start Quoting Him Now.’

To many students and colleagues, Kenneth Arrow is a source of inspiration and a focus of friendship and respect:

… an inspirational teacher and colleague … The intellectual standards he set and the enthusiasm with which he approaches our subject are surely part of all of us. Those of us who have had a chance to know him well are particularly fortunate. We are far richer for the experience. (Heller, Starr and Starrett, 1986, vol. 1, pp. xi, xvii)

Arrowâ€”Debreu model of general equilibrium

John Geanakoplos
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

In the 1950s Kenneth Arrow and Gerard Debreu showed that the market system could be comprehensively analysed in terms of the neoclassical methodological premises of individual rationality, market clearing, and rational expectations, using the two mathematical techniques of convexity and fixed point theory. In so doing they greatly advanced the use of mathematics in economics.

Article

I. Introduction

It is not easy to separate the significance and influence of the Arrowâ€”Debreu model of general...
equilibrium from that of mathematical economics itself. In an extraordinary series of papers (Arrow, 1951; Debreu, 1951; Arrow and Debreu, 1954), two of the oldest and most important questions of neoclassical economics, the viability and efficiency of the market system, were shown to be susceptible to analysis in a model completely faithful to the neoclassical methodological premises of individual rationality, market clearing, and rational expectations, through arguments at least as elegant as any in economic theory, using the two techniques (convexity and fixed point theory) that are still, after 30 years, the most important mathematical devices in mathematical economics. Fifteen years after its birth (for example, Arrow, 1969), the model was still being reinterpreted to yield fresh economic insights, and 20 years later the same model was still capable of yielding new and fundamental mathematical properties (for example, Debreu, 1970; 1974). When we consider that the same two men who derived the most fundamental properties of the model (along with McKenzie, 1954) also provided the most significant economic interpretations, it is no wonder that its invention has helped earn for each of its creators, in different years, the Nobel Prize for economics.

In the next few pages I shall try to summarize the primitive mathematical concepts, and their economic interpretations, that define the model. I give a hint of the arguments used to establish the model's conclusions. Finally, on the theory that a model is equally well described by what it cannot explain, I list several phenomena that the model is not equipped to handle.

II The model

Commodities and Arrowâ€“Debreu commodities

(A.1) Let there be $L$ commodities, $l=1, \ldots, L$. The amount of a commodity is described by a real number. A list of quantities of all commodities is given by a vector in $\mathbb{R}^L$.

The notion of commodity is the fundamental primitive concept in economic theory. Each commodity is assumed to have an objective, quantifiable, and universally agreed upon (that is, measurable) description. Of course, in reality this description is somewhat ambiguous (should two apples of different sizes be considered two units of the same commodity, or two different commodities?) but the essential quantitative aspect of commodity cannot be doubted. Production and consumption are defined in terms of transformations of commodities that they cause. Conversely, the set of commodities is the minimum collection of objects necessary to describe production and consumption. Other objects, such as financial assets, may be traded, but they are not commodities. General equilibrium theory is concerned with the allocation of commodities (between nations, or individuals, across time, or under uncertainty, and so on). The Arrowâ€“Debreu model studies those allocations which can be achieved through the exchange of commodities at one moment in time.

It is easy to see that it is often important to the agents in an economy to have precise physical descriptions of commodities, as for example when placing an order for a particular grade of steel or oil. The less crude the categorization of commodities becomes, the more scope there is for agents to trade, and the greater is the set of imaginable allocations. Two agents may each have apples and oranges. There is no point in exchanging one man's fruit for the other man's fruit, but both might be made better off if one could exchange his apples for the other's oranges. Of course there need not be any end to the distinctions which in principle could be drawn between commodities, but presumably finer details
become less and less important. When the descriptions are so precise that further refinements cannot yield imaginable allocations which increase the satisfaction of the agents in the economy, then the commodities are called Arrow-Debreu commodities.

A field is better allocated to one productive use than another depending upon how much rain has fallen on it; but it is also better allocated depending on how much rain has fallen on other fields. This illustrates the apparently paradoxical usefulness of including in the description of an Arrow-Debreu commodity characteristics of the world, for example the commodity's geographic location, its temporal location (Hicks, 1939), its state of nature (Arrow, 1953; Debreu, 1959; Radner, 1968), and perhaps even the name of its final consumer (Arrow, 1969), which at first glance do not seem intrinsically connected with the object itself (but which are in principle observable).

Hicks, perhaps anticipated by Fisher and Hayek, was the first to suggest an elaborate notion of commodity; this idea has been developed by others, especially Arrow in connection with uncertainty. Hicks was also the first to understand apparently complicated transactions, perhaps involving the exchange of paper assets or other non-commodities, over many time periods, in terms of commodity trade at one moment in time. Thus saving, or the lending of money, might be thought of as the purchase today of a particular future dated commodity. The second welfare theorem, which we shall shortly discuss, shows that an "optimal" series of transactions can always be so regarded. By making the distinction between the same physical object depending, for example, on the state of nature, the general equilibrium theory of the supply and demand of commodities at one moment in time can incorporate the analysis of the optimal allocation of risk (a concept which appears far removed from the mundane qualities of fresh fruit) with exactly the same apparatus used to analyse the exchange of apples and oranges. Classifying physical objects according to their location likewise allows transportation costs to be handled in the same framework. Distinguishing commodities by who ultimately consumes them could allow general equilibrium analysis to systematically include externalities and public goods as special cases, though this has not been much pursued.

In reality, it is very rare to find a market for a pure Arrow-Debreu commodity. The more finely the commodities are described, the less likely are the commodity markets to have many buyers and sellers (that is, to be competitive). More commonly, many groups of Arrow-Debreu commodities are traded together, in unbreakable bundles, at many moments in time, in "second best" transactions. Nevertheless, this understanding of the limitations of real world markets, based on the concept of the Arrow-Debreu commodity, is one of the most powerful analytical tools of systematic accounting available to the general equilibrium theorist. Similarly, the model of Arrow-Debreu, with its idealization of a separate market for each Arrow-Debreu commodity, all simultaneously meeting, is the benchmark against which the real economy can be measured.

Consumers

(A.1) Let there be \( H \) consumers, \( h=1, \ldots, H \). Each consumer \( h \) can imagine consumption plans \( x \in \mathbb{R}^L \) lying in some consumption set \( X^h \). (A.2) \( X^h \) is a closed subset in \( \mathbb{R}^L \) which is bounded from below. Each consumer \( h \) also has well-defined preferences \( \succeq_h \) over every pair \( (x, y) \in X^h \times X^h \), where \( x \succeq y \) means \( x \) is at least as desirable as \( y \). Typically it is assumed that (A.3) \( \succeq_h \) is a complete, transitive,
Notice that in general equilibrium consumers make choices between entire consumption plans, not between individual commodities. A single commodity has significance to the consumer only in relation to the other commodities he has consumed, or plans to consume. Together with transitivity and completeness, this hypothesis about consumer preferences embodies the neoclassical ideal of rational choice.

Rationality has not always been a primitive hypothesis in neoclassical economics. It was customary (for example, for Bentham, Jevons, Menger, Walras) to regard satisfaction, or utility, as a measurable primitive; rational choice, when it was thought to occur at all, was the consequence of the maximization of utility. And since utility was often thought to be instantaneously produced, sequential consumer choice on the basis of sequential instantaneous utility maximization was sometimes explicitly discussed as irrational (see, for example, Böhm-Bawerk on saving and the reasons why the rate of interest is always positive).

Once utility is taken to be a function not of instantaneous consumption, but of the entire consumption plan, then rational choice is equivalent to utility maximization. Debreu (1951) proved that any preference ordering \( \succeq_h \) defined on \( X^h \times X^h \) satisfies (A.1)â€”(A.3) if and only if there is a utility function \( u^h : X^h \to \mathbb{R} \) such that \( x \succeq_h y \) exactly when \( u^h(x) \geq u^h(y) \).

Under the influence of Pareto (1909), Hicks (1939) and Samuelson (1947), neoclassical economics has come to take rationality as primitive, and utility maximization as a logical consequence. This has had a profound effect on welfare economics, and perhaps on the scope of economic theory as well. In the first place, if utility is not directly measurable, then it can only be deduced from observable choices, as in the proof of Debreu. But at best this will give an â€œordinalâ€™ utility, since if \( f : \mathbb{R} \to \mathbb{R} \) is any strictly increasing function, then \( u^h \) represents \( \succeq_h \) if and only if \( \Sigma^H \sum_{h=1}^\infty u^h(x) \) is very different from the Benthamite sum \( \Sigma^H \sum_{h=1}^\infty f(h \circ u^h) \). In the second place, the ideal of rational choice or preference, freed from the need for measurement, is much more easily extended to domains not directly connected to the market and commodities such as political candidates or platforms, or â€œsocial statesâ€™. The elaboration of the nature of the primitive concepts of commodity and rational choice, developed as the basis of the theory of market equilibrium, prepared the way for the methodological principles of neoclassical economics (rational choice and equilibrium) to be applied to questions far beyond those of the market.

Although the rationality principle is in some respects a weakening of the hypothesis of measurable utility and instantaneous utility maximization, when coupled with the notion of consumption plan it is also a strengthening of this hypothesis, and a very strong assumption indeed. For example there is not room in this theory for the Freudian split psyche (or self-deception), or for Odysseus-like changes of heart. Perhaps more importantly, a consumer's preferences (for example how thrifty he is) do not change according to the role he plays in the process of production (for example, on whether he is a capitalist or landowner), nor do they change depending on other consumers' preferences, or the supply of commodities. As an instance of this last case, note that it follows from the rationality hypothesis that the surge in the microcomputer industry influenced consumer choice between typewriters and word processors only through availability (via the price), and not through any learning effect. (Consumers can
â€œlearnâ€™ in the Arrowâ€“Debreu model, for example their marginal rates of substitution can depend on the state of nature, but the rate at which they learn is independent of production or consumption â€“ it depends on the exogenous realization of the state. We shall come back to this when we consider information.) If for no other reason, the burden of calculation and attention which rational choice over consumption plans imposes on the individual is so large that one expects rationality to give way to some kind of bounded rationality in some future general equilibrium models.

Two more assumptions on preferences made in the model of Arrowâ€“Debreu are nonsatiation and convexity:

- (A.4) For each \( x \in X^h \), there is a \( y \in X^h \) with \( y \succ h^x \), that is, such that \( y \succ h^x \) and not \( x \succ h^y \).
- (A.5) \( X^h \) is a convex set, and \( h \) is convex, that is, if \( y \succ h^x \) and \( 0 < t < 1 \), then \( [ty + (1-t)x] \succ h^x \).

The nonsatiation hypothesis seems entirely in accordance with human nature. The convexity hypothesis implies that commodities are infinitely divisible, and that mixtures are at least as good as extremes. When commodities are distinguished very finely according to dates, so that they must be thought of as flows, then the convexity hypothesis is untenable. In a standard example, a man may be indifferent between drinking a glass of gin or of scotch at a particular moment, but he would be much worse off if he had to drink a glass of half ginâ€“half scotch. On the other hand, if the commodities were not so finely dated, then they would be more analogous to stocks, and a consumer might well be better off with a litre of gin and a litre of scotch, than two litres of either one. In any case, as we shall remark later, if every agent is small relative to the market (that is, if there are many agents) then the non-convexities in preferences are relatively unimportant.

Each agent \( h \) is also characterized by a vector of initial endowments

- (A.6) \( e^h \in X^h \subset \mathbb{R}^L \) for all \( h = 1, \ldots, H \).

The endowment vector \( e^h \) represents the claims that the consumer has on all commodities, not necessarily commodities in his physical possession. The fact that \( e^h \in X^h \) means that the consumer can ensure his own survival even if he is deprived of all opportunity to trade. This is a somewhat strange hypothesis for the modern world, in which individuals often have labour but few other endowments, e.g. land. Doubtless the hypothesis could be relaxed; in any case, survival is not an issue that is addressed in the Arrowâ€“Debreu model.

Each individual \( h \) is also endowed with an ownership share of each of the firms \( j = 1, \ldots, J \)

- (A.7) For all \( h = 1, \ldots, H \), \( j = 1, \ldots, J \), \( d^h_j \geq 0 \), and for all \( j = 1, \ldots, J \), \( \sum_{h=1}^H d^h_j = 1 \).

- Firms. (A.8) Let there be \( J \) firms, \( j = 1, \ldots, J \).

The firm in Arrowâ€“Debreu is characterized by its initial distribution of owners, and by its
technological capacity $Y_j \subset \mathbb{R}^L$ to transform commodities. Any production plan $y \in \mathbb{R}^L$, where negative components of $y$ refer to inputs and positive components denote outputs, is feasible for firm $j$ if $y \in Y_j$. A customary assumption made in the Arrow-Debreu model is free disposal: if $l = 1, \ldots, L$ is any commodity, and $v_1$ is the unit vector in $\mathbb{R}^L$, with one in the $l$th coordinate and zero elsewhere, then

\begin{itemize}
  \item (A.9) For all $l = 1, \ldots, L$ and $k > 0$, $-kv_1 \in Y_j$, for some $j = 1, \ldots, J$.
\end{itemize}

Although it is strange, when thinking of nuclear waste etc., to think that any commodity can be disposed without cost (i.e. without the use of any other inputs), as we shall remark later, this assumption can be relaxed, if negative prices are introduced (or if weak monotonicity is assumed).

The empirically most vulnerable assumption to the Arrow-Debreu model, and one crucial to its logic, is:

\begin{itemize}
  \item (A.10) For each $j$, $Y_j$ is a closed, convex set containing 0.
\end{itemize}

This convexity assumption rules out indivisibilities in production (e.g. half a tunnel), increasing returns to scale, gains from specialization, etc. As with consumption, if the indivisibilities of production are small relative to the size of the whole economy, then the conclusions we shall shortly present are not much affected. But when they are large, or when there are significant increasing returns to scale, the model of competitive equilibrium that we are about to examine is simply not applicable. Nevertheless, convexity is consistent with the traditionally important cases of decreasing and constant returns to scale in production.

We conclude by presenting three final assumptions used in the Arrow-Debreu model.

\begin{itemize}
  \item (A.11) Let $e = \sum_{h=1}^{H} e^h$,
  \item $\mathcal{F} = \{ y \in \mathbb{R}^L | y = \sum_{j=1}^{J} Y_j, y \in Y_j, j = 1, \ldots, J \}$,
  \item $\mathcal{F} = \{ y \in \mathbb{R}^L | y \geq 0 \}$, and
  \item $\mathcal{K} = \{ (y_1, \ldots, y_J) \in Y_1 \times \ldots \times Y_J | \sum_{j=1}^{J} y_j \in \mathbb{R}_+^L \}$.
  \item Then $\mathcal{F} \cap \mathbb{R}_+^L \neq \varnothing$, and $K$ is compact.
\end{itemize}

Assumption (A.11) requires that the level of productive activity that is possible even if the productive sector appropriates all the resources of the consuming sector is bounded (as well as closed). Notice that these assumptions are consistent with firms owning initial resources, as well as individuals. In the original Arrow-Debreu model (1954), the firms were prohibited from owning initial resources (they were assigned to the firm owners: with complete markets there is little difference, but with incomplete markets the earlier assumption is restrictive).

\begin{itemize}
  \item (A.12) The economy is irreducible.
\end{itemize}
We shall not elaborate this assumption here. It means that for any two agents $h$ and $h'$, the endowment $e^h$ of agent $h$ is positive in some commodity $l$, which (taking into account the possibilities of production) agent $h'$ could use to make himself strictly better off. It certainly seems reasonable that each agent's labour power could be used to make another agent better off.

Lastly, we assume that

- (A.13) The commodities are not distinguished according to which firm produces them, or who consumes them.

Assumption (A.13) is made simply for the purposes of interpretation. When put together with the definition of competitive equilibrium, it implies that there are no externalities to production or consumption, no public goods, etc. Mathematically, however, (A.13) has no content. In other words, if we dropped assumption (A.13), the Arrow–Debreu notion of competitive equilibrium would still make sense (even in the presence of externalities and public goods) and it would still have the optimality properties we shall elaborate in Section III, but it would require an entirely different interpretation.

Consumers, for example, would be charged different prices for the same physical commodities (same, that is, according to date, location and state of nature). In more technical language, a Lindahl equilibrium is a special case of an (A.1)–(A.12) Arrow–Debreu equilibrium, with the commodity space suitably expanded and interpreted. Thus each physical unit of a public good is replaced by $H$ goods, one unit for the public good indexed by which agent consumes it. Also the physical technology set describing the production of the public good is replaced by a different set in the Arrow–Debreu model, lying in a higher dimensional space, where the output of the one physical public good is replaced by the joint output of the same amount of $H$ goods. In an Arrow–Debreu equilibrium, consumers will likely pay different prices for these $H$ goods, i.e. for what in reality represents the same physical public good. Hence the differential pay principle for the optimal provision of public goods elucidated by Samuelson, which appeared to point to a qualitative difference between the analytical apparatus needed to describe optimality in public goods and private goods economies, is thus shown to be explicable by exactly the same apparatus used for private goods economies, simply by multiplying the number of commodities. The same device can also be used for analysing the optimal provision of goods when there are externalities, provided that negative prices are allowed. Assumption (A.13) thus seriously limits the normative conclusions that can be drawn from the model. From a descriptive point of view, however, rationality and the price taking behaviour which equilibrium implies make (A.13) necessary.

### III Equilibrium

Price is the final primitive concept in the Arrow–Debreu model. Like commodity it is quantifiable and directly measurable. As Debreu has remarked, the fundamental role which mathematics plays in economics is partly owing to the quantifiable nature of these two primitive concepts, and to the rich mathematical relationship of dual vector spaces, into which it is natural to classify the collections of price values and commodity quantities. Properly speaking, price is only sensible (and measurable) as a relationship between two commodities, i.e. as relative price. Hence there should be $L^Z - L$ relative prices...
in the Arrow-Debreu model. But the definition of Arrow-Debreu equilibrium immediately implies that it suffices to give $L^{-1}$ of these ratios, and all the rest are determined.

For mathematical convenience (namely to treat prices and quantities as dual vectors), one price is specified for each unit quantity of each commodity. The relative price of two commodities can be obtained by taking the ratio of the Arrow-Debreu prices of these commodities. I shall proceed by specifying the definition of Arrow-Debreu equilibrium, and then I make a number of remarks emphasizing some of the salient characteristics of the definition. The longest remark concerns the differences between the historical development of general equilibrium, up until the time of Hicks and Samuelson and the particular Arrow-Debreu model of general equilibrium.

An Arrow-Debreu economy $E$ is an array

\[ E = \{L, H, J, (\mathbf{x}^h, \mathbf{e}^h, >_h), (\gamma^i), (\alpha^j), h = 1, \ldots, H, j = 1, \ldots, J\} \]

satisfying assumptions (A.1)-(A-13). An Arrow-Debreu equilibrium is an array

\[ \{(\mathbf{p}_l), (\mathbf{x}^h_l), (\gamma^i_l), l = 1, \ldots, L, h = 1, \ldots, H, j = 1, \ldots, J\} \]

satisfying:

For all $j = 1, \ldots, J, \gamma_j \in \mathbb{R}$,

\[
\arg \max \left\{ \sum_{l=1}^{L} \mathbf{p}_l \gamma_1 (\gamma = \gamma_1, \ldots, \gamma_L) \in \gamma^j \right\}
\]  

(1)

For all $h=1, \ldots, H$, $H \mathbf{x}^h \in B^h(\mathbf{p})$, where $B^h(\mathbf{p})$

\[
= \left\{ \mathbf{x} \in \mathbb{R}^L : \sum_{l=1}^{L} \mathbf{p}_l \mathbf{x}_l = \sum_{l=1}^{L} \mathbf{p}_l \mathbf{e}^h_l + \sum_{j=1}^{J} \alpha^j \sum_{l=1}^{L} \mathbf{p}_l \gamma^j_l \right\}
\]  

(2)

and if $\mathbf{x} \in B^h(\mathbf{p})$, then not $\mathbf{x} >_h \mathbf{x}^h$,

For all $l = 1, \ldots, L$, $\sum_{h=1}^{H} \mathbf{x}^h_l = \sum_{h=1}^{H} \mathbf{e}^h_l + \sum_{j=1}^{J} \gamma^j_l$.

(3)
The most striking feature of general equilibrium is the juxtaposition of the great diversity in goals and resources it allows, together with the supreme coordination it requires. Every desire of each consumer, no matter how whimsical, is met precisely by the voluntary supply of some producer. And this is true for all markets and consumers simultaneously.

There is a symmetry to the general equilibrium model, in the way that all agents enter the model individually motivated by self-interest (not as members of distinct classes motivated by class interests), and simultaneously, so that no agent acts prior to any other on a given market (e.g. by setting prices). If workers' subsistence were not assumed, for example, that would break the symmetry; workers income could have to be guaranteed first, otherwise demand would (discontinuously) collapse. As it is, at the aggregate level, supply and demand equally and simultaneously determine price; in equilibrium, both the consumers' marginal rates of substitution and the producers' marginal rates of transformation are equal to relative prices (assuming differentiability and interiority). There are gains to trade both through exchange and through production. This point of view represents a significant break with the classical tradition of Ricardo and Marx. We shall come to the main difference between the classical and neoclassical approaches shortly. Another difference is that there need not be fixed coefficients of production in the Arrow-Debreu model, the sets $Y$ are much more general. Also in an Arrow-Debreu equilibrium, there is no reason for there to be a uniform rate of profit. There is none the less one aspect of the model which these authors would have greatly approved, namely the shares $d_{hj}$ which allow the owners of firms to collect profits even though they have contributed nothing to production.

Notice that in general equilibrium each agent need only concern himself with his own goals (preferences or profits) and the prices. The implicit assumption that every agent knows all the prices is highly non-trivial. It means that at each date each agent is capable of forecasting perfectly all future prices until the end of time. It is in this sense that the Arrow-Debreu model depends on rational expectations. Each agent must also be informed of the price $q_j$ of each firm $j$, where $q_j = \sum_{i=1}^{L} \tilde{P}_i \tilde{Y}_i$. (Firms that produce under constant returns to scale must also discover the level of production, which cannot be deduced from the prices alone.) Assuming that the man on the spot (Hayek's expression) knows much better than anyone else what he wants, or best how his changing environment is suited to producing his product, decentralized decision making would seem to be highly desirable, if it is not incompatible with coordination. Indeed, harmony through diversity is one of the sacred doctrines of the liberal tradition.

The greatest triumph of the Arrow-Debreu model was to lay out explicitly the conditions (roughly $(A.1)$) under which it is possible to claim that a properly chosen price system must always exist that, like the invisible hand, can guide diverse and independent agents to make mutually compatible choices. The idea of general equilibrium had gradually developed since the time of Adam Smith, mostly through the pioneering work of Walras (1874), von Neumann (1937), Hicks (1939) and Samuelson (1947). By the late 1940s the definition of equilibrium, including ownership shares in the firms, was well-established. But it was Arrow-Debreu (1954) that spelled out precise microeconomic assumptions at the level of the individual agents that could be used to show the model was consistent. The axiomatic and rigorous approach that characterized the formulation of general equilibrium by Arrow-Debreu has been enormously influential. It is now taken for granted that a model is not
properly defined unless it has been proved to be logically consistent. Much of the clamour for a microeconomic foundations to macroeconomics, for example, is a desire to see an axiomatic clarity similar to that of the Arrowâ€“Debreu model applied to other areas of economics. Of course, there were other earlier economic models that were similarly axiomatic and rigorous; one thinks especially of von Neumannâ€“Morgenstern's *Theory of Games* (1944). But game theory was, at the time, on the periphery of economics. Competitive equilibrium is at its heart. The central mathematical techniques, convexity theory (separating hyperplane theorem) and Brouwer's (Kakutani's) fixed point theorem, used in Arrowâ€“Debreu are, 30 years later, still the most important tools used in mathematical economics. Both elements had played a (hidden) role in von Neumann's work. Convexity had been prominent in the work of Koopmans (1951) on activity analysis, in the work of Kuhn and Tucker (1951) on optimization, and in the papers of Arrow (1951) and Debreu (1951) on optimality. Fixed point theorems had been used by von Neumann (1937), by Nash (1950) and especially by McKenzie (1954), who one month earlier than Arrowâ€“Debreu had published a proof of general equilibrium using Kakutani's theorem, albeit in a model where the primitive assumptions were made on demand functions, rather than preferences. McKenzie (1959) also made an early contribution to the notion of an irreducible economy (assumption (A.9)).

The first fruit of the more precise formulation of equilibrium that began to emerge in the early 1950s was the transparent demonstration of the first and second welfare theorems that Arrow and Debreu simultaneously gave in 1951. Particularly noteworthy is the proof that every equilibrium is Pareto optimal. So simple and illuminating is this demonstration that it is no exaggeration to call it the most frequently imitated argument in all of neoclassical economic theory.

Among the confusions that were cleared away by the careful axiomatic treatment of equilibrium was the reliance of the discussions by Hicks and Samuelson on interior solutions and differentiability. When discussing the optimal allocation of housing, for example, it is evident that most agents will consume nothing of most houses, but this does not affect the Pareto optimality of a free (and complete) market allocation of housing. Similarly, it is not necessary to either the existence of Arrowâ€“Debreu equilibrium, nor to the first and second welfare theorems, that preferences or production sets be either differentiable or strictly convex. In particular, it is possible to incorporate the â€”neoclassical production functionâ€” with constant returns to scale with variable inputs, the classical fixed coefficients methods of production, and the strictly concave production functions of the Hicksâ€“Samuelson vintage, all in the same framework.

This is not to say that differentiability has no role to play in the Arrowâ€“Debreu model. In his seminal paper (1970), Debreu resurrected the role of differentiability by showing, via the methods of transversality theory (a branch of differential topology) that almost every differentiable economy is regular, in the sense that small perturbations to the economic data (e.g. the endowments) make small changes in all the equilibrium prices. Before Debreu, comparative statics could be handled only under specialized hypotheses, for example, the invertibility of excess demand at all prices, etc. We shall give a fuller discussion of the three crucial mathematical results of the Arrowâ€“Debreu model â€” existence, optimality and local uniqueness â€” in the next section.

Observe finally, that although the commodities may include physical goods dated over many time periods, there is only one budget constraint in an Arrowâ€“Debreu equilibrium. The income that could be obtained from the sale of an endowed commodity, dated from the last period, is available already in
IV. Pareto optimality

The first theorem of welfare economics states that any Arrowâ€”Debreu equilibrium allocation \( \bar{x} = (\bar{x}^h), h = 1, \ldots, H \) is Pareto optimal in the sense that if \( ((x^h), (y^j)) \) satisfies

\[
\sum_{h=1}^{H} x^h = \sum_{j} y^j + \epsilon,
\]

then it cannot be the case that \( x^h > \bar{x}^h \) for all \( h \). The second theorem of welfare analysis states the converse, namely that any Pareto optimal allocation for an Arrowâ€”Debreu economy \( E \) is a competitive equilibrium allocation for an Arrowâ€”Debreu economy \( \tilde{E} \) obtained from \( E \) by rearranging the initial endowments of commodities and ownership shares.

The first welfare theorem expresses the efficiency of the ideal market system, although it makes no claim as to the justice of the initial distribution of resources. The second welfare theorem implies that any income redistribution is best effected through a lump sum transfer, rather than through manipulating the market, e.g. through rent control, etc.

The connection between competitive equilibrium and Pareto optimality has been perceived for a long time, but until 1951 there was a general confusion between the necessity and sufficiency part of the arguments. The old proof of Pareto optimality (see Lange, 1942) assumed differentiable utilities of production sets, and a strictly positive allocation \( \bar{x} \). It noted the first order conditions to the problem of maximizing the \( i \)th consumer's utility, subject to maintaining all the others at least as high as they got under \( \bar{x} \), and feasibility, are satisfied at \( \bar{x} \), if and only if \( \bar{x} \); is a competitive equilibrium allocation for a rearranged economy \( \tilde{E} \). This first order, or infinitesimal, proof of equivalence between competitive equilibrium and Pareto optimality could have been made global by postulating in addition that preferences and production sets are convex.

The Arrow and Debreu (1954) proofs of the equivalence between competitive equilibrium and Pareto optimality, under global changes, do not require differentiability, nor do they require that all agents consume a strictly positive amount of every good. In fact the proof of the first welfare theorem, that each competitive equilibrium is Pareto optimal, does not even use convexity.

The only requirement is local nonsatiation, so that every agent spends all his income in equilibrium. If \( (x, y) \) Pareto dominates the equilibrium allocation \( (\bar{p}, \bar{x}, \bar{y}) \), then for all \( h \), \( \bar{p} \cdot x^h < \bar{p} \cdot \bar{x}^h \). Since profit maximization implies that for all \( j \), \( \bar{p} \cdot \bar{y}^j < \bar{p} \cdot y^j \), it follows that

\[
\bar{p} \cdot (\sum_{h} x^h - \sum_{j} y^j) > \bar{p} \cdot (\sum_{h} \bar{x}^h - \sum_{j} \bar{y}^j),
\]

contradicting feasibility.

The proof of the second welfare theorem, on the other hand, does require convexity of the preferences and production sets (though not their differentiability, nor the interiority of the candidate allocation \( \bar{x} \)). Essentially it depends on Minkowski's theorem, which asserts that between any two disjoint convex sets in \( \mathbb{R}^L \) there must be a separating hyperplane.

In this connection let us mention one more remarkable mathematical property of the Arrowâ€”Debreu model. Let us suppose that all production takes place under constant returns to scale: if \( \forall \in \gamma^j \), then so is \( \lambda \forall \), for \( \lambda \geq 0 \). We say that a feasible allocation \( \bar{x} \) for the economy \( E \) is in the core if there is no coalition of consumers \( S \subseteq \{1, \ldots, H\} \) such that using only their initial endowments of resources, as well as access to all the production technologies, they cannot achieve an allocation for themselves which they all prefer.
The core is meant to reflect those allocations which could be maintained when bargaining (the formation of coalitions) is costless. In a status quo core allocation, any labour union or cartel of owners that threatens to withhold its goods from the market knows that another coalition could form and by withholding its goods, prevent some members of the original coalition from being better off than they were under the status quo. It is easy to see that any competitive equilibrium is in the core. Debreuâ€“ Scarf (1963), building on earlier work of Scarf, showed by using the separating hyperplane theorem, that if agents are small relative to the market, in the sense they made precise through the notion of replication, then the core consists only of competitive allocations. Such a theorem can also be proved even if there are small nonconvexities in preferences (see Aumann, 1964, for a different formulation of the small agent).

Existence of equilibrium

Suppose that agents' preferences and firms' production sets are strictly convex, and that agents strictly prefer more of any commodity to less (strict monotonicity) and that they all have strictly positive endowments. Let \( \hat{I} \) be the set of \( L \)-price vectors, all non-negative, summing to one. Let \( f^h(p) \) be the commodity bundle most preferred by agent \( h \), given the strictly positive prices \( p \in \Delta^{++} \). Similarly let \( g^j(p) \) be the profit maximizing choice of firm \( j \), given prices \( p \in \Delta^{++} \). Finally, let

\[
 f(p) = \sum_{h=1}^{H} f^h(p) - \sum_{j=1}^{J} g^j(p) - \varepsilon .
\]

It is easy to show that \( f \) is a continuous function at all \( p \in \Delta^{++} \). A price \( \bar{p} \in \Delta^{++} \) is an Arrowâ€“Debreu equilibrium price if and only if \( \bar{p} \) is a fixed point of \( f \).

In general there is no reason to expect a continuous function to have a zero. Thus Wald could prove only with great difficulty in a special case that an equilibrium necessarily exists. Now observe that the function must satisfy Walras's Law, \( \hat{p} \cdot f(p) = 0 \), for all \( p \). So \( f \) is not arbitrary.

Consider the convex, compact set \( \hat{I}_e \) of prices \( p \in \Delta \) with \( p_l \geq \varepsilon > 0 \), for all \( l \). Consider also the continuous function \( \varphi : \Delta_e \to \Delta_e \) mapping \( p \) to the closest point \( \hat{p} \) in \( \hat{I}_e \) to \( f(p) + \varepsilon \). By Brouwer's fixed point theorem, there must be some \( \bar{p} \) with \( \varphi(\bar{p}) = \bar{p} \). From strict monotonicity, it follows that \( \bar{p} \) cannot be on the boundary of \( \hat{I}_e \), if \( \hat{\mu} \) is chosen sufficiently small. From Walras's Law it follows that if \( \bar{p} \) is in the interior of \( \hat{I}_e \), then \( f(\bar{p}) = 0 \). The demonstration of the existence of equilibrium by Arrow and Debreu, as modified later by Debreu (1959), followed a similar logic.

Note the essential role of convexity in two parts of the above proof. It was used with respect to agents' characteristics to guarantee that their optimizing behaviour is continuous. And it was also used to ensure that the space \( \hat{I} \) has the fixed point property. Smale (1976) has given a path-following proof (related to Scarf's, 1973 algorithm) that on closer inspection does not require convexity of the price space. (Dierker, 1974, and Balasko, 1986, have given homotopy proofs.) This is not only of computational importance. It appears that there may be economic problems, dealing with general equilibrium with incomplete markets, in which the price space is intrinsically nonconvex, and in which the existence of equilibrium can only be proved using path-following methods (see Duffieâ€“Shafer, 1985).

To weaken the assumption of strict convexity, in the above proof, one can replace Brouwer's fixed point
Debreu model of general equilibrium: The New Palgrave Dictionary of Economics

An important conceptual point arises in connection with strict monotonicity. If that is dropped, and the production sets do not have free disposal, then, in order to guarantee the existence of equilibrium, the definition must be revised to require either \( f_i(\bar{p}) = 0 \), or \( f_i(\bar{p}) < 0 \) and \( \bar{p}_l = 0 \). There may be free goods, like air, in excess supply. One cannot drop monotonicity and free disposal without allowing for negative prices.

Finally, it can be shown that if there are small nonconvexities in either preference or production, and if all the agents are small relative to the market (either in the replication sense of Debreuâ€“Scarf, or the measure zero sense of Aumann), then there will be prices at which the markets nearly clear. On the other hand, increasing returns to scale over a broad range is definitely incompatible with equilibrium.

Local uniqueness and comparative statics

Another property of the excess demand function \( f(p) \) is that it is homogeneous of degree zero. So instead of taking \( p \hat{=} \bar{1} \), let us fix \( p_1 = 1 \). Similarly, let \( F(p) \) be the \( L \hat{=} 1 \) vector of excess demands for goods \( l = 2, \ldots, L \). If \( F(p) = 0 \), then by Walras's Law, \( f(p) = 0 \).

Suppose furthermore that agent characteristics are smooth. Then \( F(P) \) is a differentiable function. If \( D_p F(\bar{p}) \) has full rank at an equilibrium \( \bar{p} \), then \( \bar{p} \) is locally unique. Moreover, the equilibrium \( \bar{p} \) will move continuously, given continuous, small changes in the agents' characteristics, such as their endowments \( e \). If \( D_p F(\bar{p}) \) has full rank at all equilibria \( \bar{p} \), then there are only a finite number of equilibria. Debreu (1970) called an economy \( E \) regular if \( D_p F(\bar{p}) \) has full rank at all equilibrium \( \bar{p} \) of \( E \).

The problem of trying to give sufficient conditions on preferences etc. to guarantee that \( D_p F \) has full rank in equilibrium has proved intractable (except for restrictive, special cases). But Debreu (1970) solved the problem in classic style, appealing to the transversality theorem of differential topology (or Sard's theorem), to show that if one were content with regularity for \( \bar{e} \) almost all \( \bar{e} \) TM economies, then the problem is simple. He proved that for almost all economies, \( D_p F \) has full rank at every equilibrium. Hence, in almost all economies comparative statics (the change in equilibrium, given exogenous changes to the economy) is well defined.

Observe that excess demand \( F \) depends on the agents' characteristics, including their endowments, so we could write \( F(e, p) \). Now the transversality theorem says that (given some technical conditions) if \( D_e F(e, \bar{p}) \) has full rank at all equilibria \( \bar{p} \) for the economy \( E(e) \) with endowments \( e \), for all \( e \), then for \( \bar{e} \) almost all \( \bar{e} \) TM economies, \( D_e F(e, \bar{p}) \) has full rank at all equilibrium \( \bar{p} \) for \( E(e) \). But it is easy to show that \( D_e F(e, \bar{p}) \) always has full rank. Along similar lines, Debreu proved that the \( \bar{e} \) TM generic regularity of equilibrium.

There is one unfortunate side to this comparative statics story. One would like to show not only that comparative statics are well defined, but also that they have a definite form. In a concave programming problem, for example, a small increase in an input results in a decrease in that input's shadow price, and an increase in output approximately equal to the size of the input increase multiplied by its original shadow price. Given the strong rationality hypothesis of the Arrowâ€“Debreu model, one would hope for some sort of analogous result. Following a conjecture of Sonnenschein, Debreu proved in 1974 that given any function \( f(p) \) on \( \bar{1} \), satisfying Walras's Law, he could find an Arrowâ€“Debreu economy such that \( f(p) \) is its aggregate excess demand on \( \bar{1} \). The assumptions (A.1)â€“(A.13) do not permit any a
priori predictions about the changes that must occur in equilibrium given exogenous changes to the economy. An increase in the aggregate endowment of a particular good, for example, might cause its equilibrium price to rise. The possibility of such pathologies is disappointing. It means that to make even qualitative predictions, the economist needs detailed data on the excess demands $F$.

**V What the model doesn’t explain**

We have already discussed the implications of the notion of Arrow-Debreu commodities and the second welfare theorem for insurance, namely that since every Pareto optimal allocation is supportable as an Arrow-Debreu equilibrium, every optimal allocation of risk bearing can be accomplished by the production and trade of Arrow-Debreu commodities, i.e. without recourse to additional kinds of insurance markets specializing in risks. Every Arrow-Debreu commodity is as much a diversifier in location, or time, or physical quality as it is for risk. This leads to a great simplification and economy of analysis. But it also means that, from the positive point of view, the Arrow-Debreu economy cannot directly provide an analysis of insurance markets (except as a benchmark case). In this section I shall try to point out a few of the other phenomena which needle into the background in the Arrow-Debreu model, but which would emerge if the assumption of a finite, but complete set of Arrow-Debreu commodities, and consumers was dropped.

There are four currently active lines of research which attempt to come to grips in a general equilibrium framework with some of these phenomena, while preserving the fundamental neoclassical Arrow-Debreu principles of agent optimization, market clearing, and rational expectations, that I think are particularly worthy of attention. They are the theory of general equilibrium with incomplete asset markets which can be traced back to Arrow’s (1953) seminal paper on securities; overlapping generations economies, whose study was initiated by Samuelson (1958) in his classic consumption loan model; the Cournot theory of market exchange with few traders, first adapted to general equilibrium by Shapley-Shubik (1977), and the model of rational expectations equilibrium, pioneered by Lucas (1972).

Let us note first of all that in Arrow-Debreu equilibrium there is no trade in shares of firms. A stock certificate is not an Arrow-Debreu commodity, for its possession entitles the owner to additional commodities which he need not obtain through exchange. Note also that in Arrow-Debreu equilibrium, the hypothesis that all prices will remain the same, no matter how an individual firm changes its production plan, guarantees that firm owners unanimously agree on the firm objective, to maximize profit. If there were a market for firm shares, there would not be any trade anyway, since ownership of the firm and the income necessary to purchase it would be perfect substitutes. In an incomplete markets equilibrium, different sources of revenue are not necessarily perfect substitutes. There could be active trade on the stock market. Of course, such a model would have to specify the firm objectives, since one would not expect unanimity. The theory of stock market equilibrium is still in its infancy, although some important work has already been done. (See Drèze, 1974, and Grossman and Hart, 1979.)

Bankruptcy is not allowed in an Arrow-Debreu equilibrium. That follows from the fact that all agents must meet their budget constraints. In a game theoretic formulation of equilibrium (such as I shall discuss shortly), it is achieved by imposing an infinite bankruptcy penalty. Since every Arrow-Debreu
equilibrium is Pareto optimal, there would be no benefit in reducing the bankruptcy penalty to the point where someone might choose to go bankrupt. But with incomplete markets, such a policy might be Pareto improving, even allowing for the deadweight loss of imposing, the penalties. Money does not appear in the Arrowâ€“Debreu model. Of course, all of the reasons for its life existence: transactions demand, precautionary demand, store of value, unit of account, etc. are already taken care of in the Arrowâ€“Debreu model. One could imagine money in the model: at data zero every agent could borrow money from the central bank. At every date afterwards he would be required to return to the bank exactly what he borrowed (or else face an infinite bankruptcy penalty). In such a model the Arrowâ€“Debreu prices would appear as money prices. The absolute level of money prices and the aggregate amount of borrowing would not be determined, but the allocations of commodities would be the same as in Arrowâ€“Debreu. There is no point in making the role of money explicit in the Arrowâ€“Debreu model, since it has no effect on the real allocations. However, if one considers the same model with incomplete asset markets, the presence of explicitly financial securities can be of great significance to the real allocations.

In the Arrowâ€“Debreu model, all trade takes place at the beginning of time. If markets were reopened at later dates for the same Arrowâ€“Debreu commodities, then no additional trade would take place anyway. At the other extreme, one might consider a model in which at every date and state of nature only those Arrowâ€“Debreu commodities could be traded which were indexed by the corresponding (date, state) pair. An intermediate case would also permit the trade of some (but not all) differently indexed Arrowâ€“Debreu commodities. Now the Arrowâ€“Debreu proofs of the existence and Pareto optimality of equilibrium do not apply to such an incomplete markets economy, as Hart (1975) first pointed out. We have already noted the existence problem. As for efficiency, the Pareto optimality of Arrowâ€“Debreu equilibria might suggest the presumption that, though there might be a loss to eliminating markets, trade on the remaining markets would be as efficient as possible. In fact, it can be shown (generically) that equilibrium trade does not make efficient use of the existing markets. The Arrowâ€“Debreu model of general equilibrium is relentlessly neoclassical; in fact it has become the paradigm of the neoclassical approach. This stems in part from its individualistic hypothesis, and its celebrated conclusions about the potential efficacy of unencumbered markets. (Although Arrow, for example, has always maintained that a proper understanding of Arrowâ€“Debreu commodities is also useful for showing how inefficient is the limited real world market system.) But still more telling is the fact that the assumption of a finite number of commodities (and hence of dates) forces upon the model the interpretation of the economic process as a one-way activity of converting given primary resources into final consumption goods. If there is universal agreement about when the world will end, there can be no question about the reproduction of the capital stock. In equilibrium it will be run down to zero. Similarly when the world has a definite beginning, so that the first market transaction takes place after the ownership of all resources and techniques of production, and the preferences of all individuals have been determined, one cannot study the evolution of the social norms of consumption in terms of the historical development of the relations of production. One certainly cannot speak about the production of all commodities by commodities (Sraffa, 1960) (since at date zero there must be commodities which have not been produced by commodities, i.e. by physical objects which are traded).

It seems natural to suppose that as $L$ becomes very large, so that the end of the world is put off until the distant future, that this event cannot be of much significance to behaviour now. But let us not forget the
rationality imposed on the agents. Far off as the end of the world might be, it is perfectly taken into account. Thus, for example, social security (funded as it is in the US by taxes on the young) could not exist if rational agents agreed on a final stopping time to transactions.

Consider a model satisfying all the assumptions (A.1)-(A.13), except that \( L \) and \( H \) are allowed to be infinite, such as the overlapping generations model. It can be shown that there is a robust collection of economies which have a continuum of equilibria, most of which are Pareto sub-optimal, which differ enormously in time 0 behaviour. Thus in a model where time does not have a definite end, the optimality and comparative statics properties of equilibria are radically different. (For example, there may be a continuum of equilibria, indexed by the level of period 0 real wages inversely related to the rate of profit or the level of output or employment. The interested reader can consult the entry on the overlapping generations model of general equilibrium. A systematic study of economies where only \( L \) is allowed to be infinite was begun by Bewley, (1972). Such economies tend to have properties similar to those of Arrow-Debreu.)

There is no place in the Arrow-Debreu model for asymmetric information. The second welfare theorem, for example, relies on lump sum redistributions, i.e. redistributions that occur in advance of the market interactions. But if agents cannot be distinguished except through their market behaviour, then the redistribution must be a function of market behaviour. Rational agents, anticipating this, will distort their behaviour and the optimality of the redistribution will be lost.

Similarly, in the definition of equilibrium no agent takes into account what other agents know, for example about the state of nature. Thus it is quite possible in an Arrow-Debreu equilibrium for some ignorant agents to exchange valuable commodities for commodities indexed by states that other agents know will not occur. This problem received enormous attention in the finance literature, and some claim (see Grossman, 1981) that it has been solved by extending the Arrow-Debreu definition of equilibrium to a rational expectations equilibrium (Lucas, 1972; see also Radner, 1979). But this definition is itself suspect; in particular, it may not be implementable.

Even if rational expectations equilibrium (REE) were accepted as a visible notion of equilibrium, it could not come to grips with the most fundamental problems of asymmetric information. For like Arrow-Debreu equilibrium, in REE all trade is conducted anonymously through the market at given prices. Implicit in this definition is the assumption of large numbers of traders on both sides of every market. But what has come to be called the incentive problem in economics revolves around individual or firm specific uncertainty, i.e. trade in commodities indexed by the names of the traders, which by definition involves few traders.

This brings us to another major riddle: how are agents supposed to get to equilibrium in the Arrow-Debreu model? The pioneers of general equilibrium never imagined that the economy was necessarily in equilibrium; Walras, for example, proposed an explicit tâ€œtâ€â€œtonnement procedure which he conjectured converged to equilibrium. But that idea is flawed in two respects: in general, it can be shown not to converge, and more importantly, it is an imaginary process in which no exchange is permitted until equilibrium is reached. This illustrates a grave shortcoming of any equilibrium theory, namely that it cannot begin to specify outcomes out of equilibrium. The major crisis of labour market clearing in the 1930s, and again recently, argues strongly that there are limits to the applicability of equilibrium analysis.

One is led naturally to consider market games, in which the outcomes are well-specified even when agents do not make their equilibrium moves. The most famous market game is Cournot's duopoly
model, which has been extended to general equilibrium by Shapleyâ€”Shubik (1977). When there are a large number of agents of each type, the Nash equilibria of the Shapleyâ€”Shubik game give nearly identical allocations to the competitive allocations of Arrowâ€”Debreu. This justifies (to first approximation) the price taking behaviour of the Arrowâ€”Debreu agents. But note that the informational requirements of Nash equilibrium are at least twice that of Arrowâ€”Debreu competitive equilibrium (each agent must know the aggregates of birds and offers on each market). It is also extremely interesting that trade takes place in the Shapleyâ€”Shubik game even if there is only one trader on each side of the market. Hence many problems in asymmetric information which have no place in the Arrowâ€”Debreu model, because they involve too fine a specification of the commodities to be consistent with price taking, might be sensible in a market game context. Finally, it can be shown that REE is not consistent with the Shapleyâ€”Shubik game, or indeed with any continuous game.

We have indicated some of the ways in which it is possible to extend general equilibrium analysis to phenomena outside the scope of the Arrowâ€”Debreu model, while at the same time preserving the neoclassical methodological premises of agent optimization, rational expectations, and equilibrium. It is important to note that these variations have extended the definition of equilibrium as well; this is most obvious in the case of market games, where Nash equilibrium replaces competitive equilibrium. All of the models have retained, on the other hand, more or less the same notion of rationality, sometimes at the cost of increasing the demands on the rationality of expectations. A great challenge for future general equilibrium models is how to formulate a sensible notion of bounded rationality, without destroying the possibility of drawing normative conclusions.

Arrow's theorem

Kenneth J. Arrow
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Any satisfactory method of making a social choice should be in some measure representative of the individual criteria which enter into it, should use the range of possible actions, and should observe consistency conditions among the choices made for different data sets. Arrow's Theorem, or the Impossibility Theorem, states that there is no social choice mechanism which satisfies such reasonable conditions and which will be applicable to any arbitrary set of individual criteria. This article sets out the proof of the theorem.

Article

Economic or any other social policy has consequences for the many and diverse individuals who make up the society or economy. It has been taken for granted in virtually all economic policy discussions since the time of Adam Smith, if not before, that alternative policies should be judged on the basis of their consequences for individuals; political discussions are less uniform in this respect, the welfare of an abstract entity, the state or nation, playing a role occasionally even in economic policy. It follows that there are as many criteria for choosing social actions as there are individuals in the society. Furthermore, these individual criteria are almost bound to be different in some measure so that there will be pairs of policies such that some individuals prefer one and some the other. In the economic context, policies invariably imply distributions of goods, and in most policy choices, some individuals will receive more goods under one policy and others under the other. Individuals may also have different
evaluations because of different concepts of justice or other social goals. 
The individual criteria may be based on individual preferences over bundles of goods or individual preferences of a more social nature, with preferences over goods supplied to others. From the viewpoint of the formal theory of social choice, the criteria may even be judgements by others as to the welfare of individuals. The only assumption is that there is associated with each individual a criterion by which social actions are evaluated for that individual. Whatever their origin, these criteria differ from individual to individual.

Every society has a range of actions, more or less wide, which are necessarily made collectively. Much of the debate on the foundations of social decision theory began with criteria for evaluating alternative tariff structures, including as the most famous illustration moving from a tariff to free trade. The redistribution of income through governmental taxes and subsidies provides another important case of an inherently collective decision which would be judged differently by different individuals.

If every individual prefers one policy to another, it is reasonable to postulate, as is always done by economists, that the first policy should be preferred. The problem arises of making social choices (between alternative collective policies) when some individual criteria prefer one policy and some another.

The fundamental question of social choice theory, then, is the following: given a range of possible social decisions, one of which has to be chosen, and given the criteria associated with the individuals in the society, find a method of making the choice. Not all methods of decision would be regarded as satisfactory. The method should be in some measure representative of the individual criteria which enter into it. For example, we would want the Pareto condition to be satisfied, that an alternative not be chosen if there is another preferred by all individuals. The method should use all the data, that is, both the range of possible actions and the individual criteria, and there are consistency conditions among the choices made for different data sets.

A pure case of social choice in action is voting, whether for the election to an office or a legislative decision. Here, the candidates or alternative legislative proposals are evaluated by each voter, and the evaluations lead to messages in the form of votes. The social decision, which candidate to elect or which bill to pass, is made by aggregating the votes according to the particular voting scheme used. The social decision then depends on both the range of alternatives (candidates or legislative proposals) available and the ranking each voter makes of the alternatives.

Voting procedures have one very important property which will play a key role in the conditions required of social choice mechanisms: only individual voters’ preferences about the alternatives under consideration affect the choice, not preferences about unavailable alternatives.

Arrow's Theorem, or the Impossibility Theorem, states that there is no social choice mechanism which satisfies a number of reasonable conditions, stated or implied above, and which will be applicable to any arbitrary set of individual criteria.

Some terminology will be introduced in section 1 of this entry. In section 2, there will be a brief review of the relevant literature as it was known to me prior to the discovery of the theorem. In section 3, I state the theorem with some variants and discuss the meaning of the conditions on the social choice mechanisms.

1 The language of choice
The formulation of choice and the criteria for it are those standard in economic theory since the ‘marginalist revolution’ of the 1870s as subsequently refined. There is a large set of conceivable alternatives; in any given decision situation, some given subset of these alternatives is actually available or feasible. This subset will be referred to as the opportunity set. Each individual can evaluate all alternatives. This is expressed by assuming that each individual has a preference ordering over the set of all alternatives. That is, for each pair of alternatives, the individual either prefers one to the other or else is indifferent between them (completeness), and these choices are consistent in the sense that if alternative \( x \) is preferred or indifferent to alternative \( y \) and \( y \) is preferred or indifferent to \( z \), then \( x \) is preferred or indifferent to \( z \) (transitivity). This preference ordering is analogous to the preference ordering over commodity bundles in consumer demand theory. I have adopted the ordinalist viewpoint that only the ordering itself and not any particular numerical representation by a utility function is significant.

The profile of preference orderings is a description of the preference orderings of all individuals. For a given profile, the social choice mechanism will determine the choice of an alternative from any given opportunity set. In the case of an individual, it is assumed that the choice made from any given set of alternatives is that alternative which is highest on the individual's preference ordering. Analogously, it is assumed that social choices can be similarly rationalized. The social choice mechanism will have to be such that there exists a social ordering of alternatives such that the choice made from any opportunity set is the highest element according to the social ordering. Therefore, a social choice mechanism or constitution is a function which assigns to each profile a social ordering.

2 The relevant literature

I will here review the literature on the justification of economic policy as I knew it in 1948–50. There was some work in economics and more in the theory of elections of which I was unaware, which I will briefly note.

The best-known criterion for what is now known as social choice was Jeremy Bentham's proposal for using the sum of individuals’ utilities. Curiously, despite its natural affinity with marginal economics, it received very little serious use, possibly because its distributional implications were unacceptably extreme. Edgeworth applied the criterion to taxation (1925: originally published in 1897): see also Sidgwick (1901, ch. 7).

The use of the sum-of-utilities criterion required interpersonally comparable cardinal utility. A reluctance to make interpersonal comparisons led to the proposal of the compensation principle by Kaldor (1939) and Hicks (1939). Consider a choice between a current alternative \( x \) and a proposed chance to another alternative \( y \). In general, some individuals will gain by the change and some will lose. The compensation principle asserts that the change should be made if the gainers could give up some of their goods in \( y \) to the losers so as to make the losers better off than under \( x \) without completely wiping out the gains to the winners. Notice that the compensation is potential, not actual. Since the only information used is the preference relation of each individual among three different alternatives, \( x, y, \) and a potential alternative derived from \( y \) by transfers of goods, no interpersonal comparisons are needed. However, it turns out that the compensation principle does not define a social ordering. Indeed,
Scitovsky (1941) showed that it was possible that the compensation principle would call for changing from \( x \) to \( y \) and then from \( y \) to \( x \).

A different approach which sought to avoid not only interpersonal comparisons but also cardinal utility was the social welfare function concept of Bergson (1938). For each individual, first choose a utility function which represents his or her preference ordering. Then define social welfare as a prescribed function \( W(U_1, \ldots, U_n) \) of the utilities of the \( n \) agents. For a given profile of preference orderings, if one of the utility functions is replaced by a monotone transformation (which represents therefore the same preference ordering), the function \( W \) has to be transformed correspondingly, so that social preferences defined by \( W \) are unchanged. In this formulation, a given social welfare function is associated with a given profile. There are no necessary relations among social welfare functions associated with different profiles.

It was also known to me, though I do not know how, that majority voting, which could be considered as a social decision procedure, might lead to an intransitivity. Consider three voters A, B and C and three alternatives, a, b and c. Suppose that A has preference ordering abc, B has ordering bca, and C the ordering cab. Then a majority prefer a to b, a majority prefer b to c, and a majority prefer c to a. Therefore, if we interpret a majority for one alternative to another as defining social preference, the relation is not an ordering. This paradox had in fact been discovered by Condorcet (1785), and there had been a small and sporadic literature in the intervening period (for an excellent survey, see Black, 1958, Part II; also, Arrow, 1973), but all of this literature was unknown to me when developing the Impossibility Theorem.

There was one further very important paper, which I did know, the remarkable paper of Black (1948) on voting under single-peaked preferences. Suppose the set of alternatives can be represented in one dimension, for example, a choice among levels of expenditure (this was the case studied by Bowen (1943) who anticipated part of Black's results). Suppose individuals have different preference orders over the alternatives, but these preferences have a common pattern; namely, there is a most preferred alternative from which preference drops steadily in both directions. Put another way, of any three alternatives, the one in the intermediate position is never inferior to both of the others. Under this single-peakedness condition, majority voting defined a transitive relation and therefore an ordering. Hence, if the preferences of individuals are restricted to satisfy the single-peakedness condition, there does exist a constitution as defined earlier.

### 3 Statement of the impossibility theorem

I now state formally the conditions to be imposed on constitutions and then state the Impossibility Theorem, which simply asserts the non-existence of constitutions satisfying all of the conditions. The theorem as stated in the original paper (Arrow, 1950) and in a subsequent book (Arrow, 1951) is not correct as written, as shown by Blau (1957). To avoid confusion, I give a corrected statement and then explain the error.

**Condition U:** The constitution is defined for all logically possible profiles of preference orderings over the set of alternatives.

**Condition M** (Monotonicity): Suppose that \( x \) is socially preferred to \( y \) for a given profile. Now suppose a
new profile in which $x$ is raised in preference in some individual orderings and lowered in none. Then $x$ is preferred to $y$ in the social ordering associated with the new profile.

**Condition I** (Independence of Irrelevant Alternatives): Let $S$ be a set of alternatives. Two profiles which have the same ordering of the alternatives in $S$ for every individual determine the same social choice from $S$.

To state the next condition, it is necessary to define an imposed constitution as one in which there is some pair of alternatives for which the social choice is the same for all profiles.

**Condition N** (Non-imposition): The constitution is not imposed.

A constitution is said to be *dictatorial* if there is some individual, any one of whose strict preferences is the social preference according to that constitution.

**Condition D** (Non-dictatorship): The constitution is not dictatorial.

**Theorem 1**: There is no constitution satisfying Condition U, M, I, N and C.

A sketch of the argument can be given. From Condition I, the preference between any two alternatives depends only on the preferences of individuals between them and not on preferences about any other alternatives. Define a set of individuals to be *decisive* for alternative $x$ against alternative $y$ if the social preference is for $x$ against $y$ whenever all the individuals in the set prefer $x$ to $y$. First, it can be shown that a set which is decisive for one alternative against one other is decisive for any alternative against any other. Hence, we can speak of a set of individuals as being decisive or not without reference to the alternatives being considered. If a set is not decisive, its complement (the voters not in the given set) can guarantee a weak preference, that is, preference or indifference. The set of all voters can easily be shown to be decisive, so there are decisive sets. The second stage in the proof is to take a decisive set with as few members of possible. If there were only one member, then by definition there would be a dictator, contrary to Condition D. Therefore, split the smallest decisive set so chosen into two subsets, say $V_1$ and $V_2$, and let $V_3$ contain all other voters. We now use an argument similar to that which showed the intransitivity of majority voting. Take any three alternatives, $x, y$ and $z$. Suppose the members of $V_1$ all have the preference ordering, $xyz$, the members of $V_2$ the ordering $yoz$, and the members of $V_3$ the ordering $zyx$. Since $V_1$ and $V_2$ each have fewer members than the smallest decisive set, neither is decisive. Since all voters other than those in $V_2$ prefer $x$ to $y$, $x$ must be preferred or indifferent socially to $y$. Since $V_1$ and $V_2$ together constitute a decisive set and $y$ is preferred to $z$ in both sets, $y$ must be preferred socially to $z$. By transitivity, then, $x$ is socially preferred to $z$. But $x$ is preferred to $z$ only by the members of $V_1$, which would therefore be decisive for $x$ against $z$ and hence a decisive set. This, however, contradicts the construction that $V_1$ is a proper subset of the smallest decisive set and therefore is not a decisive set. The theorem is therefore proved.

Notice that Condition U, that the constitution be defined for all profiles, is essential to the argument. We consider the consequences of particular profiles.

In Arrow (1951, p. 59), the theorem is stated with a weaker version of Condition U (and a corresponding restatement of Condition M).

**Condition U′**: The constitution is defined for a set of profiles such that, for some set of three alternatives, each individual can order the set in any way.

Since the contradiction requires only three alternatives, I supposed that the more general assumption would be sufficient. This is not so, as first pointed out by Blau (1957). The reason is that the non-
dictatorship Condition $D$ may hold for the set of all alternatives and not hold for a subset, such as the triple of alternatives just described. To illustrate, suppose there are four alternatives altogether. Let $S$ be a set of three of them, and let $w$ be the fourth. Suppose each individual may have any ordering such that $w$ is either best or worst. There are two individuals in the society. The constitution provides that the social preference between any pair in $S$ follows the preferences of individual 1, but $w$ is best or worst according to individual 2's preference ordering. This constitution would satisfy all the conditions of the Arrow 1951 version and therefore provides a counter-ex. What is true, of course, is that individual 1 is a dictator over the alternatives in $S$. If we still wish to retain the weaker Condition $U'$, the theorem remains valid if a stronger non-dictatorship condition is imposed (see Murakami, 1961).

Condition $D'$: No individual shall be a dictator over any three alternatives.

The conditions are fairly straightforward and need little comment. If it is reasonable to limit the range of possible individual orderings because of prior knowledge about the range of possible beliefs, then Condition $U$ or $U'$ could be replaced by a corresponding range condition. As has already been remarked, if preference orderings are restricted to the single-peaked type, then majority voting defines a constitution. There has been a considerable literature on range restrictions which imply that majority voting defines a constitution and some on more general voting methods. In a world of multi-dimensional issues, these restrictions are not particularly persuasive.

Conditions $M$ and $N$ embody different aspects of the value judgement that social decisions are made on behalf of the members of the society and should shift as values shift in a corresponding way. Condition $D$ expresses a very minimal degree of democracy.

Condition $I$ (independence of irrelevant alternatives) is central to the social choice approach whether in the Impossibility Theorem or in other, more positive, results. It is implicit in Rawls's difference principle of justice (Rawls, 1971), as well as in utilitarianism or methods based on voting.

The above conditions have not included the Pareto principle explicitly. Condition $P$: If every individual prefers $x$ to $y$, then $x$ is socially preferred to $y$.

It is not hard to prove, however, that this condition is implied by some of the previous conditions, specifically Conditions $M$, $I$ and $N$. Further, if the Pareto condition is imposed, then the Impossibility Theorem holds without assuming Monotonicity or Non-imposition. Of course, it is obvious that the Pareto principle implies Non-imposition, since any choice can be enforced by unanimous agreement.

Theorem 2: there is no constitution satisfying Conditions $U$, $P$, $I$, and $D$.

This entry has dealt with Arrow’s theorem itself and not with subsequent developments, which have been very abundant. The reader is referred to the entry on social choice in this work, and the surveys by Sen (1986) and Kelly (1978).

The application of economic theory and analysis to problems in the performing arts (music, theatre, dance), the visual and literary arts and other art forms has expanded greatly over the last 30 years. A basic issue has been to identify the ways in which artistic goods and services differ from other goods and services in the economy, thereby warranting particular attention. This article considers the economic analysis of demand and supply conditions in the arts, market structures (including factor markets) and a range of public policy issues in the area of cultural policy.

Article

The definition of art has been a philosophical conundrum for centuries, but there is probably a reasonable consensus on what comprises ‘the arts’. These include the performing arts (music, dance, opera and theatre), the visual and plastic arts (painting, drawing, print-making, photography, sculpture, craft, and so on), the literary arts (poetry, fiction, drama, screenplays, and some forms of non-fiction such as biography), certain types of film, and some emerging practices such as video art that derive from new information and communications technologies. The application of economic theory and analysis across these various art forms comprises the discipline that has come to be known as cultural economics.
Although the ambit of this field has expanded in recent years to embrace wider economic questions relating to culture in an anthropological sense, such as the role of culture in economic development. Apart from some issues relating to the definition of cultural goods, this contribution does not deal with culture in the broader sense but rather is confined to the arts as defined above, and considers the conditions of demand, supply and exchange of artistic products, and some consequent issues for policy.

**Characteristics of cultural goods**

The goods and services produced by the arts, as well as some neighbouring commodities such as television programmes, video games and heritage services, can be called cultural goods and services. A fundamental question is whether such goods have unique characteristics that distinguish them as a commodity class from other goods and services in the economy. A reasonable definition of cultural goods attributes to them three necessary features: they require some input of human creativity in their manufacture; they possess or convey some symbolic meaning or messages; and they contain, at least potentially, some form of intellectual property. This definition extends to include a wide range of goods with only minor cultural content, such as fashion design, some forms of advertising, and some architectural services. Nevertheless, while there may be some blurring of boundaries at the cultural edges, there is little doubt that goods and services produced by the arts, as a subset of cultural goods, fit this definition nicely.

An alternative (or perhaps additional) definitional approach has been to portray cultural goods as embodying or giving rise to a form of value that lies beyond the reach of conventional economic assessment, and is not expressible (or is only imperfectly expressible) in market prices or in individual willingness-to-pay judgements. In the case of art works, such ‘cultural’ value might derive from ineffable aesthetic or spiritual qualities that such works of art are known to possess. These sources of value are only partially comprehensible within standard neoclassical price theory; indeed, they can be fully understood only by extending the analytical range to wider areas of economics, and beyond economics into other disciplines such as philosophy, psychology and aesthetics.

A further distinctive characteristic of the arts as consumption goods is that they are subject to the phenomenon of path dependence or, more specifically, rational addiction; that is, they are commodities for which an individual's present consumption depends on his or her past consumption, and patterns of demand tend to be cumulative. Although it is generally agreed that increased exposure to the arts in the past and the present will generate increased demand in the future (with consequent lessons for arts in education), this is hardly a sufficient condition for defining artistic goods, since a number of other commodities, not least addictive drugs, share a similar characteristic.

As economic commodities it is appropriate to categorize cultural goods as being capital goods, intermediate goods, or goods for final consumption. When classified as capital items (reusable goods whose services are combined with other inputs to produce further outputs), cultural goods have come to be known within economics as cultural capital, distinguished from other forms of capital by reference to either or both of the above definitions. This concept is especially relevant in the analysis of artworks and cultural heritage, where the interpretation of tangible or intangible cultural property as long-lasting assets created by the investment of resources, subject to depreciation unless properly maintained and yielding a rate of return over time, is readily understood.

It is important to note that cultural goods are generally very heterogeneous, suggesting that working in...
characteristics space may be a preferred way to analyse their demand and supply. For instance, demand for paintings can be thought of in Lancastrian terms as determined by the works’ colour, size, style, school, and so on, and similar collections of characteristics can readily be imagined for other types of artistic commodities. Nevertheless, such heterogeneity does not vitiate the application of the tools of demand and supply analysis to the arts, as demonstrated further below.

**Demand**

A demand function for any type of artistic good or service could be expected to contain the usual sorts of explanatory variables: own price, price of substitutes, product quality characteristics and socio-demographic indicators relating to consumers’ age, gender, income, education, and so forth. Within standard demand models, interest has focused on empirical questions: price and income elasticities, the relative importance of education and income, the cost of time, and the influence of quality aspects (to the extent that they can be measured). Results from a variety of art forms, time periods, geographical locations and data sources have varied widely, and even apparently plausible hypotheses, such as that the arts are a luxury good, have been by no means universally upheld. Nevertheless, the weight of evidence suggests, inter alia, that education is generally a more powerful predictor of arts demand than is income, and that output quality characteristics exert a strong influence on consumption patterns, perhaps overshadowing price as a determinant of demand behaviour in particular circumstances.

One topic of considerable interest in the demand for the performing arts is the emergence of so-called superstars, performers such as rock musicians and film actors whose incomes are greater than those of their competitors by a much larger differential than marginal productivity theory would suggest. Rosen (1981) attributed this phenomenon to two features of the demand for superstars’ services. First, since consumers rationally prefer one good performance to two mediocre ones, particular types of services (such as rock music) are imperfect substitutes on the demand side, leading to convexity in sellers’ returns and to a skewness in the distribution of earnings. Second, scale economies in joint consumption allow relatively few sellers to supply the entire market. Add to this the possible ‘herding’ behaviour of consumers, who follow the lead of others in making their demand decisions, and a plausible explanation as to why some performers command excessively high rents is obtained. Paradoxically, however, having broken away from the pack, superstars may finish up receiving less than their full earnings potential because some of their incremental contribution may have to be shared with employers, agents, managers and other beneficiaries of their superstardom.

Compared with the performing arts, the demand for art objects such as paintings – occurring in what is generally known as ‘the art market’ – raises some quite different questions. Durable works of art are sought by buyers not just for their aesthetic qualities but also because they are financial assets whose value may appreciate over time. Demand for paintings, prints, drawings, movable sculptures and other collectables such as silverware and rare books is readily separable into demand for art as a source of aesthetic gratification and demand for art as financial instrument. Both demands are affected by some of the same sorts of considerations – the reputation of the artist, the opinion of critics and market analysts, fashions in taste, past prices, and so on. At the same time other influences affect one or other aspect of demand specifically; for instance, demand for art as asset is constrained by some unattractive features of works of art as investments compared with alternative instruments, in particular their indivisibility, their illiquidity and their riskiness. In freely functioning markets, prices are expected to reflect all these
influences, providing in equilibrium a means of balancing their respective importance. Since quite extensive and detailed data on prices in various art markets are available, a substantial econometric effort has been devoted to analysing price patterns across time and space for a wide range of types and styles of works of art. While much of this research yields results of interest only to art market specialists and connoisseurs – for example, do prices for paintings and prints by the same artist follow similar trends? – some of it addresses the more general issue of rates of return to art investment over time. Although contrary examples can be found, the general conclusion is that a collection of works of art will yield a lower return over the long term than a corresponding portfolio of stocks and bonds, the differential being attributable in part to the consumption services provided by the art for the period for which it is held.

Finally on the demand side, we can point to the demand for museum and heritage services. This demand includes attendances at art museums and heritage sites which provide private consumption experiences to the visitor, the specialist demand for conservation and restoration services provided by curators, art historians, and so on who staff the institutions concerned, and the demand for the public-good output of these cultural facilities, seen in the form of non-participant benefits accruing to the local and wider communities. With regard to direct visits to museums and sites, empirical experience suggests some price sensitivity, leading to arguments for free admission to publicly funded or operated facilities on the grounds that their educational and access benefits outweigh their potential for revenue raising. Nevertheless, in some instances, especially in the heritage field, revenue from visitors such as tourists is the only reliable source of ongoing funds for restoring or maintaining the facility concerned. However, regardless of the income-earning prospects of museum and heritage assets, the demand for their public-good output may well prove more decisive than the private-use demand for their services in rationalizing their existence in economic terms. In this respect demand estimation methods using stated preference techniques such as contingent valuation methods have proved useful in evaluating option, existence and bequest demands for these items of cultural capital and in quantifying willingness to pay for their services.

**Supply**

Artistic goods and services for final consumption are produced by a variety of types of enterprises ranging from single-person firms through small for-profit and not-for-profit companies to large corporate organizations in both private and public sectors. At the simplest end of this spectrum is the individual artist who produces goods or services for direct sale to the public – the visual artist selling paintings from her home, or the busker playing his saxophone in the shopping mall. From an economic viewpoint these artists can be seen as single-proprietor firms, probably unincorporated and subject to more than the usual vagaries of production, cost and market uncertainties that attend such producers elsewhere in the economy. Their labour time and their talent are likely to be their principal inputs, and their production functions are likely to relate as much to the quality as to the quantity of their output. We return to the economic circumstances of individual artists below.

Across many fields in the arts – including opera, theatre, dance, classical music, jazz, independent filmmaking, small-scale literary publishing, contemporary visual art and craft, and so on – the predominant firm types, in terms of numbers of firms, are small and medium-sized enterprises, constituted on either a for-profit or a not-for-profit basis. Microeconomic theory offers straightforward means for
characterizing the production and cost conditions under which all these firms operate, with differences according to specific features of the various industries. For example, in the performing arts the unit of output in both production and cost function estimations is generally taken as paid attendances, in a manner similar to the way output is measured in other service-providing firms such as hospitals and universities. Standard functional forms can be used to investigate elasticities of output with respect to various inputs, economies of scale and scope, technical and allocative efficiencies, and productivity growth.

While production and cost conditions may be expected to be similar for these firms whether they are profit-oriented or otherwise, the structure and behaviour of for-profit and not-for-profit firms will differ markedly. Much attention in the economics of the arts has been focused on the latter because of the prevalence of not-for-profit firms at the ‘serious’ end of the artistic spectrum, producing innovative output or work which, though judged artistically worthy, does not appeal to a mass audience. Not only is there insufficient demand to sustain commercial production of this sort of work, but also the motives of the firms producing it are artistic rather than pecuniary. They can therefore be modelled as constrained maximizers of output quality (and possibly of the quantity of output as well if they wish to spread their art to as wide an audience as possible); the constraint is a break-even restriction whereby earned plus unearned revenue must at least cover costs over some specified period. Other model specifications have also been investigated, for example incorporating an objective of maximizing revenues from sponsorship and donations.

An issue of continuing interest in the economics of the performing arts is that of productivity lag, first identified by Baumol and Bowen (1966) and subsequently labelled ‘Baumol’s disease’ or ‘the cost disease’. Essentially the hypothesis states that labour productivity in the live arts remains static over time – it still takes the same number of workers the same amount of time to perform *Hamlet* today as it did in Shakespeare’s day. In a two-sector model in which one sector suffers from this technological disadvantage, wage rises in the productive sector are transmitted to the stagnant sector, causing a widening gap in the latter between revenues and costs, since firms in the stagnant sector cannot cover wage rises with improved labour productivity. Applying this to the live arts, Baumol and Bowen predicted that performing firms would have to access increasing levels of non-box-office revenue over time in order to stay in business. Empirical studies of this phenomenon have confirmed that costs of live performances have indeed risen as the model implies, but that the impact of these cost increases on firms has been somewhat muted; most performing companies have been able to mitigate the effects of slow productivity growth through a variety of strategies, including tapping new sources of unearned revenue, exploiting the potential of new recording and distribution technologies, expanded ancillary activities such as merchandising, and so on.

Finally in this section we turn to large-scale production in the arts. There are certainly some not-for-profit firms in the arts with multi-million dollar budgets, including major art museums, the world’s principal opera companies and symphony orchestras, national theatre companies in several countries, and so on. In almost all cases some level of public funding is involved, together with significant levels of private-sector support from foundations, corporations and individual donors to supplement box-office revenue. In some countries these large-scale enterprises are government business undertakings, subject to varying degrees of independence or control in their governance and their operational decision-making. However, the majority of large-scale producers of artistic goods are profit-seeking firms operating in commercial markets where complex production processes are required and/or where

http://www.dictionaryofeconomics.com.proxy.library.csi...edu/article?id=pde2008_E000224&goto=a&result_number=65&n=5&n=10&n=2008-12-29 23:54:53
substantial scale economies exist. These firms include theatre companies staging popular shows, commercial and independent film producers, music publishers, record companies, major book publishers, art auction houses and so on. Taken together, these firms form a significant component (measured in terms of value of output) of the so-called creative or copyright industries, terms reflecting two of the necessary characteristics of cultural goods discussed earlier. From an economic point of view, these industries are notable for their peculiar contractual arrangements that reflect, among other things, the inherent uncertainties that attend every stage of artistic production processes whereby ‘nobody knows’ what the quality or market potential of the final product will be (Caves, 2000).

Market structures

It is perhaps surprising that there is little in the industrial organization literature dealing with structure, conduct and performance in the arts. There are many interesting questions concerning competition, market efficiency and pricing behaviour in the arts that await the attention of economists. As may be evidenced from the preceding section, the range of market structures in the arts is quite wide, providing considerable scope for empirical investigation.

At one extreme can be found instances of almost atomistic competition, as in the so-called primary market for visual art. Here there are many small producers, mostly individual artists selling on their own or through small local galleries, art fairs, and so on. Although the product is not exactly homogeneous, buyers tend to be not very discriminating, and prices may well be competed down to little more than cost of production plus some modest return to labour. Moving further across the market structure spectrum, we can suggest that the live performing arts in medium-to-large towns and cities show some evidence of monopolistic competition: a relatively large number of small firms competing through product differentiation and other non-price strategies for customers drawn from a single pool. Higher levels of concentration appear in other areas of the arts, especially in local markets for live performance characterized by one or two dominant firms when close substitutes are not available; the markets for opera or orchestral music in a given city may be examples. In all of the above cases, market conditions affect the pricing and output decisions of participating firms. Given that non-pecuniary motives play an important role in influencing the behaviour of economic agents in the arts, the competitive outcomes in the markets discussed might be expected to diverge somewhat from those predicted under more conventional conditions.

Factor markets

The input into artistic production processes that provides the unique qualities of artistic goods and services is, of course, the creative labour of artists themselves. Labour markets in the arts have been widely studied in both theoretical and empirical terms in an effort to understand whether and in what ways they differ from conventional labour markets. A principal finding relates again to the non-pecuniary motives for artistic production. Artists in general do not regard work as a chore whose only purpose is to earn an income. Rather, their commitment to making art means that they have a positive preference for working at their chosen profession, and empirical evidence indicates that they often forgo lucrative alternative employment in order to spend more time pursuing their creative work. This can be
modelled as a time allocation problem where the worker has to choose between preferred but less remunerative work in the arts on the one hand and better-paid but less desired non-arts work on the other. The choice is subject to a minimum-income constraint, necessary to prevent starvation, a condition often romantically associated with artists but rarely observed in practice. Such a ‘work preference’ model of labour supply yields predictions of behaviour at variance with the usual textbook construct – for example, a wage rise in the non-arts occupation may induce less work in that occupation because it enables more time to be devoted to the arts, a phenomenon akin to the backward-bending supply curve of labour in the conventional model.

The generally low levels of average earnings available from artistic practice mean that arts labour markets are characterized by ubiquitous multiple job-holding and much fluidity in career paths. The distribution of earnings across any population of arts workers is almost always skewed towards the lower end. Some attention has been paid to the role of risk in affecting entry and exit decisions in arts labour markets. Given the superstar phenomenon noted above, where extremely high incomes are earned by very few, some writers have portrayed these labour markets as winner-take-all lotteries to which artists submit themselves willingly. An alternative explanation of persistent labour market participation when expected monetary returns are low lies in the supposition that artists earn a sufficient level of psychic income to offset the meagre levels of their pecuniary rewards.

Turning to capital markets, we note simply that a similar psychic component may be present in rewarding suppliers of capital to the arts. For example, investors willing to back a theatre company putting on a new show may perhaps do so in expectation that the show will be a hit and they will earn a handsome return on their investment; however, a more plausible explanation for such a risky decision may be that these donors are motivated by a love of the theatre and hence that their satisfaction will derive largely if not entirely from the psychic rewards from helping to make it happen. Indeed, much private capital flows to the arts not as investments or loans but as untied donations with no strings attached, as discussed further below.

Policy issues

Government provision of financial assistance to the arts is widespread across the developed world, though the extent of intervention varies substantially between countries and between jurisdictions within countries. It is not clear whether such assistance is in accord with the wishes of voters or whether it is a case of imposed preferences whereby the arts are seen by governments as a merit good. It is also entirely possible that public subsidies to the arts are consistent with the restoration of Pareto optimality in an economy subject to market failure, if it is indeed the case that the arts give rise to public goods or positive externalities. Some economists remain sceptical of the latter proposition on empirical rather than theoretical grounds, and there is as yet not a great deal of evidence to resolve the issue one way or the other. In these circumstances more attention has been focused on the appropriate means for intervention once a normative rationale is accepted. The instruments governments have at their disposal include public-sector provision of artistic services (for example, through public art galleries); direct subsidies to cultural production or consumption; indirect support through the tax system; regulation; provision of information; assistance through the education system; and so on. An issue of considerable interest is the specification of optimal decision rules for allocation of public financing among competing avenues of artistic activity, a process apparently driven as much by rent-seeking or political expediency
as by the pursuit of economic efficiency.
The use of the tax system as a means of providing assistance has been of particular significance to the arts, especially via the tax deductibility allowed to philanthropic donors who give money to not-for-profit performing companies, museums, galleries, and so on. Such giving is likely to be motivated by a desire to secure the sorts of public-good benefits of the arts mentioned earlier, in circumstances where direct government support is regarded as inadequate. In some countries, most notably the United States, the cost of indirect support for the arts, measured in terms of tax revenue forgone, greatly exceeds the amount of direct financing by the public sector. Given that governments can manipulate the incentives facing donors by changing marginal tax rates, by raising or lowering thresholds and ceilings on allowable donations, and so on, much interest has focused on elasticities of giving with respect to variables such as the tax price. The critical issue from a policy viewpoint is whether the price elasticity is greater or less than unity in absolute terms, since a price elastic response would imply that lowering the tax price would increase recipients’ revenue by more than the tax receipts forgone. However, despite many empirical studies, no clear consensus as to the size of these elasticities has emerged. Other policy issues of concern in this field include whether increased government support for the arts crowds out or crowds in private donations, and whether it is good or bad policy to use an instrument that allows private individuals to direct the allocation of public resources via their charitable-giving decisions.

One way in which public policy can assist the functioning of markets in the arts is via the creation and enforcement of property rights in artistic goods and services. Efficient copyright regimes aim to facilitate public access to information, at the same time as allowing creators to regulate the use of their work and to capture remuneration that would otherwise be lost to piracy, free-riding, unauthorized commercial exploitation, and the like. While often seen as a purely legal matter, copyright has a number of economic implications for the arts. In particular, artistic output in the form of literary works, paintings, photographs, musical compositions, and so forth can generally be reproduced at low or negligible cost, and in the absence of copyright protection their price would be driven down to marginal cost, so reducing or eliminating the incentive to the artist to create further output. Nevertheless, some exceptions to universal copyright coverage exist, for example in the ‘fair use’ provisions of copyright law, which allow free access for certain scholarly or public-interest purposes, or where high transactions costs of enforcement outweigh the potential gains to the rights holder. Other intellectual property issues of interest to economists include the market effects of moral rights (the rights that artists have over attribution and integrity of their works) and, in the visual arts, the phenomenon of droit de suite (the payment of a royalty to the artist or his or her heirs each time a given work is resold).

An area of growing importance in policy terms in recent years has been the role of the arts in urban and regional development. This role may be evident in a specific sense, for example in the impact of an arts festival on the local economic base, or in the use of community arts projects to engage and motivate disaffected youth in areas of high unemployment. In a wider context, the creative industries may be seen as a source of new enterprise, income growth and employment creation in depressed industrial regions. Empirical studies have looked at the impact of arts events, facilities, and so forth on a local or regional economy, and at the more general contribution that the arts industries make to economic activity, as a basis for policy formulation in a field increasingly engaging the attention of governments at both national and local levels.

Public policy towards the arts, heritage, the creative industries, cultural trade, and so forth can be gathered together under the somewhat fuzzy heading of ‘cultural policy’. Given the significant economic
content of all of these areas, it can be expected that economic theory and analysis will continue to make an important contribution to policy-making in this field in the future.

Further reading

Recent surveys of the economics of the arts include Throsby (1994), Blaug (2001) and Ginsburgh (2001). Major contributions to the literature on the economics of the arts from the mid-1960s to the mid-1990s are collected together in Towse (1997). A broader view of cultural economics is contained in Throsby (2001). An accessible account of the principal topics in contemporary cultural economics is provided in Towse (2003), while a comprehensive research-oriented coverage of the economics of art and culture is contained in Ginsburgh and Throsby (2006).

Article

1 Introduction

Artificial neural networks (ANNs) constitute a class of flexible nonlinear models designed to mimic biological neural systems. Typically, a biological neural system consists of several layers, each with a large number of neural units (neurons) that can process the information in a parallel manner. The models with these features are known as ANN models. Such models can be traced back to the simple input–output model of McCulloch and Pitts (1943) and the ‘perceptron’ of Rosenblatt (1958). The early yet simple ANN models, however, did not receive much attention because of their limited applicability and also because of the limitation of computing capacity at that time. In seminal works, Rumelhart, McClelland and PDP Research Group (1986) and McClelland, Rumelhart and PDP Research Group (1986) presented the new developments of ANN, including more complex and flexible ANN structures and a new network learning method. Since then, ANN has become a rapidly growing research area.

As far as model specification is concerned, ANN has a multi-layer structure such that the middle layer is built upon many simple nonlinear functions that play the role of neurons in a biological system. By allowing the number of these simple functions to increase indefinitely, a multi-layered ANN is capable of approximating a large class of functions to any desired degree of accuracy, as shown in, for example, Cybenko (1989), Funahashi (1989), Hornik, Stinchcombe and White (1989; 1990), and Hornik (1991; 1993). From an econometric perspective, ANN can be applied to approximate the unknown conditional mean (median, quantile) function of the variable of interest without suffering from the problem of model misspecification, unlike parametric models commonly used in empirical studies. Although nonparametric methods, such as series and polynomial approximators, also possess this property, they usually require a larger number of components to achieve similar approximation accuracy (Barron, 1993). ANNs are thus a parsimonious approach to nonparametric functional analysis.

ANNs have been widely applied to solve many difficult problems in different areas, including pattern recognition, signal processing, and language learning. Since White (1988), there have also been numerous applications of ANN in economics and finance. Unfortunately, the ANN literature is not easy to penetrate, so it is hard for applied economists to understand why ANN works and how it can be implemented properly. Fortunately, while the ANN jargon originated from cognitive science and computer science, they often have econometric
interpretations. For example, a ‘target’ is, in fact, a dependent variable of interest, an ‘input’ is an explanatory variable, and network ‘learning’ amounts to the estimation of unknown parameters in a network. The purpose of this article is thus twofold. First, it introduces ANN using familiar econometric terminology and hence serves to bridge the gap between the fields of ANN and economics. Second, it provides an overview of ANN modelling approach and its implementation methods. For an early review of ANN from an econometric perspective, we refer to Kuan and White (1994). This article proceeds as follows. We introduce various ANN model specifications and the choices of network functions in Section 2. We present the ‘universal approximation’ property of ANN in Section 3. Model estimation and model complexity regularization are discussed in Section 4. Section 5 concludes.

2 ANN model specifications

Let \( Y \) denote the collection of \( n \) variables of interest with the \( t \)-th observation \( Y_T(n \times 1) \) and \( X \) the collection of \( m \) explanatory variables with the \( t \)-th observation \( X_T(m \times 1) \). In the ANN literature, the variables in \( Y \) are known as targets or target variables, and the variables in \( X \) are inputs or input variables. There are various ways to build an ANN model that can be used to characterize the behavior of \( y_t \) using the information contained in the input variables \( x_t \). In this section, we introduce some network architectures and the functions that are commonly used to build an ANN.

2.1 Feedforward neural networks

We first consider a network with an input layer, an output layer, and a hidden layer in between. The input (output) layer contains \( m \) input units (\( n \) output units) such that each unit corresponds to a particular input (output) variable. In the hidden layer, there are \( q \) hidden units connected to all input and output units; the strengths of such connections are labelled by (unknown) parameters known as the network connection weights. In particular, \( \mathbf{Y}_h = (Y_h, 1, \ldots, Y_h, m) \) denotes the vector of the connection weights between the \( h \)-th hidden unit and all \( m \) input units, and \( \mathbf{Jo} = (\Jo, 1, \ldots, \Jo, q) \) denotes the vector of the connection weights between the \( j \)-th output unit and all \( q \) hidden units. An ANN in which the sample information (signals) are passed forward from the input layer to the output layer without feedback is known as a feedforward neural network. Figure 1 illustrates the architecture of a three-layer feedforward network with three input units, four hidden units and two output units.

Figure 1
A feedforward network with three input units, four hidden units and two output units
Artificial neural networks are designed to function as a biological neural system. The input units are the neurons that receive the information (stimuli) from the outside environment and pass them to the neurons in a middle layer (that is, hidden units). These neurons then transform the input signals to generate neural signals and forward them to the neurons in the output layer. The output neurons in turn generate signals that determine the action to be taken. Note that all information from the units in one layer is processed simultaneously, rather than sequentially, by the units in an 'upper' layer. (This concept, also known as parallel processing or massive parallelism, differs from the traditional concept of sequential processing and has led to a major advance in designing computer architecture.)

Formally, the input units receive the information \( x_t \) and send to all hidden units, weighted by the connection weights between the input and hidden units. This information is then transformed by the activation function \( G \) in each hidden unit. That is, the \( h \)-th hidden unit receives \( x'_t Y_h \) and transforms it to \( G(x'_t Y_h) \). The information generated by all hidden units is further passed to the output units, again weighted by the connection weights, and transformed by the activation function \( F \) in each output unit. Hence, the \( j \)-th output unit receives

\[
\sum_{h=1}^{q} \beta_{j,h} G(x'_t Y_h)
\]

and transforms it into the network output:

\[
\sigma_{j,t} = F \left( \sum_{h=1}^{q} \beta_{j,h} G(x'_t Y_h) \right), \quad j = 1, \ldots, n.
\]

(1)

The output \( O_j \) is used to describe or predict the behaviour of the \( j \)-th target \( Y_j \).
In practice, it is typical to include a constant term, also known as the bias term, in each activation function in (1). That is,

\[
\phi_{t,j} = F\left( \beta_{j,0} + \sum_{h=1}^{q} \beta_{j,h}C(Y_{h,0} + x_t'Y_h) \right), \ j = 1, \ldots, n,
\]  

(2)

where \( Y_{h,0} \) is the bias term in the \( h \)-th hidden unit and \( \beta_{j,0} \) is the bias term in the \( j \)-th output unit. A constant term in each activation function adds flexibility to hidden-unit and output-unit responses (activations), in a way similar to the constant term in (non)linear regression models. Note that when there is no transformation in the output units, \( F \) is an identity function (that is, \( F(a) = a \)) so that

\[
\phi_{t,j} = \beta_{j,0} + \sum_{h=1}^{q} \beta_{j,h}C(Y_{h,0} + x_t'Y_h), \ j = 1, \ldots, n.
\]  

(3)

It is also straightforward to construct networks with two or more hidden layers. For simplicity, we will focus on the three-layer networks with only one hidden layer. While parametric econometric models are typically formulated using a given function of the input \( x_t \), the network (2) is a class of flexible nonlinear functions of \( x_t \). The exact form of a network model depends on the activation functions \( (F \) and \( G) \) and the number of hidden units \( (q) \). In particular, the network function in (3) is an affine transformation of \( G \) and hence may be interpreted as an expansion with the ‘basis’ function \( G \).

The networks (2) and (3) can be further extended. For example, one may construct a network in which the input units are connected not only to the hidden units but also directly to the output units. This leads to networks with short-cut connections. Corresponding to (2), the outputs of a feedforward network with short cuts are

\[
\phi_{t,j} = F\left( \beta_{j,0} + x_t'\alpha_j + \sum_{h=1}^{q} \beta_{j,h}C(Y_{h,0} + x_t'Y_h) \right), \ j = 1, \ldots, n,
\]

where \( \alpha_j \) is the vector of connection weights between the output and input units, and, corresponding to (3), the outputs are

\[
\phi_{t,j} = \beta_{j,0} + x_t'\alpha_j + \sum_{h=1}^{q} \beta_{j,h}C(Y_{h,0} + x_t'Y_h), \ j = 1, \ldots, n.
\]

Figure 2 illustrates the architecture of a feedforward network with two input units, three hidden units, one output unit and short-cut connections. Thus, parametric econometric models may be interpreted as feedforward networks with short-cut connections but no hidden-layer connections. The linear combination of hidden-unit activations,

\[
\sum_{h=1}^{q} \beta_{j,h}C(Y_{h,0} + x_t'Y_h),
\]

in effect characterizes the nonlinearity not captured by the linear function of \( x_t \).
2.2 Recurrent neural networks

From the preceding section we can see that there is no ‘memory’ device in feedforward networks that can store the signals generated earlier. Hence, feedforward networks treat all sample information as ‘new’; the signals in the past do not help to identify data features, even when sample information exhibits temporal dependence. As such, a feedforward network must be expanded to a large extent so as to represent complex dynamic patterns. This causes practical difficulty because a large network may not be easily implemented. To utilize the information from the past, it is natural to include lagged target information $y_{t-k}$, $k = 1, ..., s$, as input variables, similar to linear AR and ARX models in econometric studies. Yet such networks do not have any built-in structure that can ‘memorize’ previous neural responses (transformed sample information). The so-called recurrent neural networks overcome this difficulty by allowing internal feedbacks and hence are especially appropriate for dynamic problems.

Jordan (1986) first introduced a recurrent network with feedbacks from output units. That is, the output units are connected to input units but with *time delay*, so that the network outputs at time $t-1$ are also the input information at time $t$. Specifically, the outputs of a Jordan network are

$$
O_{t,j} = F\left(\beta_{j,0} + \sum_{h=1}^{q} \beta_{j,h} G(y_{t-h}) + x_t \gamma_{j} + \theta_{t-1} \delta_{j} \right), \quad j = 1, ..., n,
$$

(4)
where $\delta_h$ is the vector of the connection weights between the $h$-th hidden unit and the input units that receive lagged outputs $o_{t-h}, o_{t-h+1}, \ldots$. The network (4) can be further extended to allow for more lagged outputs $o_{t-2}, o_{t-3}, \ldots$.

Similarly, Elman (1990) considered a recurrent network in which the hidden units are connected to input units with time delay. The outputs of an Elman network are:

$$o_t = F\left(\beta_{j,0} + \sum_{h=1}^H \beta_{j,h} a_{t-h}, a_{t-h} - C(Y_{t-h} + x_t'Y_{t-h} + a_{t-1}'\delta_h), h - 1, \ldots, q, \right)$$

(5)

where $a_{t-1} = (a_{t-1,1}, \ldots, a_{t-1,q})'$ is the vector of lagged hidden-unit activations, and $\delta_h$ here is the vector of the connection weights between the $h$-th hidden unit and the input units that receive lagged hidden-unit activations $a_{t-1}$. The network (5) can also be extended to allow for more lagged hidden-unit activations $a_{t-2}, a_{t-3}, \ldots$. Figure 3 illustrates the architectures of a Jordan network and an Elman network.

Figure 3
Recurrent neural networks: Jordan (left) and Elman (right)

From (4) and (5) we can see that, by recursive substitution, the outputs of these recurrent networks can be expressed in terms of current and all past inputs. Such expressions are analogous to the distributed lag model or the AR representation of an ARMA model (when the inputs are lagged targets). Thus, recurrent networks incorporate the information in the past input variables without including all of them in the model. By contrast, a feedforward network requires a large number of inputs to carry such information. Note that the Jordan network and the Elman network summarize past input information in different ways and hence have their own merits. When the previous ‘location’ of a network is crucial in determining the next move, as in the design of a robot, a Jordan network seems more appropriate. When the past internal neural responses are more important, as in language learning.
2.3 Choices of activation function

As far as model specifications are concerned, the building blocks of an ANN model are the activation functions $F$ and $G$. Different choices of the activation functions result in different network models. We now introduce some activation functions commonly employed in empirical studies. Recall that the hidden units play the role of neurons in a biological system. Thus, the activation function in each hidden unit determines whether a neuron should be turned on or off. Such an on/off response can be easily represented using an indicator (threshold) function, also known as a *heaviside* function in the ANN literature, that is,

$$
G(\gamma_{h,0} + x_{i}^{'}Y_{h}) = \begin{cases} 
1, & \text{if } \gamma_{h,0} + x_{i}^{'}Y_{h} \geq \epsilon, \\
0, & \text{if } \gamma_{h,0} + x_{i}^{'}Y_{h} < \epsilon,
\end{cases}
$$

where $\epsilon$ is a pre-determined threshold value. That is, depending on the strength of connection weights and input signals, the activation function $G$ will determine whether a particular neuron is on ($G(\gamma_{h,0} + x_{i}^{'}Y_{h}) = 1$) or off ($G(\gamma_{h,0} + x_{i}^{'}Y_{h}) = 0$).

In a complex neural system, neurons need not have only an on/off response but may be in an intermediate position. This amounts to allowing the activation function to assume any value between zero and 1. In the ANN literature, it is common to choose a *sigmoid* ($S$-shaped) and *squashing* (bounded) function. In particular, if the input signals are ‘squashed’ between zero and 1, the activation function is understood as a smooth counterpart of the indicator function. A leading example is the logistic function:

$$
G(\gamma_{h,0} + x_{i}^{'}Y_{h}) = \frac{1}{1 + \exp(-[\gamma_{h,0} + x_{i}^{'}Y_{h}])},
$$

which approaches 1 (zero) when its argument goes to infinity (negative infinity). Hence, the logistic activation function generates a partially on/off signal based on the received input signals.

Alternatively, the hyperbolic tangent ($\tanh$) function, which is also a sigmoid and squashing function, can serve as an activation function:

$$
G(\gamma_{h,0} + x_{i}^{'}Y_{h}) = \frac{\exp(\gamma_{h,0} + x_{i}^{'}Y_{h}) - \exp(-[\gamma_{h,0} + x_{i}^{'}Y_{h}])}{\exp(\gamma_{h,0} + x_{i}^{'}Y_{h}) + \exp(-[\gamma_{h,0} + x_{i}^{'}Y_{h}])}.
$$

Compared with the logistic function, this function may assume negative values and is bounded between $-1$ and 1. It approaches 1 (-1) when its argument goes to infinity (minus infinity). This function is more flexible because the negative values, in effect, represent ‘suppressing’ signals from the hidden unit. See Figure 4 for an illustration of the logistic and $\tanh$ functions. Note that for the logistic function $G$, a re-scaled function $\tilde{G}$ such that $\tilde{G}(a) = 2G(a) - 1$ also generates values between $-1$ and 1 and may be used in place of the $\tanh$ function. (A choice of the activation function in classification problems is the so-called *radial basis function*. We do not discuss this choice because its argument is not an affine transformation of inputs and hence does not fit in our framework here. Moreover, the networks with this activation function provide only *local* approximation to unknown functions, in contrast with the approximation property discussed in Section 3.)
The aforementioned activation functions are chosen for convenience because they are differentiable everywhere and their derivatives are easy to compute. In particular, when $G$ is the logistic function,

$$\frac{dG(a)}{da} = G(a)[1 - G(a)];$$

when $G$ is the tanh function,

$$\frac{dG(a)}{da} = \left(\frac{2}{\exp(a) + \exp(-a)}\right)^2 = \text{sech}^2(a).$$

These properties facilitate parameter estimation, as will be seen in Section 4.1. Nevertheless, these functions are not necessary for building proper ANNs. For example, smooth cumulative distribution functions, which are sigmoidal and squashing, are also legitimate candidates for activation function. In Section 3, it is shown that, as far as network approximation property is concerned, the activation function in hidden units does not even have to be sigmoidal, yet boundedness is usually required. Thus, sine and cosine functions can also serve as an activation function.

As for the activation function $F$ in the output units, it is common to set it as the identity function so that the outputs of (3) enjoy the freedom of assuming any real value. This choice
3 ANN as an universal approximator

What makes ANN a useful econometric tool is its *universal approximation* property, which basically means that a multi-layered ANN with a large number of hidden units can well approximate a large class of functions. This approximation property is analogous to that of nonparametric approximators, such as polynomials and Fourier series, yet it is not shared by parametric econometric models.

To present the approximation property, we consider the network function element by element. Let \( f_{G,q} : \mathbb{R}^m \times \Theta \rightarrow \mathbb{R} \) denote the network function with \( q \) hidden units, the output activation function \( F \) being the identity function, and the hidden-unit activation function \( G \), that is,

\[
f_{G,q}(x; \Theta) = \beta_0 + \sum_{h=1}^{q} \beta_h G(Y_{h,0} + x^T Y_h),
\]

as in (3), where \( \Theta_{m,q} \) is the parameter space whose dimension depends on \( m \) and \( q \), and \( \Theta \subseteq \Theta_{m,q} \) (note that the subscripts \( m \) and \( q \) for \( \Theta \) are suppressed). Given the activation function \( G \), the collection of all \( f_{G,q} \) functions with different \( q \) is:

\[
\mathcal{F}_G = \bigcup_{q=1}^{\infty} \{ f_{G,q}(x; \Theta) = \beta_0 + \sum_{h=1}^{q} \beta_h G(Y_{h,0} + x^T Y_h) \};
\]

when the union is taken up to a finite number \( N \), the resulting collection is denoted as \( \mathcal{F}_G^N \). Intuitively, \( \mathcal{F}_G \) is capable of functional approximation because \( f_{G,q} \) can be viewed as an expansion with the 'basis' function \( G \) and hence is similar to a nonparametric approximator.

More formally, we follow Hornik (1991) and consider two measures of the closeness between functions. First define the *uniform distance* between functions \( f \) and \( g \) on the set \( K \) as

\[
d_K(f, g) = \sup_{x \in K} | f(x) - g(x) |.
\]

Let \( K \) denote a compact subset in \( \mathbb{R}^m \) and \( C(K) \) denote the space of all continuous functions on \( K \). Then, when the activation function \( G \) is continuous, bounded and nonconstant, the collection \( \mathcal{F}_G \) is dense in \( C(K) \) for all \( K \) in \( \mathbb{R}^m \) in terms of \( d_K \) (Theorem 2 of Hornik, 1991). (Hornik, 1991, considered the network without the bias term in the output unit, that is, \( \beta_0 = 0 \). Yet as long as \( G \) is not a constant function, all the results in Hornik, 1991, carry over; see Stinchcombe and White, 1998, for details.) That is, for any function \( g \) in \( C(K) \) and any \( \varepsilon > 0 \), there is a network function \( f_{G,q} \) in \( \mathcal{F}_G \) such that \( d_K(f_{G,q}, g) < \varepsilon \). As \( \mathcal{F}_G^N \) is not dense in \( C(K) \) for any finite number \( N \), this result shows that any continuous function can be approximated arbitrarily well on compacta by a three-layered feedforward network \( f_{G,q} \) provided that \( q \), the number of hidden units, is sufficiently large.

Taking \( x \) as random variables, defined in the probability space with the probability measure \( \mathbb{P} \), we consider the \( L_r \)-norm of \( f(x) - g(x) \):
for $r \leq r < \infty$. For $r = 2$ ($r = 1$), this is the well-known measure of mean squared error (mean absolute error). Then, when the activation function $G$ is bounded and nonconstant, the collection $\mathcal{G}$ is dense in the $L_r$ space (Theorem 1 of Hornik, 1991). That is, any function $g$ (with finite $L_r$-norm) can also be well approximated by a three-layered feedforward network $f_{G,q}$ in terms of $L_r$-norm when $q$ is sufficiently large.

It should be emphasized that the universal approximation property of a feedforward network hinges on the three-layered architecture and the number of hidden units, but not on the activation function per se. As stated above, the activation function in the hidden unit can be a general bounded function and does not have to be sigmoidal. Hornik (1993) provides results that permit even more general activation functions. Moreover, a feedforward network with only one hidden layer suffices for such approximation property. More hidden layers may be helpful in certain applications but are not necessary for functional approximation. Barron (1993) further derived the rate of approximation in terms of mean squared error $E \| f - g \|^2$. It was shown that three-layered feedforward networks $f_{G,q}$ with $G$ a sigmoidal function can achieve the approximation rate of order $O(1/q)$, for which the number of parameters grows linearly with $q$ (with the order $O(mq)$). This is in sharp contrast with other expansions, such as polynomial (with $p$ the degree of the polynomial) and spline (with $p$ the number of knots per coordinate), which yield suitable approximation when the number of parameters grows exponentially (with the order $O(p^m)$). Thus, it is practically difficult for such expansions to approximate well when the dimension of the input space, $m$, is large.

4 Implementation of ANNs

In practice, when the activation functions in an ANN are chosen, it remains to estimate its connection weights (unknown parameters) and to determine a proper number of hidden units. Given that the connection weights of an ANN model are unknown, this network must be properly "trained" so as to "learn" the unknown weights. This is why parameter estimation is referred to as network learning and the sample used for parameter estimation is referred to a training sample in the ANN literature. As the number of hidden units $q$ determines network complexity, finding a suitable $q$ is known as network complexity regularization.

4.1 Model estimation

The network parameters can be estimated by either online or offline methods. An online learning algorithm is just a recursive estimation method which updates parameter estimates when new sample information becomes available. By contrast, offline learning methods are based on fixed training samples; standard econometric estimation methods are typically offline.

To ease the discussion of model estimation, we focus on the simple case that there is only one target variable $y$ and the network function $f_{G,q}$. Generalization to the case with multiple target variables and vector-valued network functions is straightforward. Once the activation function $G$ is chosen and the number of hidden units is given, $f_{G,q}$ is a nonlinear parametric model for the target $y$; the network with multiple outputs is a system of nonlinear models. If we take mean squared error as the criterion, the parameter vector of interest $\theta^*$ thus minimizes

$$E \left[ (y - f_{G,q}(x; \theta))^2 \right].$$ (6)

It is well known that

$$E \left[ (y - f_{G,q}(x; \theta))^2 \right] = E \left[ (y - E(y|x))^2 \right] + E \left[ (E(y|x) - f_{G,q}(x; \theta))^2 \right].$$
As $\mathbb{E}(y|x)$ is the best $L_2$ predictor of $y$, $\theta^*$ must also minimize the mean squared approximation error: $\mathbb{E}[\mathbb{E}(y|x) - f_{G,q}(x; \theta)]^2$. This shows that, among all three-layered feedforward networks with the activation function $G$ and $q$ hidden units, $f_{G,q}(x; \theta^*)$ provides the best approximation to the conditional mean function.

Given a training sample of $T$ observations, an estimator of $\theta^*$ can be obtained by minimizing the sample counterpart of (6):

$$\frac{1}{T} \sum_{t=1}^{T} [y_t - f_{G,q}(x_t; \theta)]^2,$$

which is just the objective function of the nonlinear least squares (NLS) method. The NLS method is an offline estimation method because the size of the training sample is fixed.

Under very general conditions on the data and nonlinear function, it is well known that the NLS estimator is strongly consistent for $\theta^*$ and asymptotically normally distributed (see, for example, Gallant and White, 1988).

In many ANN applications (for example, signal processing and language learning), the training sample is not fixed but constantly expands with new data. In such cases, offline estimation may not be feasible, but online estimation methods, which update the parameter estimates based solely on the newly available data, are computationally more tractable. Moreover, online estimation methods can be interpreted as ‘adaptive learning’ by biological neural systems. It should be emphasized that when there is only a given sample, as in most empirical studies in economics, recursive estimation is not to be preferred because it is, in general, statistically less efficient than the NLS method in finite samples.

Note that the parameter of interest $\theta^*$ is the zero of the first order condition of (6):

$$\mathbb{E}[\nabla f_{G,q}(x; \theta) (y - f_{G,q}(x; \theta)))] = 0,$$

where $\nabla f_{G,q}(x; \theta)$ is the (column) gradient vector of $f_{G,q}$ with respect to $\theta$. To estimate $\theta^*$, a recursive algorithm proposed by Rumelhart, Hinton and Williams (1986) is

$$\hat{\theta}_{t+1} = \hat{\theta}_t + \eta_t \nabla f_{G,q}(x_t; \hat{\theta}_t) [y_t - f_{G,q}(x_t; \hat{\theta}_t)],$$

where $\eta_t > 0$ is a parameter that re-scales the adjustment term in the square bracket. It can be seen from (7) that the adjustment term is determined by the gradient descent direction and the error between the target and network output: $y_t - f_{G,q}(x_t; \hat{\theta}_t)$, and it requires only the information at time $t$, that is, $y_t$, $x_t$, and the estimate $\hat{\theta}_t$. (The algorithm (7) is analogous to the numerical steepest-descent algorithm. However, (7) utilizes only the information at time $t$, whereas numerical optimization algorithms are computed using all the information in a given sample and hence are offline methods.)

The algorithm (7) is known as the error back-propagation (or simply back-propagation) algorithm in the ANN literature, because the error signal $[y_t - f_{G,q}(x_t; \hat{\theta}_t)]$ is propagated back through the network to determine the change of each weight. The underlying idea of this algorithm can be traced back to the classical stochastic approximation method introduced in Robbins and Monro (1951). White (1989) established consistency and asymptotic normality of $\hat{\theta}_t$ in (7). Note that the parameter $\eta_t$ in the algorithm is known as
learning rate. For consistency of \( \hat{\theta}_t \), it is required that \( \eta_t \) satisfies \( \sum_{t=1}^{\infty} \eta_t = \infty \) and \( \sum_{t=1}^{\infty} \eta_t^2 < \infty \), for example, \( \eta_t = 1/t \). The former condition ensures that the updating process may last indefinitely, whereas the latter implies \( \eta_t \to 0 \) so that the adjustment in the parameter estimates can be made arbitrarily small. (In many applications of ANN, the learning rate is often set to a constant \( \eta_0 \); the resulting estimate \( \hat{\theta}_t \) loses consistency in this case. Kuan and Hornik (1991) established a convergence result based on small-\( \eta_0 \) asymptotics.) Instead of the gradient descent direction, it is natural to construct a recursive algorithm with a Newton search direction. Kuan and White (1994) proposed the following algorithm:

\[
\hat{H}_{t+1} = \hat{H}_t + \eta_t \{ \nabla f_{G,q}(x_t; \hat{\theta}_t) \nabla f_{G,q}(x_t; \hat{\theta}_t)' - \hat{H}_t \}, \quad \hat{\theta}_{t+1} = \hat{\theta}_t + \eta_t \hat{H}_{t+1}^{-1} \nabla f_{G,q}(x_t; \hat{\theta}_t) [ v_t - f_{G,q}(x_t; \hat{\theta}_t) ],
\]

where \( \hat{H}_{t+1} \) characterizes a Newton direction and is recursively updated via the first equation. Kuan and White (1994) showed that \( \hat{\theta}_t \) in (8) is \( \sqrt{t} \)-consistent, statistically more efficient than \( \hat{\theta}_t \) in (7), and asymptotically equivalent to the NLS estimator. The algorithm (8) may be implemented in different ways; for example, there is an algorithm that is algebraically equivalent to (8) but does not involve matrix inversion. See Kuan and White (1994) for more discussions on the implementation of the Newton algorithms.

On the other hand, estimating recurrent networks is more cumbersome. From (4) and (5) we can see that recurrent network functions depend on \( \theta \) directly and also indirectly through the presence of internal feedbacks (that is, lagged output and lagged hidden-unit activations). The indirect dependence on parameters must be taken into account in calculating the derivatives with respect to \( \theta \). Thus, NLS optimization algorithms that require analytic derivatives are difficult to implement. Kuan, Hornik and White (1994) proposed the dynamic back-propagation algorithm for recurrent networks, which is analogous to (7) but involves more updating equations. Kuan (1995) further proposed a Newton algorithm for recurrent networks, analogous to (8), and showed that it is \( \sqrt{t} \)-consistent and statistically more efficient than the dynamic back-propagation algorithm. We omit the details of these algorithms; see Kuan and Liu (1995) for an application of these estimation methods for both feedforward and recurrent networks.

Note that the NLS method and recursive algorithms all require computing the derivatives of the network function. Thus, a smooth and differentiable activation function, as the examples given in Section 2.3, are quite convenient for network parameter estimation. Finally, given that ANN models are highly nonlinear, it is likely that there exist multiple optima in the objective function. There is, however, no guarantee that the NLS method and the recursive estimation methods discussed above will deliver the global optimum. This is a serious problem because the dimension of the parameter space is typically large. Unfortunately, a convenient and effective method for finding the global optimum in ANN estimation is not yet available.

4.2 Model complexity regularization

Section 3 shows that a network model \( f_{G,q} \) can approximate unknown function when the number of hidden units, \( q \), is sufficiently large. When there is a fixed training sample, a complex network with a very large \( q \) may over fit the data. Thus, there is a trade-off between approximation capability and over-fitting in implementing ANN models.

An easy approach to regularizing the network complexity is to apply a model selection criterion, such as Schwarz (Bayesian) information criterion (BIC), to the network models with various \( q \). (Alternatively, one may consider testing whether some hidden units may be dropped from the model. This amounts to testing, say, \( \beta_P = 0 \) for some \( h \). Unfortunately, the parameters in that hidden-unit activation function \( (\gamma_{h,0}, \gamma_{h}) \) are not identified under this null hypothesis. It is well known that, when there are unidentified nuisance parameters, standard econometric tests are not applicable.) As is well known, BIC consists of two terms: one is based on model fitness, and the other penalizes model complexity. Hence, it is suitable for regularizing network complexity; see also Barron (1991). A different criterion introduced in Rissanen (1986; 1987) is predictive stochastic complexity (PSC) which is just an average of squared prediction errors:

\[
PSC = \frac{1}{T-k} \sum_{t=k+1}^{T} [ y_t - f_{G,q}(x_t; \hat{\theta}_t) ]^2,
\]
where $\hat{\theta}_t$ is the predicted parameter estimate based on the sample information up to time $t - 1$, and $k$ is the total number of parameters in the network. Given the number of inputs, the network with the smallest BIC or PSC gives the desired number of hidden units $q^*$. Rissanen showed that both BIC and PSC can be interpreted as the criteria for ‘minimum description length’ in the sense that they determine the shortest code length (asymptotically) that is needed to encode a sequence of numbers. In other words, these criteria lead to the least complex model that still captures the key information in data. Swanson and White (1997) showed that a network selected by BIC need not perform well in out-of-sample forecasting, however.

Clearly, PSC requires estimating the parameters at each $t$. It would be computationally demanding if the NLS method is to be used, even for a moderate sample. For simplicity, Kuan and Liu (1995) suggested a two-step procedure for implementing ANN models. In the first step, one estimates the network models and computes the resulting PSCs using the recursive Newton algorithm, which is asymptotically equivalent to the NLS method. When a suitable network structure is determined, the Newton parameter estimates can be used as initial values for NLS estimation in the second step. This approach thus maintains a balance between computational cost and estimator efficiency.

5 Concluding remarks

In this article, we introduce ANN model specifications, their approximation properties, and the methods for model implementation from an econometric perspective. It should be emphasized that ANN is neither a magical econometric tool nor a ‘black box’ that can solve any difficult problems in econometrics. As discussed above, a major advantage of ANN is its universal approximation property, a property shared by other nonparametric approximators. Yet, compared with parametric econometric models, a simple ANN need not perform better, and a more complex ANN (with a large number of hidden units) is more difficult to implement properly and cannot be applied when there is only a small data-set. Therefore, empirical applications of ANN models must be exercised with care.

Artificial regressions

James G. MacKinnon
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

An artificial regression is a linear regression that is associated with some other econometric model, which is usually nonlinear. It can be used for a variety of purposes, in particular computing covariance matrices and calculating test statistics. The best-known artificial regression is the Gauss–Newton regression, whose key properties are shared by all artificial regressions. The chief advantage of artificial regressions is conceptual: because econometricians are very familiar with linear regression models, using them for computation reduces the chance of errors and makes the results easier to comprehend intuitively.

Keywords

artificial regressions; binary response model regression; bootstrap; double-length artificial regression; efficient score tests; Gauss–Newton regression; generalized method of moments; heteroskedasticity; heteroskedasticity-consistent covariance matrices; instrumental variables; Lagrange multiplier tests; multivariate nonlinear regression models; non-nested hypotheses; outer product of the gradient regression; RESET test; score tests; specification

Article

An artificial regression is a linear regression that is associated with some other econometric model, which is usually, but not always, nonlinear. It can be used for a variety of purposes, in particular, computing covariance matrices and calculating test statistics. The best-known artificial regression is the Gauss–Newton regression (GNR), which is discussed in the next section. All artificial regressions share the key properties of the GNR.

The Gauss–Newton regression
A univariate nonlinear regression model may be written as

\[ y_t = x_t(\beta) + u_t, \quad u_t \sim \text{IID}(0, \sigma^2), \quad t = 1, \ldots, n, \]

(1)

where \( y_t \) is the \( t \)th observation on the dependent variable, and \( \beta \) is a \( k \)-vector of parameters to be estimated. Here the scalar function \( x_t(\beta) \) is a nonlinear regression function which may depend on exogenous and/or predetermined variables. The model (1) may also be written using vector notation as

\[ y = x(\beta) + u, \quad u \sim \text{IID}(0, \sigma^2 I), \]

(2)

where \( y \) is an \( n \)-vector with typical element \( y_t \), \( x(\beta) \) is an \( n \)-vector with typical element \( x_t(\beta) \), and \( I \) is an \( n \times n \) identity matrix.

The Gauss–Newton regression that corresponds to (2) is

\[ y - x(\beta) = X(\beta) b + \text{residuals}, \]

(3)

where \( b \) is an \( n \)-vector of regression coefficients, and the matrix \( X(\beta) \) is \( n \times k \) with \( t \)th element the derivative of \( x_t(\beta) \) with respect to \( \beta_i \), the \( i \)th component of \( \beta \). The regressand here is a vector of residuals, and the regressors are matrices of derivatives. When regression (3) is evaluated at the least-squares estimates \( \hat{\beta} \), it becomes

\[ \hat{u} = y - \hat{x} = \hat{X} b + \text{residuals}, \]

(4)

where \( \hat{x} = x(\hat{\beta}) \) and \( \hat{X} = X(\hat{\beta}) \). Since the regressand of this artificial regression must be orthogonal to all the regressors, running the GNR (4) is an easy way to check that the NLS estimates actually satisfy the first-order conditions.
The usual OLS covariance matrix for $\hat{b}$ from regression (4) is

$$s^2(\hat{X}'\hat{X})^{-1}, \text{ where } s^2 = \frac{1}{n-k} (y - \hat{y})'(y - \hat{y}).$$

(5)

This is also the usual estimator of the covariance matrix of the NLS estimator $\hat{\beta}$ under the assumption that the errors are IID. If that assumption were relaxed to allow for heteroskedasticity of unknown form, then (5) would be replaced by a heteroskedasticity-consistent covariance matrix (HCCME) of the form

$$(\hat{X}'\hat{X})^{-1}\hat{\Omega}\hat{X}(\hat{X}'\hat{X})^{-1}.$$  

(6)

where $\hat{\Omega}$ is an $n \times n$ diagonal matrix with squared residuals, probably rescaled, on the principal diagonal. The matrix (6) is precisely what a regression package would give if we ran the GNR (4) and requested an HCCME. Similar results hold if we relax the independence assumption and use a HAC estimator. In every case, a standard estimator of the covariance matrix of $\hat{b}$ from the artificial regression (4) is also perfectly valid for the NLS estimates $\hat{\beta}$.

If we evaluate the GNR (3) at a vector of restricted estimates $\hat{\theta}$, we can use the resulting artificial regression to test the restrictions. For simplicity, assume that $\hat{\theta} = [\hat{\theta}_1' \ 0']'$, where $\hat{\theta}_1$ is a $k_1$-vector and $\hat{\theta}_2$, which is equal to 0 under the null hypothesis, is a $k_2$-vector. In this case, the GNR becomes

$$\hat{\alpha} = \hat{X}_1\hat{\theta}_1 + \hat{X}_2\hat{\theta}_2 + \text{residuals}.$$  

(7)

The ordinary $F$ statistic for $b_2=0$ is asymptotically valid as a test for $\beta_2=0$, and it is asymptotically equal, under the null hypothesis, to the $F$ statistic for $\beta_2=0$ in the nonlinear regression (1). Of course, when $X_2$ has just one column, the $t$ statistic for the scalar $b_2$ to equal zero is also asymptotically valid.

Yet another test statistic that is frequently used is $n$ times the uncentred $R^2$ from regression (7), which is asymptotically distributed as $\chi^2(k_2)$ under the null hypothesis.

The GNR (3) can also be used as part of a quasi-Newton minimization procedure if it is evaluated at any
vector, say $\beta_{(j)}$, where $j$ denotes the $j$th step of an iterative procedure. In fact, this is where the name of the GNR came from. It is not hard to show that the vector

$$b_{(j)} \equiv (X_{(j)}' X_{(j)})^{-1} X_{(j)}(y - x_{(j)}),$$

where the notation should be obvious, is asymptotically equivalent to the vector that defines a Newton step starting at $\beta_{(j)}$. The vector $b_{(j)}$ is asymptotically equivalent to what we would get by postmultiplying minus the inverse of the Hessian of the sum of squared residuals function by the gradient. Because of this, the GNR has the same one-step property as Newton's method itself. If we evaluate (3) at any consistent estimator, say $\hat{\beta}$, then the one-step estimator $\beta' = \hat{\beta} + \hat{b}$ is asymptotically equivalent to the NLS estimator $\hat{\beta}$.

For more detailed treatments of the Gauss–Newton regression, see MacKinnon (1992) and Davidson and MacKinnon (2001; 2004).

Properties of artificial regressions

A very general class of artificial regressions can be written as

$$r(\theta) = R(\theta)b + \text{residuals},$$  

(8)

where $\theta$ is a parameter vector of length $k$, $r(\theta)$ is a vector of length an integer multiple of the sample size $n$, and $R(\theta)$ is a matrix with $k$ columns and as many rows as $r(\theta)$.

In order to qualify as an artificial regression, the linear regression (8) must satisfy three key properties.

1. The regressand $r(\hat{\theta})$ is orthogonal to every column of the matrix of regressors $R(\hat{\theta})$, where $\hat{\theta}$ denotes a vector of unrestricted estimates. That is,

$$R'(\hat{\theta})r(\hat{\theta}) = 0.$$  

(9)
2. The asymptotic covariance matrix of \( n^{1/2}(\hat{\theta} - \theta_0) \) is given either by

\[
\lim_{n \to \infty} \left( n^{-1} R'(\hat{\theta}) R(\hat{\theta}) \right)^{-1}, \text{ or by}
\]

\[
\lim_{n \to \infty} s^2 \left( n^{-1} R'(\hat{\theta}) R(\hat{\theta}) \right)^{-1},
\]

where \( s^2 \) is the OLS estimate of the error variance obtained by running regression (8) with \( \theta = \hat{\theta} \). Of course, this is also true if \( \hat{\theta} \) is replaced by any other consistent estimator of \( \theta \).

3. If \( \hat{\theta} \) denotes a consistent estimator, and \( \hat{b} \) denotes the vector of estimates obtained by running regression (8) evaluated at \( \hat{\theta} \), then

\[
\lim_{n \to \infty} n^{1/2}(\hat{\theta} + \hat{b} - \theta_0) = \lim_{n \to \infty} n^{1/2}(\hat{\theta} - \theta_0).
\]

This is the one-step property, which holds because the vector \( \hat{b} \) is asymptotically equivalent to a single Newton step.

There exist many artificial regressions that take the form of (8) and satisfy conditions 1, 2, and 3. Some of these will be discussed in the next section. We have seen that the GNR satisfies these conditions and that its asymptotic covariance matrix is given by (11).

The most widespread use of artificial regressions is for specification testing. Of course, any artificial regression can be used to test restrictions on the model to which it corresponds. We simply evaluate the artificial regression for the unrestricted model at the restricted estimates, as in (7). However, in many cases, we can also use artificial regressions to test model specification without explicitly specifying an alternative. Consider the artificial regression
\[ r(\hat{\theta}) = R(\hat{\theta}) b + Z(\hat{\theta}) c + \text{residuals}, \]

(13)

which is evaluated at unrestricted estimates \( \hat{\theta} \). Here \( Z(\theta) \) is a matrix with \( r \) columns, each of which is supposed to be asymptotically uncorrelated with \( r'(\theta) \), that has certain other properties which ensure that standard test statistics for \( c=0 \) are asymptotically valid. In effect, regression (13) must have the same properties as if it corresponded to an unrestricted model. See Davidson and MacKinnon (2001; 2004) for details.

When the artificial regression (13) is a GNR, \( r(\hat{\theta}) = \hat{u} \) and \( R(\hat{\theta}) = \hat{X} \). Such a GNR can be used to implement a number of well-known specification tests, including the following ones.

- If we let \( Z(\hat{\theta}) \) be a vector of squared fitted values, then the \( t \) statistic for the coefficient on the test regressor to be zero can be used to perform one version of the well-known RESET test (Ramsey, 1969).
- If we let \( Z(\hat{\theta}) \) be an \( n \times p \) matrix containing the residuals lagged once through \( p \) times, either the \( F \) statistic for \( c=0 \) or \( n \) times the uncentred \( R^2 \) can be used to perform a standard test for \( p \)th order serial correlation (Godfrey, 1978).
- If we let \( Z(\hat{\theta}) \) be the vector \( \hat{w} - \hat{\kappa} \), where \( \hat{w} \) denotes the fitted values from a non-nested alternative model, then the \( t \) statistic on the test regressor can be used to perform a non-nested hypothesis test, namely, the \( P \) test proposed by Davidson and MacKinnon (1981).

Like all asymptotic tests, the three tests just described may not have good finite-sample properties. This is particularly true for the \( P \) test and other non-nested hypothesis tests. Finite-sample properties can often be greatly improved by bootstrapping, which is quite easy to do in these cases. For a recent survey of bootstrap methods in econometrics, see Davidson and MacKinnon (2006).

More artificial regressions

A great many artificial regressions have been proposed over the years, far more than there is space to discuss here. Some of them apply to very broad classes of econometric models, and others to quite narrow ones.

One of the most widely applicable and commonly used artificial regressions is the outer product of the gradient (OPG) regression. It applies to every model for which the log-likelihood function can be written as

\[ \ell(\theta) = \sum_{t=1}^{n} \ell_t(\theta), \]
where $\ell_t$ is the contribution to the log-likelihood made by the $t$th observation, and $\Theta$ is a $k$-vector of parameters. The $n \times k$ matrix of contributions to the gradient, $G(\Theta)$, has typical element

$$G_{tt}(\Theta) = \frac{\partial \ell_t(\Theta)}{\partial \theta_i}.$$  

(15)

Summing the elements of the $i$th column of this matrix yields the $i$th element of the gradient. The OPG regression is

$$t = G(\Theta) \theta + \text{residuals},$$  

(16)

where $t$ is an $n$-vector of ones.

It is easy to see that the OPG regression satisfies condition 1, since the inner product of $t$ and $G(\Theta)$ is just the gradient, which must be zero when evaluated at the maximum likelihood estimates $\hat{\Theta}$. That it satisfies condition 2 follows from the fact that the plim of the matrix $n^{-1} G'(\Theta) G(\Theta)$ is the information matrix, which implies that the asymptotic covariance matrix is given by (10). The OPG regression also satisfies condition 3, and it is therefore a valid artificial regression.

Because it applies to such a broad class of models, the OPG regression is easy to use in a wide variety of contexts. This includes information matrix tests (Chesher, 1983; Lancaster, 1984) and conditional moment tests (Newey, 1985), both of which may be thought of as special cases of regression (13).

However, because $n^{-1} G'(\hat{\Theta}) G(\hat{\Theta})$ tends to be an inefficient estimator of the information matrix, tests based on the OPG regression often have poor finite-properties, iterative procedures based on it may converge slowly, and covariance matrix estimates may be poor. Davidson and MacKinnon (1992) contains some simulation results which show just how poor the finite-properties of tests based on the OPG regression can be. However, these properties can often be improved dramatically by bootstrapping.

Another artificial regression that applies to a fairly general class of models estimated by maximum likelihood is the *double-length artificial regression* (DLR), proposed by Davidson and MacKinnon (1984). The class of models to which it applies may be written as
where \( f_t(\cdot) \) is a smooth function that depends on the random variable \( y_t \), on a \( k \)-vector of parameters \( \theta \), and, implicitly, on exogenous and/or predetermined variables. This class of models is much more general than may be apparent at first. It includes both univariate and multivariate linear and nonlinear regression models, as well as models that involve transformations of the dependent variable. The main restrictions are that the dependent variable(s) must be continuous and that the distribution(s) of the error terms must be known.

As its name suggests, the DLR has \( 2n \) observations. It can be written as

\[
\begin{bmatrix} f(y, \theta) \\ x_t \end{bmatrix} = \begin{bmatrix} -F(y, \theta) \\ K(y, \theta) \end{bmatrix} b + \text{residuals.}
\]

Here \( f(y, \theta) \) is an \( n \)-vector with typical element \( f_t(y_t, \theta) \), \( x_t \) is an \( n \)-vector of ones, \( F(y, \theta) \) is an \( n \times k \) matrix with typical element \( \partial f_t(y_t, \theta) / \partial \theta_i \), and \( K(y, \theta) \) is an \( n \times k \) matrix with typical element \( \partial k_t(y_t, \theta) / \partial \theta_i \) where

\[
k_t(y_t, \theta) = \log \left| \frac{\partial f_t(y_t, \theta)}{\partial y_t} \right|
\]

is a Jacobian term that appears in the log-likelihood function for the model (17). The information matrix associated with the DLR (18) has the form

\[
\frac{1}{n} (F'(\theta)F(\theta) + K'(\theta)K(\theta)).
\]

In most cases, this is a much more efficient estimator than the one associated with the OPG regression. As a result, inferences based on the DLR are generally more reliable than inferences based on the OPG regression. See, for example, Davidson and MacKinnon (1992). The DLR is not the only artificial
artificial regressions: The New Palgrave Dictionary of Economics

regression for which the number of ‘observations’ is a multiple of the actual number. For other examples, see Orme (1995).

Ideally, an information matrix estimator should depend on the data only through estimates of the parameters. A Lagrange multiplier, or score, test based on such an estimator is often called an efficient score test. Because (19) often does not satisfy this condition, using the DLR generally does not yield efficient score tests. In contrast, at least for models with no lagged dependent variables, the GNR does yield efficient score tests, as do several other artificial regressions.

A number of somewhat specialized artificial regressions can be obtained as modified versions of the Gauss–Newton regression. These include two different forms of GNR that are robust to heteroskedasticity of unknown form, a variant of the GNR for models estimated by instrumental variables, a variant of the GNR for models estimated by the generalized method of moments, a variant of the GNR for multivariate nonlinear regression models, and the binary response model regression (BRMR), which applies to models like the logit and probit model. See Davidson and MacKinnon (2001; 2004) for detailed discussions and references.

Of course, any quantity that can be computed using an artificial regression can also be computed directly by using a matrix language. Why then use artificial regressions for computation? This is, to some extent, simply a matter of taste. One potential advantage is that most statistics packages perform least squares regressions efficiently and accurately. In my view, however, the chief advantage of artificial regressions is conceptual. Because econometricians are very familiar with linear regression models, using them for computation reduces the chance of errors and makes the results easier to comprehend intuitively.

Keywords

Ashton, T.S.; economic history

Article

T.S. Ashton was born in Lancashire in 1889, graduated from Manchester University in 1909 and returned there in 1921 (after some years at the Universities of Sheffield and Birmingham) to teach political economy and economic history in the Faculty of Commerce. By the time he took up Eileen Power's chair of economic history at the London School of Economics in 1944, he had made a substantive and distinctive contribution to the history of the industrial revolution in three research monographs: Iron and Steel and in the Industrial Revolution (1924), The Coal Industry of the Eighteenth Century (1929, written with Joseph Sykes), and An Eighteenth Century Industrialist: Peter Stubs of Warrington (1939). Over the next decade this unassuming, humane, passionately non-dogmatic scholar had become the leader of a new generation of economic historians, a generation whose members had been schooled in the theories and analytical techniques of economics rather than in the thinking habits of a history faculty.

The two industrial studies and the business history published while Ashton was in Manchester were exercises in applied economics, based on detailed investigation of primary sources (including a mass of business ledgers, letters and accounts) and of a wide range of 18th-century material reflecting economic and social events, transactions and opinions. These researches gave him a formidable armoury of qualitative and quantitative data from which he set out in the 1940s explicitly to ‘find answers (partial and provisional though these may be) to the questions economists ask, or should ask, of the past’.

Ashton's last three books constituted a coherent and cumulative contribution to the economic history of the first country to make the transition to modern economic growth. His highly original essay The Industrial Revolution (1948) appeared just when the industrialization problems of developing countries were assuming major importance on the applied economists' research agenda and became a long-running bestseller. His Economic History of England: The Eighteenth Century (1955), the prime example of a new genre of economic history, contained the first systematic attempt to use standard economic theory
to explain long-term changes in the general level of prices and economic activity over that century, and also injected a characteristic objectivity into the perennial controversy over the standard of living of workers during the industrial revolution. In his last book, *Economic Fluctuations in England 1700–1800* (1959), he shifted his analysis of 18th-century economic change to a short-run focus. But by then only the pure theorists and the econometricians were actively interested in cyclical analysis, and Ashton was effectively distanced from both groups by his persistent concern with taking account of social as well as economic factors in economic change and by his realistically discriminating approach to the use of either abstract concepts or statistical evidence.

Abstract

Assets and liabilities come into prominence when double-entry bookkeeping and the balance sheet were invented, a prerequisite for the development of complex market economies. Production is a function of the size and structure of real assets, including human capital. We derive more satisfaction from the use of assets rather than from their consumption. Like any business, the household has a balance sheet of assets and liabilities. The lack of capital accounting in government means that many of its activities have no real ‘bottom line’, and their value is usually assessed in non-economic terms, sometimes resulting in catastrophic mistakes of judgement.

Article

The concepts of assets and liabilities are very closely related. Liabilities can be regarded as negative assets. The term ‘assets’ is related to the French ‘assez’, meaning ‘enough’. It emerges as a legal concept, particularly in laws relating to bankruptcy, the question being whether in bankruptcy assets are enough to meet all the liabilities. Historically, there has been a tendency to distinguish between real, personal and equitable assets, but these distinctions are now of little importance.

In accounting, assets and liabilities come into prominence with the invention of double-entry bookkeeping and the balance sheet, a concept which seems to have originated in northern Italy at least by the 12th or 13th century. This concept was important as a prerequisite for the development of complex markets and profit-oriented economies as an improvement in the information system. Before the invention of the balance sheet it was hard for a merchant to know whether he had made any profit or
It is the convention of the balance sheet that assets are listed on one side and liabilities and equity on the other side, equity being defined fundamentally as net assets; that is, assets minus liabilities, which are negative assets. Accounting practice divides both assets and liabilities into a number of categories. Assets are commonly divided into current, deferred and fixed assets. Current assets consist of cash, bank deposits, short-term notes, accrued interest, inventories of goods in process or finished goods which are expected to be sold within the accounting period, usually six months or a year. Sometimes items like repair parts are included in this category, even though their life on the shelf may be longer. Another item may be deferred assets, such as insurance, advertising payments which are paid in advance where the services have not yet been performed. Finally, there are fixed assets of a lasting nature, such as buildings and machines. There is also a category of intangible assets, like goodwill, value of patents, and so on. These tend to have a rather dubious status in accounting practice.

Liabilities have a somewhat similar categorization. Current liabilities are those which are expected to be paid off in the accounting period – wage claims, short-term loans, accounts payable, and so on. Current assets minus current liabilities is sometimes called ‘working capital’. Somewhat corresponding to fixed assets are long-term loan obligations. The sum of all assets minus the sum of all liabilities is the equity or net worth. This is usually divided into paid-up capital and undistributed profits.

Every time an event happens to an organization that has a balance sheet, the items in the balance sheet change. Thus, in production, when wheat is ground into flour the stock of wheat diminishes and of flour increases. Likewise, the stock of money may diminish as wages are paid, and the product of the work is added to assets. Assets diminish as machinery and buildings depreciate. Exchanges, purchases and sales are reflected in an increase in what is acquired and a decrease in what is given up for it. When money is borrowed, cash is increased on the asset side and the debt is increased on the liability side. It is a convention of cost accounting that both exchange and production represent transfers of equal values. When something is purchased, it is valued at the amount paid for it, so that the net worth does not change. Similarly, in production, the value of what is produced is equal to what has been consumed (i.e. destroyed) in the process, whether this is the money used to pay wages, raw materials used up or depreciation.

Profit is the growth of net worth, which happens when some asset is revalued, usually at the moment of sale. If it is sold for more than the accounting cost, the difference is an increase in net worth. Before sale, the asset is valued at cost. After the sale, if it is profitable, the asset disappears from the accounts but a larger sum of money than the value of the asset is entered, and this is why the net worth increases. When profits are distributed the liquid assets are diminished and the net worth diminishes by the same amount. Interest-bearing liabilities grow at the rate of interest, which accrues. This diminishes the net worth, this being the growth of a negative asset. Interest paid, cash or some liquid asset, diminishes by the same amount as accrued interest diminishes. There is no change in the net worth. Profit is made by constant manipulation of the assets through production and exchange to increase the total value of assets at a greater rate than interest on liabilities is accruing. Debt is presumably incurred because of a belief that it will increase the total volume of assets sufficiently so that some kind of economies of scale will permit a rate of growth of the increased assets more rapid than the rate of interest on the liabilities that are incurred in order to expand the assets.

An important problem in accounting, by no means satisfactorily solved, is how to deal with inflation and deflation. In order to get a net worth or ‘bottom line’, both assets and liabilities have to be expressed in...
terms of the monetary unit. In the case of physical assets, this means multiplying the quantity of the assets by some valuation coefficient which will turn it into a number of monetary units. Where the asset is constantly being bought and sold, the price, or ratio of exchange, is generally used as a valuation coefficient. In the case of fixed capital, the value is usually reckoned by taking an original purchase price and depreciating it over time by various methods, either at a constant percentage rate or at a constant amount per year. This figure is very arbitrary in any case and in periods of inflation and deflation becomes extremely misleading. Inflation tends to increase accounting profits because fixed capital tends to be undervalued.

Another element in the situation is that all profit-making involves buying something at a certain price or cost at one time and selling it at a later time. If in the time interval all prices have risen, there is a spurious profit, which is not really represented by purchasing power. Thus there is much to be said for having a profit figure indexed, although the technical difficulties in this have so far prevented very much application of this principle. Inflation, therefore, produces illusory high profits; deflation, likewise, produces illusory low profits. This happened in the Great Depression, when accounting profits in 1932 and 1933 were negative. Unfortunately, it is accounting profits rather than real profits which tend to govern business expectations and decisions.

Beyond accounting, assets and liabilities make a very important contribution to the understanding of both the description and the dynamics of the economic system. Every liability is or should be an asset in some other balance sheet, for every debt is an asset to the creditor and a liability to the debtor. When we sum all the balance sheets in society, therefore, we should come out with an overall balance sheet that consists merely of real assets on one side and the total net worth of the society on the other. There is some question as to whether we should include money of various kinds in real assets. Bank deposits, of course, are assets to the holder and liabilities to the bank, so if we sum all assets, including banks, deposits would disappear. Even paper money is in a certain sense a liability of the government, although it is not usually reckoned as such, for it has to be accepted by government in payment of taxes. An important proposition follows from the concept of the aggregate balance sheet, that an increase in net assets, that is, investment, will produce an increase in the total of net worth, which is profit. This may be offset by other events. This is an important clue, however, to the dynamics of a great depression, which exhibits positive feedback: a decline in investment produces a decline in profits, a decline in profits produces a further decline in investment, a further decline in profits, and so on. This is clearly what happened between 1929 and 1933 in the capitalist world.

The relation of assets and liabilities to income, production and consumption is very important. Real assets can be regarded as a kind of ecosystem of goods, with the stock of each good representing a population. Production is then equivalent to births, consumption to deaths. Production minus consumption is the increase in the total stock of a particular good. The net national product is equal to the total production of goods, which is equal to the total consumption, plus an increase in the total stock of goods, just as an increase in any population is equal to the number of births minus the number of deaths in a given period.

Production is a function of the size and structure of real assets themselves, which is particularly clear if we include the value of the human bodies and minds (i.e. human capital) in the total, as ideally we should. Economists have an unfortunate way of regarding households as a kind of black box outside the economy proper. Actually they are very much a part of it, and household capital – houses, furniture, automobiles, clothing, and so on – is very close to half of the total in a modern society. When we fly
Over a city we see far more houses than factories. If we compare the capital around us at our workplace with the capital around us in our home, for a considerable part of the population the home capital is much larger than the capital at work.

Another very important problem is the contribution of assets, particularly household assets to economic welfare. There is a long tradition in economics that regards consumption as the main method of measurement of riches. It is clear, however, that we get most of our satisfaction from the use and enjoyment of assets rather than from their consumption. I get no satisfaction out of the fact that my car, house and clothing are wearing out. What I get satisfaction out of is using them. An increase in durability, especially of household capital, therefore, is an addition to economic welfare. This is a point much neglected by economists. Consumption, then, can usually be seen as a bad thing, and production as what is necessary to offset it. There are exceptions to this rule. We like eating. We like the activity of producing in itself, even though it involves the using up of raw materials and so on. Thus the economic welfare function would include both assets of all kinds and certain forms of production and consumption, that is, income. Economists have often confused consumption with household expenditure or purchases, again because they regard the household as outside the economy. In modern society this can be very misleading, for household purchases are governed in no small degree by the depreciation of household capital to the point where it has to be replaced, so this depreciation is a very important aspect of consumption and income. Household purchases are exchange, not consumption. The production of assets include households also tends to be neglected, and it is an important part of the total economy in terms of cooking, mending, painting and repairing. The household has a balance sheet of assets and liabilities just as much as a business does and cannot be understood without it.

Human capital, both in terms of assets and liabilities, is a concept which has achieved some recognition. Economic development is primarily a process in human learning and the increase in human capital. A natural catastrophe or a war which destroys physical capital is restored remarkably quickly if the human capital remains intact and the knowledge and the know-how are unimpaired. We often do not realize that an enormous destruction of capital takes place every year just by depreciation and consumption. Even spectacular disasters are often just a relatively small addition to this annual destruction. The fact that some human beings have a negative human capital, both for themselves and for society, cannot be overlooked, though our social accounting system is ill-equipped to deal with this problem. In political decisions, however, we do recognize it. The criminal justice system is at least intended to diminish negative human capital; the educational system, to increase positive human capital. The fact that there is very little capital accounting in government means that considerable parts of its activity, like unilateral national defence organizations, do not really have a ‘bottom line’, and their value is usually assessed in non-economic terms, which can easily lead into catastrophic mistakes of judgement.

assortative matching

Li, Hao
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article reviews the simple economics of matching by characteristics. The goal is to understand sorting patterns in the marriage market and other matching markets by focusing on the nature of the gain from match and the mechanism of the market force of competition.

Keywords

assortative matching; Becker, G.; Beckmann, M.; complements and substitutes; incomplete information; Koopmans, T.; marriage markets; matching frictions; matching markets; mixed matching; price discrimination; self-matching; substitutes and complements; transferable utility; wage heterogeneity, sources of

Article

In a marriage market the competition for spouses leads to sorting of mates by characteristics such as wealth and education. ‘Positive assortative matching’ refers to a positive correlation in sorting between the values of the traits of husbands and wives (matching of likes); ‘negative assortative matching’ refers to a negative correlation (matching of unlike). While it has been long recognized that sorting of husbands and wives by characteristics occurs in all cultures and societies, economists have tried to understand sorting patterns in the marriage market and other matching markets by focusing on the nature of the gain from match and the mechanism of the market force of competition.

The basic framework

A simple framework to illustrate the economic approach to sorting in matching markets is a two-sided marriage market with an equal number of men and women, who differ in one-dimensional characteristics called ‘type’ and have common preferences for higher types over lower types. In positive
assortative matching, the highest-type man mates the highest-type woman, and the second-highest-type man mates the second-highest-type woman, and so on. Negative assortative matching is between the highest-type man and the lowest-type woman, between the second-highest-type man and the second-lowest type woman, and so on. We assume transferable utility and zero reservation utility from remaining single for each market participant. Then, the gain from a match can be represented by an increasing, positive-valued function $f$, which gives the match output $f(x, y)$ of any pair of type $x$ man and type $y$ woman. Consider two men, with types $x_H > x_L$, and two women, with types $y_H > y_L$. If type $x_H$ and type $x_L$ command the same price in terms of the utility transfer they demand from the wife for the match, then both type $y_H$ and type $y_L$ would prefer the higher-type man because $f$ is increasing in male type. Competition for type $x_H$ naturally leads to a higher price for type $x_H$ than for type $x_L$.

Whether the higher female type $y_H$ can outbid type $y_L$ for type $x_H$ or vice versa depends on whether the male type and the female type are complements or substitutes in the match output function $f$. If

$$f(x_H, y_H) - f(x_H, y_L) > f(x_L, y_H) - f(x_L, y_L),$$

(1)

then the male type and the female type are complementary, because the marginal product of the female type is greater when matched with a higher male type (the left-hand side of inequality (1) than with a lower male type (the right-hand side of (1)). In this case, type $y_L$ is willing to offer type $x_H$ at most $f(x_H, y_L) - f(x_L, y_L)$ more than she offers type $x_L$, but by inequality (1) this difference is smaller than $f(x_H, y_H) - f(x_L, y_H)$, which is the most type $y_H$ is willing to offer. Thus, type $y_L$ will be outbid by type $y_H$ for type $x_H$ when the male type and the female type are complements. Since the argument is valid for any two pairs of men and women, the competition for spouses must lead to positive assortative matching. Conversely, if inequality (1) is reversed, male type and female type are substitutes. A lower female type can outbid a higher type for any male type, and the competition for spouses leads to negative assortative matching.

The differentiable version of inequality (1) is

$$\frac{\partial^2 f(x, y)}{\partial x \partial y} > 0.$$  

(2)

Conditions (1) and (2) are commonly referred to as the (strict) ‘supermodularity’ condition of the match output function $f$. See Topkis (1998) for a comprehensive mathematical treatment of supermodularity, and Milgrom and Roberts (1990) and Vives (1990) for applications in game theory and economics. Inequality (1) can be rewritten as
f (x_H, y_H) + f (x_L, y_L) > f (x_L, y_H) + f (x_H, y_L).

(3)

Condition (3) suggests that positive assortative matching maximizes the sum of match outputs in the marriage market when male type and female type are complements in the match output function. This result is a direct application of Koopmans and Beckmann's (1957) theorem of equivalence between efficient matching, which maximizes the sum of match outputs among all feasible pairwise matchings, and competitive equilibrium matching, which obtains when each woman y takes as given a schedule of utility transfers \( u(x) \) to men and chooses the male type that maximizes her utility. Competitive equilibrium matching can also be obtained as each man x takes as given a schedule of utility transfers \( v(y) \) to women and chooses the female type that maximizes his utility. Shapley and Shubik (1972) model the marriage market with transferable utilities as a cooperative game. They show that a pair of transfer schedules that support an equilibrium matching correspond to the core of the game, so that no pair of a man and a woman not matched in equilibrium can form a blocking coalition that produces a match output greater than the sum of their respective transfers.

Applications of assortative matching

The results of Koopmans and Beckmann (1957) and Shapley and Shubik (1972) are obtained in a matching market without any hierarchical ordering of types. By introducing one-dimensional, heterogeneous types, Becker (1973) seeks to explain why sorting of mates by wealth, education and other characteristics is similar in the marriage market. He constructs a household production function and derives condition (1) for each of the characteristics separately by considering how the characteristic affects household output while holding other characteristics fixed. Becker's model can accommodate dissimilar sorting of mates by some characteristics as well; for example, negative assortative matching by wage rates may arise because the benefits from the division of labour within a household can make the earning abilities of the man and the woman substitutes for each other.

Sattinger (1980) uses condition (2) to explain why the distribution of earnings of workers is skewed to the right relative to the distribution of their measured skills. In a market that matches a continuum of workers with different skills to a continuum of positions of different capital investment, the distribution of earnings would have the same shape as the distribution of skills if matching is random. In Sattinger's theory of differential rents, positive assortative matching of worker skill and job capital investment occurs because skill and capital investment are complements. In this case, the distribution of earnings will not resemble the distributions of outputs of workers at a job with the average capital investment. Instead, workers with higher skills are paid more than those with lower skills both because they are more productive at any job and because they occupy positions with greater capital investments. Formally, in equilibrium the wage schedule \( u \) satisfies the first-order condition of type y's maximization problem of choosing x to maximize \( f(x, y) - u(x) \)
\[ \frac{\partial f(x, m(x))}{\partial x} = u'(x), \]

where \( m(x) \) is the capital investment of the job occupied by the worker with skill \( x \) in equilibrium. It can be shown that condition (2) and positive assortative matching imply that \( f(x, y) - u(x) \) is concave in \( x \) at \( x = m^{-1}(y) \), so the second-order condition is satisfied for each \( y \). The first-order condition implies that the worker's wage increases at the rate of the marginal product of the worker's skill \( x \) at his equilibrium job, so that the rate of increase of \( u \) is augmented by the complementarity (condition 2) and positive assortative matching \( (m'(x) > 0) \). Therefore, with positive assortative matching, the distribution of earnings will be positively skewed relative to the distribution of skills.

Kremer (1993) highlights the role of positive assortative matching in economic development. In his model of a one-sided, many-to-many matching market, each firm consists of a fixed number of workers, each employed for a production task. Workers have different skills, with a higher-skilled worker less likely to make mistakes in performing his task. Condition (1) is assumed to capture the complementarity among worker skills in the sense that the production process of a firm requires completion of each task without mistakes. Self-matching obtains in equilibrium where each firm employs workers of identical skills. Kremer uses this form of positive assortative matching to explain the large wage and productivity differences between developing and developed countries that cannot be accounted for by their differences in levels of physical or human capital.

Self-matching will generally be inefficient and will not occur in equilibrium if production tasks in a firm differ in skill requirements. In Kremer and Maskin (1996), a firm consists of two workers with a match output function \( f(x, y) \) that satisfies the supermodularity conditions (1) and (2) but is asymmetric in that \( f(x, y) > f(y, x) \) for any \( x > y \). The interpretation of the asymmetry is that the first argument in \( f \) represents the skill of the worker who does the manager's job, while the second argument represents the skill of the worker who performs the assistant's job. In any given firm, it is optimal to make the higher-skilled worker the manager and the lower-skilled worker the assistant, but it is no longer generally true that self-matching maximizes the total match outputs. Indeed, we can have

\[ 2f(z_H, z_L) > f(z_H, z_H) + f(z_L, z_L) \]

for some \( z_H > z_L \), so that two firms each with the higher type \( z_H \) as the manager and the lower type \( z_L \) as the assistant produce more in total than two firms with the manager and the assistant having the same skill level. Note that inequality (4) does not contradict inequality (3) due to the asymmetry in \( f \). Mixed matching may do better than self-matching because it can be more important to exploit the asymmetry in the match output function and have each high-skill worker as the manager of a firm than to exploit the asymmetry in the competition.
complementarity in $f$ and have one high-skill worker as the assistant to the other high-skill worker. Kremer and Maskin find that efficient matching in their model depends on the skill distribution in the matching market, because the trade-off between the asymmetry and the complementarity in the match output function depends on the relative scarcity of high-skilled workers.

**Frictions in matching markets**

Assortative matching may be hindered by the presence of frictions in the matching market. For example, if there is a moral hazard problem in producing the match output by each matched pair, transferability of utilities will be restricted by incentive compatibility constraints. Legros and Newman (2002) discuss this and other examples of transaction costs, and find that equilibrium matching in these examples can be inefficient. Frictions can also arise due to incomplete information about type. Roth and Xing (1994) provide detailed descriptions of labour markets for entry-level professionals (such as lawyers and medical interns) in which early matches are sometimes made before complete information about matching characteristics, such as qualifications of job candidates and desirability of job positions becomes available. The complementarity in the match output function between the type of the applicant and the type of the job implies that there will be matching efficiency loss if matches are formed before the uncertainty about types is resolved. If all market participants are risk neutral, this efficiency loss is sufficient to rule out early matches as applicants compete for job positions. However, when some participants are risk averse, early matches provide them with some insurance against the payoff risks associated with late matches formed after complete information about types becomes available. Li and Suen (2000) apply competitive equilibrium analysis to the early matching market to determine the pattern of early matching, the terms of early matches, and the distribution of benefits in the early market. Early matching need not be positive-assortative in terms of expected type. Higher expected types of workers may face greater payoff risks from late matches due to the complementarity in the match output function. In this case, they may be willing to match with lower expected types of jobs to insure against the risks, while owners of higher expected types of jobs are content with waiting for late matches if they are risk neutral.

Private information about type may also result in frictions in the matching market. For example, many users of Internet dating agencies complain about the problems of misrepresentation and exaggeration by some users in the information they provide to the agencies. This problem arises because current matching services adopt a uniform pricing policy, and this in practice results in almost random matching. Damiano and Li (2007) point out that the complementarity in the match output function implies a version of the standard single-crossing condition in mechanism design problems, and an intermediary can use price discrimination to improve matching efficiency and generate greater revenue. They consider the problem of a monopoly matchmaker that uses a pair of fee schedules to sort different types of agents on the two sides into exclusive meeting places. The revenue-maximizing sorting need not be positive assortative (that is, efficient in the first-best sense). Conditions necessary and sufficient to recover positive assortative matching require that the complementarity in the match output function to be sufficiently strong to overcome the incentive cost to the matchmaker of eliciting private type information.

Matching frictions can arise also because finding type information about potential partners takes time or
assortative matching: The New Palgrave Dictionary of Economics

involves costly effort. In the search and matching framework, each market participant randomly meets a currently unmatched agent from the other side of the market, and decides whether to form a match or to search again in the next period. Search is costless, but agents must trade off the benefit from starting to produce with the encountered partner right away against the opportunity cost of waiting for a better partner. With an exogenous probability of separation of matched agents who then re-enter the market, Shimer and Smith (2000) characterize the stationary search and matching equilibrium where the matching decisions of each type and the type distributions of unmatched agents are time-invariant. Types $x$ and $y$ in an agreeable match are assumed to use the Nash bargaining solution to split the net surplus, defined as the match output $f(x, y)$ minus the sum of the (endogenous) continuation payoffs $g(x)$ to $x$ and $h(y)$ to $y$ as unmatched agents. Shimer and Smith modify the definition of positive assortative matching in the frictionless world to allow for set-valued mutually agreeable matches. The match set of a type $x$ is the intersection of the set of types that type $x$ agrees to match with and the set of types that agree to match with $x$. In Shimer and Smith’s definition, matching is positive-assortative where, if for any male types $x_H > x_L$ and female types $y_H > y_L$ such that $y_H$ is in the match set of $x_L$ and $y_L$ is in the match set of $x_H$, then $y_H$ is in the match set of $x_H$ and $y_L$ is in the match set of $x_L$. When match sets are convex, positive assortative matching requires the lowest and the highest type of the match set to be increasing in $x$. However, match sets need not be convex even though the match output function is supermodular. This is because the net surplus $f(x, y) - g(x) - h(y)$ is not necessarily quasi-concave in $y$ for fixed $x$, so one cannot say anything about how match sets vary across different $x$. Shimer and Smith provide conditions on $f$ in addition to supermodularity to ensure convexity of match sets and re-establish positive assortative matching in a stationary equilibrium.

The stationary search and matching equilibrium does not capture the dynamics of matching in markets where there is no entry of a new cohort in each period and each matched pair receives their match output after the market closes for all participants. For example, many entry-level markets for professionals (such as academic economists) are organized around annual recruitment cycles. In these markets, matches are formed sequentially without centralized matching procedures. Damiano, Li and Suen (2005) consider such markets by constructing a two-sided, finite-horizon search and matching model with heterogeneous types and complementarity between types. The quality of the pool of potential partners deteriorates as agents who have found mutually agreeable matches exit the market. When search is costless and all agents participate in each matching round, the market performs a sorting function in that high types of agents have multiple chances to match with their peers. The matching efficiency measured by the total expected match outputs improves as the number of matching rounds increases; positive assortative matching is achieved if there are as many matching rounds as there are types. However, this sorting function is lost if agents incur an arbitrarily small cost in order to participate in each round. With a sufficiently rich type space relative to the number of matching rounds, the market unravels as almost all agents rush to participate in the first round, and match and exit with anyone they meet.

assumptions controversy

Lawrence A. Boland
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

While the controversy concerning the realism of the assumptions of economic theory goes back to the mid-19th century, the issue today concerns only a reaction to Milton Friedman's famous 1953 methodology essay. That essay advanced the position that the assumptions of economic theory do not have to be realistic so long as they and the theories they form are useful. Many ideologically motivated critiques of this essay were published in the 1950s, 1960s and 1970s but all were problematic since they did not recognize that Friedman's essay was nothing more than a restatement of the common methodology called Instrumentalism.

Keywords

Article

Today, any reference to an ‘assumptions controversy’ immediately calls to mind the many critical reactions to Milton Friedman's famous 1953 essay. But historians of economic thought will also point out that there was an assumptions controversy going back to the mid-19th century involving John Stuart Mill, John Elliot Cairnes and Nassau Senior (for an excellent review of this ‘old’ assumptions controversy, see Hirsch, 1980). This old controversy was mainly between Mill and Senior and was about whether economics was an empirical science or a hypothetical one. The controversy was mediated by Cairnes and ultimately decided in his favour. For Cairnes, economic theory was true ‘because it rested on premises which were undeniably true’ (Hirsch, 1980, p. 105). But any application of theory can be compromised by ‘disturbing causes’ and so the application needed ‘to be compared with the facts’ to see just what disturbing causes needed ‘to be added in specific instances to make theory and facts correspond’ (1980, p. 105). According to Abraham Hirsch, Cairnes's position reigned for over three-
assumptions controversy : The New Palgrave Dictionary of Economics

quarters of a century.
Friedman's essay was defending the use of perfect competition assumptions in applied economics against criticism of the assumption of universal maximization. The critics could easily find support in the philosophy of science of the day that claimed science is concerned with propositions that are meaningful because they are verifiable. But Friedman argued that, even in science, assumptions did not have to be true – only the logically derived results matter and theory should be judged according to whether these work or are useful. Friedman even argued it was acceptable to use simple assumptions that were obviously false on the grounds that one's theory might otherwise be so complex as to be useless.

**Ideology as method**

Given the strong objections of most economists of this period to Friedman's views on markets, the suspicion must arise that ideology accounted for much of the interest in his methodology (Boland, 2003). In particular, in the 1960s when Keynesian policies were thought by most mainstream economists to be obviously correct, Friedman's advocacy of a very limited role for the government was seen as a throwback to before the programmes of US President Franklin Roosevelt's New Deal that many other people thought helped overcome the Great Depression. But ideological arguments are not what academia is about. Instead, if one objects to Friedman's methodology, one must provide philosophical or scientific arguments against it to win the day. So, between 1957 and 1971 the controversy raged, not in the field of ideology but in the fields of semantics and methodology.

Ideology aside, it is difficult to understand why anyone would see Friedman's position to be very strong. After all, as I argued in Boland (1979), one can easily see Friedman's methodological position as nothing more than an up-to-date version of Instrumentalism (see instrumentalism and operationalism). And as such, if one were to ask Friedman or any Instrumentalists to defend their methodology – the methodology that claims the truth status of assumptions do not matter, only whether possibly false assumptions are useful – their only defence is to say that the Instrumentalist methodology itself works and hence is useful. There does not seem to be any other possible defence. But leading critics prior to 1979 seemed to think telling criticism could be provided. Unfortunately, none of their critiques was logically successful even though many opponents of Friedman's ideology wished to think so. To be effective, criticism of a doctrine must be in terms that a proponent of that doctrine would accept. Changing terms or imposing different objectives for the doctrine will not yield an effective or fair critique. All of the famous critiques published in the 1950s, 1960s and 1970s failed in this way.

**Friedman's Instrumentalist methodology**

As explained in Boland (1979), any theory, in terms of Friedman's viewpoint, is an argument for some given propositions or towards specific predictions. As such a theory consists only of a conjunction of assumption statements, that is, statements, each of which is assumed (or asserted) to be true; in order for the argument to be sufficient it must be a deductive argument. To be logically sufficient, an argument must satisfy the requirements of what logicians call **modus ponens**. To do so means that whenever all of the statements that make up the argument are true, all logically derived statements **must** be true. But
quantificational logic also requires that, for a sufficient deductive argument in favour of some proposition, at least some of the assumptions must be in the form of universal general statements (in the form: ‘all X have property Y’). With these two requirements in mind it should be evident that no purely inductive argument (one consisting only of particular statements such as observation reports) can be sufficient. The reason is simply that there is no purely inductive logic that satisfies modus ponens; that is, no inductive argument can guarantee that whenever all of the statements or assumptions that make up the argument are true that the conclusions will necessarily be true. Philosophers call this the problem of induction. It is a problem because without an inductive logic one cannot prove the truth status of any needed assumption in the form of a universal general statement (for example, ‘all firms are profit maximizers’). Friedman's 1953 essay attempts to overcome this key methodological problem.

Friedman's method simply dismisses the need to know that one's assumptions are true before deriving one's conclusions. The argument of his essay is that we are explaining given observation statements (for example, statements about the state of the economy) that are known already to be true. This means that the only requirement for any explanatory theory is that it does logically entail the truth of the observation statements – hence it forms a sufficient argument in favour of those observation statements. Moreover, there is no claim that the assumptions of the theory are necessarily true – only that, if they are true, the observed statements would be true. In other words, it is the sufficiency of the argument formed by any theory's assumption that matters, not the necessity of the theory's assumptions. In this sense, theories are tools or instruments for deriving known true statements. The test of an instrument can be only whether it works or is useful. This view of the role of theories is the essence of the doctrine of Instrumentalism. Proponents of Instrumentalism seem to think they have solved the problem of induction by ignoring the truth status of assumptions and thus they also imply that modus ponens will be of limited use. This is because Instrumentalist methodology does not begin with a search for the true assumptions but rather for true or useful (that is, successful) conclusions. Instrumentalist analysis of the sufficiency of a set of assumptions always begins by assuming the conclusion is true and then asks what set of assumptions will do the logical job of yielding that conclusion.

The failed critiques

Any valid or fair criticism of an Instrumentalist argument can only be about the argument's sufficiency. As a result, to refute an Instrumentalist argument one must show that the theory in question is insufficient, and thus inapplicable. The failure to recognize the logical requirements of any refutation of Friedman's 1953 methodology led to several failed critiques that nevertheless perpetuated the assumptions controversy. The first prominent shots fired in the assumptions controversy were by Tjalling Koopmans (1957) and Eugene Rotwein (1959), and the last – before the pot was stirred up again by Boland (1979) – was by Louis De Alessi (1971). In between were the critiques by Paul Samuelson (1963), Jack Melitz (1965) and Donald Bear and Daniel Orr (1967). As explained in Boland (1979), none of them dealt fairly or effectively with the Instrumentalism underlying Friedman's methodology as presented in his 1953 article. It should be acknowledged that the title of his article (‘The methodology of positive economics’) can be misleading. However, most misunderstandings are likely the result of his introduction, where he seems to be giving another contribution to the traditional discussions about methodology. Traditional discussions were about issues such as the verifiability or
refutability of truly scientific theories. But Friedman's essay does not do this. Instead, he actually gives an alternative to that type of discussion.

Following traditional discussion, Koopmans sees all theorists seeking to develop or analyse the 'postulational structure of economic theory' so as to obtain 'those implications that are verifiable or otherwise interesting' (1957, p. 133). Unlike Friedman's essay, which presumes that what one assumes depends on one's purposes, Koopmans presumes all theories are directly analysable independently of their uses. Koopmans's critique of Friedman's essay is based on a restatement of Lionel Robbins's methodological position (1935) which itself seems to be a restatement of what Cairnes argued. Koopmans's basic concern (but not Friedman's) is the sources of the basic premises or assumptions of economic theory. For the followers of Robbins, the assumptions of economic analysis are promulgated and used because they are (obviously) true. The truth of the assumptions is never in doubt. The only question is whether they are necessary for the mathematical derivation of the interesting implications. Koopmans objects to Friedman's dismissal of the problem of clarifying the truth of the premises, the problem that Koopmans wishes to solve using mathematics. Koopmans is an inductivist and as such defines successful explanation as being logically based on inductively and observably true premises. Friedman does not consider assumptions or theories to be the embodiment of truth but only as instruments for the generation of useful (because successful) predictions.

In order to criticize Friedman's argument, Koopmans offers an interpretation of his own theory of the logical structure of Friedman's view. His interpretation contradicts Friedman's purpose (that some, but not necessarily all, conclusions need to be successful). It is most important to keep in mind that Friedman's methodology is concerned only with the sufficiency of a theory's set of assumptions. Koopmans falsely assumes that Friedman's methodology has a concern for necessity. In other words, Koopmans's theory of Friedman's methodology is itself void because (by Koopmans's own rules) at least one of its assumptions is false (for more, see Boland, 1979, pp. 515–17).

Many self-proclaimed 'empiricists' accept the obviousness of the premises of economic theory. For them, the truth of one's conclusions (or predictions) rests solely (and firmly) on the demonstrable truth of the premises – and the presumption that one must also justify every claim for the truth of one's conclusions or predictions arrived at by modus ponens. Needless to say, such empiricists do not see a problem of induction. Friedman clearly does, and in this sense he is not an orthodox empiricist (despite the term ‘positive’ in his title, which usually means ‘empirical’). According to the empiricist critic Rotwein, Friedman is criticizing views such as his by claiming that they represent ‘a form of naive and misguided empiricism’ (Rotwein, 1959, p. 555). Actually, Rotwein sees the thrust of Friedman's essay as a family dispute among empiricists.

Obviously, there is ‘good’ and ‘bad’ naivety. Good naivety exposes the dishonesty or ignorance of others. But Friedman's essay does not join with the empiricist's pretence that there is an inductive logic, one that would serve as a foundation for Rotwein's verificationist empiricism. Rotwein twists the meaning of ‘validity’ into a matter of probabilities so that he can use something like modus ponens (1959, p. 558). But modus ponens will not work with statements whose truth status is a matter of probabilities (see Haavelmo, 1944), and thus Friedman is correct in rejecting this approach to empiricism (for more, see Boland, 1979, pp. 517–18).

A more sophisticated critique of Friedman's methodology is the one by Bear and Orr (1967). They criticize only certain aspects while accepting others. In particular, they dismiss Friedman's
Instrumentalism while simultaneously recommending what they call his ‘as if’ principle. Their reason is that they too accept the view that the problem of induction is still unsolved but they see his principle as an adequate means of dealing with that problem. Their main complaint is that Friedman erred by ‘confounding… abstractness and unrealism’ (1967, p. 188, n. 3). Each part of Friedman's argument is, of course, designed only to be sufficient, but they ignore this and just claim Friedman's arguments against the necessity of testing and against the necessity of ‘realism’ of assumptions are both wrong. They go further to claim, ‘all commentators except Friedman seem to agree that the testing of the whole theory (and not just the predictions of theory) is a constructive activity’ (1967, p. 194, n. 15). However, this criticism is unfair because Friedman's concept of testing (as verifying) does not correspond to theirs. Of course, it is not always clear what various writers mean by ‘testing’, mostly because its meaning is too often taken for granted. Where Friedman sees testing only in terms of verification or ‘confirmation’, Bear and Orr appear to adopt Karl Popper's view that a successful test is a refutation (Bear and Orr, 1967, pp. 189 ff.). In a similar vein, another critic, Melitz (1965, pp. 48 ff.), seems to be saying that a successful test is confirmation or disconfirmation. In both critiques, the logic of the criticism is an allegation of an inconsistency between the critic's concepts of testing and Friedman's rejection of the necessity of testing assumptions. The logic of such criticism may be valid, but in each case the criticism is based on a rejection of Instrumentalism even though it is an absolutely essential part of Friedman's essay. Consequently, the critics are wrong as the alleged inconsistency does not exist within Friedman's Instrumentalist methodology. Moreover, it is unfair for critics to assert criticisms only on the basis of an inconsistency between their concept of testing and Friedman's methodological judgements which are based on his concept (for more, see Boland, 1979, pp. 520–1).

De Alessi (1965; 1971) offered more friendly criticisms. First, he meekly criticizes Friedman for seeing only two attributes of theories; a theory can be viewed as a language and as a set of substantive hypotheses. De Alessi says, ‘Unfortunately, Friedman's analysis has proved to be amenable to quite contradictory interpretations’ (1965, p. 477). And, like Koopmans's criticism, it is presumed that Friedman is relying on modus ponens. But Instrumentalism, by not requiring true assumptions, cannot use modus ponens. So, such a presumption is false.

In his later article, De Alessi says Friedman argues that some assumptions and conclusions are ‘interchangeable’. De Alessi notes that such ‘reversibility’ of an argument allows it to be tautological. Moreover, whenever an argument is tautological, it cannot also be empirical, that is, positive. The logic of De Alessi's argument may be correct – but it is not clear that Friedman was indicating ‘reversibility’ of (entire) arguments with the term ‘interchangeable’. The only methodological point Friedman was making was that the status of a statement's being an ‘assumption’ is not necessarily automatic.

The most celebrated criticism of Friedman's methodology was presented by Samuelson (1963) in his discussion of Ernest Nagel (1963). Samuelson claims that Friedman is in effect saying that a ‘theory is vindicable if (some of) its consequences are empirically valid to a useful degree of approximation; the (empirical) unrealism of the theory “itself”, or of its “assumptions”, is quite irrelevant to its validity and worth’ (1963, p. 232). Samuelson labels this the ‘F-Twist’. And about this he says it is ‘fundamentally wrong in thinking that unrealism in the sense of factual inaccuracy even to a tolerable degree of approximation is anything but a demerit for a theory or hypothesis (or set of hypotheses)’ (1963, p. 233). But Samuelson admits that his characterization of Friedman's view may be ‘inaccurate’ – supposedly why he labelled it the ‘F-Twist’ rather than the ‘Friedman-Twist’. Nevertheless, Samuelson willingly
assumptions controversy: The New Palgrave Dictionary of Economics

applies his potentially false assumption in his explanation of Friedman's view. His justification for using a false assumption is Friedman's own ‘as if’ principle. In this way, Samuelson argues that followers of Friedman's methodology must concede defeat if one can discredit or refute Friedman's view by using Friedman's view. Samuelson admits there is ‘cheap humor’ in this line of argument. Nevertheless, he is attempting to criticize Friedman by using Friedman's own methodology. But by Samuelson's own mode of argument, his assumption that attributes the F-Twist to Friedman is false and the attempt to apply this by means of *modus ponens* is thus logically invalid.

Surely it is illogical (and at best pointless) to criticize someone's view with an argument that gives different meanings to the essential terms. But this is just what the prominent critics do. Similarly, using assumptions that are allowed to be false while relying on *modus ponens*, as Samuelson does, is also illogical. Beyond preaching to the choir, an effective criticism must deal properly with Friedman's Instrumentalism. Any criticism that ignores his Instrumentalism will be an irrelevant critique. For this reason, the critiques of Koopmans, Rotwein and De Alessi are clear failures. None of the famous critics was willing to straightforwardly criticize Instrumentalism.

**Towards resolving the assumptions controversy**

The obvious critique that might succeed is to dispute the success of the observations that Friedman and his followers choose to explain by using his Instrumentalist methodology. For example, it is all too easy to find special cases where maximum dependence on the market can solve social problems. Of course, many people would still not accept Friedman's advocacy of policies involving minimum government if based only on selected examples. But any dispute about Friedman's policy views would open the door to straightforward ideological arguments on the floor of academia. Without this (or at least a critique of the positive claims that are claimed to underlie Friedman's policy views), the controversy will never be decided in favour of Friedman's critics other than to simply recognize – as argued in Boland (1979) – that the only justification for Instrumentalist methodology is a self-serving appeal to Instrumentalism itself. Surely this would be a weak if not dishonest defence.

Attwood, Thomas (1783–1856)

B.A. Corry
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
Attwood, M.; Attwood, T.; Birmingham School; Chartism; Cobbett, W.; full employment; Mill, J. S.; paper currency; Ricardo, D.

Article
In British social and political history the name of Thomas Attwood is usually connected with the Birmingham Political Union, of which he was a founder, and hence the part that movement played in the peaceful enactment of the great Reform Act of 1832. Later he was also associated with the Chartist movement. However, Attwood also has a place in the history of economic thought as an early exponent of anti-classical monetary and macroeconomic ideas and as the leading member of the so-called Birmingham School.

Thomas Attwood was born in 1783, the son of a banker and into whose profession he followed. From an early age he was also active in public affairs in the City of Birmingham. In 1811 he was elected high Bailiff of that town and the following year, with Richard Spooner (later to be another notable member of the Birmingham School) he represented Birmingham manufacturers’ interests against the Orders in Council that had restricted UK trade with the USA and the Continent. He was first drawn into monetary controversy by the depression that followed the ending of the Napoleonic wars in 1815. Birmingham was then an important manufacturing town and had become the centre of small arms manufacture during the wars. Hence the abrupt reduction in government demand had a quick and sharp effect on the local economy. Attwood was particularly incensed by the cavalier attitude adopted by some orthodox classical economists towards the distress brought about by the post-war depression. Ricardo, for example, expressed little knowledge of it and doubted the claims of Birmingham industrialists. Attwood's first pamphlet – The Remedy – appeared anonymously in 1816 and this was followed in 1817, under his own name, by A Letter to Nicholas Vansittart on the Creation of Money, and its Action upon National Prosperity.

Those early pamphlets give us the theme that was to dominate all of Thomas Attwood's writings in the field of monetary economics. His prime object was the abolition of the metallic standard and its
replacement with a flexible, managed, currency which, he believed was essential for a full employment policy. Throughout his many subsequent writings he never wavered from this position.

In 1830 Attwood was a founder of the Birmingham Political Union for the Protection of Public Rights: its aim was to secure middle and lower class representation in the House of Commons and the Union played a crucial role in supporting the Grey administration during the passage of the Reform Bill of 1832. In the same year together with Joshua Scholefield he was returned unopposed as a Member of Parliament for the new Parliamentary Borough of Birmingham. He continued to agitate for further Parliamentary reform and in 1839 was a presenter of the mammoth Chartist Petition to Parliament. His place in the Chartist movement was uneasy and ambiguous. He never endorsed the use of physical force that was advocated by some of the more extreme leaders of the movement. More fundamentally the central tenet of Attwood's monetary proposals – the introduction of an inconvertible paper currency – was utterly rejected by the Chartists who attacked what they termed ‘rag botheration’ (paper currency) as enthusiastically as Cobbett.

Attwood felt, and rightly so, that his monetary ideas were never taken seriously by the establishment and he undoubtedly suffered from what may be termed a persecution complex. He was for example, caricatured by Disraeli in the Runnymede Letters and by J.S. Mill in the Currency Juggle. Attwood died in 1856 a disappointed man. Birmingham honoured him with a statue in Stephenson's Place (1859).

His brother Matthias also wrote some important pamphlets in monetary matters but never took up the extreme position of his brother Thomas.

Attwood, Thomas (1783–1856) : The New Palgrave Dictionary of Economics

The auctioneer is a fictitious agent, introduced by Leon Walras, who matches supply and demand in a market with perfect competition. The process is called ‘tâtonnement’, finding the market clearing price for all commodities, resulting in general equilibrium. No actual trading occurs during this process. The concept of the auctioneer sidesteps the important question of the coordinating power of the price mechanism. There are in fact only a few special cases for which the auctioneer process leads the economy to an equilibrium.

Keywords

auctioneer; auctions; competitive equilibrium; Keynesianism; monopolistic competition; perfect competition; tâtonnement; Walras, L.; Walras's Law

Article

Walras (1874) introduced the idea of a tâtonnement to provide a theoretical account of the formation of equilibrium prices. This account was not meant to be taken descriptively but rather as a ‘Gedanken Experiment’. It was hoped that its study would provide insights into the actual modus operandi of the price mechanism.

Consider an economy of $H$ households, $F$ firms and $n$ goods. Let $p \in \Delta \subset \mathbb{R}_+^n$, where $p$ is a price vector and $\Delta$ the simplex. Given the endowments of households $(e^h \in \mathbb{R}_+^n)$, $x^h - e^h$ is the net trade vector of household $h$ where $x^h \in \mathbb{R}_+^n$ is the vector of demand of household $h$. Assume that

$$x^h - e^h = \xi_h(p)$$
where \( \xi_h(p) \) is a continuous function from \( \Delta \) to \( \mathbb{R}^n \). Let \( y^f \in \mathbb{R}^n \) be an activity of firm \( f \), where \( v_i^f > 0 \) is interpreted as ‘the firm supplies good \( i \)’ and \( v_i^f < 0 \) is interpreted as ‘the firm demands good \( i \) as an input’. Let \( y = \sum f y^f \) and assume that

\[
y = \eta(p)
\]

is a continuous function from \( \Delta \) to \( \mathbb{R}^n \). Then define

\[
z = \sum_h (x^h - e^h) - y
\]

which by our assumptions can be written as, say

\[
z = \sum_h \xi_h(p) - \eta(p) = \theta(p)
\]

It is known that addition of budget constraints implies

\[
p \cdot z = 0 \text{ all } p \in \Delta.
\]

(Walras's Law). An equilibrium of the economy is \( p^* \in \Delta \) such that

\[
\theta(p^*) \leq 0.
\]

It should be added that the net trades \( \xi_h(p) \) are assumed to be utility maximizing for each household under the budget constraint:
where \( 1 \geq \lambda^f_h y \geq 0, \sum_h \lambda^f_h = 1 \), is the share of \( h \) in the profits of firm \( f \). Similarly \( \eta^f(p) = y^f \) satisfies for all \( f \): \( p \cdot \eta^f(p) \geq p \cdot y^f \) all \( y \) which the firm can choose amongst.

A tâtonnement is now described as follows. A fictitious agent called the auctioneer announces \( p \in \Delta \).

Households now report to this auctioneer their desired net trades \([\xi_h(p)\]) and firms report to him their desired activities \([\eta^f(p)\]). From these reports the auctioneer can deduce \( \Theta(p) \). In its light he calculates a new price vector \( p' \) as follows:

\[
\frac{p^i_j}{\sum_i p^i_j} = \begin{cases} \frac{p^i_j}{\sum_i p^i_j} \text{ if } \theta_j(p) = 0 \text{ or if } \theta_j(p) < 0 \text{ and } p = 0 \frac{p^i_j}{\sum_i p^i_j} \text{ if } \theta_j(p) > 0 \text{ and } p > 0 \frac{p^i_j}{\sum_i p^i_j} \text{ if } \theta_j(p) < 0 \text{ and } p < 0 \end{cases}
\]

He announces \( p' \) agents send back messages which allow him to calculate \( \Theta(p') \). The process continues until and if the rule for calculating a new price vector yields the preceding price vector. No actual trading occurs during this process.

The rule which we have supposed the auctioneer follows in changing his price announcement is only one of a number of possible ones. Indeed, it is not the one proposed by Walras. He supposed the auctioneer to concentrate on one market at a time; specifically he changes only one price. Suppose he changes the \( i \)th price. Then he changes it until, given all other prices which are held constant, the \( i \)th market is in equilibrium. (He assumed that there always is such a price and that it is unique.) Thereafter he moves on to the next market. Of course, this process may never terminate in an equilibrium.

In all of this one ought to specify what it is that the auctioneer knows. So far we have assumed that he does not know the function \( \Theta(p) \). If, however, he does know this function we may think of the auctioneer as being concerned to find a solution to \( \theta(p) \leq 0 \) for \( p \in \Delta \). He is then no more than a programmer. In this case, for instance, he may adopt Newton's method (Arrow and Hahn, 1971; Smale, 1976). That is he proceeds as follows: Let \( J(p) \) be the \((n-1) \times (n-1)\) Jacobian of the first \((n-1)\) excess demand functions \( \hat{\theta} = \theta_1(p), \ldots, \theta_{n-1}(p) \). The price of the \( n \)th good is set identically equal to unity (it is the numeraire). Then define \( \hat{p} = (p_1, \ldots, p_{n-1}) \) and let \( \hat{q} = (q_1, \ldots, q_{n-1}) \) solve:

\[
\hat{\theta}(\hat{p}) - J(\hat{p})(\hat{q} - \hat{p}) = 0
\]

where it is assumed that a solution exists:
The auctioneer now follows the rule: raise $p_i$, if $q_i - p_i > 0$, lower $p_i$ if $q_i - p_i < 0$ if $q_i - p_i < 0$ and $p_i > 0$ and leave $p_i$ unchanged if either $q_i = p_i$ or $q_i < p_i$ and $p_i = 0$. Under certain technical assumptions this way of calculating will lead the auctioneer to an equilibrium (see Arrow and Hahn, 1971).

This example demonstrates that it is possible to think of a tâtonnement as a kind of computer program. If one adopts this view, however, one will certainly not be mimicking the invisible hand. For instance, in the Newton method the price change in any one market depends on the excess demand functions in all markets and that is not what any version of ‘the law of supply and demand’ stipulates. Moreover the proposal violates the supposed economy in information of decentralized economies – that is, much more is known to the auctioneer than can be known to any one agent. From the point of view of positive theory, therefore, this second interpretation of the auctioneer is not helpful, although it has found application in the theory of planning (e.g. Heal, 1973).

Assuming that the auctioneer only knows aggregate excess demands at the announced $p$, it has been customary ever since a famous paper by Samuelson (1941; 1942) on Hicksian stability to formulate the rule followed by the auctioneer dynamically. For instance:

$$
\frac{d \theta_i(p)}{dt} = \begin{cases} 0 & \text{if } \theta_i(p) < 0 \text{ and } p_i = 0 \\
 -k_i \theta_i(p) & \text{otherwise with } k_i > 0.
\end{cases}
$$

Even if this process leads to $p^*$ it will do so only as $t \to \infty$. This is awkward since no one is allowed to trade while the process is still in motion. Some economists have by-passed this by saying that the time here involved is not calendar, but ‘model-time’. On reflection it is not clear what that means unless it is ‘computer time’ which is meant and, if it is, one must again ask whether the construction will then have anything to do with any actual price mechanism.

Arrow (1959) has suggested an alternative interpretation which, however, much restricts the applicability of the tâtonnement. Suppose we think of time as divided into trading periods and let the auctioneer follow the rule:

$$
p_i(t) = p_i(t-1) + k_i \theta_i[p(t-1)] k_i > 0
$$

(with the usual boundary condition to avoid negative prices). Now suppose (a) that one is concerned with a pure exchange economy and (b) that all goods last for only one period so that agents in each period receive new endowments (identical for each period). Then we can allow the agents to trade during the process.
without the trade in any one period affecting the excess demand at any \( p \) in a subsequent period. So now (a) we think of the process in real time and (b) even if it converges to \( p^* \) only as \( t \to \infty \) or does not converge at all, agents can trade.

This very restrictive case clarifies the reason why in general the tâtonnement prohibits trade out of equilibrium. Let \( \hat{e} = (e^1, \ldots, e^H) \), the endowment matrix of a pure exchange economy in which goods are durable. Let us now take explicit note of \( e \) in the excess demand function (since it was constant it was omitted hitherto) and write

\[
\sum_h (x^h - e^h) = \theta(p, \hat{e}).
\]

Assuming that \( \theta(p, \hat{e}) = 0 \) has a unique solution, the latter will depend on \( e \) and may be written as \( p^*(\hat{e}) \). If now trading takes place out of equilibrium, \( e \) will be changing and so therefore will \( p^*(\hat{e}) \). Thus when there is such out of equilibrium trading, the equilibrium which the tâtonnement is groping for will depend on the manner of the groping. To exclude this dependence was the purpose of excluding out of equilibrium trade. But there was another reason, namely, the lack of any clear theory of how trade would proceed when either some prospective buyers or sellers could not carry out their trading intentions.

The fictitious auctioneer is also a consequence of theoretical lacunae and indeed of a certain logical difficulty. If prices are to be changed by the economic agents of the theory, that is either by households or firms or both then it is not easy to see how those same agents are also to treat prices as given exogenously as is required by the postulate of perfect competition. This difficulty was first noted by Arrow (1959) who argued that out of equilibrium price changes not brought about by an auctioneer require a departure from the perfect competition assumption if they are to be understood. Take for instance a situation for which \( \hat{\theta}_i(p, \hat{e}) > 0 \). Then at \( p \) there will be unsatisfied buyers. But that means that any firm raising its price for good \( i \) by a little will not, as in the usual perfect competition setting, lose all its customers. The reason is that buyers cannot be sure of obtaining the good from any of the other firms which have not yet raised their price. Hence the demand curve for good \( i \) facing a producer of that good is not perfectly elastic. (On the other hand, in equilibrium it well might be.) The postulate of the auctioneer sidesteps these problems at the cost of an understanding of how prices are actually changed. It has enabled theorists to ignore the role of monopolistic competition in the process of price formation – a circumstance which until recently has left the whole matter without proper theoretical foundations.

But it must also be admitted that there are formidable theoretical difficulties to be faced in banishing the auctioneer. Whether we think of prices as formed by a bargaining process or by monopolistic competition or in some form of auction process, strategic considerations, that is to say, game theoretic tools, will be required. In addition, careful attention will have to be given to the information available to each of the agents involved in the process. Some progress has been made (e.g. Roth, 1979; Schmeidler, 1980; Rubinstein and Wolinsky, 1985) but there is a very long way to go. (Some economists have banished the auctioneer without considering these matters by the simple device of treating it as axiomatic that at all times the economy is in competitive equilibrium. There is nothing favourable to be said for this move.)

There is now also a somewhat subtler point to consider: the behaviour postulated for the auctioneer will implicitly define what we are to mean by an equilibrium: that state of affairs when the rules tell the auctioneer...
to leave prices where they are. But the auctioneer's pricing rules are not derived from any consideration of the rational actions of agents on which the theory is supposed to rest. Thus the equilibrium notion becomes arbitrary and unfounded. If, on the other hand, we had a theory of price formation based on the rational calculations of rational agents then the equilibrium notion would be a natural corollary of such a theory. For instance, one might then be led to describe a situation in which there is unemployment as one of equilibrium because neither firms nor workers, given their information and beliefs, find it advantageous to change the wage.

This line of reasoning leads one to a central objection to the auctioneer and indeed the tâtonnement: it sidesteps the important question of the coordinating power of the price mechanism. Here is an example. In an oligopolistic industry with excess supply it may not be advantageous for any one firm to reduce its price given its beliefs as to the strategies of its competitors. Yet it may be to all of the firms’ advantage to have the price reduced: there is a cooperative solution which dominates the competitive one. Put another way, there are significant externalities in price signalling. To leave these unstudied is to leave very important matters in darkness. The auctioneer is a coordinator *deus ex machina* and hides what is central.

These considerations are most striking in the context of Keynesian theory. As long as the auctioneer is in the picture no state of the economy in which there is involuntary unemployment can qualify as an equilibrium – the auctioneer would be reducing wages. But without the auctioneer the observation that a worker would prefer to work at the going real wage to being idle does not logically entail the proposition that the wage will be reduced. That proposition would require a great deal of further theoretical underpinning turning on the beliefs of workers, the strategies of other workers and the strategies of employers. It would also turn on the information available to agents. For instance, if lowering one's wage is regarded as a signal of lower quality of work then one may be reluctant to offer to work at a lower wage. The fictitious auctioneer makes sure that none of these matters is studied or understood. The use of this fiction encourages the view that all Pareto-improving moves will, in a competitive economy, be undertaken. This view, however, lacks any foundations other than the auctioneer himself.

One might just about convince oneself that, notwithstanding all these objections, the tâtonnement and its auctioneer are worthwhile, if it were the case that it provided one story which showed how equilibrium was brought about. Unfortunately, however, it does not do this for there are only a few special cases for which the auctioneer process leads the economy to an equilibrium. In many others it will not do so. Indeed, in so far as one holds the view that an equilibrium is the normal state of an economy one should not be tempted to understand this circumstance by means of a tâtonnement.

auctions (applications)

Patrick Bajari
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

We survey some recent empirical work concerning the analysis of auctions. We begin by describing a two-step nonparametric approach for estimating bidding models that is commonly used in the applied literature. Two applications of this approach are considered: empirical work on bidding in Treasury markets, and empirical tests for collusion in auctions.

Keywords

auctions; bid rigging; cartels; collusion; conditional independence; discriminatory auctions; exchangeability; first-price auctions; sealed-bid auctions; statistical decision theory; structural estimation; uniform price auctions

Article

In this article, we survey some recently developed methods for the econometric analysis of action data and related applications. Since the mid-1990s, auctions have been an active area of research in empirical industrial organization. Auctions are an attractive setting for empirically testing game theory, for three reasons. First, real-world auctions have well-defined rules, which often correspond closely to game forms in economic theory. The mapping between the data and economic theory is typically less ambiguous in auctions than in other applications in empirical industrial organization. Second, the theoretical literature on auctions is well developed and offers many testable implications. Third, there are many high quality, easily accessible data sets. For example, detailed data sets from public sector procurements or online auctions can easily be collected from the Internet.

In this survey, we shall describe the estimation strategy proposed in Guerre, Perrigne and Vuong (2000) (henceforth GPV) and two substantive applications. The empirical literature in auctions is diverse. Numerous useful alternative approaches have been proposed, so it is impossible to cover all of them in a short survey. However, the work of GPV and related extensions is widely viewed as one of the most
important recent additions to the literature. This survey will omit many of the technical details which are required to correctly implement these estimators. Instead, we discuss the estimators somewhat informally, focusing on what we believe is the key intuition behind these methods. Fortunately, there are several excellent surveys that discuss these estimators and related applications in considerable detail. See, in particular, Athey and Haile (2007), Hendricks and Porter (2007) and Hong and Paarsch (2006).

1 The first-price auction

Following GPV, consider a first-price sealed-bid auction with independent private values. There are \( i = 1, \ldots, N \) bidders. Bidder \( i \)'s valuation for winning the auction is denoted by \( v_i \) and is private information. The bidders are symmetric in the sense that each bidder's valuation is an i.i.d. draw from a distribution \( F(v) \), which is common knowledge. After learning their valuations, each bidder independently and simultaneously submits a bid \( b_i \). Bidders are risk neutral, and bidder \( i \) receives utility \( v_i - b_i \) if \( i \) is the high bidder and zero otherwise. The equilibrium bid function is symmetric and strictly increasing under fairly mild regularity conditions. Let \( b = b(v) \) denote the equilibrium bid function and \( \phi(b) = b^{-1}(v) \) denote the inverse bid function.

Bidder \( i \)'s expected utility from bidding \( b_i \) is equal to

\[
(v_i - b_i) F(\phi(b_i))^N - 1.
\]

Bidder \( i \) wins the auction when the other \( N-1 \) bidders bid less than \( b_i \). Bidder \( j \neq i \) bids less than \( b_i \) when \( j \)'s valuation is less than \( \phi(b_i) \). The probability of this event is \( F(\phi(b_i)) \). Therefore the probability that bidders \( j \neq i \) bid less than \( b_i \) is \( F(\phi(b_i))^N - 1 \). Expected utility is the product of the surplus bidder \( i \) receives conditional on winning, \( (v_i - b_i) \), times the probability that \( i \) wins the auction. Given \( v_i \), the first-order condition for utility maximization is

\[
(v_i - b_i) (N - 1) f(\phi(b_i)) \phi'(b_i) - F(\phi(b_i)) = 0.
\]

Suppose that the econometrician observes \( t = 1, \ldots, T \) independent repetitions of the auction described above. For each auction \( t \), the econometrician observes all of the bids \( b_{i,t} \). The object that GPV wish to estimate is the distribution of bidder valuations, \( F(v) \). GPV's approach is structural in the sense that they attempt to recover the economic primitives of the model. As we shall discuss in our applications, structural estimation of the model may allow the economist to answer a number of substantive questions.
For example, we can assess the efficiency of the observed auction mechanism or test between competing models, such as competition versus collusion.

GPV note that an econometric approach based directly on evaluating eq. (2) may be difficult. This equation involves the inverse bid function, $\Phi$, and its derivative, $\Phi'$, which in turn are complicated, nonlinear functions of the unknown $F(v)$. In principle, it is possible to estimate parametric auction models based on eq. (2), as in Paarsch (1992), Donald and Paarsch (1993), Hong and Shum (2002) and Bajari and Hortacsu (2003). However, these methods rely on restricting attention to carefully chosen parametric distributions or require the use of reasonably sophisticated numerical methods. (Despite these limitations, it is worth noting that many parametric approaches generate superconsistent estimators, which converge much more quickly than the nonparametric rate of convergence as in GPV. This may be useful when the sample size available to the econometrician is limited. See Donald and Paarsch, 1993, and Hirano and Porter, 2003, for a discussion.)

A key insight of GPV is that the econometric analysis of the first-price auction is greatly simplified by a change of variables. Let $G(b) = F(\Phi(b_i))$ denote the equilibrium distribution of the bids. If we substitute $G(b)$ into (1), we can write expected utility as

$$ (v_i - b_i) G(b_i)^{N-1}. $$

The first-order conditions now become

$$ (v_i - b_i)(N - 1) g(b_i) - G(b_i) = 0 \tag{3} $$

$$ v_i = b_i + \frac{G(b_i)}{(N - 1) g(b_i)}. \tag{4} $$

The right-hand side of eq. (4) involves the bid, $b_i$, the distribution of the bids, $G$, and the density of the bids, $g$. GPV observe that if we have access to a large number of independent repetitions of the same auction, then both $G$ and $g$ can be consistently estimated using standard techniques. Given estimate $\hat{G}$ and $\hat{g}$ of $G$ and $g$, we can form an estimate $\hat{v}_{i,t}$ of bidder $i$'s private information $v_{i,t}$ in auction $t$ by
evaluating the empirical analogue of eq. (4):

\[ \hat{v}_{i,t} = b_{i,t} + \frac{\hat{C}(b_{i,t})}{(N - 1)\hat{g}(b_{i,t})}. \]  

(5)

To summarize, the estimator proposed by GPV is as follows:

1. Given bids \( b_{i,t} \) for \( i=1,\ldots,N \) and \( t=1,\ldots,T \), estimate the distribution and density of bids \( \hat{C}(b) \) and \( \hat{g}(b) \).
2. Compute \( \hat{v}_{i,t} \) for \( i=1,\ldots,N \) and \( t=1,\ldots,T \) using eq. (5). Use the empirical cdf of the \( \hat{v}_{i,t} \) to estimate \( F \).

This procedure is attractive for three reasons. First, it does not impose parametric assumptions on \( F \) during estimation. Since the economist is likely to have poor a priori information about the distribution of values, this is desirable for empirical work. Second, the procedure described above is computationally simple to implement since it does not require evaluation of \( \phi \) and \( \phi' \). Finally, it is possible to demonstrate that \( F(v) \) is nonparametrically identified. The intuition is quite simple. As \( T \) grows arbitrarily large, the economist will be able to estimate \( G \) and \( g \) very precisely under standard regularity conditions. Equation (4) implies that for any given bid \( b_i \) we can recover the latent valuation \( v_i \) that generates this bid (that is, \( v_i = \phi(b_i) \)). Since the distribution of \( b_i \) is known, it can easily be demonstrated that \( F(v) \) is therefore identified.

GPV also demonstrate that the first-price auction model can be tested. Given estimates \( \hat{C} \) and \( \hat{g} \), define \( \xi(b) \) as

\[ \xi(b) = b + \frac{\hat{C}(b)}{(N - 1)\hat{g}(b)}. \]

Theoretical models of bidding imply that the bid function should be increasing, that is, bidders with higher valuations should submit higher bids. Therefore, if \( \hat{C}(b) / (N - 1)\hat{g}(b) \) is sufficiently close to \( C(b) / (N - 1)g(b) \), \( \xi(b) \) should be monotonically increasing if the model is correctly specified. This prediction of the theory could be rejected by the data since \( \hat{C} \) and \( \hat{g} \) are estimated nonparametrically and do not impose a priori that \( \xi(b) \) is increasing.
2 Generalizations and applications

Following GPV, a large number of authors have proposed similar estimators for other auction models. In these papers, a key step is typically to rewrite the first-order conditions in terms of the equilibrium distribution of the bids (for example $G$ and $g$). Next, as in eq. (4), the economist attempts to isolate private information on the left-hand side as a function of the bids on the right-hand side. Following GPV, the economist then nonparametrically estimates the distribution of the bids from the data and recovers the latent private information by evaluating the empirical analogue of the first-order condition. This basic algorithm often needs to be modified for different auctions. However, attempting to follow these steps as a first pass will typically take the economist a long way towards deriving an estimator. Listed in Table 1, in alphabetical order, are some recent papers which build on the insights of GPV in other auction models.

Next, in order to illustrate how these techniques are used in practice, we briefly summarize Hortaçsu (2002) who analyses bidding in Treasury bill auctions, and Bajari and Ye (2003) who test for collusion in procurement auctions.

### 2.1 Auctions for Treasury bills

Hortaçsu (2002) asks how governments should conduct auctions for Treasury bills. Treasury bill auctions are an example of a multiple unit auction since large numbers of T-bills are typically sold during a single auction. Since there are multiple units, a ‘bid’ in a Treasury auction is a demand curve, instead of a scalar as in the example of Section 1. Two commonly used mechanisms for conducting a Treasury bill auction are the uniform price auction and the discriminatory auction. In a uniform price auction, the auctioneer begins by aggregating all of the individual demand curves into a market demand...
curve. The supply curve is vertical, with an intercept equal to the number of T-bills that the government wishes to sell. The market-clearing price is determined by the intersection of the supply and demand curve. Each bidder pays his demanded quantity at the market-clearing price, analogous to a competitive market. By contrast, in a discriminatory auction, the intersection of the supply and market demand curves determines the price for the last unit purchased. Analogous to first-degree price discrimination, bidder $i$ pays the area under his demand curve, so that the price for the first unit purchased will be higher than for the last unit purchased.

There is no general consensus about which auction mechanism should be preferred. Since the equilibria to these auctions are quite complicated, it is difficult to characterize revenue in each auction. Each year, nearly $4$ trillion dollars of securities are sold in T-bill auctions. Given the size of these markets, econometrically modelling the determination of the bids and comparing revenue from alternative auction mechanisms is an interesting public policy question.

The particular market that Hortaçsu examines is the short-term (13-week) market for T-bills in Turkey. This market is run using a discriminatory auction. Hortaçsu uses the Wilson (1979) auction of shares model as a starting point for his econometric analysis. He assumes that bidders have private values. According to surveys of bidders, 42 per cent of purchases in the auctions are to meet reserve requirements imposed by the Turkish Central bank. Thirty-seven per cent of purchases are for resale in the secondary market. Ten per cent are to fulfil customer orders and ten per cent are to fulfil collateral requirements, for investment funds administered by the bank, and for buy-and-hold purposes. Other than those shares purchased for resale, the other sources of demand are probably best modelled as private values.

Let $s_i$ denote bidder $i$'s private information about her willingness to pay for government debt and $v_i(q, s_i)$ denote bidder $i$'s valuation for the $q$th unit. Assume that private information is distributed i.i.d. $s_i \sim F(s)$. Let $y_i(p)$ denote the demand curve submitted by bidder $i$. Hortaçsu assumes that $y_i(p)$ is strictly decreasing and differentiable. If there are $N$ bidders and $Q$ units of debt for sale, the market-clearing price $p^c$ will satisfy

$$Q = \sum_i y_i(p^c).$$

The cdf of the market-clearing price, conditional on $i$'s bid function $y_i(p)$ is

$$H(p, y_i(p)) = \Pr\left\{y_i(p) \leq Q - \sum_{j \neq i} y_j(p)\right\} = \Pr\left\{p^c \leq p \mid y_i(p)\right\}. \tag{6}$$
Equation (6) is analogous to a residual supply curve. The term $H(p, y_i(p))$ is the probability that the market-clearing price will be less than $p$ given $i$'s own bid, $y_i(p)$. However, unlike a residual supply curve in a model with certainty, the bidder has to take into account her uncertainty about the bids of others.

Given a bid $y_i(p)$, the surplus that a bidder gets, conditional on $p^c$ is equal to

$$
\int_0^{y_i(p^c)} v_i(q, s_i) \, dq - \int_0^{y_i(p^c)} \nu_i^{-1}(q) \, dq.
$$

There are two terms in the above sum. The first term is the integral of $v_i(q, s_i)$ from 0 to $y_i(p^c)$. This is bidder $i$'s valuation for the units that she wins. The second term is the integral of $i$'s inverse demand curve. This determines the total payment that $i$ just made for the units that she won. Therefore, $i$’s expected profit from submitting a bid of $y_i(p)$ is equal to

$$
\int_0^\infty \left\{ \int_0^{y_i(p^c)} \{v_i(q, s_i) - \nu_i^{-1}(q)\} \, dq \right\} dH(p^c, y_i(p)).
$$

Following Wilson (1979), the first-order condition for maximization implies that

$$
v_i(y_i(p), s_i) = p + \frac{H(p, y_i(p))}{\partial p} \cdot \frac{\partial}{\partial p} H(p, y_i(p)).
$$

(7)

That is, a bidder's valuation will be equal to the price on the submitted demand curve plus a bid-shading factor, $H(p, y_i(p)) \cdot \partial \frac{\partial}{\partial p} H(p, y_i(p))$. Just as in the first-price auction example in Section 1, Hortaçsu notes that $H(p, y_i(p))$ is the cdf of the equilibrium distribution of bids given $y_i(p)$. Given a large number of repetitions of the same, or similar auctions, this object can be estimated from the observed bidding data. And, similar to the first-price auction example above, an estimate of bidder $i$’s valuation, $v_i(y_i(p), s_i)$ can be recovered by evaluating the empirical analogue of eq. (7). While the econometric details are somewhat involved, a key economic insight was expressing the first-order conditions in terms of a function of the bids which, in principle, can be recovered from the data.

Using his estimates of bidder valuations, Hortaçsu examines two applied questions. The first is to...
explore the impact of reserve requirements on bidding behaviour. He constructs a variable, $\% \text{SHORTFALL}_{i,t-1}$, which is the fraction of orders in the previous Treasury auction that were unfulfilled. He finds that when bidders have a large shortfall in previous auctions, they are more likely to bid aggressively in upcoming auctions. Using his survey on bidder demands, he interprets this as derived demand from satisfying reserve requirements to hold a required portfolio of Turkish Treasury notes. For instance, he finds that the $R^2$ of a regression of the intercept of the submitted bid function on $\% \text{SHORTFALL}_{i,t-1}, \%\text{SHORTFALL}_{i,t-2}$ and an auction fixed effect is 0.61. Bidder-fixed effects only increase $R^2$ to 0.64.

A second applied question Hortaçsu examines is whether a uniform price auction would generate increased revenue. This is complicated to answer since changing to a uniform price auction would generate an entirely new equilibrium in this market. However, Hortaçsu demonstrates that it is possible to construct a simple upper bound on revenue given estimates of $v_i(q, s_i)$ for $i=1,\ldots, N$. Since bidders typically engage in demand reduction in a uniform price auction, they will bid at most $v_i(q, s_i)$ so that $v_i(q, s_i)$ is an upper bound on $i$'s bid. Assuming that this upper bound is binding for all bidders, he generates an upper bound on the market-clearing price in the auction. Using his structural estimates, Hortaçsu finds that switching to a uniform price auction would generate a revenue loss of at least 3.8 per cent on average in the auctions in his sample.

Hortaçsu therefore argues that the discriminatory price auction generates higher revenue since bidders are being forced to pay the area under their demand curves. Even after accounting for changes in the strategic incentives to shade bids, discriminatory auctions generate more revenue. However, this conclusion is subtle. Recall that bids are the steepest when shortfalls are the highest. It is hard to argue that forcing banks to hold Turkish Treasury debt is optimal for securing deposits. More likely, this policy was implemented in order to guarantee that there is a constant demand for government debt even if the government engages in irresponsible fiscal or monetary policies. These results suggest that the reserve requirements plus the discriminatory mechanism may be imposing a burden on the banking sector by forcing banks to hold more than the optimal number of domestic T-bills.

2.2 Collusion application

Next, we briefly discuss an application by Bajari and Ye (2003) that tests for collusive bidding behaviour in procurement auctions. Bid rigging is an important antitrust problem. For instance, Pesendorfer (2000) notes that 55 per cent of the criminal antitrust cases filed by the US Department of Justice involved bid rigging. One well-known example of bid rigging was the ‘concrete club’ in New York where organized crime figures placed an implicit ‘tax’ of two per cent on every ton of concrete used in certain construction jobs in the 1980s. However, the costs of collusion were likely much larger than two per cent. Mafia informer Sammy ‘The Bull’ Gravano, who was involved in bid-rigging in the concrete industry, stated ‘If one of them (contractor) gets a contract for, say, thirteen million, the next thing you know, after he knows he's got it, he jacks up the whole thing before it's over to a sixteen- or seventeen-million-dollar job. Now he's increased the cost thirty-three percent. So our greed (the Mafia) is compounded by the greed of them so-called legitimate guys (contractors)’ (Maas, 1997, p. 271).

While bid-rigging is an important antitrust problem, it can be difficult to detect. Bajari and Ye (2003),
expanding on the methods in Section 1, and on the work of Porter and Zona (1993; 1999), propose three statistical tests that can be used to potentially detect bid rigging in procurement auctions. Certainly, no test for bid-rigging can hope to be foolproof. However, it may be a basis for determining which sets of bids are most worrisome and whether further investigation of certain firms is warranted. Bajari and Ye apply their methods to a set of contracts in the highway construction industry for ‘seal coating’ jobs in Minnesota, North Dakota and South Dakota. Seal coating is a type of highway repair that attempts to extend the life of the road by sealing surface cracks. The surface of the highway is initially sprayed with a coating of oil. Next, a ‘chip spreader’ distributes a uniform layer of sand and aggregate on the road. Finally, rollers are used to bind the oil, sand and aggregate. Bidding is conducted using sealed bids. While there are a large number of fringe firms in the industry, the market is dominated by a few large bidders that regularly compete against each other. Since all of the bids are publicly available shortly after they are submitted, collusion has occurred in seal coating in many markets. Bajari and Ye note that three of the largest bidders in their data have been fined for previous attempts to rig bids. The owner of the largest firm in the data set served prison time for a bid rigging conviction. Bajari and Ye consider a first-price auction model similar to the example discussed in Section 1. However, they drop the assumption that all bidders are \textit{ex ante} identical. In the construction industry, they argue it is important to allow for asymmetric bidders for three reasons. First, transportation costs are substantial in this market so that firms located closest to the project will tend to have lower cost. Second, there is a skewed size distribution of firms in the industry. Therefore, it is important to allow for firm specific difference in productivity. Third, project backlog increases the opportunity cost of taking on additional work and is likely therefore to be an additional source of \textit{ex ante} asymmetries. In the model, \(N\) firms compete for a contract to build a single and indivisible public works project. Firm \(i\)'s cost to complete the project, \(c_i\), is a random variable with cumulative distribution function \(F_i(\cdot; z_i; \theta_i)\) and probability density function \(f_i(\cdot; z_i; \theta_i)\). Here \(z_i\) reflects publicly observed cost shifters from firm \(i\). For instance, in the application, these include distance to the project, a firm fixed effect to capture differences in productivity, backlog at the time bids are submitted and an engineering cost estimate. The term \(\theta_i\) is a set of firm specific parameters. In the model, firm \(i\) is risk neutral and has profits of \(b_i - c_i\) if it is the low bidder and zero otherwise. Let \(G_i(b; z)\) be the equilibrium distribution of bids submitted by firm \(i\). Note that the distribution of the bids depends on \(z=(z_1, \ldots, z_N)\), the publicly observed information for all firms in the industry. Then \(i\)'s expected profits from submitting a bid of \(b_i\) when \(i\)'s costs are \(c_i\) is equal to

\[ (b_i - c_i) \prod_{j \neq i} (1 - G_j(b_i, z)) \]

(8)

It can easily be shown that the first-order condition to the model must satisfy
As in Section 1, if the economist has estimates of $\hat{\gamma}_i$ and $\hat{\theta}_i$, it is possible to generate an estimate of $c_i$ by evaluating the empirical analogue of the above equation for all bidders in the sample.

Bajari and Ye (2003) propose three tests for collusive bidding. We next describe the basic spirit of these tests, referring the interested reader to the text for complete details. The first test for competitive bidding is that conditional on $z$, the bids of all firms $I=1,\ldots,N$ must be distributed independently. This is a fairly robust prediction of the theory of competitive bidding and is in fact more general than the particular model described above. Because bidders have private information which is independently distributed, their bids, which are a deterministic function of this private information, must also be independently distributed. Obviously, one limitation of such a test is if some component of $z$ is observed by the firms, but not by the econometrician. Following Porter and Zona (1993; 1999), their estimation strategy allows for the inclusion of an auction-specific fixed effect. Thus, they control for project specific cost shifters which are common to all of the firms.

Second, they demonstrate that the equilibrium distribution of competitive bids must be exchangeable. Let $\pi$ be a permutation of the bidder identities $\{1,\ldots,N\}$, that is, a one-to-one map from $\{1,\ldots,N\}$ to $\{1,\ldots,N\}$. If the equilibrium bid function is unique, the bid distribution must be exchangeable: that is, $G_i(b_i, z_1, z_2, z_3, \ldots, z_N) = G_{\pi(i)}(b_{\pi(1)}, z_{\pi(1)}, z_{\pi(2)}, z_{\pi(3)}, \ldots, z_{\pi(N)})$. In words, exchangeability means that if you permute the cost shifters of all the bidders, then the equilibrium bids must also permute in a symmetric fashion. Conditional independence and exchangeability are necessary for equilibrium bidding. If other regularity conditions hold, conditional independence and exchangeability are also sufficient for competitive bidding: that is, the economist can reverse engineer a competitive bidding model that rationalizes the observed bids.

Porter and Zona (1993, 1999) study the bidding behaviour of known cartels in construction and in the supply of school milk. Many of the irregular patterns of bidding that they describe can be characterized as failures of conditional independence and exchangeability. For instance, the bids of cartel members are more correlated with each other than with non-cartel members. Also, cartel members do not shift their bids aggressively in response to shifts in the $z_i$ of other cartel members which is a failure of exchangeability.

Bajari and Ye (2003) test for conditional independence and exchangeability in their data set. Given the limited number of observations available to them, they test these conditions in a regression framework. Essentially, they run a regression of $b_i$ on $z_i$ and $z_{-i}$, including auction fixed effects and bidder fixed effects. Conditional independence is tested by asking whether the fitted residuals from bidder $i$'s bid function is correlated with the fitted residuals from $j \neq i$'s bid function. Exchangeability is formulated as a test of the equality of certain regression coefficients. In total, 46 separate hypothesis tests are conducted. Forty-one of these tests are consistent with the implications of competitive bidding (that is, conditional independence and exchangeability). Therefore, they argue that most of the bids in the market...
appear to be competitive. However, reduced form tests suggest that bidding by two coalitions of firms appear to be suspicious. They label these coalitions ‘candidate cartels’. Interestingly, all of the members of the candidate cartels had previously been convicted of bid rigging.

The third and final test for bid rigging uses structural estimates based on eq. (9). Bajari and Ye consider a non-nested hypothesis test between three models. Model M1 is that the data-generating process is the no collusion model. Model M2 is that the first candidate cartel is engaged in efficient collusion, but that other firms in the industry are competitive. Model M3 is that the second candidate cartel engages in bid rigging. The costs $c_i$ can be estimated under each of these three alternatives using the empirical analogue of eq. (9). The different models generate different first-order conditions and hence, different estimated costs, $c_i$.

Bajari and Ye then ask which set of markups is ‘most reasonable’. To answer this question, they consulted with two managers at one of the biggest firms in this market (which was not in a candidate cartel). From each manager, they elicited their beliefs about the distribution of markups in this industry. Bajari and Ye argue that it is reasonable to suppose that these managers have informative priors about markups for two reasons. First, all bidders in this industry must be bonded. The bonding companies are contractually liable to complete the project if the contractors go bankrupt. Contractors are typically required to give weekly profit and loss statements to the bonding companies. The bonding companies are therefore well informed about profit margins for firms in the industry. Profit margins in the industry are a common topic of conversation between contractors and bonding companies and are one source of information.

Second, the contractors in this industry compete against each other quite frequently and over many years. The contractors have access to similar cost information and study the bids of competing contractors in detail after the bids are publicly opened. Given that contractors closely follow cost conditions and bids in the industry, they will have a lot of information about their competitors’ markups. There is an issue, of course, about whether the contractors would lie about their beliefs. However, Bajari and Ye shared their estimates with the contractor, which included empirical analysis of the behaviour of competing firms. Lying about the industry would reduce the value of these estimates. Also, the information from the contractor that was verifiable from external sources about the industry did seem to be accurately reported.

The stated beliefs of the experts were quite close. Below, we average the elicited beliefs from the contractors:

\[
\begin{align*}
25\text{th percentile} &= 3\% \\
50\text{th percentile} &= 5\% \\
75\text{th percentile} &= 7\% \\
99\text{th percentile} &= 15%.
\end{align*}
\]

For example, the 25th percentile of the bids has a markup of three per cent and the median bid has a markup of five per cent.

Table 2 shows the estimated distribution of markups from the three alternative structural models, M1, M2 and M3.

**Distribution of markups under**

http://www.dictionaryofeconomics.com.proxy.library.csi...edu/article?id=pde2008_A000216&goto=e&result_number=74 2008-12-30 03:08
Bajari and Ye note that the markups under M1 (competitive bidding) correspond most closely to the elicited prior beliefs. The markups under models M2 and M3 seem to be too large, particularly on the tails. They argue that this is evidence against the collusive models since they generate markups that seem implausibly large compared to the beliefs of an informed party. Bajari and Ye formalize this intuition by posing the selection of M1, M2 or M3 as a problem in statistical decision theory. As the table above suggests, the competitive model M1 is most favoured. Therefore, they cautiously interpret the data as being consistent overall with non-collusive behaviour.

3 Conclusion

In this short survey, I have attempted to provide an overview of recent empirical papers concerning auctions. Many recent papers build on the pioneering work of Guerre, Perrigne and Vuong (2000). A key insight of this paper was that a first-price sealed-bid auction model can be simply estimated using a two-step procedure. In the first step, the economist flexibly estimates the empirical distribution of the bids. In the second step, the economist evaluates the empirical analogue of the first-order condition for utility maximization. The method of Guerre, Perrigne and Vuong estimates the structural primitives of the model without imposing ad hoc parametric restrictions. We also discussed two applications of these recently developed estimators. Hortaçsu (2002) studied bidding in Treasury auctions in Turkey. His model predicted that discriminatory auctions generate higher revenue than uniform price auctions. Bajari and Ye (2003) applied these methods to test for collusion in sealed-bid auctions. They applied these methods to searching for suspicious bidding patterns in a market where the largest firms had recently been sanctioned for collusion.

Auctions (Empirics)

Isabelle Perrigne and Quang Vuong
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The structural analysis of auction data relying on game theoretic models has undergone a tremendous development since the mid-1990s. This article reviews some important contributions for first-price and ascending auctions. It stresses identification of the structure and the development of tractable econometric methods, while addressing bidders’ asymmetry, common value, bidders’ risk aversion, endogenous entry, dynamic and multi-unit auctions as well as the choice of the reserve price and the auction mechanism. Various domains are studied, such as auctions of timber, gas lease, treasury bills, agricultural products, electricity and construction procurements.

Keywords

affiliated private value model; asymmetric information; auctions; Bayesian Nash equilibrium; bidding; collusion; game theory; log-normal distribution; maximum likelihood; maximum likelihood; nonlinear least squares; nonparametric estimation; nonparametric methods; reserve price; risk aversion

Article

Auctions and procurements are widely used market mechanisms for allocating public contracts, financial securities, agricultural products, natural resources, artwork, and electricity, to name a few commodities. Recent years have also witnessed the developments of auction websites and business-to-business auctions. In general, auctions have well-defined rules that can be captured by an economic model. Relying on the concept of the Bayesian Nash equilibrium, game theory has greatly contributed to the modelling of auctions, where a seller or buyer faces a limited number of bidders who behave strategically. The auction is typically an incomplete information game where the asymmetry of information between the seller/buyer and the bidders and among the bidders themselves plays a crucial role.

While auctions are largely used in economic life and data are rich and accessible, until recently the
empirical analysis of auction data has been confined to testing some predictions generated by game theoretic models. One influential example of the reduced form approach is the work by Porter and his coauthors on the role of private information in oil and gas auctions, as surveyed in Porter (1995). This approach has also been used to test for collusive behaviour in timber and milk auctions. Although important, this approach does not allow for policy evaluations that require knowledge of the informational structure of the game such as the choice of the reserve price and the auction mechanism that would generate greater revenue for the seller/buyer.

The structural approach addresses such questions by assuming that observed bids are the equilibrium bids of some auction model. Specifically, \( b_i = s_i(v_i) \) where \( b_i \) and \( v_i \) are bidder's \( i \) (observed) bid and (unobserved) private information, respectively, and \( s_i(\cdot) \) is bidder's \( i \) equilibrium strategy in the corresponding auction game. Bidders’ private information is assumed to be derived from some distribution that is common knowledge to all bidders. This distribution and the bidders’ preferences are the key elements that explain bidding behaviour. They are the structural elements of the induced econometric model for the observed bids. The structural approach then exploits the equilibrium relations \( b_i = s_i(v_i) \) to recover bidders’ private information, which can be exploited for policy purposes. A major difficulty in implementing this approach arises from the numerical complexity or the implicit form of the equilibrium strategies. Of its nature, the structural approach raises challenging questions. One question is related to identification, namely, whether the auction structure can be uniquely recovered from observables while minimizing parametric restrictions. This question relates to whether auction models can be distinguished from observables. A second question concerns the model validity, namely, whether an auction model imposes testable restrictions on observables. A third difficulty is to develop tractable estimation methods. Since ascending (English) auctions and first-price sealed-bid auctions involve different equilibrium strategies and different identification and estimation problems, they are treated separately.

**Econometrics of first-price auctions and applications**

Two kinds of methods can be distinguished. Direct methods start from a parameterization of the private information distribution \( F(\cdot) \) and sometimes require the computation of equilibrium strategies. Indirect methods exploit the first-order condition(s) to estimate \( F(\cdot) \) from the observed bid distribution without computing the equilibrium strategies. Direct methods require explicit forms for the equilibrium strategies, while indirect methods can be considered when no explicit form exists. The structural approach was initiated by Paarsch (1992) using a direct method to analyse tree planting contract auctions with symmetric bidders. If the latent distribution is parameterized as \( F(\cdot; \theta) \), then \( b_i = s(v_i; \theta) \), which is distributed as \( \mathcal{G}(\cdot; \theta) = F[s^{-1}(\cdot; \theta); \theta] \). This raises two difficulties. First, a limited number of distributions lead to tractable equilibrium strategies. Second, the standard regularity conditions of maximum likelihood (ML) estimation are violated because the bid distribution support depends on \( \theta \). Paarsch and coauthors have extended ML estimation to this problem. Laffont, Ossard and Vuong (1995) propose an alternative direct method based on simulations while analysing Dutch auctions of vegetables. This method allows a large family of distributions to be entertained. It exploits the revenue equivalence theorem for independent private value models to write the expectation \( m_g(\theta) \) of the winning bid in a Dutch auction as the expectation of the second highest value. The authors develop a simulated nonlinear
least squares estimator based on minimizing \( Q_L(\theta) = (1 / L) \sum_{j=1}^{L} [b_j^w - m_\theta(\theta)] \), where \( m_\theta(\theta) \) is replaced by a simulator, \( L \) is the number of auctions and \( b^w \) is the winning bid, while correcting for its inconsistency. This idea has been extended by others when the expected winning bid can be simulated. This limits the number of models to be considered. Bayesian estimation methods, though computationally demanding, have also been developed.

In contrast, the indirect method initiated by Guerre, Perrigne and Vuong (2000) requires neither the computation nor the simulation of equilibrium strategies. It uses the differential equation (s) or first-order condition(s) to express each private value as a function of its corresponding bid. Within the symmetric independent private value paradigm, the differential equation is

\[
s'(v_j) = [v_j - s(v_j)] (l - 1) [f(v_j) / F(v_j)],
\]

where \( I \) is the (known) number of bidders, \( s'(\cdot) \) is the derivative of \( s(\cdot) \) and \( f(\cdot) \) is the private value density. Because \( b_i = s(v_i) \), bids are also i.i.d. with \( G(b) = F[s^{-1}(b)] = F(v) \) leading to \( g(b) = f(v) / s'(v) \). Hence, the differential equation can be written as

\[
v_j = b_j + \frac{1}{l - 1} \frac{G(b_j)}{g(b_j)} \equiv \xi(b_j, G, l).
\]

Relying on (1), the authors show that the model is nonparametrically identified: that is, one can recover uniquely the distribution \( F(\cdot) \) from the observed bid distribution without parametric restrictions. Moreover, they derive the restrictions imposed by the model on observables: that is, bids must be i.i.d. (since private values are i.i.d.) and \( \xi(\cdot) \) should be strictly increasing (since \( s(\cdot) \) is strictly increasing). These two restrictions can be used to test the validity of the model. Equation (1) calls for a two-step estimation procedure. The first step consists in estimating nonparametrically \( G(\cdot) \) and \( g(\cdot) \), while the second step estimates nonparametrically \( f(\cdot) \) from the estimated private values \( \hat{v}_i \) using (1). In practice, auctioned goods are heterogeneous. Observed characteristics can be introduced in the econometric model by writing (1) with conditional bid distribution and density. Nonparametric estimation can be a drawback when a limited number of auctions is available and/or when the number of exogenous variables is relatively large. It can, however, provide a preliminary estimate of the underlying density, which can be used later to specify \( F(\cdot) \) when using a parametric two-step estimation procedure. In addition to not parameterizing \( F(\cdot) \), the indirect method does not require an explicit form for the equilibrium strategy, as it relies on the first-order condition(s). The method provides key insights on questions at the core of the structural approach, as discussed above. It can be easily extended to the case of a binding reserve price, where the number of actual (observed) bidders is smaller than the number \( I \) of potential bidders as only bidders with private values above the reserve price effectively participate.

Alternatively, the seller may not announce his reserve price, keeping it secret as in timber and wine auctions. Although the equilibrium strategy in such a model does not have an explicit form, the above method allows a simple expression to be obtained for the inverse equilibrium strategy, which can be
used to develop a two-step estimation procedure as above. Likewise, the method can be easily extended to situations in which only the winning bids are observed, as in Dutch auctions, which are widely used for agricultural products such as vegetables and flowers.

Independence among private values can be restrictive. One can expect some affiliation or positive correlation among private values and some common value $\nu$ affecting all bidders’ utilities, that is, bidder's $i$ utility becomes $V_i = U(\sigma_i, \nu)$. In the private value paradigm $V_i = \sigma_i$, while in the pure common value paradigm $V_i = \nu$. The vector $(\sigma_1, \ldots, \sigma_b, \nu)$ is distributed as $F(\cdot, \ldots, \cdot)$, which is affiliated and exchangeable in its first $I$ arguments under bidders’ symmetry. Affiliation means that, if one bidder values the auctioned object highly, other bidders are also likely to value it highly. In the common-value model bidders receive signals about the value of the object, which is unknown at the time of the auction. This model has been widely used to explain bidding behaviour in gas lease auctions where firms have imperfect information about the amount of oil. The general framework is considered by Laffont and Vuong (1996), who study the problem of identification and theoretical restrictions. They show that any symmetric affiliated value model is observationally equivalent to some symmetric affiliated private value (APV) model because $U(\cdot)$ is unidentified, as any dependence across utilities arising from $\nu$ can be replaced by a dependence among private values. Similarly, the pure common value is unidentified from observed bids. If some additional information is available, such as the ex post common value, identification can be achieved. On the other hand, the symmetric APV model is identified.

Regarding estimation, a two-step estimation procedure can be developed. Let $B_1 = S(V_1)$ with $V_1 = \max j \neq i \sigma_j$. When $V_i = \sigma_i$, (1) becomes

$$V_i = \sigma_i + \frac{G_{B_1|b_1}(b_i|b_i)}{G_{B_1|b_1}(b_i|b_i)} \equiv \xi(b_i, G).$$

(2)

Regarding theoretical restrictions, $\xi(\cdot)$ needs to be strictly increasing and the bid distribution $G(\cdot, \ldots, \cdot)$ must be affiliated and exchangeable. An interpretation of the APV model is that affiliation arises from some latent variable $\nu$. Building on this interpretation, Li, Perrigne and Vuong (2000) propose a model with private information conditionally independent upon some common component. Specifically, each piece of private information is the product of two unobserved independent components, one specific to the auctioned object and common to all bidders, the other specific to each bidder, that is, $\sigma_i = \nu \eta_i$. Hence, $\log \sigma_i = \log x + \log \varepsilon_i$ with $\log x = [\log \nu + E(\log \eta)]$ and $\log \varepsilon_i = [\log \eta_i - E(\log \eta)]$ showing that $\log \varepsilon_i$ can be interpreted as an error term in a measurement error model with $\log x$ unobserved. Because the $V_i$ can be recovered from (2) when $V_i = \sigma_i$, the densities for $\log x$ and $\log \varepsilon$ are nonparametrically identified and estimated with the use of characteristic functions. When $V_i = \nu$, (2) gives $E[\nu \sigma_1 = \sigma, V_1 = \sigma]$. Under loglinearity of the latter, that is, $\log E[\nu \sigma_1 = \sigma, V_1 = \sigma] = C + D \log \sigma$, the pure common value model is identified up to location and scale. It is important to test whether a common value or private value paradigm is the more appropriate.
Recent developments exploit how $\mathbb{E} [\forall \sigma_1 = \sigma, \forall 1 = \sigma]$ varies with the number of bidders to formulate such tests.

Several auction data provide evidence of bidders’ asymmetry, which can arise from, for example, different firms’ sizes, different access to information such as the drainage auctions, and different capacity constraints and locations as in construction procurements. Collusion may also lead to asymmetry as a cartel of bidders behaves differently from other bidders. Asymmetry is \textit{ex ante} known to all bidders. A common feature of asymmetric auction models is that they lead to intractable systems of differential equations. Hence, the direct approach is difficult to implement as it requires the numerical determination of the equilibrium strategies for any trial parameter value. Let $F_1(\cdot), \ldots, F_l(\cdot)$ be the private value distributions of the $I$ bidders whose identities are observed. For simplification, independent private values are considered, though the method can be easily extended to affiliated private values. Let $G_1(\cdot), \ldots, G_l(\cdot)$ be the corresponding bid distributions. The intractable system of differential equations can be rewritten as

$$
\nu_i = b_i + \frac{1}{\sum_{j \neq i} \frac{G_j(b_j)}{G_j(b_i)}}, \quad i = 1, \ldots, l.
$$

This method has been used to analyse joint bidding in gas lease auctions and snow removal procurements, where asymmetry arises from a firm’s location relative to contract location. Bidders’ risk neutrality is often assumed because the value of the object is small relative to bidders’ assets. Recent studies have suggested that bidders may be risk averse in timber auctions. The experimental literature has noted a tendency to bid above the Bayesian Nash equilibrium, which can be rationalized by risk aversion. In a private value framework, the bidder’s utility becomes $U(\nu_i - b_i)$ with $U(\cdot)$ strictly increasing and concave. Campo et al. (2006) study the identification and estimation of risk aversion. Using an indirect approach and omitting wealth to simplify, the differential equation defining the equilibrium strategy becomes

$$
\nu_i = b_i + \lambda^{-1} \left( \frac{1}{l-1} \frac{G(b_i)}{g(b_i)} \right) = \xi(b_i, U, \theta, \lambda),
$$

where $\lambda^{-1}(\cdot)$ denotes the inverse of $\lambda(\cdot) = U(\cdot) / U'(\cdot)$. The model is not identified only from observed bids. In fact, any bid distribution can be rationalized by a constant relative or absolute risk aversion model. Additional restrictions, such as parameterizing either the utility function or the private value distribution, are not sufficient to identify the model as an increase in the risk aversion parameter.
can be compensated by a shrinkage of all the quantiles of $F(\cdot)$. Consequently, the authors parameterize a single quantile of $F(\cdot)$ to achieve identification of the model while exploiting auction heterogeneity.

Under parameterization of $U(\cdot)$ and a conditional quantile, (4) at any quantile provides an estimating equation for the parameters of the utility function and the quantile of $F(\cdot)$. The method can be easily extended to affiliated private values and bidders’ asymmetry in private values. Alternatively, if the number of bidders is exogenous, that is, $F(\cdot)$ is independent of $I$, nonparametric identification can be achieved. More generally, exclusion restrictions help in identifying the model. Regarding asymmetry, bidders may have heterogeneous preferences, that is, they may have different attitudes towards risk given their assets, experience, and so on. Thus, (4) evaluated at any quantile for two different bidders provides additional identifying restrictions since the corresponding quantile of $F(\cdot)$ is equal.

Construction procurement data show that firms with more experience tend to be less risk averse. Risk aversion has important implications for several policy issues including the announcement of the reserve price and the auction format. These results allow more advanced auction models to be considered, in which risk aversion plays a key role. Examples includes stochastic values when uncertainties affect bidders’ ex post value and financially constrained bidders.

Identical commodities such as treasury bills and electricity are sold sometimes through multi-unit auctions. A bidder acquires a share of the quantity supplied. Each bidder submits several (quantity, price) pairs. Hortaçsu (2002) studies discriminatory share auctions of treasury bills while considering private values in light of empirical evidence. Each bidder strategy is a demand function $\nu(\rho, \sigma_i)$ where $\sigma_i$ is bidder’s $i$ private information. The clearing price $P_c$ equates the bidder’s demand function with the residual supply curve $Q - \sum_{j \neq i} \nu(\rho, \sigma_j)$, where $Q$ is the total supply. Let $G(\rho, x)$ be the distribution of the residual supply faced by bidder $i$ at price $\rho$ given $\nu(\rho, \sigma_i) = x$, that is,

$$G(\rho, x) = \Pr[x \leq Q - \sum_{j \neq i} \nu(\rho, \sigma_j) | \nu(\rho, \sigma_i) = x] = \Pr[P_c \leq \rho | \nu(\rho, \sigma_i) = x].$$

The optimal bid $p$ for the quantity $\nu(\rho, \sigma_i)$ is

$$\nu[\nu(\rho, \sigma_i), \sigma_i] = \rho + \frac{G(\rho, \nu(\rho, \sigma_i)}{\partial G(\rho, \nu(\rho, \sigma_i)) / \partial \rho},$$

where $\nu[\nu(\rho, \sigma_i), \sigma_i]$ is bidder’s $i$ marginal utility from winning the $\nu(\rho, \sigma_i)$th unit. With the use of a re-sampling strategy to estimate $G(\cdot, \cdot)$, the results are used to compare the discriminatory price mechanism with the uniform price mechanism. The problems of identification of the private information distribution and the restrictions imposed by the model on observables remain to be solved. This method has also been applied to electricity auctions.

The preceding developments ignore dynamic considerations, while bidders frequently participate in several auctions over time. Jofre-Bonet and Pesendorfer (2003) consider a dynamic auction to analyse highway construction procurements where previously won uncompleted contracts introduce capacity constraints affecting firms’ actual costs. This involves inter-temporal optimization, while introducing asymmetry among bidders arising from different capacity constraints, location and size. If we use an
indirect approach, the inverse equilibrium strategies solve

\[
c_i = b_i - \frac{1}{\sum_{j \neq i} g_j(b_j)} + \beta \sum_{j \neq i} \frac{g_j(b_j)}{1 - C_j(b_j)} \left[ V_j(\omega(i)) - V_j(\omega(j)) \right], i = 1, \ldots, l,
\]

where \( \beta \) is a discount factor, \( \omega(i) \) is a transition function indicating the sizes and remaining times of all current projects for bidder \( i \), \( V_j(\cdot) \) is the value function determining the discounted sum of expected future profits. The system (5) is similar to (3) with cost \( c_i \) and \( 1 - C_j(\cdot) \) as the firm with the lowest bid wins the procurement. Because the value function can be written as a function of the bid distributions, identification comes down to whether the cost distributions and the discount factor can be uniquely recovered from observed bids. Identification is obtained when the discount factor is known. Relying on standard numerical methods to approximate the value function, a two-step parametric procedure allows us to estimate the cost distributions \( F_1(\cdot), \ldots, F_l(\cdot) \).

Econometrics of ascending auctions and applications

In the private value paradigm, a dominant strategy for every bidder is to exit the auction at his valuation. The bidding process ends when a single bidder remains. In the button auction model, the winning bid can be interpreted as the second highest among \( I \) values. Athey and Haile (2002) study identification of ascending auctions while emphasizing data requirements. When private values are independent and the number of bidders is observed, the transaction price is the \((I-1)\)th order statistic \( \nu^{(I-1)} \) whose distribution is

\[
F^{(I-1):\nu}(\nu) = \frac{\nu}{(I-2)!} \int_0^{F(\nu)} t^{I-2}(1-t) dt,
\]

from which the distribution \( F(\nu) \) is recovered. When bidders are asymmetric and bidders’ identities are known, a similar argument can be used to show that \( F_1(\cdot), \ldots, F_l(\cdot) \) are identified. Nonparametric estimation can be performed. The problem becomes complicated when one considers more general frameworks. When private values are affiliated, the winning bid is not sufficient to recover affiliation among bids and hence \( F(\cdot, \ldots, \cdot) \). Additional observations are needed. However, many ascending auctions do not match the button auction model. In practice, bidders do not continuously indicate whether they are still participating. Moreover, because bid increments are often
used, bidders may fail to reveal their willingness to pay or even to bid. In the empirical literature it is agreed that, at most, the winning bid can be rationalized by the ascending auction model. An alternative approach is proposed by Haile and Tamer (2003), who formulate an incomplete model based on two simple assumptions: (a) bidders do not bid more than they are willing to pay; and (b) bidders do not allow an opponent to win at a price they can beat. These assumptions do not allow us to identify the private value distribution but provide some bounds on this distribution. Assumption (a) implies

$$b^{(i)} \leq v^{(i)}$$

or equivalently

$$F^{(i)}(v) \leq \mathcal{C}^{(i)}(v)$$

for \(i = 1, ..., l\). This inequality is used to construct the upper bound for \(F(\cdot)\) as

$$F^U(v) = \min_{i,l} \mathcal{C}^{(i)}(v; i, l),$$

where \(\varphi(\cdot)\) is a strictly increasing function defined as

$$F(v) = \varphi \left[ F^{(i)}(v); i, l \right].$$

Assumption (b) implies that all losing bidders have valuations no higher than the winning bid plus a bid increment \(\Delta\), i.e.

$$v_i \leq b^{(i)} + \Delta \text{ if } b_j < b^{(i)}.$$ 

Let \(\mathcal{C}_\Delta^{(i)}(\cdot)\) be the distribution of \(b^{(i)} + \Delta\). Thus

$$\mathcal{C}_\Delta^{(i)}(v) \leq F^{(l-1)}(v),$$

which is used to construct the lower bound for \(F(\cdot)\) as

$$F^L(v) = \max_{l} \mathcal{C}_\Delta^{(i)}(v; l-1, l).$$

Nonparametric estimation of \(F^U(\cdot)\) and \(F^L(\cdot)\) is proposed. Tight estimated bounds suggest that the data do not deviate much from the button auction model. Bounds for the optimal reserve price can also be derived. The method is illustrated on timber auction data, and can be extended to affiliated private values and asymmetric bidders.

In a common value paradigm, bidding takes a more complex form as bidders obtain information during the auction when their rivals drop out. The auction can be modelled as a game with several rounds with \(l-1\) rounds indexed by \(k = 0, 1, ..., l-2\). Bidders are indexed in the inverse order of their dropping out. Each bidder observes a signal \(\sigma_i\) of his value \(v_i\). An interesting feature of the ascending common value auction is that bidder's \(j\) dropping out is useful to bidder \(i\) for evaluating his own \(v_i\). In this game, every bidder has \(l-1\) bidding functions \(s_{ik}(\cdot), k = 0, ..., l-2\). With asymmetric bidders, the equilibrium bid functions at round \(k\) are given by

$$s_{ik}(\sigma_j) = E[v_j|\sigma_i; \sigma_j = s_{jk}^{-1}(s_{ik}(\sigma_j)), j = 1, ..., l-k, j \neq i, \Omega_k], i = 1, ..., l-k,$$
where \( \Omega_k = \{ \sigma_j = s_{j, l-j}^{-1}(P_{l-j}), \ j = l - k + 1, \ldots, l \} \) is the public information set containing the observed signals of the bidders who have dropped out prior to round \( k \) and \( P_k \) is the (observed dropping out) price. Thus, at round \( k \) the \( l - k \) inverse bidding strategies are solutions of the system of nonlinear equations

\[
P_k = E[\nu_i|\sigma_i = s_{ik}^{-1}(P_k); \sigma_j = s_{jk}^{-1}(P_k), j = 1, \ldots, l - k, j \neq i, \Omega_k].
\]

(6)

Using log-normal distributions and a multiplicative form for \( \nu_i \) and \( \sigma_i \), Hong and Shum (2003) develop a tractable econometric model based on (6) that is estimated by either maximum likelihood or simulated nonlinear least squares. An illustration of the method is proposed on spectrum auctions which are organized in multiple rounds.

The recent development of auction websites provides new data opportunities. Bajari and Hortaçsu (2003) analyse coin auctions within a common value framework in light of resale opportunities, while bidders face an entry cost leading to endogenous entry. Another interesting characteristic is that the reserve price can be either posted or secret. As is well known, bidding activity is concentrated at the very end of the auction. The authors show that this practice, known as ‘sniping’, can be explained by a two-stage game in which no bidding is an equilibrium in the first stage, while second stage bids are the equilibrium bids in a sealed-bid second-price auction. Empirical results show that bidders’ entry increases with a secret reserve price.

**Concluding remarks**

The structural approach to analysing bidding data has been a field of extremely active research in the recent years. It has also contributed to the development of new econometric techniques. Many interesting problems remain to be addressed. Since auction models can be viewed as simple forms of asymmetric information, one can expect that more progress will be made in the analysis of complex asymmetric information models such as contracts.

Experiments permit rigorous investigations of auction theory generating a dialogue with theorists and policymakers. In single-unit private value auctions the revenue equivalence theorem fails, but the comparative static predictions of Nash bidding theory hold, indicating that bidders are responsive to the primary economic forces present in the theory. In single-unit common value auctions inexperienced bidders invariably suffer from a ‘winner's curse’, and the comparative static predictions of the theory fail, but more experienced bidders do substantially better. Recent research dealing with Internet auctions, mixed private and common value auctions and multi-unit demand auctions are surveyed as well.

Article
Experimental work in auctions interacts with theory, providing a basis for testing and modifying theoretical developments. It has advantages and disadvantages relative to empirical work with field data, so that we view the two as complimentary. Experimental work is used increasingly as a test bed for new auction formats such as the Federal Communication Commission's (FCC) sale of spectrum (air-wave) rights. Until recently most of theoretical and experimental work was devoted to single-unit demand auctions. With the success of the FCC's spectrum auctions, much of the interest has shifted to auctions in which...
individual bidders demand multiple units. Experimental work in this area is still in its infancy. In keeping with the historical development of the field, we first report on single-unit demand auctions and then move to multi-unit demand auctions and Internet auctions.

**Single-unit, private-value auctions**

Initial experimental research on auctions focused on the independent private values (IPV) model investigating the revenue equivalence theorem. In the IPV model each bidder knows his valuation of the item with certainty, bidders’ valuations are drawn identically and independently from each other, and bidders know the distribution from which their rivals’ values are drawn (but not their values) and the number of bidders. Under the revenue equivalence theorem the four main auction formats – first- and second-price sealed-bid auctions, English and Dutch auctions – yield the same average revenue for risk neutral bidders. Further, first-price sealed-bid and Dutch auctions are theoretically isomorphic – they yield the same revenue for each auction trial regardless of risk preferences – as are second-price sealed-bid and English clock auctions. These isomorphisms are particularly attractive as it is hard to control bidders’ risk preferences. These theoretical results are also quite surprising and counter-intuitive as the Dutch auction starts with a high price which is lowered until a bidder accepts at that price. And in the English auctions the price starts low and increases until only one bidder is left standing and pays the price where the next-to-last bidder dropped out; while in a first- (second-) price sealed-bid auction the high bidder wins the item and pays the highest (second-highest) bid.

An experimental session typically consists of 20–40 auction periods under a given auction institution. Subjects’ valuations are determined randomly prior to each auction period (by the experimenter) and are private information. Valuations are typically independent and identical draws (i.i.d) from a uniform distribution. In each period the high bidder earns a profit equal to his value less the auction price; other bidders earn zero profit. Bids are commonly restricted to be non-negative and rounded to the nearest penny. Theory does not specify what information feedback bidders ought to get after each auction. Although such information is unimportant in a one-shot auction, it may be important, even critical, to learning given that experimental sessions typically consist of a number of auction periods. Information feedback usually differs between different experimenters, with almost all experimenters reporting back the auction price to all bidders and own earnings to the winning bidder.

Strategic equivalence usually fails between the relevant auction formats: Coppinger, Smith and Titus (1980) and Cox, Roberson and Smith (1982) found higher prices in first-price than in Dutch auctions (about five per cent higher) with these differences holding across auctions with different numbers of bidders. Further, bidding was significantly above the risk-neutral Nash equilibrium (RNNE) in the first-price auctions for all numbers of bidders $n\geq 3$, which is consistent with risk-averse bidders.

Kagel, Harstad and Levin (1987) reported failures of strategic equivalence in second-price and English clock auctions, with winning bids in the second-price auctions averaging 11 per cent above the predicted equilibrium price. In contrast, market prices converge rapidly to the predicted equilibrium in the clock auctions. Bidding above value in second-price auctions is widespread, with 62 per cent of all bids above values, 30 per cent of all bids essentially equal to value (within five cents of it), and eight per cent of all bids below it (Kagel and Levin, 1993). (In clock auctions price rises by fixed increments with bidders counted as active until they drop out – and are not permitted to re-enter the auction. This format insures
clear information flows as a consequence of announcing irrevocable drop-out prices.) Bidding above value in second-price auctions is attributable to a number of factors: (a) it is sustainable since average profits are positive, (b) figuring out the dominant strategy is not that obvious, and (c) the feedback from losses that would promote the dominant bidding strategy is weak (Kagel, Harstad and Levin, 1987). Subsequent research generalizes the superiority of the (dynamic) clock auction format compared to the (static) sealed-bid format to Vickrey-style auctions in which bidders demand multiple units. The closer conformity to equilibrium outcomes in the clock auctions results from the clock format in conjunction with bidders knowing that the auction ends when the next-to-last bidder drops out. This induces bidders to remain active as long as the clock price is less than their value (as they have nothing to lose by remaining active and might win the item) and to drop out once the price is greater than their value (as they will lose money for sure should they win the item) (Kagel and Levin, 2006).

Efficiency in private value auctions can be measured by the percentage of auctions won by the high-value holder. In Cox, Roberson and Smith (1982) 88 per cent of the first-price auctions were Pareto efficient compared with 80 per cent of the Dutch auctions. In contrast, efficiency in first- and second-price auctions may be quite comparable; for example, 82 per cent of the first-price auctions and 79 per cent of the second-price auctions reported in Kagel and Levin (1993) were Pareto efficient. More work needs to be devoted to comparing efficiency across auction institutions.

A number of papers have explored bidding above the RNNE in first-price sealed-bid auctions, questioning the risk-aversion interpretation. This has generated some heated debate (see the December 1992 issue of the American Economic Review). Isaac and James (2000) compare estimates of risk preferences from first-price auctions with estimates using the Becker–DeGroot–Marshall (BDM) procedure for comparably risky choices. The Spearman rank–correlation coefficient between individual subject risk parameters is significantly negatively correlated under the two procedures. Subjects whose bids in the first-price auction are relatively risk neutral remain risk neutral under BDM, but those who are relatively risk averse in the first-price auction become relatively risk loving under BDM. The net result is that aggregate measures of risk preferences show that bidders are risk averse in the first-price auction but risk neutral, or moderately risk loving, under the BDM procedure. Although it is well known from the psychology literature that different elicitation procedures will yield somewhat different quantitative predictions, a negative correlation between measures seems rather astonishing. (See Dorsey and Razzolini, 2003, for a similar investigation.)

Neugebauer and Selten (2006) compare treatments with different information feedback: (i) a bidder only learns if s/he won the auction or not, (ii) the winning bid (market price) is revealed to bidders whether they win or not; and (iii) the winning bid is revealed to bidders and the winner learns the second highest bid as well. They find that average bids are highest under treatment (ii) and exceed the RNNE for every given market size. In contrast, bidding above the RNNE does not occur consistently, or is not as strong, in the other two treatments. They use ‘learning direction theory’ to argue that the information feedback in (ii) promotes bidding above the RNNE. However, the result for treatment (iii) contrasts with results from Kagel, Harstad and Levin (1987) and Dyer, Kagel and Levin (1989a), who find consistent bidding above the RNNE when providing bidders with all bids and valuations following each auction. Perhaps the best conclusion at this point is that subjects typically act ‘as if’ they are risk averse in first-price auctions, while the underlying basis of their behaviour remains open to interpretation.

In spite of the reported deviations from equilibrium outcomes reported above, the comparative static
Implications of the IPV model tend to hold (albeit with varying levels of noise). Bidding in first-price auctions increases regularly in response to increased numbers of bidders. For example, in a series of first-price sealed-bid auctions, 86 per cent of subjects increased their bids when the number of bidders increased from five to ten, with the majority of these increases (60 per cent) being statistically significant, with no subjects decreasing their bids by a statistically significant amount (Battalio, Kogut and Meyer, 1990). More aggressive bidding in response to increased numbers of rivals would seem to be a natural reaction, and can be rationalized by plausible ad hoc rules of thumb.

Kagel and Levin (1993) provide a more stringent test of the comparative static implications of the IPV model using a third-price auction in which the high bidder wins the item and pays the third-highest bid. In this case the model predicts that bids will be above values and will be reduced in response to increases in \( n \). They find that 85–90 per cent of all bids are above value compared with 58–67 per cent in second-price auctions and less than 0.5 per cent in first-price auctions. Further, comparing auctions with \( n=5 \) and \( n=10 \) (i) in first-price auctions all bidders increased their bids on average (average increase of $0.65 per auction; \( p < .01 \)), (ii) in second-price auctions the majority of bidders did not change their bids on average (average decrease of $0.04; \( p > .10 \)), and (iii) in third-price auctions 46 per cent of all subjects decreased their bids on average (average decrease of $0.40 per auction; \( p < .05 \)). Even stronger qualitative support for the theory is reported when the calculations are restricted to valuations lying in the top half of the domain of valuations (where bidders have a realistic chance of winning and might be expected to take bidding more seriously). Thus, although a number of bidders in third-price auctions clearly err in response to increased numbers of rivals by increasing, or not changing, their bids, the change in pricing rules has relatively large and statistically significant effects on bidders’ responses in the direction that Nash equilibrium bidding theory predicts. This experiment also illustrates one of the great strengths of the experimental method as there are no third-price auctions outside the lab, where it was developed for the explicit purpose of providing unusual, counter-intuitive predictions to use in testing the theory. The results are increased confidence in the fundamental ‘gravitational’ forces underlying the theory, in spite of violations of its point predictions. The latter could be the result of some uncontrolled factor impacting on behaviour and/or simple miscalibration on subjects’ part.

**Single-unit common value auctions**

In common value auctions (CVA) the value of the item is the same to all bidders. What makes common value auctions interesting is that bidders receive signals (estimates) that are correlated (affiliated) with the value of the item but they do not know its true value. Mineral rights auctions (for example, outer continental shelf – OCS – oil lease auctions) are usually modelled as a common value auction. There is a common value element to most auctions. Bidders for a painting may purchase it for their own pleasure, a private value element, but also for investment and eventual resale, the common value element. Experimental research on CVAs has focused on the ‘winner’s curse’. Although all bidders obtain unbiased estimates of the item's value, they typically win in cases where they have (one of) the highest signal value. Unless this adverse selection problem is accounted for, it will result in winning bids that are systematically too high, earning below normal or negative profits – a disequilibrium phenomenon. Oil companies claim they fell prey to the winner's curse in early OCS lease sales, with similar claims made in a variety of other settings (for example, free agency markets for professional athletes and...
corporate takeovers). Economists are naturally sceptical of such claims as they involve out-of-equilibrium play. Experiments clearly show the presence of a winner's curse for inexperienced bidders under a variety of circumstances and with different experimental subjects: average undergraduate or MBA students (Bazeramn and Samuelson, 1983; Kagel and Levin, 1986), extremely bright (Cal Tech) undergraduates (Lind and Plott, 1991), experienced professionals in a laboratory setting (Dyer, Kagel and Levin, 1989b), and auctions in which it is common knowledge that one bidder knows, with certainty, the value of the item (Kagel and Levin, 1999). Further, these deviations from equilibrium predictions cannot be explained by simple miscalibration on bidders’ part as the theory's comparative static implications are systematically violated when bidders suffer from a winner's curse; for example, bidder responses to additional information or increased numbers of rivals.

Kagel et al. (1989) find that inexperienced bidders suffer a pervasive winner's curse in first-price, sealed-bid auctions. For the first nine auctions, profits averaged minus $2.57 compared with the RNNE prediction of $1.90, with only 17 per cent of all auctions having positive profits. This is not a simple matter of bad luck as 59 per cent of all bids, and 82 per cent of the high bids, were above the expected value of the item conditional on winning the auction. Although public information in first-price auctions is predicted to raise sellers’ revenue, it reduces it for inexperienced bidders as subjects use the public information to help overcome the winner's curse (Kagel and Levin, 1986). Similarly, ‘public information’ reduces revenue in English clock auctions when bidders suffer from a winner's curse (Levin, Kagel and Richard, 1996). Further, experienced bidders appear to adjust to the winner's curse through a ‘hot stove’ learning process: with the losses, bids are lowered and losses are mitigated, or eliminated, but there is no real understanding of the adverse selection problem. For example, an increase in $n$ generates higher individual bids, although theory predicts a slight reduction (Kagel and Levin, 1986). Efforts to explain the winner's curse in terms of limited liability for losses and/or the ‘joy of winning’ fail as well (Kagel and Levin, 1991; Holt and Sherman, 1994). In short, inexperienced subjects do not perform well in pure common value auctions.

Experienced subjects learn to overcome the worst effects of the winner's curse, earning positive average profits. But these rarely exceed 65 per cent of the RNNE profit, and virtually all subjects are not best responding to their rivals’ overly aggressive bids (Kagel and Richard, 2001). However, once bidders overcome the worst effects of the winner's curse, public information raises sellers’ revenue, English auctions raise more revenue than sealed-bid auctions, and a number of other comparative static implications of the theory are satisfied as well (Kagel and Levin, 2002). Experienced bidders learn to overcome the winner's curse through a combination of individual learning and market selection process whereby bankrupt bidders self-select out of further experimental sessions. Ability as measured by composite SAT/ACT scores (standardized college entrance exam scores) matters in terms of avoiding the winner's curse, with the biggest and most consistent impact resulting from those with below median scores being more susceptible to the winner's curse. Economics and business majors consistently bid more aggressively than others (thus, lose more), and women, at least initially, are much more susceptible to a winner's curse than men. However, there is still a winner's curse even for the best-calibrated demographic and ability groups (Casari, Ham and Kagel, 2007).

Experiments combining common-value and private-value elements
Goeree and Offerman (2002) provide the only experimental study to date in which the object's expected value depends on both private and common value elements. (The difficulty here is in combining private and common value information into a single statistic that maps into a bid.) Actual bids lie in between the RNNE benchmark of fully rational bidding and the naive benchmark in which subjects completely fail to account for the winner's curse. The winner's curse effect is more pronounced the less important a bidder's private value is relative to the common value. Realized efficiency is roughly at the level predicted under the RNNE, with the winner's curse only raising seller revenue and cutting into bidder profits. This occurs because (a) almost all bidders suffer from a winner's curse and (b) the degree of suffering is roughly the same across bidders, so that the size of the private value element serves to dictate who wins the item.

In an almost common value auction one bidder, the advantaged bidder, has an added private value for the item, unlike all the other (regular) bidders who care only about the common value. With only two bidders, even a tiny private value advantage is predicted to have an explosive effect in second-price sealed-bid auctions: the advantaged bidder always wins and revenue decreases dramatically as the regular bidder lowers her bid to protect against a winner's curse. This effect extends to a variety of English auctions that start with more than two bidders, raising serious concerns about the English auction format (Klemperer, 1998). Three experiments have looked at almost common value auctions using both second-price sealed-bid and clock auctions (Avery and Kagel, 1997; Rose and Levin, 2005; and Rose and Kagel, 2005). In all cases the response to the private value advantage has been proportional rather than explosive. This is true even with experienced bidders who earn a respectable share of RNNE profits in pure common value first-price and clock auctions (Rose and Kagel, 2005). The apparent reason for these failures is that bidders do not fully appreciate the adverse selection effect conditional on winning, which is exacerbated for regular bidders with an advantaged rival. As such, the behavioural mechanism underlying the explosive effect is not present, and there are no forces at work to replace it.

Internet auctions

Internet auctions provide new opportunities to conduct experiments to study old and new puzzles. Lucking-Reiley (1999) has used the Internet to sell collectable trading cards under the four standard auction formats, testing the revenue equivalence theorem. He finds that Dutch auctions produce 30 per cent higher revenue than first-price auctions, a reversal of previous laboratory results, and that English and second-price auctions produce roughly equivalent revenue. These results are interesting but lack the controls present in more standard laboratory experiments; that is, there may well be a common value element to the trading cards, and Dutch auctions provide an opportunity to use the game cards immediately, which cannot be done until the fixed closing date in the first-price auctions. Garratt, Walker and Wooders (2004) conduct a second-price auction, recruiting subjects with substantial experience bidding on eBay. Using induced valuations, they find that average bids are close to valuations, but those with prior experience as sellers tend to underbid and those with prior experience as buyers tend to overbid.

In eBay auctions which have a fixed closing time many bidders snipe (submit bids seconds before the closing time), while other bidders increase their bids over time in response to higher bids. This seems
puzzling since eBay has a number of characteristics similar to a second-price auction. In addition, there is substantially more last-minute bidding for comparable (private-value) items in eBay than in Amazon auctions, which automatically extend the deadline in response to last-minute bids. Roth and Ockenfels (2002) argue that sniping results from the fixed deadline in eBay, suggesting at least two rational reasons for sniping. Because there are differences between eBay and Amazon other than their ending rules, they conduct a laboratory experiment in which the only difference between auction institutions is the ending rule—a dynamic eBay auction with a .8 (1.0) probability that a late bid will be accepted (eBay.8 and eBay1, respectively) and an Amazon-style auction with a .8 probability that a late bid will be accepted, in which case the auction is automatically extended (Ariely, Ockenfels and Roth, 2005). The results show quite clearly that there is more late bidding in both eBay auctions than in the Amazon auction. Further, there is significantly more late bidding in eBay1 than in eBay.8, which at least rules out one possible rational explanation for sniping—implicit collusion on the part of snipers in an effort to get the item at rock-bottom prices since not all last-minute bids will be recorded (due to congestion) at the website.

Salmon and Wilson (2008) investigate the Internet practice of second-chance offers to non-winning bidders when selling multiple (identical) items. They compare a two-stage game with a second-price auction followed by an ultimatum game between the seller and the second-highest bidder with a sequential English auction. As predicted, the auction-ultimatum game mechanism generates more revenue than the sequential English auction.

Multi-unit demand auctions

Most of the work on multi-unit demand auctions has been devoted to mechanism design issues, in particular dealing with problems created by complementarities, or synergies, between items. Absent package bidding, the latter can create an ‘exposure’ problem whereby efficient outcomes require submitting bids above the stand-alone values for individual units since the value of the package is more than the sum of the individual values. Correcting for this problem by permitting package bids increases the complexity of the auction significantly, and creates a ‘threshold’ problem whereby ‘small’ bidders (for example, those with only local markets) could, in combination, potentially outbid a large competitor who can internalize the complementarities. But the small bidders have no means to coordinate their bids. Leading examples of this line of research are Porter et al. (2003), Kwasnica et al. (2005), and Goeree, Holt and Ledyard (2006). Much more work remains to be done in this area.

Goeree, J.K. and Offerman, T. 2002. Efficiency in auctions with private and common values: an

**How to cite this article**

Auctions occupy a deservedly prominent place within microeconomics and game theory, for at least three reasons.

First, the auction is, in its own right, an important device for trade. Auctions have long been a common way of selling diverse items such as works of art and government securities. In recent years, their
importance in consumer markets has increased through the ascendancy of eBay and other Internet auctions. At the same time, the use of auctions for transactions between businesses has expanded greatly, most notably in the telecommunications, energy and environmental sectors, and for procurement purposes generally.

Second, auctions have become the clearest success story in the application of game theory to economics. In most applications of game theory, the modeller has considerable (perhaps excessive) freedom to formulate the rules of the game, and the results obtained will often be highly sensitive to the chosen formulation. By way of contrast, an auction will typically have a well-defined set of rules, yielding clearer theoretical predictions.

Third, there has been an increasing wealth of auction data available for empirical analysis in recent years. In conjunction with the available theory, this has led to a growing body of empirical work on auctions. Moreover, auctions are very well suited for laboratory experiments and they have been a very fruitful area for experimental economics.

This article is limited in its scope to auction theory. Other related articles, reviewing empirical and experimental work on auctions and the theoretical analysis of mechanism design, are cross-referenced at the end.

1 Introduction

Auction theory is often said to have originated in the seminal 1961 article by William Vickrey. While Vickrey's insights were initially unrecognized and it would be many years before his work was followed up by other researchers, it eventually led to a formidable body of research by pioneers including Wilson, Clarke, Groves, Milgrom, Weber, Myerson, Maskin and Riley. The first wave of theoretical research into auctions was concluded in the mid-1980s, by which time there was a widespread sense that it had become a relatively complete body of work with very little remaining to be discovered. See McAfee and McMillan (1987) for an excellent review of the first wave of auction theory.

However, the perception that auction theory was complete began to change following two pivotal events in the 1990s: the Salomon Brothers scandal in the US government securities market in 1991, and the advent of the Federal Communications Commission (FCC) spectrum auctions in 1994. In the aftermath of the former, the Department of the Treasury sought input from academia concerning the US Treasury auctions. In the preparation for the latter, the FCC encouraged the active involvement of auction theorists in the design of the new auctions.

Each of these two episodes undoubtedly benefitted from the participation of academics. In particular, the FCC introduced an innovative dynamic auction format – the simultaneous ascending auction – whose empirical performance appears far superior to previous static sealed-bid auctions. The Treasury's experimentation with, and eventual adoption of, uniform-price auctions in place of pay-as-bid auctions also appears to have resulted from economists' input.

At the same time, these two pivotal events underscored some extremely serious limitations in auction theory as it existed in the early to mid-1990s. It became apparent then that the theory that had been developed was almost exclusively one of single-item auctions, and that relatively little was established concerning multi-item auctions. As the flip side of the same coin, these episodes made it obvious that many of the empirically important examples of auctions involve a multiplicity of items. As a result, a second wave of theoretical research into auctions, focusing especially on multi-item auctions, emerged...
This article begins by reviewing the theory of single-item auctions, largely completed during the first period of research. It continues by reviewing the theory of multi-unit auctions, still a work in progress as of 2007.

The scope and detail of the present article is necessarily quite limited. For deeper and more comprehensive treatments of auctions, three notable books, by Krishna (2002), Milgrom (2004) and Cramton, Shoham and Steinberg (2006), are especially recommended to readers. Earlier survey articles by McAfee and McMillan (1987) and Wilson (1992) also provide excellent treatments of the literature on single-item auctions. A compendium by Klemperer (2000) brings together many of the best articles in auction theory.

2 Sealed-bid auctions for single items

Much of the analysis within traditional auction theory has concerned sealed-bid auctions (that is, static games) for single items. Bidders submit their sealed bids in advance of a deadline, without knowledge of any of their opponents’ bids. After the deadline, the auctioneer unseals the bids and determines a winner. The following are the two most commonly studied sealed-bid formats:

- **First-price auction**: the highest bidder wins the item, and pays the amount of his bid.
- **Second-price auction**: the highest bidder wins the item, and pays the amount bid by the second-highest bidder.

Note that the above auction formats (and, indeed, all of the auctions described in this article) have been described for a regular auction in which the auctioneer offers items for sale and the bidders are buyers. Each can easily be restated for a ‘reverse auction’ (that is, procurement auction) in which the auctioneer solicits the purchase of items and the bidders are sellers. For example, in a second-price reverse auction, the lowest bidder is chosen to provide the item and is paid the amount bid by the second-lowest bidder.

2.1 The private values model

A seller wishes to allocate a single unit of a good or service among $n$ bidders ($i=1,\ldots, n$). The bidders bid simultaneously and independently as in a non-cooperative static game. Bidder $i$'s payoff from receiving the item in return for the payment $y$ is given by $v_i - y$ (whereas bidder $i$'s payoff from not winning the item is normalized to zero). Each bidder $i$'s valuation, $v_i$, for the item is private information. Bidder $i$ knows $v_i$ at the time he submits his bid. Meanwhile, the opposing bidders $j \neq i$ view $v_i$ as a random variable whose realization is unknown, but which is drawn according to the known joint distribution function $\hat{F}(v_1, \ldots, v_n)$. This model is referred to as the *private values* model, on account that each bidder's valuation depends only on his own – and not the other bidders’ – information. (By contrast, in a *pure common values* model, $v_i = v_j$, for all $i, j=1, \ldots, n$; and in an *interdependent values* model, bidder $i$'s valuation is allowed...
to be a function of $v_{-i} = \{v_j \mid j \neq i\}$, as well as of $v_i$. With private values, some especially simple and elegant results hold, particularly for the second-price auction.

Two additional assumptions are frequently made. First, we generally assume that bidders are *risk neutral* in evaluating their payoffs under uncertainty. That is, each bidder seeks merely to maximize the mathematical expectation of his payoff. Second, we often assume *independence* of the private information. That is, the joint distribution function, $\hat{F}(v_1, \ldots, v_n)$, is given by the product of separate distribution functions, $F_i(\cdot)$, for each of the $v_i$. However, both the risk neutrality and independence assumptions are unnecessary for solving the second-price auction, which we analyse first.

### 2.2 Solution of the second-price auction

Sincere bidding (that is, the truthful bidding of one's own valuation) is a Nash equilibrium of the sealed-bid second-price auction, under private values. That is, if each bidder $i$ submits the bid $b_i = v_i$, then there is no incentive for any bidder to unilaterally deviate. Moreover, sincere bidding is a weakly dominant strategy for each bidder; and sincere bidding by all bidders is the unique outcome of elimination of weakly dominated strategies. These facts make the sincere bidding equilibrium an especially compelling outcome of the second-price auction.

Let $\hat{b}_{-i} = \max_{j \neq i} \{b_j\}$, the highest among the opponents' bids. The dominant strategy property is easily established by comparing bidder $i$'s payoff from the sincere bid of $b_i = v_i$ with his payoff from instead bidding $b'_i < v_i$ ("shading" his bid). If $\hat{b}_{-i}$ is less than $b'_i$ or greater than $v_i$, then bid-shading has no effect on bidder $i$'s payoff; in the former case, bidder $i$ wins either way, and in the latter case, bidder $i$ loses either way. However, in the event that $\hat{b}_{-i}$ is between $b'_i$ and $v_i$, the bid-shading makes a difference: if bidder $i$ bids $v_i$, he wins the auction and thereby achieves a positive payoff of $v_i - \hat{b}_{-i} > 0$; whereas, if bidder $i$ bids $b'_i$, he loses the auction and receives zero payoff. Thus, $b_i = v_i$ weakly dominates any bid $b'_i < v_i$. A similar comparison finds that $b_i = v_i$ weakly dominates any bid $b'_i > v_i$. Sincere bidding is optimal, regardless of the bidding strategies of opposing bidders.

Note that the above argument in no way uses the risk neutrality or independence assumptions, nor does it require any form of symmetry. Sincere bidding may also be viewed as an *ex post equilibrium* of the second-price auction, in the sense that the strategy would remain optimal even if the bidder were to learn his opponents’ bids before he was required to submit his own bid. Indeed, one of the strengths of the result that sincere bidding is a Nash equilibrium in weakly dominant strategies is that it basically relies only upon the private values assumption, and is otherwise extremely robust to the specification of the model.

### 2.3 Incentive compatibility in any sealed-bid auction format

Consider any equilibrium of *any* sealed-bid auction format, in the private values model. Given that bidder $i$'s valuation is private information, observe that there is nothing to force bidder $i$ to bid according
to his true valuation $v_i$ instead of some other valuation $w_i$. As a result, the equilibrium must have a structure that gives bidder $i$ the incentive to bid according to his true valuation. This requirement is known as *incentive compatibility*.

In the following derivation, we assume that the support of each bidder $i$'s valuation is the interval $[\bar{v}_i, \bar{v}_i]$. We will make both the risk neutrality and independence assumptions. Let $\Pi_i(v_i)$ denote bidder $i$'s expected payoff, let $P_i(v_i)$ denote bidder $i$'s probability of winning the item, and let $Q_i(v_i)$ denote bidder $i$'s expected payment in this equilibrium, when his valuation is $v_i$. The reader should note that $Q_i(v_i)$ refers here to bidder $i$'s unconditional expected payment, *not* to his expected payment conditional on winning. Given the risk-neutrality assumption, $\Pi_i(v_i)$ is given by:

$$\Pi_i(v_i) = P_i(v_i)v_i - Q_i(v_i).$$

(1)

Next, we pursue the observation that there is nothing forcing bidder $i$ to bid according to his true valuation $v_i$ rather than according to another valuation $w_i$. Define $\pi_i(w_i, v_i)$ to be bidder $i$'s expected payoff from employing the bidding strategy of a bidder with valuation $w_i$ when his true valuation is $v_i$. Observe that:

$$\pi_i(w_i, v_i) = P_i(w_i)v_i - Q_i(w_i),$$

(2)

since bidder $i$'s probability of winning and expected payment depend exclusively on his bid, not on his true valuation. Bidder $i$ will voluntarily choose to bid according to his true valuation only if his expected payoff is greater than from bidding according to another valuation $w_i$, that is, if:

$$\Pi_i(v_i) \geq \pi_i(w_i, v_i), \text{ for all } v_i, w_i \in [\bar{v}_i, \bar{v}_i], \text{ and all } i = 1, ..., n.$$  

(3)

Inequality (3), referred to as the *incentive-compatibility constraint*, has very strong implications. Next, note that $\Pi_i(v_i) = \pi_i(v_i, v_i) = \max_{w_i \in [\bar{v}_i, \bar{v}_i]} \pi_i(w_i, v_i)$. It is straightforward to see that $\Pi_i(\cdot)$ is monotonically non-decreasing and continuous. Consequently, it is differentiable almost everywhere and equals the integral of its derivative. Applying the envelope theorem at any $v_i$ where $\Pi_i(\cdot)$ is
differentiable yields:

\[
\frac{a \prod_i (v_i)}{d v_i} = \frac{\partial \pi_i (w_i, v_i)}{\partial v_i} \bigg|_{w_i = v_i} = p_i (w_i) \bigg|_{w_i = v_i} = p_i (v_i).
\]

Integrating eq. (4), we have:

\[
\Pi_i (v_i) = \Pi_i (v_i) + \int_{v_i}^{v_i} p_i (x) \, dx, \text{ for all } v_i \in [v_b, \bar{v}_i] \text{ and all } i = 1, \ldots, n.
\]

2.4 Solution of the first-price auction

The sealed-bid first-price auction requires two symmetry assumptions in order to yield a fairly simple solution. First, we assume symmetric bidders, in the sense that the joint distribution function \(F(v_1, \ldots, v_b, \ldots, v_n)\) governing the bidders’ valuations is a symmetric function of its arguments. This assumption and the associated notation are simplest to state if independence is assumed. In this case, we write \(F_i(\cdot)\) for the distribution function of each \(v_i\); symmetry is the assumption that \(F_i = F\), for all \(i = 1, \ldots, n\), or, in other words, the assumption that the various \(v_i\) are identically distributed, as well as independent, random variables. However, a similar derivation with only slightly more cumbersome notation is possible if the bidders are symmetric but the \(v_i\) are affiliated random variables. We write \([v_b, \bar{v}]\) for the support of \(F(\cdot)\). In addition, we assume that \(F(\cdot)\) is a continuous function, so that there are no mass points in the common probability distribution of the bidders’ valuations.

Second, we restrict attention to symmetric, monotonically increasing equilibria in pure strategies. The assumed symmetry of bidders opens the possibility for existence of a symmetric equilibrium. (Meanwhile, asymmetric equilibria are also possible in symmetric games, but Maskin and Riley, 2003, establish that, under slightly stronger assumptions, the construction here gives the unique equilibrium of the auction.) Any pure-strategy equilibrium can be characterized by the bid functions \(\{B_i(\cdot)\}_{i=1}^n\), which give bidder \(i\)'s bid \(B_i(v_i)\) when his valuation is \(v_i\). Our assumption is that \(B_i = B\), for all \(i=1, \ldots, n\), where \(B(\cdot)\) is a strictly increasing function.

Observe that, in any symmetric equilibrium, bidder \(i\) wins against bidder \(j\) if and only if \(B(v_j) < B(v_i)\) and, given strict monotonicity, if and only if \(v_j < v_i\). (We can ignore the event \(v_j = v_i\); this is a zero-probability event, since we have assumed the distribution of valuations has no mass points.) Consequently, bidder \(i\) wins the item if and only \(v_j < v_i\) for all \(j \neq i\). Since the \(\{v_j\}_{j \neq i}\) are i.i.d. random...
variables, bidder $i$ has probability $F(v_i)^{n-1}$ of winning the auction when his valuation is $v_i$. We write: $P_i(v_i) = F(v_i)^{n-1}$, for all $v_i \in [\underline{v}, \overline{v}]$ and all $i=1, \ldots, n$.

Moreover, in a first-price auction, the bidder's payoff equals $v_i - B(v_i)$ if he wins the auction and zero if he loses. Consequently his expected payoff equals:

$$\Pi_i(v_i) = P_i(v_i)[v_i - B(v_i)] = F(v_i)^{n-1}[v_i - B(v_i)].$$

(6)

Observe from eq. (6) that, if $v_i = \underline{v}$, bidder $i$'s probability of winning equals zero and, hence, $\Pi_i(\underline{v}) = 0$. Substituting this fact and $P_i(v_i) = F(v_i)^{n-1}$ into Eq. (5) yields:

$$\Pi_i(v_i) = \int_{v_i}^{v} F(x)^{n-1}dx, \text{ for all } v_i \in [\underline{v}, \overline{v}] \text{ and all } i = 1, \ldots, n.$$  

(7)

Combining eq. (6) with eq. (7), and solving for $B(\cdot)$, yields the equilibrium bid function:

$$B(v_i) = v_i - \frac{\Pi_i(v_i)}{F(v_i)^{n-1}} = v_i - \frac{\int_{\underline{v}}^{v} F(x)^{n-1}dx}{F(v_i)^{n-1}}.$$ 

(8)

The posited strict monotonicity is verified by differentiating eq. (8) with respect to $v_i$, which shows that $B'(v_i) > 0$. Thus, eq. (8) provides us with the unique symmetric equilibrium in pure strategies of the sealed-bid first-price auction. This result holds for arbitrary continuous distribution functions $F(\cdot)$ with support on an interval $[\underline{v}, \overline{v}]$.

3 Revenue equivalence, efficient auctions and optimal auctions

Standard practice in auction theory is to evaluate auction formats according to either of two criteria: efficiency and revenue optimization. With the quasi-linear utilities generally assumed in auction theory, efficiency means putting the items in the hands of those who value them the most. Revenue
maximization means maximizing the seller's expected revenues or, in a procurement auction, minimizing the buyer's expected procurement costs. In auctions of government assets such as spectrum licenses, the explicit objective is often efficiency. In auctions by private parties, the explicit objective is often revenue optimization.

3.1 Efficient auctions

The above solutions to the second-price and first-price auctions both yield full efficiency. In the symmetric increasing equilibrium of the first-price auction, the highest bid corresponds to the highest valuation, and so the item is assigned efficiently for every realization of the random variables. In the dominant strategy equilibrium of the second-price auction, the identical conclusion holds. Thus, in a symmetric private values model, an objective of efficiency looks kindly upon both auction formats – but does not prefer one over the other.

3.2 Revenue equivalence

One of the classic and most far-reaching results in auction theory is revenue equivalence, which provides a set of assumptions under which the sellers’ and buyers’ expected payoffs are guaranteed to be the same under different auction formats.

Revenue equivalence (Vickrey, 1961; Myerson, 1981; Riley and Samuelson, 1981) may be stated as follows. Assume that the random variables representing the bidders’ valuations are independent, and assume that bidders are risk neutral. Consider any two auction formats satisfying both of the following properties: (a) the two auction formats assign the item(s) to the same bidder(s), for every realization of random variables; and (b) the two auction formats give the same expected payoff to the lowest valuation type, \( v_i \), of each bidder \( i \). Then each bidder earns the same expected payoff under each of the two auction formats and, consequently, the seller earns the same expected revenues under each of the two auction formats.

For an auction of a single item, the result follows directly from eq. (5) above. Recall that this equation holds for any equilibrium of any sealed-bid auction format. If for every realization of the random variables the two auction formats assign the item to the same bidder, then each bidder’s probability, \( P_i(\cdot) \), of winning is the same under the two auction formats. If in addition, \( \Pi_i(\cdot) \) is the same under the two auction formats, then eq. (5) implies that the entire function \( \Pi_i(\cdot) \) is the same under the two auction formats. Since this holds for every bidder \( i \), and since the expected gains from trade are the same under the two auction formats, it follows from an accounting identity that the seller’s expected revenues are also the same under the two auction formats.

One of the most important applications of revenue equivalence is that the above solutions to the second-price and first-price auctions give the seller the same expected revenues (and also give each buyer the same expected payoffs). Revenue equivalence is applicable because, as argued above, the item is assigned efficiently for every realization of the random variables in each of these auction formats. Moreover, when \( v_i = \bar{v} \), the expected payoff of bidder \( i \) equals zero in each of these auction formats. To understand this result, observe that (all other things equal) a bidder in a first-price auction will bid lower than in a second-price auction, since the payment rule is less generous. Expected revenues will be
greater in the first-price or the second-price auction depending on whether the highest of a collection of
smaller bids or the second-highest of a collection of larger bids is greater in expectation. The revenue
equivalence theorem establishes that, in the symmetric private values model, the two effects exactly
offset one another.

3.3 Optimal auctions

Another classic result of auction theory is the determination of the auction format that optimizes
revenues. This result, known in the literature as the \textit{optimal auction}, is due to Harris and Raviv (1981),
Myerson (1981), and Riley and Samuelson (1981). Any possible auction format is considered – the item
may be assigned to the bidder who submitted the highest bid (as in the second-price or first-price
auction), but it may alternatively be allocated to another bidder, randomized in its allocation, or withheld
from sale entirely, depending on the collection of bids submitted. At the outset, this might be viewed as
a very complicated problem, since it requires selecting simultaneously the probability of winning and a
payment that optimizes revenues. However, by using analysis similar to the treatment of incentive
compatibility, above, it can be shown that the expected payment is determined up to a constant by the
probability of winning. Consequently, the problem simplifies to determining the probability of each
bidder winning (for every realization of the random variables) that optimizes revenues.

For symmetric bidders, each of whose distributions satisfies a regularity condition, a particularly simple
characterization of the optimal auction can be obtained. Let $F(\cdot)$ be the distribution function of the
valuation $v_i$ of each bidder $i$, let $f(\cdot)$ be the associated density function and suppose that
is strictly increasing in $v_i$ for all $v_i \in [v, \overline{v}]$. Then the optimal auction assigns the item to the bidder $i$
with the highest $v_i$, if and only if the highest $v_i$ exceeds the reserve valuation $r$, where $r$ is defined by

$$r = \frac{1 - F(r)}{f(r)} = v_0$$

and where $v_0$ is the seller's valuation for the item.

In other words, with symmetric bidders, both the second-price and the first-price auctions become
optimal auctions, once a reserve price of $r$ is inserted.

3.4 Full rent extraction

The optimal auctions problem can be reconsidered without the independence assumption. However,
Crémé and McLean (1985) demonstrate that, if the bidders' private information is correlated, then there
exists a mechanism that enables the seller to extract all of the gains from trade. The mechanism includes
a procedure for allocating the item efficiently. Superimposed on this, the mechanism provides rewards to
bidders if their reports of private information ‘agree’ with each other, and penalties to bidders if their
reports ‘disagree’ with each other. The amounts of the rewards and penalties – both potentially quite
large – are set so as to make the bidders indifferent between participating and not participating in the
mechanism. As such, the mechanism enables the seller to extract the entire surplus, including the
informational rents that the bidders are able to obtain under the independence assumption. This is
referred to as \textit{full rent extraction}.

Crémé and McLean's result may be viewed as fundamentally negative, in that it suggests that the
optimal auctions analysis may be of limited relevance. Real-world auction mechanisms appear to be broadly consistent with the predictions of the optimal auctions theory under the independence assumption, but they look nothing like the full rent-extracting mechanisms possible with correlated private information. Given that there are good reasons to believe that bidders’ private signals are correlated with one another, it would appear that the optimal auctions analysis does not provide us with great insight into real-world auctions. Some subsequent research has attempted to weaken the extreme conclusion of full rent extraction by positing that bidders have limited liability or by introducing opportunities for auctioneer collusion or cheating, but in many respects these devices appear to be ineffectual patches for an elegant theory (optimal auctions) that suffers from only limited empirical relevance.

4 Dynamic auctions for single items

The next two formats considered for auctioning single items are dynamic auctions: participants bid sequentially over time and, potentially, learn something about their opponents’ bids during the course of the auction. In the first dynamic auction, the price ascends; and in the second dynamic auction, the price descends:

- *English auction*: bidders dynamically submit successively higher bids for the item. The final bidder wins the item, and pays the amount of his final bid.
- *Dutch auction*: the auctioneer starts at a high price and announces successively lower prices, until some bidder expresses his willingness to purchase the item by bidding. The first bidder to bid wins the item, and pays the current price at the time he bids.

Note that, as in Section 2, each of these auction formats has been described for a regular auction in which the auctioneer offers items for sale, but can easily be restated for a ‘reverse auction’. For example, in an English reverse auction the bids would descend rather than ascend, while in a Dutch reverse auction the auctioneer would offer to buy at successively higher prices.

4.1 Solution of the Dutch auction

An insight due to Vickrey (1961) is that the Dutch auction is strategically equivalent to the sealed-bid first-price auction. To see the equivalence, consider the real meaning of a strategy $b_i$ by bidder $i$ in the Dutch auction: ‘If no other bidder bids for the item at any price higher than $b_i$, then I am willing to step in and purchase it at $b_i$. ’ Just as in the sealed-bid first-price auction, the bidder $i$ who selects the highest strategy $b_i$ in the Dutch auction wins the item and pays the amount $b_i$. Furthermore, although the Dutch auction is explicitly dynamic, there is nothing that can happen that would lead any bidder to want to change his strategy while the auction is still running. If strategy $b_i$ was a best response for bidder $i$ evaluated at the starting price $p_0$, then $b_i$ remains a best response evaluated at any price $p < p_0$, on the assumption that no other bidder has already bid at a price between $p_0$ and $p$. Meanwhile, if another bidder has already bid, then there is nothing that bidder $i$ can do; the Dutch auction is over. Hence, any
equilibrium of the sealed-bid first-price auction is also an equilibrium of the Dutch auction, and vice versa.

4.2 Solution of the English auction

By way of contrast, some meaningful learning and/or strategic interaction is possible during an English auction, so the outcome is potentially different from the outcome of the sealed-bid second-price auction. We model the English auction as a ‘clock auction’: the auctioneer starts at a low price and announces successively higher prices. At every price, each bidder is asked to indicate his willingness to purchase the item. The price continues to rise so long as two or more bidders indicate interest. The auction concludes at the first price such that fewer than two bidders indicate interest, and the item is awarded at the final price. This clock-auction description is used instead of a game where bidders successively announce higher prices, since it yields simpler arguments and clean results.

With pure private values, the reasonable equilibrium of the English auction corresponds to the dominant-strategy equilibrium of the sealed-bid second-price auction. A bidder's strategy designates the price at which he will drop out of the auction (on the assumption that at least one opponent still remains); in equilibrium, the bidder sets his drop-out price equal to his true valuation. However, matters become more complicated in the case of interdependent valuations, where each bidder's valuation depends not only on his own information, \(v_i\), but also on the opposing bidders’ information, \(v_{-i}\). We turn to this case next.

4.3 The winner's curse and revenues under interdependent values

One of the most celebrated phenomena in auctions is the ‘winner's curse’. Whenever a bidder's valuation depends positively on other bidders’ information, winning an item in an auction may confer ‘bad news’ in the sense that it indicates that other bidders possessed adverse information about the item's value. The potential for falling victim to the winner's curse may induce restrained bidding, curtailing the seller's revenues. In turn, some auction formats may produce higher revenues than others, to the extent that they mitigate the winner's curse and thereby make it safe for bidders to bid more aggressively.

The basic intuition, which is often referred to as the ‘linkage principle’ and is due to Milgrom and Weber (1982), is that the winner's curse is mitigated to the extent that the winner's payment depends on the opposing bidders’ information. Thus, under appropriate assumptions, the second-price auction will yield higher expected revenues than the first-price auction: the price paid by the winner of a second-price auction depends on the information possessed by the highest losing bidder, while the price paid by the winner of a first-price auction depends exclusively on his own information. Moreover, the English auction will yield higher expected revenues than the second-price auction: the price paid by the winner of an English auction may depend on the information possessed by all of the losing bidders (who are observed as they drop out), while the price paid by the winner of a (sealed-bid) second-price auction depends only on the information of the highest losing bidder.

These conclusions require an assumption known as ‘affiliation’, which intuitively means something very close to ‘non-negative correlation’. More precisely, let \(V = (v_1, ..., v_n)\) and \(V' = (v'_1, ..., v'_n)\) be possible realizations of the \(n\) bidders’ random variables, and let \(f(\cdot, \cdot, \cdot)\) denote the joint density function. Let
\( \mathbf{v} \vee \mathbf{v}' \) denote the component-wise maximum of \( \mathbf{v} \) and \( \mathbf{v}' \), and let \( \mathbf{v} \wedge \mathbf{v}' \) denote the component-wise minimum. The random variables \( \mathbf{v} \) and \( \mathbf{v}' \) are said to be affiliated if:

\[
f(\mathbf{v} \vee \mathbf{v}') f(\mathbf{v} \wedge \mathbf{v}') \geq f(\mathbf{v}) f(\mathbf{v}'), \quad \text{for all } \mathbf{v}, \mathbf{v}' \in [\mathbf{v} \ldots \mathbf{v}]^n. \tag{9}
\]

Affiliation provides that two high realizations or two low realizations of the random variables are at least as likely as one high and one low realization, and so on, meaning something close to non-negative correlation. Independence is included (as a boundary case) in the definition: for independent random variables, the affiliation inequality (9) is satisfied with equality. To obtain strict revenue rankings, the affiliation inequality must hold strictly.

These conclusions also rely on several symmetry assumptions. Bidders are symmetric, the equilibria considered are symmetric, and each bidder's valuation depends on all of its opponents' information in a symmetric way. Each bidder's valuation increases (weakly) in its own and its opponents' information, and attention is restricted to equilibria in monotonically increasing strategies. As before, each bidder is risk neutral in evaluating its payoff under uncertainty.

These conclusions also rely on a monotonicity assumption: each bidder's valuation increases (weakly) in its own and in the opposing bidders' information. In addition, as before, each bidder is risk-neutral in evaluating its payoff under uncertainty. Furthermore, the two symmetry assumptions of Section 2.4 are made: bidders are symmetric in the sense that the joint distribution governing the bidders' information is a symmetric function of its arguments; and attention is restricted to symmetric, monotonically increasing equilibria in pure strategies.

Under these assumptions, the sealed-bid first-price and second-price auctions and the English auction possess symmetric, monotonic equilibria. However, while these equilibria are all efficient, Milgrom and Weber (1982) establish that they may be ranked by revenues: the English auction yields expected revenues greater than or equal to those of the sealed-bid second-price auction, which in turn yields expected revenues greater than or equal to those of the sealed-bid first-price auction. Their theorem provides one of the most powerful results of auction theory, justifying the conventional wisdom that dynamic auctions yield higher revenues than sealed-bid auctions.

5 Auctions of homogeneous goods

5.1 Sealed-bid, multi-unit auction formats

The defining characteristic of a homogeneous good is that each of the \( M \) individual items is identical (or a close substitute), so that bids can be expressed in terms of quantities without indicating the identity of the particular good that is desired. Treating goods as homogeneous has the effect of dramatically simplifying the description of the bids that are submitted and the overall auction procedure. This simplification is especially appropriate in treating subject matter such as financial securities or energy
products. Any two $10,000 US government bonds with the same interest rate and the same maturity are identical, just as any two megawatts of electricity provided at the same location on the electrical grid at the same time are identical.

There are three principal sealed-bid, multi-unit auction formats for $M$ homogeneous goods. In each of these, a bid comprises an inverse demand function, that is, a (weakly) decreasing function $p_i(q)$, for $q \in [0, M]$, representing the price offered by bidder $i$ for a first, second, and so on, unit of the good. (Note that this notation may be used to treat situations where the good is perfectly divisible, as well as situations where the good is offered in discrete quantities.) The bidders submit bids; the auctioneer then aggregates the bids and determines a clearing price. Each bidder wins the quantity demanded at the clearing price, but his payment varies according to the particular auction format:

- **Pay-as-bid auction.** Each bidder wins the quantity demanded at the clearing price, and pays the amount that he bid for each unit won.
- **Uniform-price auction.** Each bidder wins the quantity demanded at the clearing price, and pays the clearing price for each unit won.
- **Multi-unit Vickrey auction.** Each bidder wins the quantity demanded at the clearing price, and pays the opportunity cost (relative to the bids submitted) for each unit won.

(Pay-as-bid auctions are also known as ‘discriminatory auctions’ or ‘multiple-price auctions’. Uniform-price auctions are often referred to in the financial press as ‘Dutch auctions’, generating some confusion with respect to the standard usage of the auction theory literature. They are also known as ‘nondiscriminatory auctions’, ‘competitive auctions’ or ‘single-price auctions’.)

Sealed-bid, multi-unit auction formats are best known in the financial sector for their long-time and widespread use in the sale of government securities. For example, a survey of OECD countries in 1992 found that Australia, Canada, Denmark, France, Germany, Italy, Japan, New Zealand, the United Kingdom and, of course, the United States then used sealed-bid auctions for selling at least some of their debt. The pay-as-bid auction was the traditional format used for US Treasury bills, as well as for government securities of most other countries. The uniform-price auction was first proposed seriously as a replacement for the pay-as-bid auction by Milton Friedman in testimony at a 1959 Congressional hearing. Wilson (1979) gave the first theoretical analysis of a uniform-price auction. In 1993 the United States began an ‘experiment’ of using the uniform-price auction for two- and five-year government notes and, beginning in 1998, the United States switched entirely to the uniform-price auction for all issues. Meanwhile, the multi-unit Vickrey auction was introduced and first analysed in Vickrey’s 1961 paper.

The pay-as-bid auction can be correctly viewed as a multi-unit generalization of the first-price auction. However, it is quite difficult to calculate Nash equilibria of the pay-as-bid auction, unless efficient equilibria exist. **Three** symmetry assumptions together guarantee the existence of efficient equilibria:

First, bidders are assumed to be symmetric, in the sense that the joint distribution governing the bidders’ information is symmetric with respect to the bidders. Second, bidders regard every unit of the good as symmetric: that is, each bidder $i$ has a constant marginal valuation for every quantity $q_i \in [0, \lambda_i]$, up to a capacity of $\lambda_i$, and a marginal valuation of zero thereafter. Third, the bidders are symmetric in their capacities: that is, $\lambda_i = \lambda$, for all bidders $i$. With these assumptions, the pay-as-bid auction has a solution
very similar to that of the first-price auction for a single item. However, without these assumptions, it inherits an undesirable property from the single-item auction: absent symmetry, all Nash equilibria of the pay-as-bid auction will generally be inefficient (Ausubel and Cramton, 2002, Theorems 3 and 4).

The uniform-price auction bears a superficial resemblance to the second-price auction of a single item, in that a high winning bid gains the benefit of a lower marginal bid. However, any similarity is indeed only superficial as, except under very restrictive assumptions, all equilibria of the uniform-price auction are inefficient. The argument is simplest in the same model of constant marginal valuations as in the previous paragraph. If the capacities of all bidders are equal (that is, if \( \lambda_i = \overline{\lambda} \) for all \( i \)) and if the supply is an integer multiple of \( \lambda \), then there exists an efficient Bayesian-Nash equilibrium of the uniform-price auction. (For example, if there are \( M \) identical units available and if every bidder has a unit demand, then sincere bidding is a Nash equilibrium in dominant strategies.) However, if the bidders’ capacities are unequal or if the supply is not an integer multiple of \( \lambda \), then all equilibria of the uniform-price auction are inefficient (Ausubel and Cramton, 2002, Theorems 2 and 5).

The intuition for inefficiency in the uniform-price auction can be found by taking a close look at optimal bidding strategies. Sincere bidding is weakly dominant for a first unit: if a bidder's first bid determines the clearing price, then the bidder wins zero units. However, the bidder's second bid may determine the price he pays for his first unit, providing an incentive to shade his bid. The extent of demand reduction, as this bid shading is known, increases in the number of units, since the number of infra-marginal units whose price may be affected increases. Further, note that the allocation rule in the auction has the effect of equating the amounts of the bidders’ marginal bids. Since a large bidder will likely have shaded his marginal bid more than a small bidder, the large bidder's marginal value is probably greater than a small bidder's. Consequently, the bidders’ marginal values will be unequal, contrary to efficiency.

Meanwhile, the Vickrey auction is the correct multi-unit generalization of the second-price auction. As in the pay-as-bid and uniform-price auctions, bidders simultaneously submit inverse demand functions and each bidder wins the quantity demanded at the clearing price. However, rather than paying the bid price or the clearing price for each unit won, a winning bidder pays the opportunity cost. If a bidder wins \( K \) units, he pays the \( K \)th highest rejected bid of his opponents for his first unit, the \((K-1)\)st highest rejected bid of his opponents for his second unit, \( \ldots \), and the highest rejected bid of his opponents for his \( K \)th unit. The dominant strategy property of the sealed-bid second-price auction generalizes because a bidder's payment is determined solely by his opponents’ bids. Consequently, given pure private values and non-increasing marginal values, sincere bidding is an efficient equilibrium in weakly dominant strategies.

### 5.2 Efficiency and revenue comparisons

Under pure private values, the dominant strategy equilibrium of the Vickrey auction attains full efficiency. It can be shown that neither the pay-as-bid nor the uniform-price auction generally attains efficiency; moreover, the efficiency ranking of these two formats is inherently ambiguous. To continue the argument of the previous subsection, it is sufficient to examine environments in which bidders have constant marginal valuations. If \( F_i = F \) and \( \lambda_i = \lambda \) for all bidders \( i \), but the supply is not an integer multiple of \( \lambda \), then the pay-as-bid auction has an efficient equilibrium while all equilibria of the uniform-price auction are inefficient. Conversely, if \( \overline{\lambda}_i = \overline{\lambda} \) for all bidders \( i \) and if the supply is an integer
multiple of $\lambda$, but $F_i \neq F_j$ for two bidders $i$ and $j$, then the uniform-price auction has an efficient equilibrium while all equilibria of the pay-as-bid auction are generally inefficient (Ausubel and Cramton, 2002).

On revenues, the policy literature has generally assumed that the uniform-price auction outperforms the pay-as-bid auction; however, the argument of the previous paragraph can be extended to reverse the assumed ranking. Maskin and Riley (1989) extend Myerson's (1981) characterization of the optimal auction to multiple homogeneous goods: with symmetric bidders and constant marginal valuations, their characterization requires allocating items efficiently. Thus, as in the previous paragraph, if $F_i = F$ and $\lambda_i = \lambda$ for all bidders $i$, but the supply is not an integer multiple of $\lambda$, then the efficient equilibrium of the pay-as-bid auction outranks all equilibria of the uniform-price auction on revenues (as well as efficiency).

5.3 Uniform-price clock auctions

The ‘clock auction’ – a practical design for dynamic auctions of one or more types of goods, with its origins in the ‘Walrasian auctioneer’ from the classical economics literature – has seen increasing use as a trading institution since 2001. A fictitious auctioneer is often presented as a device or thought experiment for understanding convergence to a general equilibrium. The Walrasian auctioneer announces a price vector, $p$; bidders report the quantity vectors that they wish to transact at these prices; and the auctioneer increases or decreases each component of price according as excess demand is positive or negative (Walrasian tâtonnement). This iterative process continues until a price vector is reached at which excess demand is zero, and trades occur only at the final price vector. In real-world applications, instead of a fictitious auctioneer serving as a metaphor for a market-clearing process, the process is taken literally; a real auctioneer announces prices and accepts bids of quantities. Applications, to date, have largely been in the electricity, natural gas, and environmental sectors.

The basic clock auction differs from the standard Sotheby's or eBay auction in that bidders do not propose prices. Rather, the auctioneer announces prices, and bidders’ responses are limited to the reporting of quantities desired at the announced prices, until clearing is attained. As such, it is closest to the auction-theorist's depiction of the English auction for a single item (or the traditional Dutch auction), but generalized, so that, instead of bidders merely giving binary responses of whether they are ‘in’ or ‘out’ as prices ascend, they indicate their quantities desired.

Observe that the uniform-price clock auction is correctly viewed as a dynamic version of the sealed-bid uniform-price auction reviewed in the previous two subsections. The important difference is that, in the dynamic auction, bidders will typically receive repeated feedback as to the aggregate demand at the various prices.

As such, the clock auction may inherit the advantages that dynamic auctions have over sealed-bid auctions. First, under conditions that can be made precise, the insight from single-item auctions that feedback about other bidders’ valuations would ameliorate the winner's curse and lead to more aggressive bidding carries over to the multi-unit environment. Second, clock auctions, better than sealed-bid auctions, allow bidders to maintain the privacy of their valuations for the items being sold. Bidders never need to submit any indications of interest at any prices beyond the auction's clearing price. Third, when there are two or more types of items, auctioning them simultaneously enables bidders to submit
bids based on the substitution possibilities or complementarities among the items at various price vectors. At the same time, the iterative nature of the auction economizes on the amount of information submitted: demands do not need to be submitted for all price vectors, but only for price vectors reached along the convergence path to equilibrium.

Unfortunately, the uniform-price clock auction also inherits the demand reduction and inefficiency of the sealed-bid uniform-price auction. Indeed, as a theoretical proposition, the problem of bidders optimally reducing their quantities bid well below their true demands can become substantially worse in the dynamic version of the auction. The *reductio ad absurdum* is provided by Ausubel and Schwartz (1999), who analyse a two-bidder clock auction game of complete information in which the bidders alternate in their moves. For a wide set of environments, the unique subgame perfect equilibrium has the qualitative description that, at the first move, the first player reduces his quantity to approximately half of the supply and, at the second move, the second player reduces his quantity to clear the market. Thus, the outcome is inefficient and the revenues barely exceed the starting price.

As a practical matter, demand reduction may not undermine the outcome of a uniform-price clock auction where there is substantial competition for every item being sold. However, if one or more of the bidders has considerable market power, it may become important to use an auction format which avoids creating incentives for demand reduction.

### 5.4 Efficient clock auctions

Ausubel (2004; 2006) proposes an alternative clock auction design, which utilizes the same general structure as the uniform-price clock auction, but adopts a different payment rule that eliminates the incentives for demand reduction. In essence, the design provides a dynamic version of the (multi-unit) Vickrey auction, and thereby inherits its incentives for truth-telling.

The Ausubel auction is easiest described for a homogeneous good. After each set of bidder reports, the auctioneer determines whether any bidder has ‘clinched’ any of the units offered (that is, whether any bidder is mathematically guaranteed to win one or more units). For example, in an auction with a supply of 5 units, and three bidders demanding 3, 2 and 2 units, respectively, the first bidder has clinched 1 unit, as his opponents’ total demand of 4 is less than the supply of 5. Rather than awarding units only at a final uniform price, the auction awards units at the current price whenever they are newly clinched. If this alternative clock auction is represented as a static auction, it collapses to the Vickrey auction in the same sense that an English auction collapses to the sealed-bid second-price auction. Consequently, it can be proven that sincere bidding is an equilibrium and, in a suitable discrete specification of the game under incomplete information, sincere bidding is the unique outcome of iterated elimination of weakly dominated strategies. Thus, unlike the uniform-price clock auction, there is no incentive for demand reduction.

### 6 Auctions of heterogeneous goods

In many significant applications, the multiple items offered within an auction are each unique, so it is not adequate for bidders merely to indicate the quantities that they desire. For example, an FCC spectrum auction might include a New York licence, a Washington licence and a Los Angeles licence.
Moreover, there might be synergies in owning various combinations: for example, a New York and a Washington licence together might be worth more together than the sum of their values separately. Such environments pose particular challenges for auction theory.

6.1 Simultaneous ascending auctions

The simultaneous ascending auction, proposed in comments to the FCC by Paul Milgrom, Robert Wilson and Preston McAfee, has been used in auctions on six continents allocating more than $100 billion worth of spectrum licenses. Some of the best known applications of the simultaneous ascending auction include: the Nationwide Narrowband Auction (July 1994), the first use of the simultaneous ascending auction; the PCS A/B Auction (December 1994–March 1995), the first large-scale auction of mobile telephone licences, which raised $7 billion; the United Kingdom UMTS Auction (March–April 2000), which raised 22.5 billion British pounds; and the German UMTS Auction (July–August 2000), which raised 50 billion euro.

In the simultaneous ascending auction, multiple items are put up for sale at the same time and the auction concludes simultaneously for all of the items. As such, it is a modern version of the ‘silent auction’ that is frequently used in fundraisers by charitable institutions. Bidders submit bids in a sequence of rounds. Each bid comprises a single item and an associated price, which must exceed the standing high bid by at least a minimum bid increment. After each round, the new standing high bids for each item are determined. The auction concludes after a round passes in which no new bids are submitted, and the standing high bids are then deemed to be winning bids. Payments equal the amounts of the winning bids.

The critical innovation in the simultaneous ascending auction is the inclusion of activity rules into the auction design. Activity rules are bidding constraints that limit a bidder's bidding activity in the current round based on his past bidding activity (that is, his standing high bids and new bids). Without activity rules, bidders would tend to wait as ‘snakes in the grass’ until nearly the end of the auction before placing their serious bids, thwarting any price discovery (the main reason for conducting a dynamic auction in the first place). Conversely, activity rules have the effect of forcing bidders to place meaningful bids in early rounds of the auction and thereby to reveal information to their opponents.

6.2 Walrasian equilibria as outcomes of simultaneous ascending auctions

A Walrasian equilibrium – consisting of prices for the various items and an allocation of the items to the bidders such that each item with a non-zero price is assigned to exactly one bidder and such that each bidder prefers his assigned allocation to any alternative bundle at the given prices – is a plausible outcome for the simultaneous ascending auction. On the assumption that a Walrasian equilibrium was reached, no bidder would have any incentive to attempt to upset the allocation, even if he believed he could obtain additional items without further increasing their prices. Thus, it becomes interesting to identify the conditions needed for existence of Walrasian equilibria with discrete items.

Kelso and Crawford (1982) show that the substitutes condition is sufficient for the existence of Walrasian equilibrium. ‘Substitutes’ literally refers to the price-theoretic condition that if the price of one item is increased while the price of every other item is held fixed, then the demand for every other item weakly increases. Moreover, the substitutes condition is ‘almost necessary’ for existence. Suppose
that the set of possible bidder preferences includes all valuation functions satisfying the substitutes condition, but also includes at least one valuation function violating the substitutes condition. Then if there are at least two bidders, there exists a profile of valuation functions such that no Walrasian equilibrium exists (Gul and Stacchetti, 1999; Milgrom, 2000).

The reader should avoid losing sight of the fact that, just because a Walrasian equilibrium exists for a discrete environment, it does not necessarily follow that the simultaneous ascending auction will terminate at a Walrasian equilibrium. The strongest statement that can be made is that, if bidders bid ‘straightforwardly’ (that is, if they demand naively the bundle of items that maximizes their utility, while ignoring strategic considerations), then a Walrasian equilibrium will be reached. However, observe that, even with homogeneous goods, consumers with weakly diminishing marginal valuations satisfy the substitutes condition. Nonetheless, the uniform-price auction is susceptible to demand reduction – meaning that bidders are likely to reduce their demands and thereby end the auction before reaching a Walrasian equilibrium. Indeed, we know from the Fundamental Theorem of Welfare Economics that the Walrasian equilibrium is efficient, so that any conclusion of inefficiency in a uniform-price auction implies that the outcome must be non-Walrasian.

6.3 Static pay-as-bid combinatorial auctions

Let us consider an example with two bidders, 1 and 2, and two items, A and B, where the substitutes condition is not satisfied and the existence of Walrasian equilibrium fails. Bidder 1 has a valuation of 3 for the package of A and B, but has a valuation of 0 for each item separately. (Thus, for Bidder 1, the goods are complements – not substitutes.) Bidder 2 has a valuation of 2 for item A, 2 for item B, and only 2 for the package of A and B. The efficient allocation assigns both items to Bidder 1. Consequently, any Walrasian equilibrium (if it exists) must assign both items to Bidder 1. However, to dissuade Bidder 2 from purchasing either item, the prices $p_A$ and $p_B$ of items A and B, respectively, must satisfy $p_A > 2$ and $p_B > 2$. Consequently, $p_A + p_B > 4$, exceeding Bidder 1's valuation for the package of two items and yielding a contradiction.

Given the argument of the previous paragraph, we should not expect the simultaneous ascending auction – or any auction format with bids for individual items – to generate the efficient allocation in this example. Bidder 1's dilemma is often referred to as the exposure problem: a bidder may refrain from bidding more than his stand-alone valuations for each of the individual items, knowing that, if he is outbid on some of the individual items, he will remain ‘exposed’ as the high bidder on the remaining items. This may prevent the available synergies from being realized. Indeed, if Bidder 1 understands this example, he may be unwilling to bid any positive price for either item, since Bidder 2 is sure to win one of the items, and therefore Bidder 1 would obtain zero value from the item that he wins.

The exposure problem can be avoided by using a combinatorial auction. The rules are modified to permit bidders to place package bids, each comprising a set of items and a price. For example, the bid $\langle \{A, B\}, p \rangle$ is interpreted as an all-or-nothing offer in the amount of $p$ for the package of A and B – with no requirement that the bidder is willing to accept a part of the package for a part of the price. The allocation is determined by a combination of compatible bids that maximizes the seller's revenues. In this example, Bidder 2 is unwilling to bid any more than 2 for any combination of items, while Bidder 1 is able to exceed 2 for $\{A, B\}$. Consequently, the solution has Bidder 1 receiving both items, the
efficient allocation.

To the extent that bidders value some of the items in the auction as substitutes, then it may be important for any two bids by the same bidder to be treated as mutually exclusive. For example, Bidder 2 in the above example may have been willing to bid 1.5 for item A and 1.5 for item B – but not if there was a significant risk that both bids would be accepted. This difficulty is avoided if the auction rules permit at most one of his bids to be accepted. (Such mutually exclusive bids are sometimes referred to as ‘XOR’ bids.) Observe that a rule of mutual exclusivity is fully expressive in the sense that it enables the bidder to express any arbitrary preferences. For example, if Bidder 2 in the above example wished to allow both of his bids to be accepted, he could effectively opt out of the mutual exclusivity by submitting a third bid comprising the package \{A, B\} at a price of 3.

In a static pay-as-bid combinatorial auction, each bidder simultaneously and independently submits a collection of package bids. The auctioneer then solves the winner determination problem: find a combination of bids (at most one from each bidder) that maximizes the seller's revenues subject to the constraint that each item can be allocated to at most one bidder. The submitter of each bid selected in the winner determination problem wins the items specified in the bid and pays the amount of the bid. Rassenti, Smith and Bulfin (1982) are credited with the first experimental study of combinatorial auctions. They studied a static combinatorial auction treating the problem of allocating airport time slots, a natural application given that landing and takeoff slots are strong complements. Bernheim and Whinston (1986) provided an important characterization of equilibria of static pay-as-bid combinatorial auctions under complete information.

6.4 The Vickrey–Clarke–Groves (VCG) mechanism

Just as the payment rule of a pay-as-bid auction for a single item or for homogeneous goods can be modified to be ‘second-price’, an analogous modification can be done in the case of a combinatorial auction for heterogeneous goods. This generalization is due to Clarke (1971) and Groves (1973). Let \( N \) be an arbitrary finite set of items and let \( L \) be the set of bidders. In the Vickrey–Clarke–Groves (VCG) mechanism, each bidder \( b \in L \) submits \( 2^{|N|} \) package bids, for all subsets of set \( N \). After the bids are submitted, the auctioneer finds a solution, \( \{x_b\}_b \subseteq L \), to the winner determination problem. While bidder \( b \) is allocated the subset \( x_b \subseteq N \), he does not pay his bid \( b(x_b) \). Rather, his payment \( \forall x_b \subseteq \mathbb{R} \) is calculated so that \( b(x_b) - \forall x_b = R^*(L) - R^*(L \setminus x_b) \), where \( R^*(L) \) denotes the maximized revenue of the winner determination problem with bidder \( b \) present and \( R^*(L/b) \) denotes the maximized revenue of the winner determination problem with bidder \( b \) absent. With sincere bidding, each bid \( b(x_b) \) corresponds to the bidder's valuation \( \forall x_b \), and \( R^*(L) \) corresponds to the (maximized) social surplus. Thus, bidder \( b \) is allowed a payoff equaling the incremental surplus that he brings to the auction. As in the Vickrey auction for homogeneous goods, a bidder's payment thus equals the opportunity cost of assigning the items to the bidder.

Applied to a setting with a single item, observe that the VCG mechanism reduces to the sealed-bid second-price auction. Applied to a setting of homogeneous goods and non-increasing marginal valuations, the VCG mechanism reduces to the (multi-unit) Vickrey auction. By the same reasoning as before, the dominance properties of these special cases extend to the setting with heterogeneous items: if bidders have pure private values, sincere bidding is a weakly dominant strategy for every bidder,
yielding an efficient allocation.

6.5 Dynamic combinatorial auctions

In auctions for a single item, we have seen that a close relationship exists between a dynamic procedure with a pay-as-bid payment rule (that is, the English auction) and a static procedure with a second price rule (that is, the sealed-bid second-price auction). Furthermore, for homogeneous goods with non-increasing marginal values, an analogous relationship holds between the dynamic Ausubel auction and the static Vickrey auction. An important question for heterogeneous goods is the extent to which outcomes of a dynamic combinatorial auction with a pay-as-bid rule map to the static VCG mechanism.

Banks, Ledyard and Porter (1989) conducted an early and influential study of dynamic combinatorial auctions. They defined several alternative sets of rules for the auction, developing some theoretical results and conducting an experimental study. Other important contributions have included Parkes and Ungar (2000), who independently provided a formulation of the ascending proxy auction described below, and Kwasnica et al. (2005).

Ausubel and Milgrom (2002) give two formulations of a combinatorial auction and use them to provide a partial answer to the relationship between dynamic combinatorial auctions and the VCG mechanism:

- **Ascending package auction.** Bidders submit package bids in a sequence of bidding rounds. Each new bid must exceed the bidder's prior bids for the same package by at least a minimum bid increment. After each round, the winner determination problem is solved, on all past and present bids, to determine a provisional allocation and provisional payments. The auction concludes after a round in which no new bids are submitted.

- **Ascending proxy auction.** Each bidder enters his valuations for the various packages into a proxy bidder. The proxy bidders then bid on behalf of the bidders in an ascending package auction in which the minimum bid increment is taken arbitrarily close to zero.

The second formulation may be viewed both as a new auction format which greatly speeds the progress of the auction, as well as a modelling device for obtaining results about the first formulation. While the first formulation is an extremely complicated dynamic game, efficiency results and a partial equilibrium characterization are available for the second formulation.

A bidder \( b \) in the ascending proxy auction is said to bid **sincerely** if he submits his true valuation, \( v_b(S) \), for every package \( S \subseteq N \); and he is said to bid **semi-sincerely** if he submits his true valuation less a positive constant, \( v_b(S) - c \), where the same constant \( c \) is used for all packages \( S \) with valuations of at least \( c \). The following results refer to the coalitional form game (with transferable utility) corresponding to the package economy: the value of any coalition that includes the seller is the total value associated with an efficient allocation among the buyers in the coalition; and the value of any coalition without the seller equals zero. The core is defined as the set of all payoff allocations that are feasible and upon which no coalition of players can improve.

Ausubel and Milgrom (2002) establish that the payoff allocation from the ascending proxy auction, given any reported preferences, is an element of the core (relative to the reported preferences). Furthermore, for any payoff vector \( \pi \) that is a bidder-Pareto-optimal point in the core, there exists a
Nash equilibrium of the ascending proxy auction with associated payoff vector $\pi$. Conversely, for any Nash equilibrium in semi-sincere strategies at which losing bidders bid sincerely, the associated payoff vector is a bidder-Pareto-optimal point in the core.

Furthermore, the set of all economic environments essentially dichotomizes into two cases. First, if all bidders’ preferences satisfy the substitutes condition, then a single point in the core dominates all other points in the core for every bidder, and it equals the payoff vector from the Vickrey–Clarke–Groves mechanism. Thus, in this first case, the outcome of the ascending proxy auction coincides with the outcome of the VCG mechanism. Second, if at least one bidder’s preferences violate the substitutes condition, then there exists an additive preference profile for the remaining bidders such that there is more than one bidder-Pareto-optimal point in the core. In this second case, the VCG payoff vector is not an element of the core; and the low revenues of the VCG mechanism may become problematic.

7 Conclusion

The proportion of goods and services transacted by auction processes has dramatically increased in recent years and is likely to increase further, making the understanding of auctions and the improvement of their designs increasingly important. At the same time, auctions will remain one of the most useful test beds for game theory, since the rules of the game are better defined than in most other markets. Consequently, auction theory will almost certainly continue to be a central area of study in economics.

J.; bounded rationality; coalitions; common knowledge; continuum of traders; contract curve; convexity; core; core equivalence; correlated equilibrium; folk theorem; game theory; non-transferable utility; perfect competition; rational behaviour; repeated games with incomplete information; Shapley value; strong equilibrium; supergames; transferable utility.

Article

Robert J. Aumann, Professor Emeritus of Mathematics at the Hebrew University of Jerusalem, and member of the interdisciplinary Center for Rationality there, shares (with Thomas C. Schelling) the 2005 Nobel Prize in Economics (Aumann and Schelling, 2005).

Aumann was born in Frankfurt, Germany, in 1930, and moved to New York with his family in 1938. In 1955 he completed his Ph.D. in mathematics at MIT under the supervision of George Whitehead. His thesis, in knot theory, was published in the Annals of Mathematics (Aumann, 1956).

In 1955, Aumann joined the Princeton University group that worked on industrial and military applications, where he realized the importance and relevance of game theory, then in its infancy. In 1956 Aumann joined the Institute of Mathematics at the Hebrew University.

Since the mid-1950s, Aumann has played an essential and indispensable role in shaping game theory, and much of economic theory, to become the great success it is today. He promotes a unified view of the
very wide domain of rational behaviour, a domain that encompasses areas of many apparently disparate disciplines, like economics, political science, biology, psychology, mathematics, philosophy, computer science, law, and statistics. Aumann's research is characterized by an unusual combination of breadth and depth. His scientific contributions are path-breaking, innovative, comprehensive and rigorous, ranging from the discovery and formalization of the basic concepts and principles, through the development of the appropriate tools and methods for their study, to their application in the analysis of various specific issues. Some of his contributions require very deep and complex technical analysis; others are (as he says at times) ‘embarrassingly trivial’ mathematically, but very profound conceptually. He has influenced and shaped the field through his pioneering work. There is hardly an area of game theory today where his footprint is not readily apparent. Most of Aumann's research is intimately connected to central issues in economic theory; on the one hand, these issues provided the motivation and impetus for his work; on the other, his results produced novel insights and understandings in economics. No less important than his own pioneering work is Aumann's indirect impact through his many students, collaborators and colleagues. He inspired them, excited them with his vision, and led them to further important results.

Here we must confine ourselves to brief commentary touching on only a small part of his output. It is important to note that the scope of each description is not indicative of the importance of the contribution. Further and more detailed accounts of Aumann's contributions may be found in Hart and Neyman (1995).

We start with Aumann's study of long-term interactions, which had a most profound impact on the social sciences. The mathematical model enabling a formal analysis is a supergame \( G^* \), consisting of an infinite repetition of a given one-stage game \( G \). (A game \( G \) in strategic form consists of a set of players \( N \), pure strategy sets \( A_i \) for each player \( i \), and payoff functions \( g_i \), which describe the payoff to player \( i \) as a function of the strategy profiles \( a \in A := \bigcup_{i \in N} A_i \).) A pure strategy in \( G^* \) assigns a pure strategy in \( G \) to each period/stage, as a function of the history of play up to that stage. A profile of supergame strategies, one for each player, defines the play, or sequence of stage actions. The payoff associated with a play of the supergame is essentially an average of the stage payoffs.

In 1959 Aumann defined the notion of a strong equilibrium – a strategy profile where no group of players can gain by unilaterally changing their strategies – and characterized the strong equilibrium outcomes of the supergame by showing that it coincides with the so-called \( \beta \)-core of \( G \). When Aumann's 1959 methodology is applied to Nash equilibrium – a strategy profile where no single player can gain by unilaterally changing his strategy – the result is essentially the so-called folk theorem for supergames: the set of Nash equilibria of the supergame \( G^* \) coincides with the set of feasible and individual rational payoffs in the one-stage game. In 1976, Aumann and Shapley (and Rubinstein, 1976, in independent work) proved that the equilibrium payoffs and the perfect equilibrium payoffs of the supergame \( G^* \) coincide.

Supergames are repeated games of complete information; it is assumed that all players know precisely the one-shot game that is being repeatedly played.

The theory of repeated games of complete information is concerned with the evolution of fundamental patterns of interaction between people (or for that matter, animals; the problems it attacks are similar to those of social biology). Its aim is to account for
phenomena such as cooperation, altruism, revenge, threats (self-destructive or otherwise), etc. – phenomena which may at first seem irrational – in terms of the usual ‘selfish’ utility-maximizing paradigm of game theory and neoclassical economics. (Aumann, 1981, p. 11)

The model of repeated games with incomplete information, introduced in 1966 by Aumann and Maschler (Aumann and Maschler, 1995), analyses long-term interactions in which some or all of the players do not know which stage game $G$ is being played. The game $G=G_k$ depends on a parameter $k$; at the start of the game a commonly known lottery $q(k)$ with outcomes in a product set $S=\times iS_i$ is performed and player $i$ is informed of the $i$-th coordinate of the outcome. The repetition enables players to infer and learn information about the other players from their behaviour, and therefore there is a subtle interplay of concealing and revealing information: concealing, to prevent the other players from using the information to your disadvantage; revealing, to use the information yourself, and to permit the other players to use it to your advantage. (Aumann, 1985, pp. 46–47)

The stress here is on the strategic use of information – when and how to reveal and when and how to conceal, when to believe revealed information and when not, etc. (Aumann, 1981, p. 23)

This problem of the optimal use of information is solved in an explicit and elegant way in Aumann and Maschler (1995).

Another substantial line of contributions of Aumann is the introduction and study of the continuum idea in game theory and economic theory.

A perfectly competitive economic model is meant to describe a situation in which there are many participants, and the influence of each one individually is negligible. The state of the economy is thus insensitive to the actions of any single agent; only the aggregate behaviour matters. For instance, in a pure exchange economy in which the initial endowment of each trader is very small relative to the whole, the quantities of goods traded by any one agent cannot essentially affect the total supply and demand.

The first question is: What is the correct way of modelling perfect competition? Aumann introduced the model of economies with a continuum of participants, as the appropriate model where each individual is indeed insignificant:

Indeed, the influence of an individual participant on the economy cannot be mathematically negligible, as long as there are only finitely many participants. Thus a mathematical model appropriate to the intuitive notion of perfect competition must contain infinitely many participants. We submit that the most natural model for this purpose contains a continuum of participants, similar to the continuum of points on a line or the continuum of particles in a fluid. (Aumann, 1964, p. 39)

The introduction of the ‘continuum’ idea in economic theory has been indispensable to the advancement of this discipline. In the same way as in most of the natural sciences, it enables a precise and rigorous
analysis, which otherwise would have been very hard or even impossible. Specifically,

the continuum can be considered an approximation to the ‘true’ situation in which there is a large but finite number of particles (or traders, or strategies, or possible prices). The purpose of adopting the continuous approximation is to make available the powerful and elegant methods of the branch of mathematics called ‘analysis,’ in a situation where treatment by finite methods would be much more difficult or even hopeless (think of trying to do fluid mechanics by solving $n$-body problems for large $n$). (Aumann, 1964, p. 41)

Once the basic model is specified, the next question is: What does perfect competition lead to? The classical economic approach is that there are prices for all goods, which every agent takes as given (he is, after all, insignificant, so his decision cannot affect the prices). In order for the economy to be in a stable situation the prices must be such that the total demand equals the total supply. This is the Walrasian competitive equilibrium. That it exists and is well defined in markets with a continuum of traders was shown by Aumann in 1966; moreover, unlike in finite markets, no convexity assumptions were required.

Another approach considers the possible trades that groups of agents – called coalitions – can make among themselves, in such a way that they all benefit. This leads to the core, a game-theoretic concept that generalizes Edgeworth’s famous ‘contract curve’: the core consists of all those allocations that no coalition can improve upon. These are clearly different concepts:

The definition of competitive equilibrium assumes that the traders allow market pressures to determine prices and that they then trade in accordance with these prices, whereas that of core ignores the price mechanism and involves only direct trading between the participants. (Aumann, 1964, p. 40)

Aumann (1964) showed that the core and the set of competitive allocations coincide in markets with a continuum of traders. By introducing the model of the continuum that expresses precisely the idea of perfect competition, he succeeded in making precise also this equivalence (originally suggested by Edgeworth, 1881, and proved in various other models – Shubik, 1959; Debreu and Scarf, 1963), which has since become one of the basic tenets of economic theory.

Aumann then turned to the study of other concepts in the context of perfectly competitive markets. A traditional idea in economics is that of ‘marginal worth’ or ‘marginal contribution’. This idea is embodied in the concept of value due to Lloyd Shapley (1953). It may be interpreted as follows:

The Shapley value is an a priori measure of a game’s utility to its players; it measures what each player can expect to obtain, ‘on the average,’ by playing the game. Other concepts of cooperative game theory … predict outcomes (or sets of outcomes) that are in themselves stable, that cannot be successfully challenged or upset … The Shapley value … can be considered a mean, which takes into account the various power relationships and possible outcomes. (Aumann, 1978, p. 995)
While the definition of competitive equilibrium or core generalizes in a straightforward manner to the continuum of players case, this is not so in the case of value. This led to a most prolific collaboration between Aumann and Shapley, starting in the late 1960s and culminating in 1974 with the publication of their book *Values of Non-Atomic Games*. They addressed deep problems, both conceptual – how to define the correct notions – and technical, and solved them masterfully. In consequence, most important and beautiful insights were obtained. One example is the ‘diagonal principle’, stating that in games with many players one need consider only coalitions whose composition constitutes a good sample of the grand coalition of all participants. It is important to note that, unlike the core (or the competitive equilibrium), the value solution is applicable in almost every interactive set-up. For instance, political contexts usually lead to situations where the core is empty, whereas the value is well defined and yields most significant insights.

Returning to perfectly competitive economies, in 1975 Aumann obtained another equivalence result, this time between the competitive allocations and the value allocations – on the assumption that the market is ‘sufficiently smooth’. (Again, the continuum of traders model allows Aumann to obtain a precise and general result; the first such result, in transferable utility markets only, is due to Shapley, 1964.) This is perhaps even more surprising than the core equivalence, since the concept of value does not capture, by its definition, considerations of stability and equilibrium.

This equivalence is indeed striking. In Aumann's view:

> Perhaps the most remarkable single phenomenon in game and economic theory is the relationship between the price equilibria of a competitive market economy, and all but one of the major solution concepts for the corresponding game. … Intuitively, the equivalence principle says that the institution of market prices arises naturally from the basic forces at work in a [perfectly competitive] market, (almost) no matter what we assume about the way in which these forces work. (From game theory)

This nicely exemplifies Aumann's view on the universality of the game theoretic approach:

> The more conventional approaches take institutions as given, and ask where they lead. The game-theoretic approach asks how the institutions came about, what led to them? Thus general equilibrium theory takes the idea of market prices for granted; it concerns itself with their existence and properties, calculating them, and so on. Game Theory asks, why are there market prices? How did they come about? (From game theory)

The fundamental insights and understandings obtained in the analysis of perfect competition enabled and facilitated the study of basic economic issues that go beyond perfect competition. We mention a few where Aumann's contributions and influence are most noticeable: monopolistic and oligopolistic competition, modelled by a continuum of traders together with one or more large participants (Shubik, 1959); public economics – models of taxation based on the interweaving of the economic activities with a political process, such as voting (Aumann and Kurz, 1977a; 1977b; Aumann, Gardner and Rosenthal, 1977; Aumann, Kurz and Neyman, 1983; 1987); fixed-price models (Aumann and Drèze, 1986).
Another fundamental contribution of Aumann is ‘Agreeing to Disagree’ (1976): it formalizes the notion of common knowledge and shows (the somewhat unintuitive result) that, if two agents start with the same prior beliefs and their posterior beliefs (about a specific event), which are based on different private information, are common knowledge, then these posterior beliefs coincide. This paper had a major impact; it led to the development of the area known as interactive epistemology and has found many applications in different disciplines like economics and computer science.

Other fundamental contributions include the introduction and study of correlated equilibrium, the study of bounded rationality, and many important contributions to cooperative game theory: extending the theory of transferable utility (TU) games to general nontransferable utility (NTU) games, formulating a simple set of axioms that characterize the NTU-value (introduced in Shapely, 1969) and the ‘Game-Theoretic Analysis of a Bankruptcy Problem from the Talmud’ (Aumann and Maschler, 1985). Aumann has been a Member of the US National Academy of Sciences since 1985, a Member of the Israel Academy of Sciences and Humanities since 1989, a Foreign Honorary Member of the American Academy of Arts and Sciences since 1974, and a corresponding fellow of the British Academy since 1995. He received the Harvey Prize in Science and Technology in 1983, the Israel Prize in Economics in 1994, the Lanchester Prize in Operations Research in 1995, the Nemmers Prize in Economics in 1998, the EMET prize in Economics in 2002, the von Neumann prize in Operations Research in 2005, and the Nobel Memorial Prize in Economic Sciences in 2005. He was awarded honorary doctorates by the University of Bonn in 1988, by the Université Catholique de Louvain in 1989, and by the University of Chicago in 1992.

Article

Aupetit was born in Sancerre (Cher). His two doctoral theses at the Faculté de Droit were respectively entitled Théorie générale de la monnaie (1901) and Les accidents du travail dans l’agriculture. Having twice failed the concours d’agrégation, the narrow gateway to a professorship at the Faculté de Droit, he entered the research department at the Banque de France, where he served as secretary-general from 1920 to 1926. He then entered private business. In 1936 he was elected a member of the Institut de France. His teaching was restricted to the Ecole Pratique des Hautes Etudes (1910–14) and to the Ecole des Sciences Politiques, from 1921 on.

Considered by Walras as his first disciple in France, Aupetit can best be judged by the master himself: ‘He is in agreement with my social economics as well as with my pure and applied economics. He is the best and most brilliant disciple and successor I may wish to have’ (Jaffé, 1965, p. 353). Aupetit’s Essai sur la théorie générale de la monnaie is a faithful though simpler and more precise reformulation of Walras’ general equilibrium and monetary theories. The postulates sustaining the quantity theory are made remarkably explicit. Questions of composite monetary standards, bimetallism, exchange rate determination and index numbers are also thoroughly discussed.

Auspitz was born on 7 July 1837 in Vienna, where he died on 8 March 1906. He grew up in a well-educated Jewish family and studied mathematics and physics but without acquiring a degree. At the age of 26, apparently with some reluctance, he became a businessman and founded one of the first sugar refineries of the Austrian empire. As a lifelong opponent of cartels, he used to donate the extra profits he obtained from the sugar cartel to the employees’ pension fund. Auspitz was also Richard Lieben's partner in the family bank, Auspitz, Lieben & Co.

A successful Liberal politician, Auspitz was a member of the Moravian Diet (1871–1900) and of the Austrian lower chamber (1873–90 and 1892–1905), where he acquired a reputation and influence as a financial expert. His first wife was Lieben's sister and a first cousin. They had two children, but the marriage was dissolved after 20 years because of the wife's insanity, whereupon Auspitz married his children's governess. He seems to have been a man of quiet energy and balanced judgement, untiring but of frail health. In some respects his life reminds one of Ricardo's.

All of Auspitz's significant scientific work was done jointly with Lieben; nothing seems to be known about their relative contributions. In 1889 appeared the Researches on the Theory of Price, the book that assured its authors of a place among the eminent mathematical economists. It is essentially an exhaustive partial-equilibrium analysis of price in terms of an ingenious geometrical apparatus. The fundamental first chapter, preprinted in 1887 to fix priorities relative to Böhm-Bawerk, provides the
basic tools. For every quantity of a given commodity, the ‘curve of total satisfaction’ indicates the maximum amount of money the buyer is willing to pay. The ‘total cost curve’, on the other hand, plots the minimum amount of money for which the seller (producer) is willing to supply each quantity. In modern terminology, these are indifference curves. The corresponding marginal curves, called respectively demand and supply curves, give the maximum (minimum) amount of money for which the buyer (seller) is willing to buy (sell) an additional unit.

On the assumption of a constant marginal utility of money, both parties choose the quantity in such a way that this marginal value is equal to the market place. The two marginal curves are thus equivalent to Marshall's reciprocal demand curves as applied to the exchange of one commodity against money. Auspitz and Lieben did not know Marshall's privately printed paper of 1879, however.

Competitive equilibrium is established where the demand curve intersects the supply curve. The vertical distances between the equilibrium point and the two indifference curves then measure the gains from trade, which leads to an analysis of consumer's and producer's surplus (but without these terms).

In subsequent chapters this apparatus is applied to a wide range of microeconomic problems and cases, including substitutes and complements, indivisibilities, disutility, technical progress, inventories, security markets, forward markets and options. Among many notable pieces of analysis one finds the argument that speculation is socially beneficial if it is profitable, and a derivation of long-run curves as envelopes of short-run curves which was not surpassed until Harrod and Viner. An important final chapter extends the analysis to monopoly, monopolistic competition, excise taxes and international trade, and includes a brilliant discussion of optimal tariffs (which disturbed free-trader Pareto; see Giornale degli Economisti, 1892).

Four appendices present the main argument in terms of univariate differential calculus, concluding with an extension to general equilibrium. In contrast to Launhardt, who, as an engineer, loved to computed numerical results for special functional forms, Auspitz and Lieben emphasize the logic of the problem. Auspitz and Lieben, though highly regarded by men like Edgeworth, Pareto and Fisher, never received the credit they deserved. In their local environment, in view of the Austrian School's intolerance for mathematics, they were academic outcasts. This is illustrated by Menger's critical review (Wiener Zeitung, 8 March 1889, quoted in Weinberger, 1931) and by Auspitz's exchange with Böhm-Bawerk of 1894, which also shows Auspitz's analytical superiority. More importantly, Auspitz and Lieben, cut off from direct scholarly intercourse, were prisoners of their idiosyncrasy, never developing the knack for felicitous terminology and expository devices that in economics is so important for academic success. It also turned out that for partial analysis Cournot's price/quantity diagram is often more illuminating than the reciprocal demand curves.

Despite their gentle, scholarly personalities, Auspitz and Lieben also managed to stir up a controversy with Walras (see Correspondence of Léon Walras and Related Papers, ed. William Jaffé, 3 vols, Amsterdam, 1965). As early as 1887, Launhardt had warned Walras of the ‘plagiarism’ of those ‘insolent Jewish pirates’. The preface to the Researches, while revealing Launhardt's diatribes as entirely unfounded, added a more substantive irritant by arguing that (1) Walras' simultaneous demand curves were not correctly constructed, in as much as the curve for one good presupposes a given price for the other, and (2) there cannot be multiple equilibria. This criticism stung Walras all the more since Edgeworth, in his presidential address of 1889, described Auspitz and Lieben as more accurate than Walras (an unwarranted observation, deleted in Papers Relating to Political Economy). Walras tried to mobilize Pareto and Bortkiewicz in his defence (without success) and began to polemicize against those
who ‘make bad theory in mathematical language’. His own reply, however (reprinted in the 4th edition of the ‘Eléments’), missed the essential point and only added to the confusion. Wicksell, as usual, got things right (Wert, Kapital und Rente, 1893). Auspitz and Lieben had overlooked the fact that Walras’ curves, in effect, related to the demand and supply of one good in terms of the other, and the impossibility of multiple equilibria depended on the constancy of the marginal utility of money. After Auspitz's death Lieben graciously acknowledged their error (to which Walras, ungraciously, replied that the point was not important after all).

Abstract

Writing on economic subjects began in Australasia (Australia and New Zealand) within a decade or two of the commencement of European settlement. There are many examples of innovative and influential contributions to economics from these countries, but there has never been a ‘school’ of Australasian economics. Between the two world wars, economics in Australia experienced a golden age, when a small group of economists influenced economic policy and advanced economic thought. Since the 1940s, however, Australasian economics has been dominated by ideas and methods associated with work in the United States.

Article

There has never been a ‘school’ of Australasian economics in the sense that English, German, Austrian, Italian, American and Swedish schools are said to have existed. This is not to say that Australians and New Zealanders have contributed little or nothing to the history of
Australasia, economics in: The New Palgrave Dictionary of Economics

economics. On the contrary, an economics literature commenced from the early decades of the 19th
century. For the most part, economic analysis was derived from ideas originating outside the region,
though imported ideas were adapted, extended and refashioned to meet peculiar Australasian conditions
and circumstances. Between the two world wars, economics in Australia experienced a golden age when
a remarkable group of economists exerted a profound impact on economic policy, and in the process
advanced economic thought. Since the Second World War, Australasian economics has been dominated
by approaches and methods that are characteristically associated with the discipline in the United States,
a phenomenon by no means unique to Australia and New Zealand.

The 19th century

Survival was difficult and far from guaranteed for some years immediately after the establishment of
European settlement in Australia in 1788. In these circumstances there was little time to write about
economics. But as private activity evolved from the original penal settlements, economic issues were
debated more frequently. By the 1840s, a flourishing private economy had developed around the wool
export trade with Britain. The pastoral industry was land intensive, giving rise to discussion about the
occupation and alienation of crown land. The growth of domestic production led to an interest in its
measurement and the contributions made by different industries. The creation of private institutions,
especially those catering to foreign trade, including banks and other financial institutions, wholesaling
and retailing, shipping and inland transport, became subjects of interest among those who wrote and
talked about economic matters. Population growth and immigration were other subjects that drew
attention. With the rise of domestic and foreign trade, instability occasioned by excessive optimism and
pessimism was manifested in booms and slumps; this, too, engaged the interest of writers.
E.G. Wakefield, though he never visited the antipodes, wrote in 1829 that the Australian colonies were

in a barbarous condition, like that of every people scattered over a territory immense in
proportion to their numbers; every man is obliged to occupy himself with questions of
daily bread; there is neither leisure nor reward for investigation of abstract truth; money-
getting is the universal object; taste, science, morals, manners, abstract politics are
subjects of little interest unless they bear on the wool question. (Quoted in Nadel, 1957, p.
36)

There is some truth in this, but, by the time Wakefield wrote, pamphlets and books by colonists on
economic topics had started to appear. In 1819, for example, W.C. Wentworth published A Statistical,
Historical, and Political Description of the Colony of New South Wales and its Dependent Settlements in
Van Diemen's Land. Wentworth estimated the national income of New South Wales and Van Diemen's
Land (since renamed Tasmania), and discussed processes of economic development that borrowed
heavily from Adam Smith. Another early writer of some significance was the Reverend John Dunmore
Lang. In 1834 he published An Historical and Statistical Account of New South Wales which provided a
description of economic progress in the colony and an analysis of the nature and causes of the
depressions of the late 1820s and the early 1840s.
William Stanley Jevons spent some years in Australia in the 1850s as assayer to the Royal Mint in
Sydney. He wrote on railways and land development, and commenced a social survey of Sydney, revealing some of the promise that later was to emerge in his work in economics. Perhaps the most important writer on economics in Australia during the second half of the century was William Edward Hearn. Born in Ireland and educated at Trinity College, Dublin, an exact contemporary of Cairnes and Cliffe Leslie, Hearn in 1854 was appointed foundation Professor of Modern History, Modern Literature, Logic and Political Economy in the University of Melbourne. As an academic (he later became a Member of Parliament), Hearn published a number of books, of which the most important was *Plutology* (1863). Written as a university textbook, it was widely known in Britain and elsewhere as an outstanding summary of the state of economic knowledge. Hearn believed that the satisfaction of wants, and the efforts to meet them, constituted the chief problems of economics.

Another prominent writer of the second half of the 19th century was Sir Anthony Musgrave, Governor of South Australia and later of Queensland. His major work, *Studies in Political Economy* (1875), contained six essays critical of J.S. Mill. He claimed that Mill had failed to explore adequately the role of money as a store of value and there were deficiencies in Mill's discussion of capital. Though Musgrave's work was often quoted, his jaundiced view of Mill's writing won him few friends among authorities overseas. David Syme, proprietor of *The Age*, a Melbourne newspaper, was yet another writer with a reputation beyond Australia. Better known for his powerful advocacy of protection, and for his writing on the disposal of crown land, Syme published as well on economic methodology and other abstract topics. His *Outlines of an Industrial Science* (1876) seems to have been known in Europe, notably in Germany. Syme supported the application of inductive approaches to economics and criticized Mill for arguing that economics should be based on deduction. He wrote as well on economic motivation and on supply and demand analysis, criticizing as he did Mill's theory of value.

Towards the end of the 19th century a number of factors combined to encourage greater scrutiny of economic issues. One was the banking and financial crisis and collapse of economic activity in eastern Australia in the 1890s. As a consequence of the depression, debate sharpened on subjects such as the causes of fluctuations in economic activity, the role of government in moderating booms and slumps, the need for a central or government bank, unemployment and tariff policy. Another issue was the projected federation of the Australian colonies. Hitherto the six colonies of Australia had acted independently, having their own administrations, including armies and navies. Ever since the middle of the 19th century there had been calls for an Australian federation; during the 1890s several inter-colonial conventions were held to draft a federal constitution, at which economic and financial considerations, including tariffs, taxation, federal–state finance, money and banking, were debated at length.

Reflecting the heightened interest in economics for these and other reasons, an Australian Economic Association was formed in Sydney in 1887. Between March 1888 and December 1898 the Association published a monthly periodical (for a short time it was published fortnightly). Contributors to the *Australian Economist* were interested principally in the issues of the day, including unemployment, wage rates, tariff policy, recovery measures, control of banks and money, land tenure, federation, socialism, state banks, education, immigration, the role of women, democracy, bimetallism, old age pensions and industrial arbitration. Short extracts from the works of prominent economists, including Jevons, Marshall and F.A. Walker, were often included, as were articles about the work of these and other economists.

The most original of the local contributors to the *Australian Economist* was Alfred De Lissa, whose work sometimes is heralded as a forerunner of the multiplier. In March 1890 he read to the Australian
Economic Association a paper on The Law of the Incomes (1890), in which he noted that incomes arising from primary production led to an increase in income in other sectors. Using production data, and taking into account leakages abroad, he concluded that, as a general rule, incomes of primary producers equalled incomes of secondary producers; the original primary income, in other words, had a general tendency to multiply by a factor of two. De Lissa later argued that the relationship between primary and secondary income would diminish progressively until the additional income reached zero. An area where Australia was clearly at the forefront of work internationally by the end of the 19th century was the official collection and interpretation of economic and social statistics. The most acclaimed of the colonial statisticians was Timothy Coghlan, the New South Wales Statistician, who pioneered the measurement of the national income using income, output and expenditure methods, an approach similar in many ways to modern national income accounting. Coghlan later worked in London as Agent-General for New South Wales. There he wrote a four-volume economic history of Australia – *Labour and Industry in Australia* (1918) – that drew upon quantitative information he had assembled when he was in Sydney. Later work in Australia by Colin Clark (1940), H.W. Arndt (1949), N.G. Butlin (1962) and G.D. Snooks (1994) acknowledged the ground-breaking statistical work, including national income estimation, of Coghlan and other 19th-century colonial statisticians.

**Economics in the universities**

When the first universities were established in Sydney in 1851 and in Melbourne in 1854, economics was not a subject that attracted much attention. At the University of Sydney, the Professor of Classics (John Woolley) and the Professor of Philosophy (Francis Anderson) took occasional classes in economics. The Professor of Mathematics (Morris Birbeck Pell) and a later Professor of Classics (Walter Scott) gave some lectures in economics outside the university. But, as a result of growing interest in the subject by business organizations, chambers of commerce, and professional associations of bankers and accountants, courses in economics over three years began at the University of Sydney in the early 1900s. A department of economics was established in 1912, to which R.F. Irvine was appointed Professor of Economics, the first separate chair of economics in Australasia. A graduate of Canterbury University College, New Zealand, Irvine had been a pupil of James Hight. Earlier, at the University of Melbourne, Hearn had taught courses in economics for both the BA and the MA. His successor, J.S. Elkington, however, seems not to have taken the same interest in economics, and as a consequence the subject languished for a time in Melbourne.

A final year course in political economy for the BA had been offered at the University of Tasmania since the university's creation in 1889. Later a lectureship in philosophy and economics was established, but the lecturer taught courses mainly in philosophy rather than in economics. The major breakthrough in Tasmania – and, as it turned out, for economics in Australia – occurred in 1917 when Douglas Copland was appointed lecturer in history and economics. In 1920 he was appointed to a chair in economics, and later was elevated to the deanship of a new Faculty of Economics and Commerce. Like Irvine, Copland was a graduate of Canterbury University College, where he, too, had been a pupil of Hight's. In 1924 Copland was the leading force behind the establishment of the Economic Society of Australia and New Zealand, which, in the following year, published the first issue of its journal, *The Economic Record*. In the same year, 1925, Copland was appointed Professor of Commerce in the
University of Melbourne.
In the University of Adelaide, founded in 1874, courses in political economy were taught by William Mitchell in the 1890s, and by Herbert Heaton in the early 1920s; in 1929 L.G. Melville was appointed to the foundation chair of economics. Meanwhile, the universities of Queensland and Western Australia, founded just before the First World War, had established combined chairs of history and economics; Henry Alcock was appointed to the chair at Queensland, and Edward Shann to the chair at the University of Western Australia. In New Zealand by the early 1920s, chairs in economics had been established at four universities: Auckland (Horace Belshaw), Canterbury (J.B. Condliffe), Otago (A.G. B. Fisher) and Wellington (Barney Murphy).

In 1914 Irvine wrote: ‘When one considers the political and economic evolution of Australia, one cannot but be astonished at the neglect of these studies [that is, economics] in Australian universities’ (Goodwin, 1966: 636). That was certainly true of Australia prior to the First World War, but it was not true of New Zealand. By the 1890s, economics had become an important subject of study at Canterbury. There, James Hight was the foundation Professor of History and Economics. More a political historian than an economist, Hight nevertheless promoted economics as a significant field of study. A number of able students were attracted to the subject, including the first two professors of economics in Australia. By the 1920s, John Maynard Keynes could justly write that training in economics at Canterbury ‘was as good as any place in the world’ (Harper, 1986, p. 41).

The golden age of Australian economics

Yet it was in Hobart where the so-called golden age of Australian economics had its origins. Soon after his arrival at the University of Tasmania, Copland became a protégé of L.F. Giblin, a graduate in mathematics of King’s College, Cambridge. Born in Tasmania, Giblin had fought on the western front in the First World War, and on leave in England had met Keynes through mutual friends. When he returned to Hobart, Giblin was appointed Tasmanian Statistician. As a member of the Council of the University of Tasmania, he was instrumental in Copland's appointment to the newly established chair in economics and for the creation of the Faculty of Economics and Commerce. Copland then attracted J.B. Brigden to fill the lectureship that he had vacated. Copland's star pupil at Hobart was Roland Wilson, who later completed doctorates in economics at Oxford and Chicago. Wilson was to become Commonwealth Statistician and later head of the Australian Treasury. The four – Giblin, Copland, Brigden and Wilson – were at the centre of the most important work undertaken in economics in Australia from the 1920s to the 1940s.

The early promise of this group, and the coming of age of Australian economics, can be seen in Copland’s paper, ‘Currency Inflation and Price Movements in Australia’, published in the Economic Journal in 1920. Using Australian data for 1901–17, and invoking Fisher's equation of exchange, Copland derived $P$ as a residual after applying data for $M$, $V$ and $T$. He then compared an actual price series with the hypothetical series for $P$, showing that the two series exhibited close agreement. Copland concluded that the ‘equation of exchange may be regarded as true for Australia’. Keynes praised Copland for this work, referring as he did to Copland's ‘masterly article’ (Coleman, Cornish and Hagger, 2006, p. 51).

Later in the 1920s, Giblin, Copland and Brigden were appointed to the committee of enquiry into the
Australian tariff (*The Australian Tariff: An Economic Enquiry*, often known as the Brigden Report) established by the federal government in 1927 (Brigden et al., 1929). The *Enquiry* concluded that, in Australian circumstances, protection had raised the ‘standard of living’. This controversial conclusion, and the analysis upon which it was based, is said to have been significant for the emergence of modern international trade theory (Coleman, Cornish and Hagger, 2006, 65–73); Keynes adjudged that the *Enquiry* was ‘a brilliant effort of the highest interest’ (Millmow, 2005, p. 1013). Similarly, Giblin's inaugural lecture in April 1930, upon his appointment to the first research chair in economics in Australia (the Ritchie Chair in the University of Melbourne), in which he produced a multiplier based on the repercussions of a decline in exports on total domestic output, is thought to have been an important stepping-stone to the eventual formulation of the Cambridge multiplier. When Giblin sent an early version of his multiplier to Keynes in August 1929, Keynes admitted that Giblin's ‘method of argument’ was ‘novel’ (Coleman, Cornish and Hagger, 2006, p. 83).

The youngest member of ‘Giblin's Platoon’, Roland Wilson, published a book in 1931 that attracted the attention of Viner, Harrod, Hicks, Robertson and Pigou. In *Capital Imports and the Terms of Trade*, Wilson disputed Mill's contention that the import of capital would improve a borrowing country's terms of trade. More importantly, Wilson focused on the consequences of capital imports for the price ratio of tradables to non-tradables. He showed that the ratio would decline. This conclusion was taken up in the 1970s, when it was incorporated in notions such as the Dutch disease and the Gregory thesis (named after R.G. Gregory, an Australian economist who argued in the 1970s that Australia's massive export of minerals would serve to push up the Australian dollar exchange rate with adverse consequences for other industries, particularly manufacturing industry in Australia).

Giblin's group, supported by other economists, played a decisive role in furnishing advice to Australian governments and banks during the early 1930s. The economists were critical of the central bank's policy to retain a fixed rate of exchange with sterling, advising the Bank of New South Wales early in 1931 that it should use its power and prestige as Australia's largest and oldest commercial bank to devalue the Australian pound. The economists’ advice was accepted and the Australian pound was devalued. The federal and state governments then appointed Copland and Giblin to a committee (the ‘Copland Committee’) charged with the responsibility of formulating policies to deal with the depression. The committee's recommendations formed the core of measures included in the famous Premiers’ Plan of 1931. A common theme running through the anti-depression measures proposed by Australian economists was that the loss of income occasioned by the decline in exports should be spread among all income groups and not be confined to export and related trades. Their work was highly praised by foreign observers. Keynes, for example, wrote in 1932 that: ‘I am sure that the Premiers’ Plan last year saved the economic structure of Australia’ (1932, p. 94). As a measure of the influence of Australian economists, Copland was invited to present the inaugural Alfred Marshall Memorial Lectures in Cambridge in 1933; the lectures were published under the title *Australia in the World Crisis, 1929–1933* (1934).

Australian economists were prominent again during and immediately after the Second World War. Shortly before the outbreak of war, the federal government established an Economic and Financial Committee (the F&E) to advise it on economic questions that might arise in the event of war. Giblin was appointed chairman of the committee, which included Copland, Brigden and Wilson. When the war came, the F&E formulated the government's approach to war finance, following principles that Keynes
had put to the British government. When it came to formulating plans for post-war reconstruction, Australian economists prepared at the government's request a domestic employment policy based on demand management. Their proposals were published in the famous government white paper of 1945, *Full Employment in Australia* (Cornish, 1981). The economists supported Keynes's Clearing Union, opposing as they did the rival Stabilization Fund of the United States Treasury. In fact, they went further than Keynes by formulating what they called the ‘international full employment approach’ or ‘positive approach’, sometimes known as ‘Australia's Keynesian crusade’ (Cornish, 1993). This policy arose from Article VII of the Mutual Aid Agreement signed in 1942. In return for United States assistance during the war, recipient countries pledged to enter discussions aimed at liberalizing foreign trade and international payments. Given uncertainty about the restoration of world trade, and concerned about the impact on employment of abolishing preferential trade arrangements, the ‘positive approach’ maintained that Australia would support Article VII provided the United States and other major economic powers committed themselves to policies aimed at maintaining full employment in their domestic economies. Such policies, it was believed, would provide a buoyant demand for Australian exports. Australian representatives promoted the ‘positive approach’ at major international conferences during the 1940s, including those at Bretton Woods, San Francisco and Havana.

**Australasian economics since the Second World War**

The numbers working in economics increased enormously after the Second World War. It is estimated that, in Australia, whereas 5,000 persons graduated in economics between 1916 and 1947, 50,000 graduated between 1947 and 1986 (Butlin, 1987). While there had been no increase in Australian universities between the two world wars, between 1945 and the early 1990s the number rose from six to more than 30. Some of the newer universities offered economics simply as a subsidiary course in business studies programmes; most, however, offered specialist degrees in economics (Groenewegen, 1996). In the 1970s, reflecting the growth of economists, the Economics Society of Australia and New Zealand was divided into two professional organizations – the Economic Society of Australia, and the New Zealand Economic Association. Yet another indicator of the expanding scale of the discipline was the increase in the number of journals dedicated to economics, from one in 1945 (*Economic Record*) to four by the mid-1960s (the additions were *Australian Economic Papers*, *Australian Economic Review* and *New Zealand Economic Papers*).

However distinctive the character of Australasian economics may have been in the interwar period, it disappeared after the Second World War as the American approach, with its emphasis on model building, mathematics and econometrics, began to dominate the discipline (Groenewegen and McFarlane, 1990). It is understandable perhaps that economists seeking to publish their work in leading international journals, many of them American-based, would want to incorporate the latest ideas and methods arising in the United States. The Americanization of the discipline also stemmed in part from the increasing number of students from Australasia going to the United States for postgraduate studies; previously the United Kingdom (Cambridge in particular) had been the destination for graduate studies in economics. Yet the American dominance of economics did not inhibit Australian and New Zealand economists from making important contributions to the subject. For example, there was the work of T.
W. Swan (1956; 1963) and W.E.G. Salter (1959) in growth theory and on issues of internal–external balance in small dependent economies; W.M. Corden's work in the theory and measurement of effective protection, tariff policy and international monetary economics (1971); Murray Kemp's formulation of general equilibrium trade models (1964); G.C. Harcourt's writing on capital theory (1986); A.W. Phillips's contributions to the theory and measurement of inflation, and the relation between wages and unemployment (1958); and the writing on Australia–Asia economic relations by J.G. Crawford (Evans and Miller, 1987), H.W. Arndt (1972) and Ross Garnaut (2001).

Article

The birth of the Austrian School of economics is usually recognized as having occurred with the 1871 publication of Carl Menger's *Grundsätze der Volkwirtschaftslehre*. On the basis of this work Menger (hitherto a civil servant) became a junior faculty member at the University of Vienna. Several years later, after a stint as tutor and travelling companion to Crown Prince Rudolph, he was appointed to a professorial chair at the University. Two younger economists, Eugen von Böhm-Bawerk and Friedrich von Wieser (neither of whom had been a student of Menger), became enthusiastic supporters of the new ideas put forward in Menger's book. During the 1880s a vigorous outpouring of literature from these two followers, from several of Menger's students, and in particular a methodological work by Menger himself, brought the ideas of Menger and his followers to the attention of the international community of economists. The Austrian School was now a recognized entity. Several works of Böhm-Bawerk and Wieser were translated into English; and by 1890 the editors of the US journal *Annals of the American Academy of Political and Social Science* were asking Böhm-Bawerk for an expository paper explaining the doctrines of the new school. What follows seeks to provide a concise survey of the history of the Austrian School of economics.
Austrian School with special emphasis on (a) the major representatives of the school; (b) the central ideas identified with the school; (c) the relationship between the school and its ideas, and other major schools of thought within economics; (d) the various meanings and perceptions associated today with the term Austrian economics.

The founding Austrians

Menger's 1871 book is recognized in the history of economic thought (alongside Jevons's 1871 Theory of Political Economy, and Walras's 1874 Eléments d'économie politique pure) as a central component of the 'marginalist revolution'. For the most part, historians of thought have emphasized the features in Menger's work that parallel those of Jevons and Walras. More recently, following especially the work of W. Jaffé (1976) attention has come to be paid to those aspects of Menger's ideas which set them apart from those of his contemporaries. A series of recent studies (Grassl and Smith, 1986) have related these unique aspects of Menger and the early Austrian economists to broader currents in the late 19th-century intellectual and philosophical scene in Austria.

The central thrust of Menger's book was unmistakable; it was an attempt to rebuild the foundations of economic science in a way which, while retaining the abstract, theoretical character of economics, offered an understanding of value and price which ran sharply counter to classical teachings. For the classical economists value was seen as governed by past resource costs; Menger saw value as expressing judgements concerning future usefulness in meeting consumer wants. Menger's book, offered to the German-speaking scholarly community of Germany and Austria, was thus altogether different, in approach, style and substance, from the work coming from the German universities. That latter work, while also sharply critical of classical economics, was attacking its theoretical character, and appealing for a predominantly historical approach. At the time Menger's book appeared, the 'older' German Historical School (led by Roscher, Knies and Hildebrand) was beginning to be succeeded by the 'younger' Historical School, whose leader was to be Gustav Schmoller. Menger, the 31-year-old Austrian civil servant, was careful not to present his work as antagonistic to that of German economic scholarship. In fact he dedicated his book – with 'respectful esteem' – to Roscher, and offered it to the community of German scholars 'as a friendly greeting from a collaborator in Austria and as a faint echo of the scientific suggestions so abundantly lavished on us Austrians by Germany …' (Menger, 1871, Preface). Clearly Menger hoped that his theoretical innovations might be seen as reinforcing the conclusions derived from historical studies of the German scholars, contributing to a new economics to replace a discredited British classical orthodoxy.

Menger was to be bitterly disappointed. The German economists virtually ignored his book; where it was noticed in the German language journals it was grossly misunderstood or otherwise summarily dismissed. For the first decade after the publication of his book, Menger was virtually alone; there was certainly no Austrian 'school'. And when the enthusiastic work of Böhm-Bewark and Wieser began to appear in the 1880s, the new literature acquired the appellation 'Austrian' more as a pejorative epithet bestowed by disdainful German economists than as an honorific label (Mises, 1969, p. 40). This rift between the Austrian and German scholarly camps deepened most considerably after the appearance of Menger's methodological challenge to the historical approach (Menger, 1883). Menger apparently wrote that work having been convinced by the unfriendly disinterest with which his 1871 book had been
received in Germany, that German economics could be rescued only by a frontal attack on the Historical School. The bitter *Methodenstreit* that followed is usually (but not invariably, see Bostaph, 1978) seen by historians of economics as constituting a tragic waste of scholarly energy. Certainly this venomous academic conflict helped bring the existence of an Austrian School to the attention of the international economics fraternity – as a group of dedicated economists offering a flood of exciting theoretical ideas reinforcing the new marginalist literature, sharply modifying the hitherto dominant classical theory of value. Works by Böhm-Bawerk (1886), Wieser (1884; 1889), Komorzynski (1889) and Zuckerkandl (1889) offered elaborations or discussions of Menger's central, subjectivist ideas on value, cost, and price. Works on the theory of pure profit, and on such applications as public finance theory, were contributed by writers such as Mataja (1884), Gross (1884), Sax (1887), and R. Meyer (1887). The widely used textbook by Philippovich (1893), who was a professor at the University of Vienna (but more sympathetic towards the contributions of the German School), is credited with an important role in spreading Austrian marginal utility theory among German-language students.

In these early Austrian contributions to the theory of value and price, emphasis was (as in the Jevonsian and Walrasian approaches) placed both on marginalism and on utility. But important differences set the Austrian theory apart from other early marginalist theories. The Austrians made no attempt to present their ideas in mathematical form, and as a consequence the Austrian concept of the margin differs somewhat from that of Jevons and Walras. For the latter, and for subsequent microeconomic theorists, the marginal value of a variable refers to the instantaneous rate of change of the ‘total’ variable. But the Austrians worked, deliberately, with discrete variables (see K. Menger, 1973). More importantly the concept of marginal utility, and the sense in which it decreases, referred for the Austrians not to psychological enjoyments themselves, but to (ordinal) marginal *valuations* of such enjoyments (McCulloch, 1977). In any event, as has been urged by Streissler (1972), what was important for the Austrians in marginal utility was not so much the adjective as the noun. Menger saw his theory as demonstrating the unique and exclusive role played, in the determination of economic value, by subjective, ‘utility’, considerations. Values are not seen (as they are in Marshallian economics) as *jointly* determined by subjective (utility) and objective (physical cost) considerations. Rather values are seen as determined *solely* by the actions of consumers (operating within a given framework of existing commodity and/or production possibilities). Cost is seen (by Menger, and especially by Wieser, whose name came to be associated closely with this insight) merely as prospective utility deliberately sacrificed (in order to command more highly preferred utility). Whereas in the development of the other marginalist theories, it took perhaps two decades for it to be seen that marginal utility value theory points directly to marginal productivity distribution theory. Menger at least glimpsed this insight immediately. His theory of ‘higher-order’ goods emphasizes how both the economic character and the value of factor services are derived exclusively from the valuations placed by consumers upon the consumers products to whose emergence these higher-order goods ultimately contribute. Böhm-Bawerk contributed not only to the exposition and dissemination of Menger's basic subjective value theory, but most prominently also to the theory of capital and interest. Early in his career he published a massive volume (Böhm-Bawerk, 1884) in the history of doctrine, offering an encyclopedic critique of all earlier theories of interest (or ‘surplus value’ or ‘normal profit’). This he followed up several years later with a volume (Böhm-Bawerk, 1889) presenting his own theory. At least part of the renown of the Austrian School at the turn of the century derived from the fame of these contributions. As we shall note later on,
a number of subsequent and modern writers (such as Hicks, 1973; Faber, 1979; and Hausman, 1981) have indeed seen these Böhm-Bawerkian ideas as constituting the enduring element of the Austrian contribution. Others, taking their cue from an oft-repeated critical remark attributed to Menger (Schumpeter, 1954, p. 847 n. 8), have seen Böhm-Bawerk's theory of capital and interest as separate from, or even as somehow inconsistent with, the core of the Austrian tradition stemming from Menger (Lachmann, 1977, p. 27). Certainly Böhm-Bawerk himself saw his theory of capital and interest as a seamless extension of basic subjectivist value theory. Once the dimension of time has been introduced into the analysis of both consumer and producer decisions, Böhm-Bawerk found it possible to explain the phenomenon of interest. Because production takes time, and because economizing men systematically choose earlier receipts over (physically similar) later receipts, capital-using production processes cannot fail to yield (even after the erosive forces of competition are taken into account) a portion of current output to those who in earlier periods invested inputs into time-consuming, 'roundabout' production processes.

Böhm-Bawerk became, indeed, so prominent a representative of the Austrian School prior to World War I that, largely due to his work, the Marxists came to view the Austrians as the quintessential bourgeois, intellectual enemy of Marxist economics (Bukharin, 1914). Not only did Böhm-Bawerk offer his own theory explaining the phenomenon of the interest 'surplus' in a manner depriving this capitalist income of any exploitative character, he had emphatically and mercilessly refuted Marxist theories of this surplus. In his 1884 work Böhm-Bawerk had systematically deployed the Austrian subjective theory of value to criticize witheringly the Marxist labour theory underlying the exploitation theory. A decade later (Böhm-Bawerk, 1896) he offered a patient, but relentless and uncompromising elaboration of that critique (in dissecting the claim that Marx's posthumously published Volume 3 of Capital could be reconciled with the simple labour theory forming the basis of Volume 1). This tension between the Marxists and the Austrians was to find later echoes in the debate which Mises and Hayek (third- and fourth-generation Austrians) were to conduct, during the 1920–40 interwar period, with socialist economists concerning the possibility of economic calculation in a centrally planned economy.

Menger retired from his University of Vienna professorship in 1903. His chair was assumed by Wieser. Wieser has been justly described as

the central figure of the Austrian School: central in time, central in the ideas he propounded, central in his intellectual abilities, that is to say neither the most outstanding genius nor one of those also to be mentioned … He had the longest teaching record … (Streissler, 1986)

Wieser had been an early and prolific expositor of Menger's theory of value. His general treatise on economics, summing up his life's contributions (Wieser, 1914), has been hailed by some (but certainly not all) commentators as a major achievement. (Hayek, 1968, sees the work as a personal achievement rather than as representative of the Austrian School.) In the decade prior to the First World War, it was Böhm-Bawerk's seminar (begun when Böhm-Bawerk rejoined academic life after a number of years as Finance Minister of Austria) that became famous as the intellectual centre of the Austrian School. Among the subsequently famous economists who participated in the seminar were Josef A. Schumpeter and Ludwig von Mises, both of whom published books prior to the war (Schumpeter, 1908; 1912;
Austrian economics: The New Palgrave Dictionary of Economics

Mises, 1912).

After the First World War

The scene in Austrian economics after the war was rather different than it had been before. Böhm-Bawerk had died in 1914. Menger, who even in his long seclusion after retirement, used to receive visits from the young economists at the university, died in 1921. Although Wieser continued to teach until his death in 1926, the focus shifted to younger scholars. These included particularly Mises, the student of Böhm-Bawerk, and Hans Mayer, who succeeded his teacher Wieser, to his chair. Mises, although an ‘extraordinary’ (unsalaried) faculty member at the university, never did obtain a professorial chair. Much of his intellectual influence was exercised outside the university framework (Mises, 1978, ch. ix).

Other notable (pre-war-trained) scholars during the 1920s included Richard Strigl, Ewald Schams, and Leo Schonfeld (later Illy). In the face of these changes the Austrian tradition thrived. New books were published, and a new crop of younger students came to the fore, many of whom were to become internationally famous economists in later decades. These included particularly Friedrich A. Hayek, Gottfried Haberler, Fritz Machlup, Oskar Morgenstern, and Paul N. Rosenstein-Rodan. Economic discussion among the Austrians was vigorously carried on, during the 1920s and early 1930s, within two partly overlapping groups. One, at the university, was led by Hans Mayer. The other centred on Mises, whose famed privatseminar met in his Chamber of Commerce office and drew not only the gifted younger economists, but also such philosophers, sociologists and political scientists as Felix Kaufmann, Alfred Schutz and Erik Voegelin. It was during this period that British economist Lionel Robbins came decisively under the influence of the intellectual ferment going on in Vienna. A distinctly important outcome of this contact was Robbins's highly influential book (Robbins, 1932). It was largely through this work that a number of key Austrian ideas came to be absorbed into the mainstream literature of 20th-century Anglo-American economics. In 1931 Robbins invited Hayek to lecture at the London School of Economics, and this led to Hayek’s appointment to the Tooke chair at that institution.

Hayek's arrival on the British scene contributed especially to the development and widespread awareness of the ‘Austrian’ theory of the business cycle. Mises had sketched such a theory as early as 1912 (Mises, 1912, pp. 396–404). This theory attributed the boom phase of the cycle to intertemporal misallocation stimulated by ‘too low’ interest rates. This intertemporal misallocation consisted of producers initiating processes of production that implicitly anticipated a willingness on the part of the public to postpone consumption to a degree in fact inconsistent with the true pattern of time preferences. The subsequent abandonment of unsustainable projects constitutes the down phase of the cycle. Mises emphasized the roots of this theory in Wicksell, and in earlier insights of the British Currency School. Indeed Mises was tempted to challenge the appropriateness of the ‘Austrian’ label widely attached to the theory (Mises, 1943). But, as he recognized, the Austrian label had become firmly attached to the doctrine. Hayek's vigorous exposition and extensive development of the theory (Hayek, 1931; 1933; 1939) and his introduction (through the theory) of Böhm-Bawerkian capital-theoretic insights to the British public, unmistakably left Hayek's imprint on the fully developed theory, and taught the profession to see it as a central contribution of the Austrian School. Given all these developments it is apparent that we must consider the early 1930s as constituting in many ways the period of greatest Austrian School influence upon the economics profession generally. Yet this triumph was to be short-lived indeed.
With the benefit of hindsight it is perhaps possible to understand why and how this same period of the early 1930s constituted, in fact, a decisive, almost fatal, turning point in the fortunes of the School. Within a few short years the idea of a distinct Austrian School – except as an important, but bygone, episode in the history of economics – virtually disappeared from the economics profession. While Hans Mayer continued to occupy his chair in Vienna until after the Second World War, the group of prominent younger economists who had surrounded Mises soon dispersed (for political or other reasons), many of them to various universities in the United States. With Mises migrating in 1934 to Geneva and later to New York, with Hayek in London, Vienna ceased to be a centre for the vigorous continuation of the Austrian tradition. Moreover, many of the group were convinced that the important ideas of the Austrian School had now been successfully absorbed into mainstream economics. The emerging ascendancy of theoretical economics, and thus the eclipse of historicist and anti-theoretical approaches to economics, no doubt permitted the Austrians to believe that they had finally prevailed, that there was no longer any particular need to cultivate a separate Austrian version of economic theory. A 1932 statement by Mises captures this spirit. Referring to the usual separation of economic theorists into three schools of thought, ‘the Austrian and the Anglo-American Schools and the School of Lausanne’, Mises (citing Morgenstern) emphasized that these groups ‘differ only in their mode of expressing the same fundamental idea and that they are divided more by their terminology and by peculiarities of presentation than by the substance of their teachings’ (Mises, 1933, p. 214). Yet the survival and development of an Austrian tradition during and subsequent to the Second World War, largely through the work of Mises himself and of Hayek, deserves and requires attention.

Fritz Machlup has, on several occasions (Machlup, 1981; 1982) listed six ideas as central to the Austrian School prior to the Second World War. There is every reason to agree that it was these six ideas that expressed the Austrian approach as understood, say, in 1932. These ideas were: (a) methodological individualism (not to be confused with political or ideological individualism, but referring to the claim that economic phenomena are to be explained by going back to the actions of individuals); (b) methodological subjectivism (recognizing that the actions of individuals are to be understood only by reference to the knowledge, beliefs, perception and expectations of these individuals); (c) marginalism (emphasizing the significance of prospective changes in relevant magnitudes confronting the decision maker); (d) the influence of utility (and diminishing marginal utility) on demand and thus on market prices; (e) opportunity costs (recognizing that the costs that affect decisions are those that express the most important of the alternative opportunities being sacrificed in employing productive services for one purpose rather than for the sacrificed alternatives); (f) time structure of consumption and production (expressing time preferences and the productivity of ‘roundaboutness’).

It seems appropriate, however, to comment further on this list. (1) With varying degrees of emphasis most modern microeconomics incorporates all of these ideas, so that (2) this list supports the cited Morgenstern–Mises statement emphasizing the common ground shared by all schools of economic theory. However (3) subsequent developments in the work of Mises and Hayek suggest that the list of six Austrian ideas was not really complete. While few Austrians at the time (of the early 1930s) were perhaps able to identify additional Austrian ideas, such additional insights were in fact implicit in the Austrian tradition and were to be articulated explicitly in later work. From this perspective, then, (4) important differences separate Austrian economic theory from the mainstream developments in microeconomics, particularly as these latter developments proceeded from the 1930s onwards. It was left for Mises and Hayek to articulate these differences and thus preserve a unique Austrian ‘presence’ in the
Later developments in Austrian economics

One early expression of such differences between the Austrian understanding of economic theory and that of other schools, was Hans Mayer's paper criticizing ‘functional price theories’ and calling for the ‘genetic-causal’ method (Mayer, 1932). Here Mayer was criticizing equilibrium theories of price that neglected to explicate the sequence of actions leading to market prices. To understand this sequence one must understand the causal genesis of the component actions in the sequence. In the light of the later writings of Mises and Hayek, it seems reasonable to recognize Mayer as having placed his finger on an important and distinctive element embedded in the Austrian understanding. Yet the Austrians themselves during the 1920s (and such students of their works as Lionel Robbins) seemed to have missed this insight. What appears to have helped Hayek and Mises articulate this hitherto overlooked element was the well-known interwar debate concerning the possibility of economic calculation under central planning. A careful reading of the contributions to that debate suggests that it was in reaction to the ‘mainstream’ equilibrium arguments of their opponents that Mises and Hayek made explicit the emphasis on process, learning and discovery to be found in the Austrian understanding of markets (Lavoie, 1985).

Mises had argued that economic calculation calls for the guidance supplied by prices; since the centrally planned economy has no market for productive factors, it cannot use factor prices as guides. Oskar Lange and others countered that prices need not be market prices; that guidance could be provided by non-market prices, announced by the central authorities, and treated by socialist managers ‘parametrically’ (just as prices are treated by producers in the theory of the firm, in perfectly competitive factor and product markets). It was in response to this argument that Hayek developed his interpretation of competitive market processes as processes of discovery during which dispersed information comes to be mobilized (Hayek, 1949, chs 2, 4, 5, 7, 8, 9). An essentially similar characterization of the market process (without the Hayekian emphasis on the role of knowledge, but with an accent on entrepreneurial activity in a world of open-ended, radical uncertainty) was presented by Mises during the same period (Mises, 1940; 1949). In the light of these Mises–Hayek developments in the theory of market process (and recognizing that these developments constituted the articulation of insights taken for granted in the early Austrian tradition: Kirzner, 1985; Jaffé, 1976), it seems reasonable to add the following to Machlup’s list of ideas central to the Austrian tradition: (g) markets (and competition) as processes of learning and discovery; (h) the individual decision as an act of choice in an essentially uncertain context (where the identification of the relevant alternatives is part of the decision itself). It is these latter ideas that have come to be developed in and made central to the revived attention to the Austrian tradition that, stemming from the work of Mises and Hayek, has emerged in the United States in recent decades.

Austrian economics today

As a result of these somewhat varied developments in the history of the Austrian School since 1930, the term ‘Austrian economics’ has come to evoke a number of different connotations in contemporary professional discussion. Some of these connotations are, at least partly, overlapping; others are, at least
partly, mutually inconsistent. If seems useful, in disentangling these various perceptions, to identify a number of different meanings that have come to be attached to the term ‘Austrian economics’ in the 1980s. The present status of the Austrian School of economics is, for better or for worse, encapsulated in these current perceptions.

1. For many economists the term ‘Austrian economics’ is strictly a historical term. In this perception the existence of the Austrian School did not extend beyond the early 1930s: Austrian economics was partly absorbed into mainstream microeconomics, and partly displaced by emerging Keynesian macroeconomics. To a considerable extent this view seems to be that held by economists in Austria today. Economists (and other intellectuals) in Austria today are thoroughly cognizant of – and proud of – the earlier Austrian School, as evidenced by several commemorative conferences held in Austria in recent years, and by several related volumes (Hicks and Weber, 1973; Leser, 1986), but see themselves today simply as a part of the general community of professional economists. Erich Streissler, holder of the chair occupied by Menger, Wieser and Mayer, has written extensively, and with the insights and scholarship of one profoundly influenced by the Austrian tradition, concerning numerous aspects of the Austrian School and its principal representatives (Streissler, 1969; 1972; 1973; 1986).

2. For a number of economists the adjective ‘Austrian’ has come to mark a revival of interest in Böhm-Bawerkian capital-and-interest theory. This revival has emphasized particularly the time dimension in production and the productivity of roundaboutness. Among the contributors to this literature should be mentioned Hicks (1973), Bernholz (1971; 1973), Faber (1979) and Orosel (1981). In this literature, then, the term ‘Austrian’ has very little to do with the general subjectivist Mengerian tradition (which had, as noted earlier, certain reservations in regard to the Böhm-Bawerkian theory).

3. For other economists (and non-economists) the term ‘Austrian economics’ has come to be associated less with a unique methodology, or with specific economic doctrines, than with libertarian ideology in political and social discussion. For these observers, to be an Austrian economist in the 1980s is simply to be in favour of free markets. Machlup (1982) has noted (and partly endorsed) this perception of the term ‘Austrian’. He has ascribed it, particularly, to the impact of the work of Mises. Mises’ championship of the market cause was so prominent, and his identification as an Austrian was at the same time so unmistakable, that it is perhaps natural that his strong policy pronouncements in support of unhampered markets came to be perceived as the core of Austrianism in modern times. This has been reinforced by the work of a leading US follower of Mises, Murray N. Rothbard, who was also prominent in libertarian scholarship and advocacy. Other observers, however, would question this identification. While, as earlier noted, many of the early contributions of the Austrian School were seen as sharply antagonistic to Marxian thought, the school on the whole maintained an apolitical stance. Among the founders of the school, Wieser was in fact explicit in endorsing the interventionist conclusions of the German Historical School (Wieser, 1914, pp. 490 ff). While both Mises and Hayek provocatively challenged the possibility of efficiency under socialism, they too, emphasized the wertfrei character of their economics. Both writers would see their free market stance at the policy level as related to, but not as central to, their Austrianism.

4. For many in the profession the term ‘Austrian economics’ has come, since about 1970, to refer to a revival of interest in the ideas of Carl Menger and the earlier Austrian School, particularly as these ideas have been developed through the work of Mises and Hayek. This revival has occurred particularly in the United States, where a sizeable literature has emerged from a number of economists. This literature
includes, in particular, works by Murray N. Rothbard (1962), Israel Kirzner (1973), Gerald P. O’Driscoll (1977; 1985), Mario J. Rizzo (O’Driscoll and Rizzo, 1985), and Roger W. Garrison (1978; 1982; 1985). The thrust of this literature has been to emphasize the differences between the Austrian understanding of markets as processes, and that of the equilibrium theorists whose work has dominated much of modern economic theory. As a result of this emphasis, this sense of the term ‘Austrian economics’ has often (and only partly accurately; see White, 1977, p. 9) come to be understood as a refusal to adopt modern mathematical and econometric techniques – which standard economics adopted largely as a result of its equilibrium orientation. The economists in this group of modern Austrians (sometimes called neo-Austrian) do see themselves as continuators of an earlier tradition, sharing with mainstream neoclassical economics an appreciation for the systematic outcomes of markets, but differing from it in its understanding of how these outcomes are in fact achieved. Largely as a result of the activity of this group, many classic works of the early Austrians have recently been republished in original or translated form, and have attracted a considerable readership both inside and outside the profession.

5. Yet another current meaning loosely related to the preceding sense of the term has come to be associated with the term ‘Austrian economics’. This meaning refers to an emphasis on the radical uncertainty that surrounds economic decision making, to an extent that implies virtual rejection of much of received microeconomics. Ludwig Lachmann (1976) has identified the work of G.L.S. Shackle as constituting in this regard the most consistent extension of Austrian (and especially of Misesian) subjectivism. Lachmann's own work (1973; 1977; 1986) has, in the same vein, stressed the indeterminacy of both individual choices and market outcomes. This line of thought has come to imply serious reservations concerning the possibility of systematic theoretical conclusions commanding significant degrees of generality. This connotation of the term ‘Austrian economics’ thus associates it with a stance sympathetic, to a degree, towards historical and institutional approaches. Given the prominent opposition of earlier Austrians to these approaches, this association has, as might be expected, been seen as ironic or even paradoxical by many observers (including, especially, modern exponents of the broader tradition of the Austrian School of economics).

[An earlier article on the Austrian School of economics was begun and substantially drafted by Professor Friedrich A. Hayek – himself a Nobel laureate in economics whose celebrated contributions are deeply rooted in the Austrian tradition. The present author gratefully acknowledges his indebtedness (in the writing of this essay) to the characteristic scholarship and treasure trove of facts contained in Professor Hayek's unfinished article, as well as to Professor Hayek's other numerous studies that relate to the history of the Austrian School.]

Averch–Johnson effect

H.A. Averch
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The Averch–Johnson effect is produced when fair rate of return regulation encourages a firm to invest more than is consistent with the minimization of its costs. This can happen when the allowed rate of return exceeds the cost of capital, since the difference between the two represents pure profit. Detailed descriptions of actual regulatory processes may be useful in suggesting guides for action, since actual outcomes depend as much on political and bureaucratic necessity as they do on economic analysis and ‘rational’ benefit–cost estimates.

Article

The Averch–Johnson effect explores some unintended consequences of fair rate of return regulation (Averch and Johnson, 1962). Such regulation may cause the firm to select excessively capital-intensive technologies, and, thereby, not produce its output at minimum social cost. Specifically, the main Averch–Johnson result is that the capital–labour ratio selected by a profit-maximizing, regulated firm will be greater than that consistent with a cost-minimizing one for any output it chooses to produce. If the fair rate of return is greater than the cost of capital, a firm will have an incentive to invest as much as it can consistent with its production possibilities, because the difference between the allowed rate and its actual cost of capital is pure profit.

This brief overview discusses (1) the effects of rate of return regulation on a monopolist's inputs and outputs; (2) the effects on incentives to innovate; (3) the empirical evidence on the existence and strength of the Averch–Johnson effect; and (4) some of the main theoretical extensions. Since 1962, the Averch–Johnson literature has been extended to include objectives other than profit maximization, more subtle interactions between regulators and firms and more complex market conditions. By making the models more complex, the number of possible regulatory outcomes has been enlarged. But the basic Averch–Johnson result, as stated above, has proven remarkably robust. So the discussion here focuses on this result and some of the main corollary results.

Choice of inputs in the basic Averch–Johnson model

Suppose there exists a single-product, profit-maximizing monopolist subject to rate of return regulation. The firm's production function is

Suppose the firm's inverse demand function is

\[ P = P(Q), \quad P'(Q) < 0. \]  

(2)

Profit is

\[ \Pi = PQ - rK - wL. \]  

(3)

Assuming, as is standard, that there is no depreciation and that the acquisition cost of capital is adjusted to one, the rate of return constraint can be written

\[ (PQ - wL) / K \leq s \text{ or } PQ - wL - sK \leq 0, \]  

(4)

or

\[ \Pi \leq (s - r)K, \]  

(5)

where \( s \) is the allowed rate of return. The fair rate of return is taken to be at least as great as the cost of capital \( (s > r) \) and less than the rate the firm could earn if it were unconstrained. Consequently, the constraint is effective, and the firm maximizes

\[ \Pi = PQ - rK - wL. \]  

(6)
subject to (4) or (5). Letting \( R \) equal total revenue \( PQ \), the necessary first order conditions are

\[
(1 - \lambda) R' F_1 - \lambda (s - r) = 0
\]

\[
(1 - \lambda) R' F_2 - (1 - \lambda) w = 0
\]

\[
R - wL - sK = 0.
\]

\( \lambda \) is the standard Averch–Johnson Lagrange multiplier. Given that the constraint is effective, that \( s > \tau \), and that the revenue function \( R = PQ \) is concave, the multiplier \( \lambda \) is greater than zero and less than one. Consequently, the marginal rate of substitution of capital for labour for the regulated firm is

\[
-\frac{dL}{dK} = \frac{r - (\lambda / (1 - \lambda) (s - r))}{w} < r / w.
\]

For any given output, the firm will not minimize cost, since this requires that the firm's marginal rate of technical substitution be equal to \( r/w \).

This result can be shown graphically in several different ways (Baumol and Klevorick, 1970; Zajac, 1970). Zajac's formulation is shown here. Fig. 1 shows the regulatory constraint (9) in relation to the firm's isoquants.

Figure 1
The Averch–Johnson (A-J) effect
The shaded region inside the constraint curve shows input combinations resulting in rates of return greater than \( s \). The firm wants to be as far up to the right on the constraint curve as possible, because, from (5), every increment of capital increases profit. Consequently, the firm will operate at the rightmost point of the constraint curve.

The output for this rightmost point can be obtained from the isoquant that intersects the constraint curve at its rightmost point. However, the least cost combination of capital and labour for producing this output, where \( -\frac{\partial L}{\partial K} = \frac{r}{w} \), lies inside the proscribed shaded area, on the firm's efficient expansion path. For any given output, the firm cannot simultaneously be on the cost-minimizing price line with slope \( -\frac{r}{w} \) and on the constraint curve.

The output of the regulated firm

One of the original rationales for regulation was that it would increase allocative efficiency by forcing monopolists to offer more output than ordinarily they would. If a larger output were always the result of rate of return regulation, then decreases in technical efficiency would be compensated by increases in allocational efficiency. In principle, regulatory agencies could seek an \( s \) that just balanced the marginal benefits of increased output against the marginal costs of decreased efficiency (Klevorick, 1971; Sheshinski, 1971; Bailey, 1973; Callen, Mathewson, and Mohring, 1976).

Increasing output, however, is not inevitable. The firm will use greater quantities of capital as \( s \) falls towards \( r \), but the amount of labour the firm chooses to use will not necessarily be larger, and so output need not be larger. However, if labour is not an inferior input – the most likely case – then the optimal amount of labour for a regulated monopoly will also increase over the unregulated one, and, consequently, so will output (Baumol and Klevorick, 1970; Bailey, 1973). Firms with linear, homogeneous production functions will produce greater output. Given two firms with identical positive, homogeneous production functions – one regulated, one unregulated – the output of the unregulated one becomes a lower bound on regulated output, and the output such that ‘regulated’ average cost equals price becomes an upper bound (Murphy and Soyster, 1982).

Technological change and the regulated firm

Even if regulated firms are inefficient in static situations, technological change conceivably could induce more output through cost reductions. And rate of return regulation might conceivably induce regulated firms to be more innovative than unregulated firms. Regulation usually guarantees some profits, if not maximal ones, and these could be used for innovation.

If technological change is exogenous to the firm, but is factor-augmenting, then the optimal constrained \( K^* \) rises (Westfield, 1971; Magat, 1976). However, factor-augmenting technological advance will not necessarily result in increased output, since the firm may again use less labour to produce its output. Technological change, of course, is not usually entirely exogenous. Through their own research and development (R&D), firms gain knowledge of feasible innovation possibilities. Profit-maximizing firms subject to both a rate of return constraint and their own innovation possibilities constraint can, depending on production conditions, choose more labour-augmenting technologies than they would without regulation, reinforcing the bias the regulated firm has towards relatively capital-intensive technologies (Smith, 1974, 1975; Okuguchi, 1975).

In any case, regulation does not unambiguously increase innovation possibilities. The R&D expenditures of the regulated firm are not always larger than those that an unregulated firm would select under the same production and demand conditions (Magat, 1976). Furthermore, there is no systematic evidence that regulated firms select more high payoff R&D projects than unregulated ones and much anecdotal evidence to indicate that they are highly conservative.

Empirical tests

In the mid-1970s and early 1980s there were a number of attempts to determine whether Averch–Johnson effects actually existed and whether, if they existed, they imposed significant social costs. The empirical investigations used different tests for the effect and different data sets, most, however, relating to electric utilities. Unsurprisingly, the empirical evidence from these efforts was mixed. But overall the number of empirical investigations that find some evidence for the Averch–Johnson effect or its behavioural consequences outnumber those that find no evidence.

Using different methods but similar data, Courville (1974) and Spann (1974) concluded that Averch–Johnson effects existed. Petersen (1975), using a cost-minimizing version of the Averch–Johnson model, found that as the allowed rate of return approached the market cost of capital, capital costs increased as did the share of those costs in total costs. Hayashi and Trapani (1976) confirmed that regulated firms have a capital–labour ratio greater than the cost-minimizing one and that tightening \( s \) decreases efficiency. However, Boyes (1976) concluded that there was no effect.

Smithson (1978) reported that there was static inefficiency among electric utilities, but he could not confirm that lowering the rate of return caused the optimal capital stock to increase. Tapon and Van der Weide (1979) found that only strictly regulated electric utility firms exhibit Averch–Johnson effects, but that less than half of the industry appears to be so regulated. Regulatory lag permits firms to avoid Averch–Johnson effects, but raises the question of the worth of public investments in regulatory institutions.
Averch–Johnson effect

The Averch–Johnson results have been extended and generalized in many ways. Three of the more significant extensions are discussed below.

Theoretical extensions

Regulatory lag and stochastic review: The original Averch–Johnson result implicitly assumed regulatory agencies were always effective in enforcing the rates they chose. In fact, regulators have great difficulty in keeping actual rates close to target rates. The regulatory process does its work episodically, through adjustments in price. Occasional adjustments, the regulator hopes, will bring the actual rates close to a tolerable level, if not back to the one originally set. Since regulation is a political, bureaucratic and legal process, there are almost always lags in enforcement. Consequently, firms may be able to escape the constraint for long periods of time (Bailey and Coleman, 1971; Klevorick, 1973).

Sufficient regulatory lag may allow the firm to be technically efficient at an unregulated monopolist's output, and it may induce more technological innovation than the case without enforcement lag. Continuous, effective regulation would prevent the firm from gaining the windfall profits that innovation may require, although Nelson argues that most technological change in the utilities industry is disembodied and has little relation to regulation (Nelson, 1984).

Demand uncertainty: Some authors argue that Averch–Johnson results hold only under some specifications of a stochastic demand function, but not others (Perrakis, 1976; Peles and Stein, 1976). Most of this discussion goes to whether the optimal capital stock would be larger, if regulated firms faced stochastic demands. If, as in the original Averch–Johnson analysis, we assume that the firm selects its capital stock and labor force simultaneously, then the basic Averch–Johnson result, the inefficient capital–labour ratio, still holds under stochastic demand (Das, 1980).

Dynamic analysis: Some authors have introduced time explicitly into the original static Averch–Johnson model. For example, El-Hodiri and Takayama (1981) interpret the 'Averch–Johnson effect' to be a larger optimal capital stock for a regulated firm than an unregulated one, and they show that this is true even with the adjustment costs attributable to time. However, much of this dynamic literature has been devoted to showing that, given a firm that maximizes the present value of profits over any number of time periods, one or more Averch–Johnson results do not hold or hold only under special conditions (Niño and Musaccio, 1983; Dechter, 1984).

The significance of the Averch–Johnson effect

From the standpoint of microeconomic theory, the original Averch–Johnson results provided impetus for increasingly complex, analytical models of the regulatory process. The Averch–Johnson approach suggested that much of the conventional, qualitative wisdom about regulation could be modelled and tested and that it was necessary to do so. Without thinking through all the potential consequences, actions and rules could be quite flawed without anyone intending them to be so. But flaws generally become apparent only after actions and rules have become entrenched, difficult to change or reverse. So explicit modelling of regulatory rules became part of the economist's stock in trade.

From a public policy perspective, the Averch–Johnson results and the very large volume of follow-on research have made economists, legislators and administrators far more sensitive to the potential unintended consequences of regulatory alternatives in general and not just rate of return alternatives. The Averch–Johnson effect has also figured directly in rate cases with utilities sometimes forced to defend themselves against charges of inefficiency.

Future lines of development

By injecting changes into the Averch–Johnson formulation one at a time, theoretical work has sought to make the model more representative of the actual regulatory process. One set of writers has pursued the effects of stochastic demand. Another set has worked on regulatory lag and stochastic review processes, but without stochastic demand. Yet another set has had the firm making global optimizations over time without either stochastic demands or random review. Economists interested in welfare issues have tried to determine an optimal fair rate of return from a strict economics perspective, but neglected politics and bureaucratic behaviour in setting rates. No model builders to date have addressed firms and regulators
as interacting organizations both suffering from bounded rationality and bounded information, although there is some recent work on what regulators might do when a firm’s costs are unknown and it has incentives to lie (Baron and Meyerson, 1982).

Regulatory systems are so complex and interactive that the standard strategy of a priori modelling with a minimum number of plausible assumptions may no longer have sufficient pay off. In complex, interactive, relatively poorly understood situations, other analytical styles such as simulation or operational gaming can be useful. They have not been tried and probably should be. In fact, brute force, detailed descriptions of actual regulatory processes may be highly useful in suggesting guides for action. Regulation remains a problem in political economy. Actual outcomes depend as much on political and bureaucratic necessity as they do on economic analysis and ‘rational’ benefit–cost estimates.

Ayres, Clarence Edwin (1891–1972)

Warren J. Samuels

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Ayres, C. E.; culture; industrialization; institutional economics; methodological collectivism; technology; values; Veblen, T.

Article

Ayres was born on 6 May 1891 in Lowell, Massachusetts, and died on 25 July 1972 in Alamogordo, New Mexico. Trained as a philosopher, with degrees from Brown and Chicago (PhD, 1917), Ayres taught at Chicago, Amherst and Reed before moving to the University of Texas at Austin in 1930, from which he retired in 1968. For one year, 1924–5, he was an associate editor of *The New Republic*, associated with Herbert Croly, John Dewey, Alvin Johnson and R.H. Tawney. He had a lifelong correspondence with another philosophically oriented, but more traditional economist, Frank H. Knight. He was profoundly influenced by Thorstein Veblen and Dewey and became, if not the, leader of institutional economics after World War II. A truly charismatic lecturer, at Texas he had long-lasting influence on a coterie of students who continued his teachings in their own careers. As his ideas evolved, particularly with regard to the nature of and relations between institutions and technology, his students came away with coherent but varying substantive understandings.

Ayres’ formulation of institutionalism stressed that science was a system of belief, that human values were only means to the continuation and enhancement of the life process, that technology, as he defined it, was a (largely) beneficent driving force in social change, and that considerations of rightness tended in practice to be matters of tradition and custom.

Technology, to Ayres, meant the use of tools, but he defined tools increasingly broadly to include intangible symbols and organizations. Technology was the surging force governing economic welfare, and constituted what he considered to be an objective industrial or developmental process. His conception of technologically instrumental value and truth emphasized the transcultural values of workability and efficiency which form a continuum. Opposed to technology was the binding force of established institutions which, through sanctioning ceremonial behaviour in favour of established or vested interests, were hostile to the conceptual and economic progress generated by technology.
Economic progress was thus fundamentally a matter of industrialization; the logic of industrialization, or technological advancement in all respects, was continually at war with outworn, inhibitive institutions. Mankind's task was to develop new institutional forms and revise old ones in order to keep pace with evolving technology.

Ayres insisted that human behaviour was socially formed, and that for such behaviour to be explained and understood the economist had to study existing behaviour patterns (institutions) and general culture. In common with other institutionalists, Ayres insisted upon methodological collectivism and challenged what he considered to be the narrow focus on market equilibrium conditions maintained by mainstream economics.

Ayres influenced many development economists, who similarly perceived that modernization was inhibited by the continuance of traditional institutions or by the maintenance of positions of power antagonistic to modernization. More generally, Ayres, again like other institutionalists, argued that to understand the allocation of resources one had to go beyond the market to the institutions and cultural forces which, in part through adaptation to and incorporation of technology, constitute the real allocational mechanism. In a sense, the neoclassical juxtaposition between cost of production and utility became for Ayres something different, a juxtaposition between technology and the institutions which formed and weighted individual and collective choice.

Charles Babbage is rarely regarded as a major contributor to economic thought. His name is synonymous with the early origins of the computer, and he was an important figure in early 19th-century scientific circles. He was educated at Trinity College and Peterhouse, Cambridge, and while still a student started the Analytical Society with Herschel and Peacock, for reforming mathematics in Britain. His interest in mathematics was the foundation for his later contributions to science, economics and statistics. After Cambridge, Babbage moved to London, where he began his lifelong work on his analytical engine and became a leading participant in scientific circles. He joined the Royal Society and was a founding member of the Cambridge Philosophical Society and the Royal Astronomical Society. Later he was to be one of Newton's illustrious successors in the Lucasian Chair of Mathematics at Cambridge. But he was also a radical if maverick intellectual and political critic. He wanted to see science reformed, to see British science play a leading part in theoretical advance, and to see this science related closely to applied technology. He also demanded a role for the state in providing support for science and university education, and for establishing a policy on technology. He wrote a controversial attack on the Royal Society, Reflections on the Decline of Science and Some of its Causes (1830), and was one of the founding trustees of the British Association for the Advancement of Science, with the purpose of bringing science and technology, from the provinces as well as the metropolis, into the forefront of culture and society.

Babbage was an early promoter of industrial exhibitions as a part of meetings of the British Association; he participated in the Mechanics Section of the Association and later wrote a book on the Great Exhibition of 1851. He took part in the great controversies over religion and science in the period, and wrote the Ninth Bridgewater Treatise in 1837 (2nd edn 1838), conveying his belief in a Newtonian universe, with a scientific Deity.
Politically, Babbage was a liberal Whig; he chaired an election committee and stood twice for Finsbury. He denounced election corruption and bribery, attacked church preferments and tithes, and was a firm supporter of the Reform Bill. His political pamphlet on income tax showed a concept of moderate reform. He identified an electoral system based on one man, one vote with the ‘advance of socialism’, for where the poor were in the majority they would vote for low taxes for themselves and high taxes for the rich, ‘thus destroying private enterprise’.

Babbage's social and academic context was clearly that of early 19th-century liberal-scientific circles, and he participated in the salon culture of the day. But there was another very important component to his intellectual make-up: an abiding interest in practical mechanics and a fascination with contemporary industrial technology. He learned from manufacturers, large and small, mechanical engineers and above all from the skilled artisans he never ceased to praise. Developing the analytical engine was itself a task of scientific and mathematical reasoning combined with practical invention. The continental tour he made in 1827–8, which was to be so formative to his later work, was not in the company of a scientific friend or even a servant, but with one of the artisans who had worked on the building of the analytical engine. Travelling through the Low Countries, Germany, Austria and Italy with a prolonged stay in Naples, Babbage lost no opportunity to visit local workshops and factories.

His transcendence of contemporary social and intellectual boundaries was the real basis for his brilliant and utterly original foray into political economy. On the Economy of Machinery and Manufactures (1832) was immensely popular: there were four editions in two and a half years, it was reprinted in the United States and translated into four continental languages. Babbage wanted to present his readers with the mechanical principles of arts and manufactures, and he hoped also to be read by the intelligent working man. To this extent the book fell within the contemporary genre of industrial-technological literature; indeed, part of it had been published in 1829 as a part of the Encyclopedia Metropolitana. Tracts on the steam engine, histories of the cotton industry and industrial manuals, dictionaries and encyclopedias were very popular at the time. Andrew Ure's later Philosophy of Manufactures (1835), an extraordinary panegyric on the factory system and steam-powered machinery, was very much a product of this genre, but it completely lacked the analysis of Babbage's contribution. The latter was much more than popular industrial observation. It was an analysis based on economic principles, especially the Smithian account of the division of labour, of manufacturing technology and the organization of industrial work. Babbage's obvious first-hand knowledge of a wide variety of industrial and business processes, combined with general analysis of production systems, made the work a tour de force. At a time of anxiety and ambiguity over the reception of new technology, he also offered authoritative policy statements on a wide range of machinery issues including patent reform, export of machinery, crises of overproduction, and technological unemployment.

The book's intellectual situation in relation to political economy was not, however, easily apparent, and apart from Mill and Marx few appreciated its significance to their discipline. Before he wrote the book Babbage had intended to deliver a series of lectures in Cambridge on the Political Economy of Manufactures, but this never materialized. He himself conceded that his first edition did not profess to examine questions of political economy, and he attempted to correct this in the next edition by introducing three new chapters: ‘The new system of manufactures’, ‘The effects of machinery in reducing the demand for labour’, and ‘On money as a medium of exchange’. But most of the topics raised by Babbage were also foreign to contemporary classical political economy. Moving back to Smith, he analysed industrial organization and the microeconomics of the manufacturing firm, never
The book was initially criticized for failing to give due attention to the factory system and steam-powered textile technology. But this was precisely its strength, for it analysed the factory and the workshop as parts of the more general organization of work, and examined machinery in the context of a more general discussion of technology, including skill. Babbage's close observation of skills and hand processes as well as machinery, of the workshop as well as the factory, was anyway a more accurate perception of contemporary industrial practice than a work concentrating on the outstanding and atypical phenomenon of the factory would have been.

Babbage analysed what he called ‘the domestic economy of the factory’. He sought to specify what arrangement of production would succeed in selling articles at a minimum price, and he made a careful analysis of economies of scale in relation to the division of labour, distinguishing the dynamics of the factory from those of the workshop. He developed Smith's principle of the division of labour to a further refinement, introducing the significance of the division of skill, or the division of mental and manual labour. Vital, he believed, to the success of any organization of work was his ‘Babbage Principle’: that the master manufacturer by dividing the work to be executed into different processes, each requiring different degrees of skill or of force, can purchase exactly that precise quantity of both which is necessary for each process.

From this emphasis on the economy of skill, Babbage introduced novel discussions of the role of accounting, time and motion studies, communications innovations, and an analysis of machine functions. He was particularly concerned with the significance of precision and measurement in all processes, with the regularity of production, and with the planning of layout. He thus regarded as some of the greatest innovations not the celebrated power techniques themselves, but the processes which helped to make the new machines work properly, for example the steam engine governor and lubrication or grease. His interest in measurement led him to support all manner of instruments for counting machines and human actions; and he devised a detailed questionnaire as a basis for job studies and early time and motion studies. He also analysed as had no one before him the role of the speed of production and the intensity of labour in increasing output. Introducing machinery was only one incomplete route to increasing productivity; the productivity of labour could be rapidly improved through greater order, precision and labour discipline. Babbage noticed the convergence of technological and economic principles on topics such as velocity and copying; in a long discussion of the significance of copying techniques he pointed out the parallels between printing, casting and moulding, stamping and turning. This core analysis of workshop organization was complemented by topical commentary on profit sharing, technological unemployment and trade unions. An important radical departure on wages and labour was provided in his ‘New System of Manufactures’ which argued for a piece-rate wage system and profit sharing, if not cooperation, as the key to overcoming the long-standing worker opposition to machinery. This was the problem which Babbage along with many of his contemporaries believed to be the major brake on Britain's industrial progress. The system was a far-reaching proposal for a worker's stake in increasing productivity, for collective decision-making on hiring, dismissal and the organization of the works. Where the system prevailed, modern methods would be chosen and an extensive division of labour introduced, not to control and subordinate labour, but as a cooperative decision by workers for
the most efficient methods. The lengths to which his suggestions went were probably surpassed only by radical and Owenite cooperatives. When it came to practical implementation Babbage held out little hope of any appeal of the system to large established firms, but thought that groups of artisans and small firms would lead the way. Babbage's chapters on trade unions and machinery and employment were, however, the comments of a reformer not a radical. He attacked the truck system, but warned that trade unions could well lead to more rapid displacement of labour through machinery or industrial relocation. Dealing with technological underemployment, he used the case of hand-weaving and the power loom, arguing that the only solution lay in better workers' planning through such institutions as savings banks and friendly societies.

Babbage's use of practical observation and statistical data, and his critique of political economy's 'closest philosophers', induced him, with Richard Jones, J.E. Drinkwater, Malthus and Quetelet, to form a Statistics Section of the British Association in 1833, followed later by the Statistical Society of London. The Statistical Section, Section F, was confined to the presentation of statistical data, avoiding areas of political controversy. But the less restrictive London Society made its brief the connection of political economy to the statistical investigation of economic improvement. Babbage was the first President of Section F, and wrote several statistical papers. His earlier ‘Letter to the Right Hon T.P. Courtenay on the proportional number of births of the two sexes under different circumstances’ (1829) compared the demographic structures of the Kingdom of Naples, France, Prussia and Westphalia. Much later he wrote ‘On the statistics of lighthouses’ for the Brussels Congress of Statistics in 1853, and ‘The clearing house’, read to the London Statistical Society and printed in its memoirs in 1856. Babbage also wrote a book on insurance, *A Comparative View of the Various Institutions for the Assurance of Lives* (1826), and is remembered for his revised actuarial tables and his popular presentation of a difficult subject.

Babbage certainly produced an original and far-seeing economic analysis of industry in *On the Economy of Machinery and Manufactures*. He applied the principles of the division of labour he elaborated to his perception of the sciences. The ultimate result of the division of skills and especially the mental division of labour was the 'science of calculation'. He argued that the science of calculation, like any technology, would be developed to a degree where machinery would take over all numerical calculation. Arithmetical exercise would thus be separated from mathematical reasoning, and the 'science of calculation' harnessed to the analytical engine would become the science of all sciences. Babbage's ultimate vision for Britain's industrial progress was one of a computer-run technology.

Bachelier was born in Le Havre, France, on 11 March 1870 and died in Saint-Servan-sur-Mer, Ille-et-Vilaine, on 28 April 1946. He taught at Besançon, Dijon and Rennes and was professor at Besançon from 1927 to 1937.

The unrecognized genius is one of the stock figures of popular history, and it is also a platitude of which many examples dissolve upon careful examination. But the story of Louis Bachelier is in perfect conformity to all the clichés. He invented efficient markets in 1900, 60 years before the idea came into vogue. He described the random walk model of prices, ordinary diffusion of probability – also called Brownian motion – and martingales, which are the mathematical expression of efficient markets. He even attempted an empirical verification. But he remained a shadowy presence until 1960 or so, when his major work was revived in English translation.

This major work was his doctoral dissertation in the mathematical sciences, defended in Paris on 19 March 1900. Things went badly from the start: the committee failed to give it the ‘mention très honorable’, key to a university career. It was very late, after repeated failures, that Bachelier was appointed to the tiny University of Besançon. After he had retired, the university archives were accidentally set on fire and no record survives, not even one photograph. Here are a few scraps I have managed to put together.

We begin with the proverbial episode of the grain of sand, or the lack of a nail. Bachelier made a mathematical error that is recounted in a letter the great probabilist Paul Levy wrote me on 25 January 1964:

I first heard of him around 1928. He was a candidate for a professorship at the University of Dijon. Gevrey, who was teaching there, came to ask my opinion. In a work published in
1913, Bachelier had defined Wiener's function (prior to Wiener) as follows: In each interval \([n\tau, (n+1)\tau]\), he considered a function \(X(t|\tau)\) that has a constant derivative equal to either \(+v\) or \(-v\), the two values being equiprobable. He then proceeded to the limit \(\tau \to 0\), keeping \(v\) constant, and claimed he was obtaining a proper function \(X(t)\)! Gevrey was scandalized by this error. I agreed with him and Bachelier was blackballed.

I had forgotten it when in 1931, reading Kolmogorov's fundamental paper, I came to ‘der Bacheliers Fall’. I looked up Bachelier's works, and saw that this error, which is repeated everywhere, does not prevent him from obtaining results that would have been correct if only he had written \(v = C \tau^{-1/2}\), and that, prior to Einstein [1905] and prior to Wiener [circa 1925], he has seen some important properties of the Wiener function, namely, the diffusion equation and the distribution of \(\max_{0 < \tau < t} X(\tau)\). We became reconciled. I had written to him that I regretted that an impression, produced by a single initial error, should have kept me from going on with my reading of a work in which there were so many interesting ideas. He replied with a long letter in which he expressed great enthusiasm for research. That Levy should have played this role is tragic, for his own career also nearly foundered because his papers were not sufficiently rigorous for the mathematical extremists.

The second and deeper reason for Bachelier's career problems was the topic of his dissertation: ‘Mathematical theory of speculation’ – not of (philosophical) speculation on the nature of chance, rather of (money-grubbing) speculation on the ups and downs of the market for consolidated state bonds: ‘la rente’. The function \(X(t)\) mentioned by Levy stood for the price of \(la rente\) at time \(t\). Hence, the delicately understated comment by Henri Poincaré, who wrote the official report on this dissertation, that ‘the topic is somewhat remote from those our candidates are in the habit of treating’. One may wonder why Bachelier asked for the judgement of unwilling mathematicians (assigning a thesis subject was totally foreign to French professors of that period), but he had no choice: his lower degree was in mathematics and probability was taught by Poincaré.

Bachelier's tragedy was to be a man of the past and of the future but not of his present. He was a man of the past because gambling is the historical root of probability theory; he introduced the continuous-time gambling on \(La Bourse\). He was a man of the future, both in mathematics (witness the above letter by Levy) and in economics. Unfortunately, no organized scientific community of his time was in a position to understand and welcome him. To gain acceptance for himself would have required political skills that he did not possess, and one wonders where he could have gained acceptance for his thoughts.

Poincaré's report on the 1908 dissertation deserves further excerpting:

The manner in which the candidate obtains the law of Gauss is most original, and all the more interesting as the same reasoning might, with a few changes, be extended to the theory of errors. He develops this in a chapter which might at first seem strange, for he titles it ‘Radiation of Probability’. In effect, the author resorts to a comparison with the analytical theory of the propagation of heat. A little reflection shows that the analogy is real and the comparison legitimate. Fourier's reasoning is applicable almost without change to this problem, which is so different from that for which it had been created. It is regrettable that [the author] did not develop this part of his thesis further.
While Poincaré had seen that Bachelier had advanced to the threshold of a general theory of diffusion, he was notorious for lapses of memory. A few years later, he took an active part in discussions concerning Brownian diffusion, but had forgotten Bachelier.

Comments in a Notice Bachelier wrote in 1921 are worth summarizing:

1906: *Théorie des probabilités continues*. This theory has no relation whatsoever with the theory of geometric probability, whose scope is very limited. This is a science of another level of difficulty and generality than the calculus of probability. Conception, analysis, method, everything in it is new. 1913: *Probabilités cinématiques et dynamiques*. These applications of probability to mechanics are the author’s own, absolutely. He took the original idea from no one; no work of the same kind has ever been performed. Conception, method, results, everything is new.

The hapless authors of academic Notices are not called upon to be modest, but Louis Bachelier had no reason for being modest. Does anyone know more about him?

Editor and literary critic as well as banker and economist, Bagehot was described in retrospect by Lord Bryce as ‘the most original mind of his generation’ (Buchan, 1959, p. 260). It is a difficult claim to sustain, certainly as far as his scattered economic writings are concerned. There was no doubt, however, about his intellectual versatility: there was an immediacy, a clarity and an irony – what he said of his friend Arthur Hugh Clough's poems, ‘a sort of truthful scepticism’ – about Bagehot's essays in different fields which make them still pre-eminently readable. Bagehot saw connections, too, between economics, politics, psychology, anthropology and the natural sciences – ‘mind and character’ – refusing to draw rigid boundaries between most of these subjects and ‘literary studies’, while recognizing in his later years that the frontiers of political economy needed to be more carefully marked. ‘Most original’ or not, he was, as the historian G.M. Young (1948) has observed, Victoranum maxime, if not Victoranum maximus: ‘he was in and of his age, and could have been of no other.’ He pre-dated academic specialization and professionalization, and he was never didactic in his approach.

His first writing on economics, a revealing if not a searching review of John Stuart Mill's *Principles of Political Economy*, appeared in 1848 before the sense of a Victorian age had taken shape. His last and most voluminous writing on the subject appeared posthumously in a volume of essays, the first on ‘the postulates of English political economy’, which his editor-friend Richard Holt Hutton entitled *Economic Studies* (1879). By then the economic confidence of the mid-Victorian years was over, and there were many signs both of economic and social strain, some of which Bagehot had predicted. It was in 1859, the *annus mirabilis* of mid-Victorian England, however, the year of Darwin's *Origin of Species*, Mill's *On Liberty* and Smile's *Self Help*, that Bagehot became editor of *The Economist*, a periodical founded by his father-in-law James Wilson, and it was through his lively editorship, which continued until his death,
that he was in regular touch with an interesting and influential, if limited, section of his contemporaries.
‘The politics of the paper’, he wrote simply, ‘must be viewed mainly with reference to the tastes of men of business.’
The mid-Victorian years constituted, in his own phrase, ‘a period singularly remarkable for its material progress, and almost marvellous in its banking development’. It was the latter aspect of the period which provided him with the theme of his best-known and brilliantly written book *Lombard Street*, which was begun in 1870 and appeared in 1873. It dealt, however, as it was bound to do, not only with the ‘marvellous development’, but with the ‘panics’ of 1857 and 1866 to which the Bank of England, the central institution in the system, had to respond. Indeed, the germ of *Lombard Street* was an article written in *The Economist* in 1857, 13 years after Peel’s Bank Charter Act, and it was in 1866 that he took up the theme again.
Bagehot’s conviction that the Bank of England neither fully understood nor fully lived up to its responsibilities was the product of years of experience which went back to his own early life between 1852 and 1859 as a country banker with Stuckey's at Langport, his birthplace, in the West of England, where his father also was a banker. The chapter on deposit banking reflects this. So, too, does his complaint that the directors of the Bank of England were ‘amateurs’, and his insistence that the ‘trained banking element’ needed to be augmented.

*Lombard Street* is a book with a distinctive purpose rather than an essay in applied economics; and, as Schumpeter has observed, ‘it does not contain anything that should have been new to any student of economics’. The main stress in it is on confidence as a necessary foundation of London's banking system. ‘Credit – the disposition of one man to trust another – is singularly varying. In England after a great calamity, everybody is suspicious of everybody; as soon as that calamity is forgotten everybody again confides in everybody.’ Bagehot underestimated the extent to which through joint stock banks’ cheques trade was expanding without increases in note issue and the extent to which the Bank of England itself was beginning to develop techniques of influencing interest rates. He also overestimated the extent to which in ‘rapidly growing districts’ of the country ‘almost any amount of money can be well employed’. In the last resort, too, his policy recommendations were deliberately restricted. He was disposed in principle to a ‘natural system’ in which each bank kept its own reserves of gold and legal tender, but in English circumstances he saw no more future in seeking to change the system fundamentally than in changing the political system. ‘I propose to retain this system because I am quite sure that it is of no manner of use proposing to alter it.’ With a characteristic glance across the Channel to France for a necessary comparison – things were done very differently there – he noted how the English system had ‘slowly grown up’ because it had ‘suited itself to the course of business’ and ‘forced itself on the habits of men’. It would not be altered, therefore, ‘because theorists disapprove of it, or because books are written against it’.

Bagehot had little use for ‘theorists’ and disdained the French for what he called their ‘morbid appetite for exhaustive and original theories’. He described political economy ‘as we have it in England’ as ‘the science of business’ and did not object to the fact that it was ‘insular’. Yet he talked of the ‘laws of wealth’ and believed that they had been arrived at in the same way as the ‘laws of motion’. Free trade was such a law. It was impossible, he argued, to write the history of ‘similar phenomena like those of Lombard Street’ without ‘a considerable accumulation of applicable doctrine’: to do so would be like ‘trying to explain the bursting of a boiler without knowing the theory of steam’, a not very helpful analogy since the invention of the steam engine preceded the discovery of the laws of thermodynamics.
Bagehot relied considerably on analogies. ‘Panics’, for example, were ‘a species of neuralgia’. The ‘unconscious “organization of capital”’ in the City of London, described by Bagehot as a ‘continental phrase’, depended on the entry into City business of a ‘dirty crowd of little men’; and this ‘rough and vulgar structure of English commerce’ was ‘the secret of its life’ because it contained ‘the propensity to variation’ which was ‘the principle of progress’ in the ‘social as in the animal kingdom’. Such an approach to political economy was radically different from that of W.S. Jevons who, like Bagehot, had been educated at University College, London, or ‘M. Walras, of Lausanne’ who, according to Bagehot himself, had worked out ‘a mathematical theory’ of political economy ‘without communication and almost simultaneously’. There were however three defects, Bagehot maintained, in the British tradition of political economy, which started with Adam Smith but was sharpened and ‘mapped’ by David Ricardo. First, it was too culture-bound; for example, it took for granted the free circulation of labour, unknown in India. Second, its expositors did not always make it clear that they were dealing not with real men but with ‘imaginary’ ones. Abstract political economy did not focus on ‘the entire man as we know him in fact, but … a man answering to pure definition from which all impairing and conflicting elements have been fined away’. It was not concerned with ‘middle principles’. Third, considered as a body of knowledge, English political economy was ‘not a questionable thing of unlimited extent but a most certain and useful thing of limited extent’. It was certainly not ‘the highest study of the mind’. There were others ‘which are much higher’.

Bagehot did not push such criticism far. He had much to say about primitive and pre-commercial economies, but he put forward no theory of economic development. Nor, despite an interest in methodology, did he draw out the full implications of his own behaviourist (and in places institutionalist) approach to economics. Finally, he offered no agenda for political economists in the future. He noted, as others noted, that during the 1870s political economy lay ‘rather dead in the public mind. Not only does it not excite the same interest as it did formerly, but there is not exactly the same confidence in it.’ His own preoccupations in that decade were more practical than theoretical despite the writing of such essays as ‘The Postulates of English Political Economy’, which first appeared in article form in the *Fortnightly* in 1876. He never completed a new essay on Mill, and an essay on Malthus, whom he took along with Smith, Ricardo and Mill to be the founders of British political economy, revealed more interest in the man than in his thought. In the year when the ‘Postulates’ appeared, he successfully suggested to the Chancellor of the Exchequer the value to the Treasury of short-term securities resembling as much as possible commercial bills of exchange. The result was the Treasury Bill. The fact that the Chancellor was then a Conservative mattered little to the liberal-conservative Bagehot, who was described by his Liberal admirer W.E. Gladstone as a ‘sort of supplementary Chancellor of the Exchequer’.

Bagehot was as out of sympathy with the liberal radicals of the 1870s as he was with the bimetallists, and he had never shown any sympathy for socialist political economy. He saw the capitalist as ‘the motive power in modern production’ in the ‘great commerce’, the man who settled ‘what goods shall be made, and what not’. Nonetheless, he stated explicitly in several places that he had ‘no objection whatever to the aspiration of the workmen for more wages’, and he came to appreciate more willingly than Jevons the role of trade unions and collective bargaining. In his first review of Mill in 1848 he had stated that ‘the great problem for European and especially for English statesmen in the nineteenth century is how shall the [wage] rate be raised and how shall the lower orders be improved’. Some of the views he expressed on this subject – and on expectations – were not dissimilar to those of the
neoclassical Alfred Marshall. He did not use the term ‘classical’ himself in charting the evolution of
British political economy.
Bagehot left no school of disciples. He was content to persuade his contemporaries. His sinuous prose
style was supremely persuasive. So, too, was his skill in sifting and assessing inside economic
intelligence. Yet while he devoted little attention to precise quantitative evidence in *Lombard Street* and,
unlike Jevons, saw little point in developing economics in mathematical form, he was always interested
in numbers as well as in words. One of his closest collaborators on the staff of *The Economist*, the
statistician Robert Giffen, his first full-time assistant, paid tribute to ‘his knowledge and feeling of the
“how much” in dealing with the complex workings of economic tendencies’. ‘He knew what tables
could be made to say, and the value of simplicity in their construction.’ Bagehot always maintained,
however, that while ‘theorists take a table of prices as facts settled by unalterable laws, a stockbroker
will tell you such prices can be made’. Statistics were ‘useful’: they needed to be interpreted by ‘men of
business’ who possessed the grasp of ‘probabilities’ and the ‘solid judgement’ which Bagehot most
admired and which he sought to express. Indeed, business for him was ‘really a profession often
requiring for its practice quite as much knowledge, and quite as much skill, as law and medicine’.
Businessmen did not go to political economy: political economy, as in the case of Ricardo, came to them.

Bailey, Samuel (1791–1870)

R.M. Rauner
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Article
Samuel Bailey was born in Sheffield, England, one of 11 children. His father was a cutler and merchant of substance. Samuel also became a merchant and banker. Throughout his life, he served on the Sheffield Town Trust (a quasi-governmental agency) and was twice a candidate for Parliament in the Reform elections of 1832 and 1835. Writing widely on banking, politics and philosophy, he lived his entire life in Sheffield, unmarried, and died there in 1870.

Bailey published his principal economic work, A Critical Dissertation…, in 1825, a time when Ricardian theory was nearing its peak of popularity and acceptance. The Westminster Review (1826) thought the Critical Dissertation inconsequential, and J.R. McCulloch (1845) later claimed that it had not shaken the foundations of Ricardo's labour theory of value. Robert Torrens, however, praised Bailey's book in 1831 at the London Political Economy Club, and John Stuart Mill brought it before his bi-weekly reading group. This attention, nevertheless, did not keep Bailey on front stage, and he had to be rediscovered later by E.R.A. Seligman (1903); the London School of Economics republished the Critical Dissertation in 1931. Schumpeter (1954) judged Bailey's tract to be a ‘masterpiece of criticism’ and to lie near the ‘front rank in the history of scientific economics’. R.M. Rauner (1961) re-examined Bailey's work from a larger perspective.

The centrepiece of Bailey’s argument was his definition of value as ultimately ‘esteem’ or a ‘mental affection’. The ‘specific feeling of value’, however, arose only when items were subject to preference or exchange. This defined value as relative, not something intrinsic like labour in Ricardo’s theory. Value is the amount of one commodity exchanged for another; it is measured in terms of a third commodity with which the two exchange if they are not directly bartered. From this position Bailey attacked Ricardo's
postulate that labour effort defined value. He showed that, despite Ricardo's claim to the contrary, constancy of labour used in production could not assure constancy in exchange value – unless value were defined differently. This, of course, is what Ricardo had done in shifting from exchange to 'real' or 'absolute' value.

Ricardo's conception of value as an absolute and his endless search for a standard of invariable value opened him to Bailey's stricture that constancy of value meant constancy in exchange ratios. Evidence and observation showed that exchange values rarely stayed constant. To the Ricardians, however, constancy of value meant constancy of labour cost of production; this, they believed, was necessary in the determination of whether individual economic welfare had changed over time. Bailey objected that exchange of commodities cannot take place between two different time periods. Exchanges occur at different times and these exchanges can be compared. But such comparisons are the only way economic welfare in different times or places can be assessed. In a later tract (1844), Bailey used this same argument, making the point that interperiod contracts could be fixed only in terms of quantities, not constancy of values. This enabled him to oppose the index number proposals (then called 'tabular standards') of Joseph Lowe and Poulett Scrope. Such standards could not assure constancy of quantities exchanged in different times, a criticism of index numbers that is still valid today.

Using relative value as his anchor, Bailey then demonstrated that Ricardo's theory of wages was faulty. He insisted that labour value – wages – was definitionally the same as all other value, namely, what a unit of labour exchanged for. Ricardo's theorem, that wages and profits varied inversely, was wrong since it implied that wages could be high (i.e. taking a large proportionate share of production) while labour value was low, wages exchanged for little and workers were near starvation.

The relative value concept applied to wages allowed Bailey an easy application of the principles of rent to labour. Just as with land, different values for labour were caused by the monopoly characteristics of labour supply, as well as by differential productivity due to varying labour skill or dexterity. This contrasted sharply with Ricardian–Malthusian subsistence wages. Unfortunately, Bailey did not use the same reasoning against capital and merely denoted profits as the gain over capital employed.

The Critical Dissertation prompted some serious attempts to clear up the loose ends in Ricardo, most notably by McCulloch (1845); by the anonymous Westminster Review article (1826), probably written by James Mill (1826); and by Thomas De Quincey (1844). But Ricardo's system held fast. Malthus (1827) devoted the largest part of his work on definitions to Bailey, mainly quarrelling over the purely relative value notion. He reaffirmed the importance of a constant, unvarying measure of value, defined as the quantity of labour commanded by commodities in exchange. Samuel Read (1829) drew on Bailey's destruction of the Mill–McCulloch theory that time used in production is congealed labour, but he did not follow Bailey on the relativity of value or the measure of value. C.F. Cotterill (1831) and H.D. Macleod (1863; 1866) both praised Bailey's work and used his treatment of the nature and measure of value in their own studies.

From a larger perspective, by stressing relative value exclusively, Bailey pulled economic analysis back from the Smith–Ricardo stream that sought a principal cause of value to explain the production and distribution of material wealth among the labouring, rentier and capitalist classes. In Bailey's argument relative values – prices – vary for all kinds of reasons affecting demand ('esteem') and supply (production under constant or increasing cost, supply-limiting) conditions. Hence, his view involves no notion of long-run growth, tendencies toward equilibrium, stationary states or other systemic visions.
Everything is relative; individual economic welfare is expressed period-by-period solely in terms of relative values. Bailey's is an incomplete treatment if one demands that value theory be integral with the determination of social, institutional and economic forces in an inter-dependent production system. On the other hand, Bailey's work freed analysis from the need to link production and distribution to socioeconomic class relationships. It pointed instead towards relationships between individual needs and perceptions, and the material goods that can satisfy them.

Bain, Joe Staten (1912–1991)

William G. Shepherd

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Bain, J. S.; barriers to entry; concentration; economies of scale; industrial organization; limit pricing; market power; market share; oligopoly group; profitability

Article

Joe S. Bain was born in Spokane, Washington, on 4 July 1912. After graduating from the University of California at Los Angeles in 1935 and gaining the doctorate from Harvard in 1940 (under Joseph Schumpeter), he spent his entire career at the University of California at Berkeley, retiring in 1975. He was appointed Distinguished Fellow of the American Economic Association in 1982.

A prolific and seminal writer, Bain helped to shape the field of industrial organization in its modern form, with special attention to market structure. Bain's analysis focused on the oligopoly group within an industry, and on barriers to new competition. He also worked on natural resource development by public enterprise, concentrating on the oil industry.

Bain's empirical work on economies of scale, entry barriers, and limit pricing broke new ground. He developed the field's intellectual format, in which technical factors may determine structure, and structure then influences behaviour and performance. Some of these concepts were already current as early as 1900. During 1925–40, as the field took shape, attention shifted to the industry and the oligopoly group within it.

In the 1930s, Bain entered a formative field which was rich in possibilities for giving new rigour to older concepts, for developing new ones, and for shaping the framework. That has been his main role and contribution. Though he did not create concepts, nor indeed the framework, he selected from among them and carried their scientific analysis further than anyone else.

The analysis grew after 1940 in a series of articles and chapters, culminating in Barriers to New Competition in 1956 and Industrial Organization in 1959. His analysis was verbal and graphical rather than mathematical. In Bain's analysis of the conditions of entry, the barriers have three possible economic sources; absolute cost advantages, product differentiation and size. Barriers then permit ‘limit pricing’ by a firm or firms which consciously apply their strategy towards entry.
Bain drew the main conclusions, and he noted the difficulties of empirical tests. The definition of barriers as a single, general phenomenon posed special problems, which are still unsolved. Since 1960, over seven new barrier ‘sources’ have been proposed, and the concept of barriers has tended to acquire just that ad hoc character which Bain frequently reproved in others’ theories.

Measurement has also proven to be difficult. It requires a merging of disparate objective and subjective data about the barriers’ causes. Whether these sources of barriers are additive, multiplicative or merely parallel was also left unclear by Bain (and all others).

Bain's measurement of scale economics was pioneering. Earlier studies had suffered from data problems and from a mingling of technical and pecuniary elements. Bain centred unerringly on technical economies. Thereby he gave the first solid normative basis for evaluating excess concentration. By estimating ‘best practice’ conditions for scale for new capacity, Bain neatly avoided the normative–positive confusion which infects cross-section studies of past costs and survivor tests of emerging sizes. His ‘engineering’ estimates supply a normative basis for appraising how much concentration is socially ‘necessary’.

Profitability was also analysed closely by Bain. He tried nearly every available method to factor out the concentration–profitability relationship. In a 1949 article (later extended in Barriers), Bain put the study of profitability on a firm scientific and normative basis. His findings of a step function, with a break at 70 per cent for eight-firm concentration, has tended to be replaced in recent research by a continuously sloping concentration–profitability relationship. Still, Bain set the basis for all good later research on the subject.

Bain's architectural choices in using and emphasizing individual elements were distinctive. Three features stand out – the triad, the industry basis, and the stress on the oligopoly group behind an entry barrier. (1) Bain developed the three-tier format of structure, behaviour and performance with what may be called a ‘soft structuralist’ emphasis. Bain used it as a broad set of concepts, by which the whole subject (theory, tests, policy lessons) is organized, not as just a format for individual cases. (2) Bain used the industry as the basic unit behaviour. It was a choice that shaped the images and methodology in distinctive ways. (3) The oligopoly group, setting limit price strategy behind an entry barrier, came to be the most distinctive part of Bain's analysis. As of 1949–50, Bain regarded concentration as the key determinant of market power and profitability.

By 1951 he appeared to regard barriers as the decisive element, which could be both necessary and sufficient to govern profitability. Yet Bain later suggested frequently that barriers would be highly correlated with the degree of concentration. In fact, all of the sources of barriers are also sources of high market shares and concentration. Do barriers shape the dominant firm's share, or do they operate jointly? Any eventual resolution of barriers’ role will probably assign barriers at least a significant role, thanks to Bain's stress on them. He put the concepts and relationships in testable form, and he began the testing of them. To a large extent he rescued the subject from a preoccupation with oligopoly interactions and games, and he gave it a strong framework.

Yet Bain's most durable contribution lies deeper, in the methods and research standards of the field. By 1960, he had helped to give it structure, precision, and high standards of research quality. He selected the main concepts and relationships, gave them extended analysis, tested them, and drew policy lessons. The individual parts were related within a framework of causation and performance. His more specific methods and results have also continued to be valid because they met these standards. Beyond the individual concepts and tests is the fact that they fit together in a system, and that this
system was carefully developed and tested. That is the way to scientific permanence.

Bairoch, Paul (1930–1999)

Elise S. Brezis
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

agricultural revolution; Bairoich, P.; city and economic development; cliometrics; colonialism; diffusion of technology; economic development; foreign aid; free trade; inequality (global); protection; technological progress; trade and economic growth; urbanization

Article

Paul Bairoch was born in Antwerp in 1930. He was the son of a Jewish family that emigrated from Poland to Belgium in the 1920s, and that later went into exile in a small village in the Gers, France, during the Second World War. After the war, Bairoch moved to Brussels, later spent a short period in Israel, and upon his return to Belgium began to study economic history. While a research fellow at the University of Brussels, Bairoch developed statistical time series on the national statistics of Belgium, worked on his doctorate, and in 1963, presented his thesis, ‘The Starting Process of Economic Growth’. He then went on to teach in a number of universities and even worked at General Agreement on Tariffs and Trade (GATT) for a time. From 1972 onwards, Bairoch was a member of the faculty at the University of Geneva, where he was director of the Center of International Economic History until his death in 1999.

A trait common to all Bairoch's research in economic history from his thesis onwards was that he based his opinions on data, and, when the data did not exist, he found a way to collect or construct new data. Bairoch can be seen as a pioneer of cliometrics, and believed that economic history cannot survive without data and statistical information. David Landes (1998, p. xiii) even gave Bairoch the nickname ‘collector and calculator of the numbers of growth and productivity’. Another characteristic typical of Bairoch's research is that he was not afraid to be nonconformist and present views that ran against the mainstream.

Bairoch worked in three main subjects: economic development and growth, urban studies and international trade.

Population, cities, and urban research
Bairoch was interested in the relationship between urbanization and economic development, and examined urban evolution from the Neolithic period to 1900. He developed series on sizes of cities from ad 800 to 1850.

Bairoch's main achievement in this field was showing that there was a typical pattern of urbanization: traditional societies reached their maximum urban population rapidly, levelling off at somewhere between 8 and 15 per cent (Europe reached this level around 1300), and maintained this proportion until the onset of industrialization, when the urban population then surged. He also observed that for non-developed countries urbanization has negative consequences for agricultural development.

**Development, industrialization, and inequality**

One of the main topics of Bairoch's research was the dynamics of development and the inequality between developed and developing countries. In his last book, *Victoires et déboires* (1997), a formidable synthesis of the economic and social history of the world, Bairoch tried to explain the pre-eminence of the West, and the setbacks (*déboires*) suffered by the Third World.

Regarding the mechanism of development of the West, Bairoch insisted on the necessity of an agricultural revolution, and also on the importance of institutions. He had also a strong interest in the development of technological progress in the 19th century, and stressed the differences between it and the diffusion of the science-based technology of the 20th century.

Bairoch also analysed at length the reasons for the backwardness of the Third World, and through the use of comparative statistics his analysis includes a comparison between its present economic progress and that of developed countries at the times of their take-offs. Bairoch's conclusions were that the absence of an agricultural revolution and failure to reduce fertility rates were among the most binding facts impeding development. He was therefore pessimistic about the prospects for development of the lagging countries, especially those in Africa.

Regarding inequality, Bairoch stressed that before the Industrial Revolution no appreciable difference in per capita income separated western Europe from the rest of the world, while the gap between the developed and the developing world increased thereafter. Moreover, regarding the effect of colonialism, Bairoch stressed that colonialism was not only largely unprofitable for the West but also harmed the Third World. Bairoch was a proponent of foreign aid to reduce inequalities.

**International trade**

Probably Bairoch's best-known work is *Economics and World History: Myths and Paradoxes* (1993), in which he sets the record straight on 20 commonly held myths about economic history, among them that free trade has historically led to periods of economic growth; a myth associated with those who 'could be described as a conservative group that romanticizes the 19th century and makes free trade almost into a sacred doctrine' (1993, p. xiv).

Bairoch claimed that the idea that free trade was the rule during the 19th century is a myth based on insufficient knowledge and misguided interpretations of the economic history of the United States, Europe, and the Third World, since protection is the rule and free trade the exception. Moreover,
Bairoch expressed doubts that free trade leads to economic growth. His thesis was that during development countries use protectionist policies, which they dismantle once they industrialize. He showed that Britain protected its home market until British firms in the main sectors dominated the market, and only later on did Britain advocate free trade.

I cannot conclude without mentioning Bairoch’s personality: he combined the best of open-minded curiosity and a powerful intellect with warmth, humanity and overwhelming kindness to all who knew him.

balanced growth

Jonathan Temple
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

‘Balanced growth’ has at least two different meanings in economics. In macroeconomics, balanced growth occurs when output and the capital stock grow at the same rate. This growth path can rationalize the long-run stability of real interest rates, but its existence requires strong assumptions. In development economics, balanced growth refers to the simultaneous, coordinated expansion of several sectors. The usual arguments for this development strategy rely on scale economies, so that the productivity and profitability of individual firms may depend on market size. The article reviews the balanced growth debate and the extent to which it has influenced development policies.

Article

In macroeconomics, ‘balanced growth’ refers to classes of equilibrium growth paths, while in development economics the term refers to a particular development strategy. These two uses of the term are clearly distinct, and each is discussed in turn. The concept of a balanced growth path is a central element of macroeconomics. It refers to an equilibrium in which major aggregates, usually but not exclusively output and the capital stock, grow at the same rate over time, and the real interest rate is constant. Most textbook growth models are constructed in a way that delivers this outcome. This is motivated partly by theoretical convenience but also by historical observation. The conventional wisdom is that real interest rates and the capital-output ratio are surprisingly stable over long spans of time, at least in developed countries.
Balanced growth is not an inevitable property of growth models. It was not until the publication of classic papers by Solow (1956) and Swan (1956) that economists saw how a balanced growth path might arise from relatively appealing assumptions. The key insight is that a stable equilibrium path requires the possibility of substitution between capital and labour. The Solow–Swan model has subsequently underpinned much empirical work on economic growth, and has also influenced short-run macroeconomics.

The existence of a balanced growth path requires strong assumptions. The usual derivation assumes that aggregate output can be written as a function of the total inputs of capital and labour, with diminishing returns to each input and constant returns to scale overall. In addition to the conditions needed for aggregation, either the production function should be Cobb–Douglas, or technical progress should be restricted to the labour-augmenting type. In other words, when technology advances, it should be ‘as if’ the economy had more labour than before, and not ‘as if’ it had more capital.

Because these assumptions are strong, any use of balanced growth to rationalize the data tends to create new puzzles. For example, why should technical progress be exclusively labour-augmenting, as stability of real interest rates would require? Acemoglu (2003) has examined this question using an incentives-based model of technical change, but in general balanced growth seems a less than inevitable outcome of a real-world growth process. The picture is even more complicated when there are multiple sectors, whether differentiated as capital and consumer goods, or as different types of final goods. As might be expected, where multiple sectors are present, the conditions needed for balanced growth become even stricter. Greenwood, Hercowitz and Krusell (1997) and Kongsamut, Rebelo and Xie (2001) are two useful references on multi-sector growth models.

None of this is to deny that balanced growth is a useful concept. The idea plays an important role in teaching and research in macroeconomics because of its simplicity and explanatory power. As with all organizing frameworks, however, it is sensible to be aware of its limitations and the possibilities that lie outside it.

In macroeconomics, balanced growth is usually associated with constant returns to scale. For most development economists, the term is more strongly associated with increasing returns and a debate that began with Rosenstein-Rodan (1943). He argued that the post-war industrialization of eastern and southeastern Europe would require coordinated investments across several industries. The idea is that expansion of different sectors is complementary, because an increase in the output of one sector increases the size of the market for others. A sector that expands on its own may make a loss but, if many sectors expand at once, they can each make a profit. This tends to imply the need for coordinated expansion, or a ‘Big Push’, and potentially justifies a role for state intervention or development planning. Another influential contribution by Nurkse (1953) made similar points, giving more emphasis to the links between market size and the incentives to accumulate capital.

In Rosenstein-Rodan's paper the argument is set out informally, and with many digressions. But the central point will have a familiar ring to students of modern game theory and the literature on coordination failures. Essentially, Rosenstein-Rodan was setting out assumptions that might give rise to multiple equilibria in levels of development. Papers by Fleming (1955) and Scitovsky (1954) further clarified some of the necessary assumptions. Fleming emphasized the importance of Rosenstein-Rodan's assumption that the industrializing sectors can draw on labour from other sectors without forcing up wages. Scitovsky noted that the proponents of balanced growth appeared to see externalities everywhere,
but under perfect competition, external effects that are mediated through markets (‘pecuniary external economies’) do not preclude Pareto efficiency. This result hints at the importance of scale economies to the balanced growth hypothesis, since then market size can influence unit costs, and Scitovsky's logic no longer applies.

The key ideas of the balanced growth hypothesis were formalized in a much-admired paper by Murphy, Shleifer and Vishny (1989). In their multi-sector model, firms in each sector use constant returns-to-scale technologies, but one firm in each sector also has access to an increasing returns-to-scale technology. This technology will be profitable to operate only given a sufficiently large market. The structure of the model, with a competitive fringe of small-scale producers, ensures that wages are independent of labour demand in the industrializing sectors. The model yields multiple equilibria that can be Pareto-ranked.

The assumptions needed for multiplicity are more complicated than earlier authors believed, however. For example, increasing returns and an elastic supply of labour are not sufficient in themselves to generate multiple equilibria. Consider an equilibrium in which no sectors have industrialized (meaning that none is using the increasing returns-to-scale technique). If a single firm then adopts the modern technique and makes a loss, this will reduce rather than increase the size of the market for other sectors, so the necessary complementarity is absent. For multiple equilibria to arise, the industrializing firm must somehow raise the size of the market for other sectors, even though it makes a loss when acting alone. In one of the models considered by Murphy, Shleifer and Vishny (1989), this is achieved by an extra assumption, namely, that industrializing firms must pay higher wages than other firms.

Although the balanced growth hypothesis has been widely discussed, it has a number of limitations. The ideas are difficult to test empirically. From a purely theoretical point of view, the argument does not generalize straightforwardly to open economies. If firms can sell their output abroad, the role of domestic market size appears much less important. The balanced growth hypothesis then requires a more complex story, perhaps one in which firms are especially reliant on domestic markets in the early stages of their development.

The ideas have also been criticized on other grounds. The most prominent sceptic was Hirschman (1958), who argued that simultaneous, coordinated investment asked too much of developing countries. He regarded growth as a necessarily unbalanced dynamic process, in which successive disequilibria create the conditions for development in other sectors. Unbalanced growth could occur either through forward and backward linkages to downstream and upstream industries or by drawing out latent capacities needed for growth, such as the application of entrepreneurial skills.

Importantly, this process is seen as too complex and unpredictable to lend itself readily to a government-inspired ‘Big Push’, partly because governments may lack the relevant information, and partly because simultaneous investment would place too many demands on limited organizational resources. Hirschman (1958, pp. 53–4) summarized his objections by saying: ‘if a country were ready to apply the doctrine of balanced growth, then it would not be underdeveloped in the first place’.

But his preferred vision has echoes of the balanced growth doctrine in its appeal to complementarities and increasing returns; Krugman (1995) discusses this point in more detail. Arguably it is not so much the assumptions that differ, but the view of equilibrium selection. One interpretation of Hirschman's critique is that the multiplicity of equilibria is illusory, because the earlier authors had missed out relevant state variables.
In practice, balanced growth ideas have had less influence on development strategies than a more
general commitment to state-led industrialization and import substitution. A perceived need for balanced
growth may have motivated some attempts at indicative planning, but state interventions have usually
tried to focus on particular sectors rather than attempting the more ambitious task of simultaneous
expansion across many industries. The reasons for this are likely to be complex, including uncertainty
over which sectors should be encouraged to expand, and the lack of obvious ways to coordinate this
without direct state control. In the academic literature, the difficulty of testing the main ideas has been
another factor limiting their influence.
For reasons like these, the balanced growth hypothesis is currently at the margins of development
thinking and policy advice. The ideas are still interesting, however, and their neglect is partly due to the
accidents of intellectual history. Formalizing Rosenstein-Rodan's original insights proved a difficult
task. The reasons for this are discussed in Krugman (1995) as part of an illuminating account of the
balanced growth debate and the role of formal models. He shows the continuing relevance of the main
ideas to economic geography and regional science, and his book can be highly recommended to anyone
interested in balanced growth, or the methods of modern economics more generally. Another useful
reference is the special issue of the *Journal of Development Economics* on increasing returns and
economic development (April 1996).

Article

Béla Balassa, holding degrees in law and economics, left his native Hungary when the Soviet tanks put down the 1956 revolution. In 1959 he received his Ph.D. in economics from Yale. From 1966 until his death in 1991 he was professor of economics at Johns Hopkins and a consultant to the World Bank. Influenced by events in his youth, Béla held a deep lifelong belief in political and economic freedom. At the World Bank, Béla was very active as Research Advisor to the Vice-President for Research, first to Hollis Chenery, then to his successors, Anne Krueger, Stanley Fischer and Larry Summers. He held this position until his death, and those of us who were then at the Bank will remember him as the Bank's most influential economic advisor during his 25 years involvement at the institution. His commitment to economic policy was extended by his involvement in his later years at the Institute for International Economics, where he wrote on trade policy issues of developed countries, notably on Japan (Balassa and Noland, 1988).

Béla was among the most prolific international trade economists of his generation, contributing several books that are still widely cited. Early in his career he made several lasting contributions, among which was his famous paper on purchasing power parity (1964) in which he used a Ricardian model to show that a country's real exchange rate would appreciate as its productivity gap narrowed. Béla also made lasting contributions to the theory of economic integration (1962) and to empirical methods, proposing a measure of 'revealed comparative advantage' and ways to measure rates of effective protection (1965). As research advisor of the Development Research Center at the World Bank, Béla fulfilled many roles during the three days a week he spent there. Whereas most members at the centre would devote most of their time to research, in addition to his highly productive research activities Béla participated very
actively in the Bank's policy dialogue, commenting on the vast majority of country reports, and invariably on all those that contained advice on trade policies. In those days trade policy was a major issue in virtually all countries. Then, import-substitution policies supported by highly restrictive trade regimes were the rule. With a handful of trade economists, including Jagdish Bhagwati and Anne Krueger, Béla would tirelessly recommend a simplification of the trade regime, moderate protection of industrial activities supported by uniform tariffs, a removal of quantitative restrictions, and a unification of the then prevailing multiple exchange rate regimes.

Béla's advice on trade policy was supported by his research carried out under the Bank's auspices. He directed and edited an influential book that examined the trade regimes of several countries in Latin America and East Asia, documenting systematically the patterns of effective rates of protection in these countries (Balassa and Associates, 1971).

Béla's research output was not only prolific but also timely. His ability to be the first to deliver relevant research on the policy issue of the day was uncanny. In the late 1970s, when developing countries were hit by oil, commodity and interest rate shocks, Béla was the first to implement a useful decomposition formula to assess the extent of purchasing power loss. Later, when the Bank launched structural adjustment lending activities and wanted to assess performance of countries having received adjustment loans, Béla again delivered the first assessment of adjustment lending.

Béla's work capacity was legendary. Despite his influential research and his sage and realistic policy advising at the World Bank, which left him only two days a week for Johns Hopkins, his contribution to teaching, thesis supervision and academic governance at Hopkins was enormous. He taught most of the courses in international and development economics. He supervised more students than almost anyone else, and he responded to their papers and thesis drafts almost instantly with demanding but constructive comments. For ten years he was an elected and re-elected member of the faculty governing council. As chair of the faculty budget committee, he persuaded the university to reverse the decline that had been permitted to occur in the real value of its tuition charge, its faculty compensation levels and its academic expenditures.

Besides all this, Béla was an informed lover of art, opera, French literature and food (his guide to Paris restaurants was prized), and he always made time for his friends and for his family.

bandit problems

Dirk Bergemann and Juuso Välimäki
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The multi-armed bandit problem is a statistical decision model of an agent trying to optimize his decisions while improving his information at the same time. This classic problem has received much attention in economics as it concisely models the trade-off between exploration (trying out each arm to find the best one) and exploitation (playing the arm believed to give the best payoff).

Article

The multi-armed bandit problem, originally described by Robbins (1952), is a statistical decision model of an agent trying to optimize his decisions while improving his information at the same time. In the multi-arm bandit problem, the gambler has to decide which arm of \( K \) different slot machines to play in a sequence of trials so as to maximize his reward. This classical problem has received much attention because of the simple model it provides of the trade-off between exploration (trying out each arm to find the best one) and exploitation (playing the arm believed to give the best payoff). Each choice of an arm results in an immediate random payoff, but the process determining these payoffs evolves during the play of the bandit. The distinguishing feature of bandit problems is that the distribution of returns from one arm only changes when that arm is chosen. Hence the rewards from an arm do not depend on the rewards obtained from other arms. This feature also implies that the distributions of returns do not depend explicitly on calendar time.

The bandit framework found early applications in the area of clinical trials where different treatments
need to be experimented with while minimizing patient losses and in adaptive routing efforts for minimizing delays in a network. In economics, experimental consumption is a leading example of an intertemporal allocation problem where the trade-off between current payoff and value of information plays a key role.

**Basic model**

It is easiest to formulate the bandit problem as an infinite horizon Markov decision problem in discrete time with time index \( t = 0, 1, \ldots \). At each \( t \), the decision maker chooses amongst \( K \) arms and we denote this choice by \( a_t \in \{1, \ldots, K\} \). If \( a_t = k \), a random payoff \( x^k_t \) is realized and we denote the associated random variable by \( x^k_t \). The state variable of the Markovian decision problem is given by \( s_t \). We can then write the distribution of \( x^k_t \) as \( F^k(\cdot; s_t) \). The state transition function \( \varphi \) depends on the choice of the arm and the realized payoff:

\[
 s_{t+1} = \varphi(x^k_t, s_t)
\]

Let \( S_t \) denote the set of all possible states in period \( t \). A feasible Markov policy \( a = \{a_t\}_{t=0}^{\infty} \) selects an available alternative for each conceivable state \( s_t \), that is,

\[
a_t: S_t \rightarrow \{1, \ldots, K\}
\]

The following two assumptions must be met for the problem to qualify as a bandit problem.

1. Payoffs are evaluated according to the discounted expected payoff criterion where the discount factor \( \delta \) satisfies \( 0 \leq \delta < 1 \).
2. The payoff from each \( k \) depends only on outcomes of periods with \( a_t = k \). In other words, we can decompose the state variable \( s_t \) into \( K \) components \( (s^1_t, \ldots, s^K_t) \) such that for all \( k \):

\[
 s^k_{t+1} = s^k_t \quad \text{if} \quad a_t \neq k,
\]

\[
 s^k_{t+1} = \varphi(s^k_t, x_t) \quad \text{if} \quad a_t = k.
\]
Notice that when the second assumption holds, the alternatives must be statistically independent. It is easy to see that many situations of economic interest are special cases of the above formulation. First, it could be that \( F_k(\cdot; \Theta^k) \) is a fixed distribution with an unknown parameter \( \Theta^k \). The state variable is then the posterior probability distribution on \( \Theta^k \). Alternatively, \( F_k(\cdot; s^k) \) could denote the random yield per period from a resource \( k \) after extracting \( s^k \) units.

The value function \( V(s_0) \) of the bandit problem can be written as follows. Let \( X^k(s^k_t) \) denote the random variable with distribution \( F_k(\cdot; s^k_t) \). Then the problem of finding an optimal allocation policy is the solution to the following intertemporal optimization problem:

\[
V(s_0) = \sup_{\alpha} \left\{ \mathbb{E} \sum_{t=0}^{\infty} \delta^t X^k(s^k_t) \right\}.
\]

The celebrated index theorem due to Gittins and Jones (1974) transforms the problem of finding the optimal policy into a collection of \( k \) stopping problems. For each alternative \( k \), we calculate the following index \( \gamma^k(s^k_t) \), which depends only on the state variable of alternative \( k \):

\[
m^k(s^k_t) = \sup_{\tau} \left\{ \frac{\mathbb{E} \sum_{u=\tau}^{T} \delta^t X^k(s^k_u)}{\mathbb{E} \sum_{u=\tau}^{T} \delta^t} \right\},
\]

(1)

where \( \tau \) is a stopping time with respect to \( \{s^k_t\} \). The idea is to find for each \( k \) the stopping time \( \tau \) that results in the highest discounted expected return per discounted expected number of periods in operation. The Gittins index theorem then states that the optimal way of choosing arms in a bandit
problem is to select in each period the arm with the highest Gittins index, $m^k(s^k_t)$, as defined by (1).

**Theorem 1: Gittins-Jones (1974)**

The optimal policy satisfies $a_t = k$ for some $k$ such that

$$m^k(s^k_t) \geq m^j(s^j_t) \text{ for all } j \in \{1, \ldots, K\}.$$  

To understand the economic intuition behind this theorem, consider the following variation on the original problem. This reasoning follows the lines suggested in Weber (1992). The arms are owned and operated by separate risk-neutral agents. The owner can rent a single arm at a time to the operators and there is a competitive market of potential operators. As time is discounted, it is clearly optimal to obtain high rental incomes in early periods of the model. The rental market is operated as a descending price auction where the fee for operating an arbitrary arm is lowered until an operator accepts the price. At the accepted price, the operator is allowed to operate the arm as long as it is profitable. Since the market for operators is competitive, the price is such that, under an optimal stopping rule, the operator breaks even.

Hence the highest acceptable price for arm $k$ is the Gittins index $m^k(s^k_t)$, and the operator operates the arm until its Gittins index falls below the price, that is, its original Gittins index. Once an arm is abandoned, the process of lowering the price offer is restarted. Since the operators get zero surplus and they are operating under optimal rules, this method of allocating arms results in the maximal surplus to the owner and thus the largest sum of expected discounted payoffs.

The optimality of the index policy reduces the dimensionality of the optimization problem. It says that the original $K$-dimensional problem can be split into $K$ independent components, and then be knitted together after the solutions of the indices for the individual problems have been computed, as in eq. (1). In particular, in each period of time, at most one index has to be re-evaluated; the other indices remain frozen.

The multi-armed bandit problem and many variations are presented in detail in Gittins (1989) and Berry and Fristedt (1985). An alternative proof of the main theorem, based on dynamic programming can be found in Whittle (1982). The basic idea is to find for every arm a retirement value $M^k_t$, and then to choose in every period the arm with the highest retirement value. Formally, for every arm $k$ and retirement value $M$, we can compute the optimal retirement policy given by:

$$V^k(s^k_t, M) \triangleq \max \left\{ \mathbb{E} [X^k(s^k_t) + \delta V^k(s^k_{t+1}, M), M] \right\}$$

(2)
bandit problems: The New Palgrave Dictionary of Economics

The auxiliary decision problem given by (2) compares in every period the trade-off between continuation with the reward process generated by arm $k$ or stopping with a fixed retirement value $M$. The index of arm $k$ in the state $s_t^k$ is the highest retirement value at which the decision is just indifferent between continuing with arm $k$ or retiring with $M = M(s_t^k)$:

$$M^k(s_t^k) = V^k(s_t^k, M(s_t^k)).$$

The resulting index $M^k(s_t^k)$ is equal to the discounted sum of flow index $m^k(s_t^k)$, or $M^k(s_t^k) = m^k(s_t^k) / (1 - \delta)$.

Extensions

Even though it is easy to write down the formula for the Gittins index and to give it an economic input, it is normally impossible to obtain analytical solutions for the problem. One of the few settings where such solutions are possible is the continuous-time bandit model where the drift of a Brownian motion process is initially unknown and learned through observations of the process. Karatzas (1984) provides an analysis of this case when the volatility parameter of the process is known.

From an analytical standpoint, the key property of bandit problems is that they allow for an optimal policy that is defined in terms of indices that are calculated for the individual arms. It turns out that this property does not generalize easily beyond the bandit problem setting. One instance where such a generalization is possible is the branching bandit problem where new arms are born to replace the arm that was chosen in the previous period (see Whittle 1981).

An index characterization of the optimal allocation policy can still be obtained without the Markovian structure. Varaiya, Walrand and Buyukkoc (1985) give a general characterization in discrete time, and Karoui and Karatzas (1997) provide a similar result in a continuous time setting. In either case, the essential idea is that the evolution of each arm depends only on the (possibly entire) history and running time of the arm under consideration, but not on the realization nor the running time of the other arms.

Banks and Sundaram (1992) show that the index characterization remains valid under some weak additional condition even if the number of indices is countable, but not necessarily finite. On the other hand, it is well known that an index characterization is not possible when the decision maker must or can select more than a single arm at each $t$. Banks and Sundaram (1994) also show further that an index characterization is not possible when an extra cost must be paid to switch between arms in consecutive periods. Bergemann and Välimäki (2001) consider a stationary setting in which there is an infinite supply of ex ante identical arms available. Within the stationary setting, they show that an optimal policy follows the index characterization even when many arms can be selected at the same time or when a switching cost has to be paid to move from one arm to another.
Bandit problems: The New Palgrave Dictionary of Economics

Market learning

In economics, bandit problems were first used to model search processes. The first paper that used a one-armed bandit problem in economics is Rothschild (1974), in which a single firm is facing a market with unknown demand. The true market demand is given by a specific probability distribution over consumer valuations. However, the firm initially has a prior probability over several possible market demands. The problem for the firm is to find an optimal sequence of prices to learn more about the true demand while maximizing its expected discounted profits. In particular, Rothschild shows that \textit{ex ante} optimal pricing rules may well end up using prices that are \textit{ex post} suboptimal (that is, suboptimal if the true distribution were to be known). If several firms were to experiment independently in the same market, they might offer different prices in the long run. Optimal experimentation may therefore lead to price dispersion in the long run as shown formally in McLennan (1984).

In an extension of Rothschild, Keller and Rady (1999) consider the problem of the monopolist facing an unknown demand that is subject to random changes over time. In a continuous time model, they identify conditions on the probability of regime switch and discount rate under which either very low or very high intensity of experimentation is optimal. With a low-intensity policy, the tracking of the actual demand is poor and the decision maker eventually becomes trapped, in contrast with a high-intensity policy demand, which is tracked almost perfectly. Rustichini and Wolinsky (1995) examine the possibility of mis-pricing in a two-armed bandit problem when the frequency of change is small. Nonetheless, they show that it is possible that learning will cease even though the state of demand continues to change.

The choice between various research projects often takes the form of a bandit problem. In Weitzman (1979) each arm represents a distinct research project with a random prize associated with it. The issue is to characterize the optimal sequencing over time in which the projects should be undertaken. It shows that as novel projects provide an option value to the research, the optimal sequence is not necessarily the sequence of decreasing expected rewards (even when there is discounting). Roberts and Weitzman (1981) consider a richer model of choice between R&D processes.

Many-agent experimentation

The multi-armed bandit models have recently been used as a canonical model of experimentation in teams. In Bolton and Harris (1999) and Keller, Rady and Cripps (2005) a set of players choose independently between the different arms. The reward distributions are fixed, but characterized by parameters that are initially unknown to the players. The model is one of common values in the sense that all players receive independent draws from the same distribution when choosing the same arm. It is assumed that outcomes in all periods are publicly observable, and as a result a free riding problem is created. Information is a public good and each individual player would prefer to choose the current payoff maximizing arm and let other players perform costly experimentation with currently inferior arms. These papers characterize equilibrium experimentation under different assumptions on the reward distributions. In Bolton and Harris (1999) the model of uncertainty is a continuous time model with unknown drift and know variance, whereas in Keller, Rady and Cripps (2005) the underlying uncertainty
Experimentation and matching

The bandit framework has been successfully applied to learning in matching markets such as labour and consumer good markets. An early example of this is given in the job-market matching model of Jovanovic (1979), who applies a bandit problem to a competitive labour market. Suppose that a worker must choose employment in one of $K$ firms and her (random) productivity in firm $k$ is parametrized by a real variable $\theta^k$. The bandit problem is then a natural framework for the study of learning about the match-specific productivities. For each $k$, $s^k_0$ is then simply the prior on $\theta^k$ and $s^k_t$ is the posterior distribution given $s^k_s$ for $s < t$. Over time, a worker's productivity in a specific job becomes known more precisely. In the event of a poor match, separation occurs in equilibrium and job turnover arises as a natural by-product of the learning process. On the other hand, over time the likelihood of separation eventually decreases as, conditional on being still on the job, the likelihood of a good match increases. The model hence generates a number of interesting empirical implications which have since been investigated extensively. Miller (1984) enriches the above setting by allowing for a priori different occupations, and hence the sequence in which a worker is matched over time to different occupations is determined as part of the equilibrium.

Experimentation and pricing

In a related literature, bandit problems have been taken as a starting point for the analysis of division of surplus in an uncertain environment. In the context of a differentiated product market and a labour market respectively, Bergemann and Välimäki (1996) and Felli and Harris (1996) consider a model with a single operator and a separate owner for each arm. The owners compete for the operator's services by offering rental prices. These models are interested in the efficiency and the division of the surplus resulting from the equilibrium of the model. In both models, arms are operated according to the Gittins index rule, and the resulting division of surplus leaves the owners of the arms as well as the operator with positive surpluses. In Bergemann and Välimäki (1996), the model is set in discrete time and a general model of uncertainty is considered. The authors interpret the experiment as the problem of choosing between two competing experience goods, in which both seller and buyer are uncertain about the quality of the match between the product and the preferences of the buyer. In contrast, Felli and Harris (1996) consider a continuous model with uncertainty represented by a Brownian motion and interpret the model in the context of a labour market. Both models show that, even though the models allow for a genuine sharing of the surplus, allocation decisions are surplus maximizing in all Markovian equilibria, and each competing seller receives his marginal contribution to the social surplus in the unique cautious Markovian equilibrium. Bergemann and Välimäki (2006) generalize the above efficiency and equilibrium characterization from two sellers to an arbitrary finite number of sellers in a deterministic setting. Their proof uses some of the techniques first introduced in Karoui and Karatzas (1997). On the other hand, if the market consists of many buyers and each one of them is facing the
same experimentation problem, then the issue of free-riding arises again. Bergemann and Välimäki (2000) analyse a continuous time model as in Bolton and Harris (1999), but with strategic sellers. Surprisingly, the inefficiency observed in the earlier paper is now reversed and the market equilibrium displays too much information. As information is a public good, the seller has to compensate an individual buyer only for the impact his purchasing decision has on his own continuation value, and not for its impact on the change in continuation value of the remaining buyers. As experimentation leads in expectation to more differentiation, and hence less price competition, the sellers prefer more differentiation, and hence more experimentation to less. As each seller has to compensate only the individual buyers, not all buyers, the social price of the experiment is above the equilibrium price, leading to excess experimentation in equilibrium.

**Experimentation in finance**

Recently, the paradigm of the bandit model has also been applied in corporate finance and asset pricing. Bergemann and Hege (1998; 2005) model a new venture or innovation as a Poisson bandit model with variable learning intensity. The investor controls the flow of funding allocated to the new project and hence the rate at which information about the new project arrives. The optimal funding decision is subject to a moral hazard problem in which the entrepreneur controls the unobservable decision to allocate the funds to the project. Hong and Rady (2002) introduce experimentation in an asset pricing model with uncertain liquidity supply. In contrast to the standard noise trader model, the strategic seller can learn about liquidity from past prices and trading volume. This learning implies that strategic trades and market statistics such as informational efficiency are path-dependent on past market outcomes.

Bank of England

Charles A.E. Goodhart
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The Bank of England, founded in 1694 to finance war against France, soon became Britain's largest bank. It became responsible for maintaining the gold standard and acting as lender of last resort. To do so, it had to withdraw from commercial banking. After failing to stay on gold (1931) the Bank became subservient to the Chancellor in macro-monetary policy and was nationalized in 1946. Operational independence to set interest rates in pursuit of an inflation target was restored in the 1990s, while its previous functions, notably bank supervision, debt management, and foreign exchange intervention, fell away.

Article

The primary motivation for the establishment of the Bank of England was the need to raise funds to help the government finance the then current war against France, although the view had also developed that a bank could help to ‘stabilize’ financial activity in London given periodic fluctuations in the availability
of currency and credit. An original proposal by William Paterson in 1693 for a government ‘fund of perpetual interest’ was turned down in favour of another proposal by Paterson in 1694 to establish a company known as the Governor and Company of the Bank of England, whose capital, once raised, would be lent in its entirety to the government.

An ordinary finance act, now known as the Bank of England Act (1694), stipulated that the Bank was to be established via stock subscriptions which were to be lent to the government. A governor, deputy governor and 24 directors were to be elected by stockholders (holding £500 or more of stock).

**The evolution of the Bank’s objectives and functions, 1694–1914**

Under its original charter the Bank was allowed to issue bank notes, redeemable in silver coin, as well as to trade in bills and bullion. The notes of the Bank competed with other paper media of exchange, which comprised notes issued by the Exchequer and by private financial companies. In addition, customers could maintain deposit accounts with the Bank, which were transferable to other parties via notes drawn against deposit receipts (known as accomptable notes), thus providing an early form of cheque.

An early customer of the Bank was the Royal Bank of Scotland, which made arrangements to keep cash at the Bank from its outset in 1727. Loans were extended, predominantly in the form of discounting of bills, to individuals and companies, and the Bank undertook a large amount of lending (often via overdrafts) to the Dutch East India Company and, from 1711, to the South Sea Company. The Bank also acted as a mortgage lender, although this business never took off, and ceased some years later. Finally, an important function of the Bank was the remittance of cash to Flanders and elsewhere for the wars against Louis XIV, which was facilitated through correspondent arrangements with banks in Holland.

In 1697 the renewal of the Bank’s charter for another ten years involved the passage of a second Bank Act, which increased the capital of the Bank and prohibited any other banks from being chartered in England and Wales. This monopoly was strengthened at the next renewal of the Bank’s charter in 1708, when any association of six or more persons was forbidden to engage in banking activity, thereby precluding the establishment of any other joint stock banks. The Bank’s position as banker to the government was consolidated in 1715 when it was decided that subscriptions for government debt issues would be paid to the Bank, and further that the Bank was to manage the government debt (the Ways and Means Act). The Bank then acted as manager of the government’s debts from that date until 1997. The Bank also encouraged the use of its own notes in preference to other media of exchange by persuading the Treasury to increase the denomination of Exchequer bills. By 1725 the Bank’s notes had become sufficiently widely used as to be pre-printed for the first time. Although a number of private banks had developed by 1750, both within and outside London, none competed seriously with the Bank in the issue of notes. By 1770 most London bankers had ceased to issue notes, using Bank of England notes (and cheques) to settle balances among themselves in what had become a well-developed clearing system. Furthermore, in 1775 Parliament raised the minimum denomination for any non-Bank of England notes to one pound and, two years later, to five pounds, effectively guaranteeing the use of Bank of England notes as the dominant form of currency. Problems relating to counterfeiting, and to the harsh treatment of those caught in the act, were, however, perennial.

In Scotland, by contrast, no note issuing monopoly existed, and banks were free to issue notes, although two banks dominated, namely, the Bank of Scotland and the Royal Bank of Scotland. Furthermore, several private note-issuing banks were in business in Ireland, and the Bank of Ireland was established in
1783. These banks relied on the Bank of England to obtain silver and gold, particularly during times of financial stress, such as 1783 and 1793. Following a dramatic rise in government expenditures after 1793 due to the war against France, which caused a large rise in the Bank's note issue, the Bank's gold holdings fell sharply. After a scare about a French invasion convertibility was suspended in 1797, and resumed only in 1821. In view of the financial exigencies of the war, and the fact that there was in such circumstances no limit to the expansion of its note issue, now effectively legal tender, by the Bank, a privately owned company, what is in retrospect surprising about the period of suspension is how comparatively low the resulting inflation was. Even so, it was high enough to set off a major debate on its causation, for example in the Parliamentary Committee on the High Price of Bullion (1810). This period saw a further consolidation of the Bank as a note issuer, since it began to issue small denomination notes (given the shortage of silver and gold coin), which became legal tender in 1812. Furthermore, in 1816 silver coin ceased to be legal tender for small payments. The government also moved most of its accounts to the Bank in 1805 (in 1834 all government accounts were finally moved to the Bank).

During the 18th century and early part of the 19th century, smaller country banks had proliferated throughout England and Wales, many issuing their own notes. Given the prohibition on joint stock banking, the capital of these banks was usually small, and they regularly became insolvent, especially when the demand for cash (coin) became strong. This contrasted sharply with Scotland, where joint stock banking and branch banking were permitted, and relatively few failures occurred. Following a severe banking crisis in 1825, during which many English country banks failed, an Act renewing the Bank's charter (in 1826) abolished the restrictions on banking activity more than 65 miles outside of London. This led to the establishment of several joint stock banks, while the Bank countered by opening several branches throughout England.

Thus, a semblance of a banking ‘system’ began to emerge by 1830, with the Bank of England as the ‘central’ bank. By far the best book on such nascent central banking at this time was that written by Henry Thornton, An Enquiry into the Nature and Effects of the Paper Credit of Great Britain (1802). The practice of banks placing surplus funds with bill brokers also developed, with the Bank beginning to extend secured loans to these brokers on a more or less regular basis. In 1833 joint stock banks were finally allowed to operate in London, although they were not permitted to issue notes and thus were essentially deposit-taking banks only. The same Act specified that Bank of England notes were legal tender, and the Bank was also given the freedom to raise its discount rate freely (until then usury laws had placed a ceiling on interest rates) in response to cash outflows. The Bank's reaction (an early reaction function), in varying its interest rate, to cash inflows and outflows became codified around this time in what became known as the Palmer rule, after Horsley Palmer, Governor 1830–33, though the rule itself is usually dated from 1827.

The position of Bank of England notes was consolidated in an important Act, passed in 1844, generally known as the Bank Charter Act, preventing all note issuers from expanding their note issue above existing levels, and prohibiting the establishment of any new note-issuing banks. The 1844 Act also separated the issue and banking functions of the Bank into different departments, and required the Bank to publish a weekly summary of accounts.

Given that it did not pay interest on its deposits, the deposit activity of the Bank could never really compete with that of other banks, which expanded rapidly from 1850 onwards. In 1854, joint stock banks in London joined the London Clearing House, and it was agreed that clearing by transfer of Bank
of England notes would be abandoned in favour of cheques drawn on bank accounts held at the Bank. Ten years later the Bank of England itself entered this clearing arrangement, and cheques drawn on bankers’ accounts at the Bank became considered as paid. Although the Bank had, from the beginning of the 19th century, periodically bought or sold exchequer bills to influence the note circulation, explicit open-market borrowing operations to support its discount rate began in 1847. From 1873 until 1890 the Bank almost always acted as a borrower rather than a lender of funds, as there were typically cash surpluses. As a result, the Bank introduced the systematic issue of Treasury bills via a regular tender offer in 1877. Treasury bills had a much shorter maturity (three to twelve months) than Exchequer bills (five or more years), and were to play an important role in raising funds from the outset of the First World War onwards. By 1890, the Bank's role as lender of last resort became undisputed when it orchestrated the rescue of Baring Brothers and Co., a bank whose solvency had become suspect, threatening to cause systemic problems. Earlier, in 1866, the failure of a discount house, Overend, Gurney and Co., had precipitated a financial panic, during which the Bank discounted large amounts of bills and extended considerable loans. The Bank, however, was criticized for not doing more to prevent the onset of such a panic, not least by Walter Bagehot in his famous book *Lombard Street* (1873).

Throughout the 19th century, the Bank streamlined its discount facilities. In 1851 it overhauled its discount rules, stipulating that only those parties having a discount account could present bills, and that these bills had to have a maturity of fewer than 95 days and be endorsed by two creditworthy firms. In the latter part of the century, however, the Bank gradually came to favour discount houses, often by presenting them with better rates of discount, and the range of firms doing discount business with the Bank declined. Discount houses were favoured because there was tension then between the Bank and the rapidly growing commercial banks – there was much banking consolidation via mergers between the 1870s and 1914 – and dealing via the intermediation of the discount houses enabled the Bank to influence market rates without having to interact directly with the joint-stock banks as counterparties. Until the First World War the Bank pursued a discount policy which was primarily aimed at maintaining its gold reserves (as noted earlier) and which was conducted largely independently of the government. During the First World War, however, a clash occurred between the Bank Governor (Cunliffe) and the Chancellor (Law), during which the government made clear that it bore the ultimate responsibility for monetary policy, and that the Bank was expected to act on its direction.

**A subservient Bank, 1914- 1992**

The First World War was a major watershed not only in the history of the Bank but in the world more widely. It ushered in a half-century of increasing government intervention in every country, of a move towards socialist economies in most, and of communism in a wide swathe of countries. Under these circumstances the Bank became increasingly subservient to the government, in practice to the Chancellor of the Exchequer and to the Treasury, in the conduct of macro-monetary policy, its previous primary function. Initially, however, there was little perception that the war and the rise of socialist ideas had irretrievably altered the context for policy. There was a desire to return to the previous regime, the gold standard, with its tried and true verities, as expressed in the Cunliffe Committee Report (the first report of the Committee on Currency and Foreign Exchange, 1919). That was probably inevitable under the
circumstances, but a much more questionable decision was to return at the pre-war parity (against gold) despite the war-induced loss of markets (especially for the UK's main staples, textiles, coal, and iron and steel) and of competitiveness. Several of the other belligerent states, notably France, had inflated, and allowed their exchange to float downwards by so much that they did not seek to re-peg at the previous parity, but could choose a more suitable and competitive rate. While the decision to return to gold at the pre-war parity, steadfastly supported by the Bank, has been much criticized, the modern theory of time inconsistency provides some defence, namely, if the Bank had started to change the chosen rate to suit the immediate conjuncture it would have been expected to do so again in future, making commitment to the regime less credible.

Be that as it may, conditions after the First World War, with a weak balance of payments and a massively inflated money stock and floating debt, were hardly conducive to the re-establishment of gold standard conditions. Indeed, the authorities initially felt forced to move in the other direction, to unpeg the sterling–dollar rate that had been established since 1916 and formally to leave the gold standard in March 1919. The ending of the war led then to an extremely sharp and short boom and bust, in which tight monetary policy played a major role in the subsequent deflation (see Howson, 1975). From then until the return to gold at the pre-war parity of $4.86 to the pound in 1925, the Bank advocated keeping the Bank rate high enough to facilitate that regime change, but decisions on Bank rate and on the conduct of monetary policy were joint, in that no proposal by the Bank could be activated without the agreement of the Chancellor and HM Treasury; the Treasury view, however, then was in line with classical thought, namely, that monetary policy could and should impinge primarily on nominal prices, with real output affected by real factors.

Despite the boom in the USA, growth in the UK was perceived as remaining low and unemployment high, at least as compared with its main comparator countries, in the 1920s. This was in part due to the continuing problems of restoring a successful economic regime in Europe, wherein German reparations had a malign effect. Although the Bank had lost much of its power to direct domestic monetary policy (to Whitehall), the Bank and its Governor, Montagu Norman, played a leading role in the various international exercises to try to restore Europe to normality and to the gold standard, (Sayers, 1976, ch. 8); and Sir Otto Niemeyer, a top Bank official, spread the gospel of establishing central banks to maintain price stability to the Dominions.

This whole structure came apart in the crisis that started in the USA in 1929 and then engulfed the rest of the world progressively through the subsequent four years. How far that collapse was itself exacerbated by the attempt to restore the gold standard has been explored by Eichengreen (1992). The UK was not in a strong economic position to avoid the world recession, but suffered a much smaller decline in output than in the USA or much of Continental Europe. The struggle to maintain the gold standard had required the maintenance of high interest rates, despite the imposition of controls on new issues in sterling by foreign governments. Despite high unemployment, wages and prices remained too sticky to allow the restoration of international competitiveness, though quite why this was so remains a debated issue.

With the gold standard collapsing in Europe and social pressures rising in the UK, there was diminishing political will to take the measures that appeared necessary to maintain the gold standard. The government decided to abandon it (in Norman's absence) in September 1931. From that moment onwards, until May 1997, the decision to alter the Bank rate moved decisively to Whitehall, effectively into the hands of the Chancellor, advised by HM Treasury. Of course, the Bank could, and did, make
suggestions and played a major role in all the discussions, but the Chancellor took the decisions. Indeed, from June 1932 until November 1951 a policy of cheap money was followed whereby Bank rate was held constant at two per cent. Norman stated in 1937, ‘I am an instrument of the Treasury’.

Meanwhile, the Bank was becoming more professional. The old system of circulating the Governor’s chair in turn among the directors of the Bank, who were appointed from city (but not commercial bank) institutions, was superseded by the continuing governorship of Montagu Norman from 1920 until 1944. While this arose by happenstance rather than intention (see Sayers, 1976, ch. 22), it gave the Bank highly skilled, even if also highly idiosyncratic, leadership. Moreover, Norman introduced economists and other able officials into both the staff and the Court (the largely ceremonial board) of the Bank, although it is (apocryphally) recorded that Norman told one such economist, ‘You are not here to tell me what to do, but to explain why I have done what I have already decided to do.’

In effect, the Bank had already become nationalized by the end of the Second World War. So the formal act of nationalization in 1946 brought about no real substantive changes, except that the Governor and his deputy (there has as yet been no woman Governor, although Rachel Lomax became the first female Deputy Governor in 2003), were appointed by the government for five years, renewable once more in most cases. Indeed, the more profound changes were brought about by Governor Gordon Richardson (1973–83) in the early 1980s. Until then, the Governor had been rather akin to a chairman, with the deputy and other internal directors as members of the board, setting strategy. Much of the executive power still lay with the Chief Cashier, who acted as leader of the heads of department, who ran the Bank. There was a clear break, a division, between the staff in the departments on the one hand and the Governors and Directors on the other. Richardson changed all that, concentrating power in the Governors’ hands, sharply demoting the role of Chief Cashier, and underlining the precedence of (internal) directors over heads of department in all policy matters.

So, as power to decide the course of monetary policy – and to set the Bank rate – passed to Whitehall, what did these professional central bank officials do? The Bank came to have three main areas of responsibility. The first was the management of markets, notably the money market, the bond (gilts) market and the foreign exchange market. The UK had come out of the Second World War with a massively inflated ratio of debt to GDP, and its management had remained difficult and delicate, at least until after the War Loan Conversion of 1932. No sooner, however, had debt management been thereby put on a sounder foundation than the Second World War led to a further upsurge in the debt ratio, which led once again to debt management becoming a major preoccupation of policy. Thereafter, a combination of generally prudent fiscal policies, so that the debt ratio fell steadily, and then unexpected inflation in the 1970s, which accelerated the decline in the debt ratio, and market reforms in the 1980s, enabled the procedures of debt management to become simpler and standardized. Similarly, the floating exchange rate in the 1930s, followed by attempts to maintain pegged exchange rates both during the Second World War and thereafter under the Bretton Woods system, against a background of perennially weak balance of payments conditions, made the management of the UK’s foreign exchange reserves and intervention on the foreign exchange market a crucial function of the Bank until 1992, when the UK was forced out of the European exchange rate mechanism. During crises the officials in charge of such foreign exchange operations were in telephone communication with the Chancellor and, occasionally, the Prime Minister at frequent intervals.

The Bank held that such market operations required a special professional expertise (though HM Treasury remained sceptical). The Bank threw itself into such activities with enthusiasm, and defended

its pre-eminent role in this respect stoutly against all outside encroachment or criticism. Indeed, its market ‘savvy’ was its most powerful lever to persuade the Chancellor to its views in any debate; ‘I am sorry, Chancellor, but the market will not accept that policy’ was the strongest card it had to play, and that card was played often and with alacrity.

Although ultra-cheap money, with Bank rate held at two per cent, was abandoned in 1951, when the Conservative Party was returned to office, monetary policy in general, and interest rates in particular, were still seen as both more ineffective and uncertain in their impact on domestic demand than the supposedly more reliable fiscal policy, a conclusion upheld by the controversial Radcliffe Report (1959). Consequently, fiscal policy was used to try to steer domestic demand while interest rates were raised to protect the balance of payments during the regular bouts of external weakness, and otherwise held low both to ease government finance and to support fixed investment. The outcome was a system in which inflationary pressures regularly threatened both the internal and external value of the currency. The chosen solution was to supplement market measures by direct interventions, in the case of external pressure via exchange controls, in the case of monetary expansion via direct controls on bank lending to the private sector. In both instances the Bank acted as the administrative agent of HM Treasury.

Such direct controls were introduced (on bank lending), or greatly extended and tightened (exchange controls), with the onset of the Second World War in 1939, but were continued, for the reasons outlined above, until 1971 for bank lending and 1979 for exchange controls. The administration of exchange controls required a large staff, but, unlike with its market operations, the Bank had little enthusiasm for acting in this guise. The Bank hoped to restore London to its former role as an international financial centre. While it succeeded in this through its encouragement of the Eurodollar market, aided by inept US policies, the continued administration of exchange controls remained an unwelcome burden. The same was true for direct controls on bank lending. Such controls were regarded by politicians as a comparatively painless way of dampening demand and inflation, while they were resented by commercial bankers. The Bank found itself in the middle of these disputes, and grew painfully aware of such controls’ stultifying effect on efficiency, dynamism and growth. The Bank, inspired by John Fforde (the then executive director in charge of domestic finance, and subsequent Bank historian), pressed hard for these controls to be dismantled, and succeeded with the liberalizing reform of Competition and Credit Control (Bank of England, 1971).

As with many other cases of banking liberalization, such as in Scandinavia at the end of the 1980s, this was followed by an expansionary boom and then a bust, the fringe (secondary) bank crisis of 1973/74 (Reid, 1982). While there remain questions about how monetary policy could have been better applied to prevent the prior monetary boom (1972/73), there was no question but that the financial crisis found both the Bank and the banks unskilled in risk management and unprepared for adverse shocks to financial stability. The long period of financial repression – that is, controls on bank lending to the private sector and force-feeding with government debt – had had the by-product of making the (core) commercial banking system safe between the mid-1930s and the early 1970s. The central banking function of maintaining financial stability, via regulation and supervision, had atrophied. This had not been so earlier, and the Bank had been closely involved in the rescue of Williams Deacon’s Bank by the Royal Bank of Scotland in 1930 (Sayers, 1976, ch. 10), and in helping to shape the structure of both the commercial banking system and the London Discount Market Association. Williams Deacon’s had got into trouble largely because of bad debts from Lancashire cotton companies. Norman, and the Bank, extended their structural interventions beyond banking to try to encourage strategic
amalgamations to shore up the positions of weakened companies in a variety of industries, such as cotton, steel, shipping, armaments (Sayers, 1976, ch. 14). The Bank's involvement in structural matters outside of banking itself was episodic depending on both circumstances and personalities. Another example of such Bank involvement was the considerable role it played in the reform of the UK capital market in the 1980s, more familiarly known as ‘Big-Bang’. But views on whether the Bank has any locus in such wider structural issues vary over time; the early 2000s saw a major withdrawal by the Bank from any such involvement.

The fringe bank crisis in the early 1970s was, however, a clarion call to put more emphasis on its third main function, bank supervision and regulation. The immediate result was a reorganization in the Bank. Initially a nucleus of a new specialized department was established in the Discount Office where the limited staff assigned to this role had sat, which rapidly absorbed staff and resources. Thereafter this became a separate department devoted to banking supervision and regulation (its first head was George Blunden, later to become Deputy Governor, who handed it on to Peter Cooke in 1976). Its position was regularized in the Banking Act (1979) which gave formal powers to the Bank to authorize, monitor, supervise, control and, under certain circumstances, withdraw prior authorization (tantamount to closure) for banks. No such powers had been available before that date. Meanwhile, other financial intermediaries, such as building societies or insurance companies, remained (lightly) regulated by various government departments.

The fringe bank crisis was almost entirely domestic, confined to British headquartered companies. Meanwhile, however, the onwards march of liberalization (involving the removal of direct controls, notably exchange controls in 1979) and of information technology were leading to a growing internationalization of financial business. For a variety of reasons, mostly relating to the innovation of the Eurodollar and Euro-markets, London regained its role as an international financial centre in the 1960s, and thus international monetary problems became of particular importance to the Bank, which took a leading role in such matters from the 1970s onwards.

Central bankers had met regularly at the headquarters of the Bank for International Settlements (BIS) in Basel for many years. It was, therefore, a logical step for supervisory officials also to come together at Basel on regular occasions to discuss matters of common interest. Thus was born (in 1974), as a result of an initiative from Gordon Richardson, the Basel Committee on Banking Regulation and Supervisory Practices. For the first 15 years of its existence it was chaired by the participant from the Bank of England, and was usually known by his name; thus, the Blunden Committee (1974–77) gave way in due course to the Cooke Committee (1977–88). The failures of Franklin National and Herstatt prompted the First Basel Concordat, which allocated responsibility for supervising internationally active banks to home and host authorities.

So by the mid-1970s, a need was perceived for banking supervision at both the domestic and, via consolidation, at the international levels. The purpose of these initiatives was to clarify where responsibility lay for the supervision of international banks, to prevent fragile, and possibly fraudulent, banking leading to avoidable failures and potential systemic crises.

Despite the growing number of bank supervisors, and notable success in reversing prior declines in capital ratios, the history of banking in the subsequent decades in the UK was spotted by occasional bank failures. Unlike the fringe bank crisis, none was, or was allowed to become, systemic, nor did individual depositors lose any money, except in the case of Bank of Credit and Commerce International (BCCI), and even in that case the deposit protection scheme provided some relief. The failures of
Johnson–Matthey (in 1984), BCCI (in 1991) and Barings (in 1995) were all isolated cases of bad, in some respects fraudulent, banking.

The main problem of the 1970s and 1980s was, however, that of combating inflation, which soared to heights previously unknown, not only in peacetime but even in wartime, during the 1970s, up to 25 per cent per annum. There were three main theories, though divisions between them were never completely distinct. The first was the cost-push theory, that inflation was driven by over-mighty trade unions, seeking to increase the relative real pay of their members; the appropriate remedy was then prices and incomes policies plus reform (and constraint) of trades unions. The second was the (vertical) Phillips curve analysis; the remedy here was to raise unemployment above the ‘natural’ rate to reduce inflation. The third was that inflation was a monetary phenomenon; the remedy was to control the rate of growth of the (appropriate) monetary aggregate.

Until the mid-1970s, both major political parties, the Bank and HM Treasury all professed some combination of theories 1 (cost-push) and 2 (Phillips curve). Left-leaning politicians, academics and officials tended to put more weight on cost-push. In the 1960 and 1970s the third, monetarist, view seemed to explain events better and gained strength, not only in the USA (Milton Friedman) but also in the UK. In particular, the surge in inflation in the UK in 1973–75 followed closely behind the rapid expansion of broad (but not narrow) money in 1972–73. So, when in opposition, the leading Conservative politicians Keith Joseph and Margaret Thatcher embraced a version of monetarism. When they came to power in 1979, they tried to commit monetary policy to follow a target for broad money, via the Medium Term Financial Strategy. In order to achieve this, nominal, and real, interest rates were kept high, and the exchange rate appreciated sharply, partly under the influence of North Sea oil and confidence in Thatcherite policies. Inflation duly declined, as planned, but broad money growth did not. This latter was partly due to the abolition of the ‘corset’ in 1980. The ‘corset’ was a reformulated, and somewhat disguised, direct control over commercial bank expansion that had been pressed into service on several occasions during the 1970s. The Bank was glad to see the end of exchange controls and direct controls over bank lending, but had never shared the government's monetarist faith in trying to set, and stick to, targets for the growth of (the various) monetary aggregates. The empirical demonstration of the unpredictability of the relationship between (broad) money and nominal incomes in the early 1980s soon weakened the government's own faith. After moving from one monetary target to several joint targets, and an attempt to hit the broad money target by ‘overfunding’, an exercise criticized by many as artificial, the government abandoned its monetary targetry in 1986. That left the question of how monetary policy, and with it control of inflation, was to be managed or, in the standard phrase, ‘anchored’. The then Chancellor, Nigel Lawson, wanted to ‘anchor’ by joining the exchange rate mechanism (ERM) of the European Monetary System and leaving the steering of monetary policy to the Bundesbank. The Prime Minister, Mrs Thatcher, and her adviser, Alan Walters, were opposed, both on economic grounds (that such a pegged system was ‘half-baked’) and for wider political reasons. There was a battle royal in which the Bank was left on the sidelines. Lawson was sacked, but eventually Mrs Thatcher was, grudgingly, persuaded to allow the UK to join the ERM in October 1990.

This was in the aftermath of German reunification, and the expenditures connected with that led the Bundesbank to keep interest rates higher than was tolerable for the UK (or Italy). The UK was in the throes of a sharp downturn in housing prices, following an unstable housing boom in the late 1980s. With the Conservatives having become politically weaker, there was just no stomach to raise interest
rates to the levels necessary to sustain the ERM. The UK was forced out in September 1992.

Independent and focused, 1992–

The ejection of the UK from the ERM left the government and HM Treasury with the recurrent problem of how to manage, to ‘anchor’, monetary policy. Both monetary and exchange rate targets had been tried, and both had been found wanting. While the economic experience of the 1980s was better than that of the stagflationary 1970s, it was hardly stellar, with a boom–bust cycle at the end of the decade. Meanwhile, a new approach had been adopted in New Zealand, whereby the central bank was given administrative freedom to vary interest rates for the purpose of hitting a target for the inflation rate, jointly set by the government and the central bank: that is, inflation targetry. This obviated one of the shortcomings of monetary targetry, namely, the unpredictability of the velocity of money; it left setting the goals of policy, the overall strategy, in the hands of government, but shifted the (constrained) discretion to vary interest rates to the professional and technical judgement of the central bank. This procedure soon generated a strong body of academic support (for example, Fischer, 1994).

Although Conservative Chancellors (both Lawson and Lamont) had toyed with the idea of giving the Bank operational independence, consecutive Prime Ministers (Thatcher and Major) refused, primarily on political grounds. Nevertheless Lamont wanted to move to an inflation target. But there was a problem of governmental credibility. To foster credibility, Lamont now encouraged (in 1992/93) the Bank to prepare and to publish an independent forecast of the likely projection for inflation, the Inflation Report (on the assumption of unchanged policies); this was a reversal of prior habits whereby HM Treasury and Ministers customarily censored Bank publications and discouraged any publication of internal Bank forecasts. The process of gradually giving the Bank a more independent role in setting monetary policy took a step further when the next Chancellor, Clarke, not only held a meeting with the Governor, and the Bank, to discuss future changes in interest rates, but published the minutes of the meeting, including the Governor's initial statement, verbatim; this was termed the Ken (Clarke) and Eddie (George) show. That said, Clarke had strong views on the appropriate policy and on a couple of occasions overruled the Governor's suggestions.

At that time – the mid-1990s – there were still question marks over the Labour Party's ability to manage the economy; financial markets are inherently suspicious of left-leaning governments. So Labour had more to gain (than the Conservatives), in terms of confidence and lower interest rates, by granting operational independence (back) to the Bank. In advance of the 1997 election the then shadow Chancellor, Gordon Brown, was cautious; while indicating general support for both inflation targetry and operational independence, he stated that he wanted time to see how well the Bank performed before granting such independence. But, within days of winning the election, he made that strategic change to the monetary regime.

This was, of course, a great prize for the Bank, but it did not come without cost. In the same month as operational independence was awarded to the Bank, both debt management and banking supervision were hived off, to a separate Debt Management Office (DMO) and Financial Services Authority (FSA) respectively. With the government debt to GDP ratio having declined and capital markets strengthened, debt management had become more of a routine and standardized exercise. Nevertheless, its departure to the DMO, and the fact that the float of the exchange rate after 1992 was kept ‘clean’, that is, without intervention, meant that much of the market operations which had been so central to the Bank in the post-
Second World War period disappeared, though its money market operations, of course, continued. The administration of direct controls had gone at the beginning of the 1980s. And now banking supervision was also taken away. This meant that almost all the prime functions that the Bank had undertaken in its post-Second World War period of subservience had now gone. Instead, the Bank was now focused on varying interest rates to achieve the inflation target set for it by the Chancellor.

There are numerous arguments, quite evenly balanced, for whether bank supervision should be kept within a central bank or put with a separate Financial Services Authority (FSA), covering both banks and other financial intermediaries (see Goodhart, 2000). Be that as it may, there are various aspects of the financial system, such as oversight of the payments’ system, and of crisis management, such as lender of last resort functions, which cannot be delegated to an FSA. Moreover, the achievement of price stability is likely to be seriously compromised by any serious bout of financial instability – and vice versa, with financial stability adversely affected by price instability. So the removal of individual bank supervision does not absolve the Bank from concern with financial stability issues more widely; indeed, the Bank is specifically charged with maintaining overall systemic stability in the financial system. But exactly what that means when responsibility for the conduct of individual bank supervision is located elsewhere is not yet entirely clear.

What it certainly does mean is that the FSA, the Bank, and the political authorities as the ultimate source of any needed fiscal support have to work extremely closely together, in advising on any new regulations (whether domestic or international), in monitoring developments (as in the Financial Stability Review), and in crisis management. This latter task would be done via the Tripartite Standing Committee (FSA, Bank, and HM Treasury), set up in 1997, although so far no such financial (as contrasted with simulated ‘war games’) crisis has occurred, though the Committee did meet after the terrorist attacks on 7 July, 2005. How successful crisis management by such a committee may be has yet to be seen.

The monetary policy function of the Bank, now its central preoccupation, has, however, been very successful by all the usual criteria. In several papers Luca Benati (for example, Benati, 2005) has demonstrated that the variance of both GDP and of inflation around its target has been lower under the inflation targetry regime (whether taken as starting in 1992 or in 1997) than under any previous historical regime. The procedures of having a Monetary Policy Committee consisting of five senior Bank officials and four outside experts (appointed by the Chancellor), with the Committee serviced by Bank staff, has worked generally smoothly and well. So the Bank's reputation and credibility have rarely been higher, although now tightly focused on one main function.

banking crises

Charles W. Calomiris
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Banking crises take a variety of forms ranging from temporary liquidity crises to massive insolvencies. They sometimes coincide with other financial crises in currency and sovereign debt markets, and sometimes occur in isolation. These differences reflect the variety of causal influences that give rise to problems for banks. The unusually crisis-prone experience of the United States historically reflected its unique industrial organization of banking. Policies intended to reduce the incidence of banking crises (especially deposit insurance) have instead often increased the risk of crises, as safety-net protection reduces market discipline, allowing banks to undertake imprudent risks.

Keywords

banking crises; central banks; currency crises; deposit insurance; devaluation; Federal Reserve System; Great Depression; liquidity crises; panic of 1907; prudential bank regulation; sovereign debt

Article

There are two distinct phenomena associated with banking system distress: exogenous shocks that produce insolvency, and depositor withdrawals during ‘panics’. These two contributors to distress often do not coincide. For example, in the rural United States during the 1920s many banks failed, often with high losses to depositors, but those failures were not associated with systemic panics. In 1907, the United States experienced a systemic panic, originating in New York. Although some banks failed in 1907, failures and depositor losses were not much higher than in normal times. As the crisis worsened, banks suspended convertibility until uncertainty about the incidence of the shock had been resolved. The central differences between these two episodes relate to the commonality of information regarding the shocks producing loan losses. In the 1920s, the shocks were loan losses in agricultural banks, geographically isolated and fairly transparent. Banks failed without resulting in system-wide concerns. During 1907, the ultimate losses for New York banks were small, but the incidence was unclear ex ante (loan losses reflected complex connections to securities market transactions, with uncertain
banking crises: The New Palgrave Dictionary of Economics

consequences for some New York banks). This confusion hit the financial system at a time of low liquidity, reflecting prior unrelated disturbances in the balance of payments (Bruner and Carr, 2007). Sometimes, large loan losses, and confusion regarding their incidence, occurred together. In Chicago in mid-1932 losses resulted in many failures and also in widespread withdrawals from banks that did not ultimately fail. Research has shown that the banks that failed were exogenously insolvent; solvent Chicago banks experiencing withdrawals did not fail. In other episodes, however, bank failures may reflect illiquidity resulting from runs, rather than exogenous insolvency.

Banking crises can differ according to whether they coincide with other financial events. Banking crises coinciding with currency collapse are called ‘twin’ crises (as in Argentina in 1890 and 2001, Mexico in 1995, and Thailand, Indonesia and Korea in 1997). A twin crisis can reflect two different chains of causation: an expected devaluation may encourage deposit withdrawal to convert to hard currency before devaluation (as in the United States in early 1933); or, a banking crisis can cause devaluation, either through its adverse effects on aggregate demand or by affecting the supply of money (when a costly bank bail-out prompts monetization of government bail-out costs). Sovereign debt crises can also contribute to bank distress when banks hold large amounts of government debt (for example, in the banking crises in the United States in 1861, and in Argentina in 2001).

The consensus views regarding banking crises’ origins (fundamental shocks versus confusion), the extent to which crises result from unwarranted runs on solvent banks, the social costs attending runs, and the appropriate policies to limit the costs of banking crises (government safety nets and prudential regulation) have changed dramatically, and more than once, over the course of the 19th and 20th centuries. Historical experience played a large role in changing perspectives toward crises, and the US experience had a disproportionate influence on thinking. Although panics were observed throughout world history (in Hellenistic Greece, and in Rome in ad 33), prior to the 1930s, in most of the world, banks were perceived as stable, large losses from failed banks were uncommon, banking panics were not seen as a great risk, and there was little perceived need for formal safety nets (for example, deposit insurance, or programmes to recapitalize banks). In many countries, ad hoc policies among banks, and sometimes including central banks, to coordinate bank responses to liquidity crises (as, for example, during the failure of Barings investment bank in London in 1890), seemed adequate for preventing systemic costs from bank instability.

Unusual historical instability of US banks

The unusual experience of the United States was a contributor to changes in thinking that led to growing concerns about banks runs, and the need for aggressive safety net policies to prevent or mitigate runs. In retrospect, the extent to which US banking instability informed thinking and policy outside the United States seems best explained by the size and pervasive influence of the United States; in fact, the US crises were unique and reflected peculiar features of US law and banking structure.

The US panic of 1907 (the last of a series of similar US events, including 1857, 1873, 1884, 1890, 1893, and 1896) precipitated the creation of the Federal Reserve System in 1913 as a means of enhancing systemic liquidity, reducing the probability of systemic depositor runs, and mitigating the costs of such events. This innovation was specific to the United States (other countries either had established central banks long before, often with other purposes in mind, or had not established central banks), and reflected the unique US experience with panics – a phenomenon that the rest of the world had not experienced
since 1866, the date of the last British banking panic (Bordo, 1985).

For example, Canada did not suffer panics like those of the United States and did not establish a central bank until 1935. Canada's early decision to permit branch banking throughout the country ensured that banks were geographically diversified and thus resilient to large sectoral shocks (like those to agriculture in the 1920s and 1930s), able to compete through the establishment of branches in rural areas (because of the low overhead costs of establishing additional branches), and able to coordinate the banking system's response in moments of confusion to avoid depositor runs (the number of banks was small, and assets were highly concentrated in several nationwide institutions). Outside the United States, coordination among banks facilitated systemic stability by allowing banks to manage incipient panic episodes to prevent widespread bank runs. In Canada, the Bank of Montreal would occasionally coordinate actions by the large Canadian banks to stop crises before the public was even aware of a possible threat.

The United States, however, was unable to mimic this behaviour on a national or regional scale (Calomiris, 2000; Calomiris and Schweikart, 1991). US law prohibited nationwide branching, and most states prohibited or limited within-state branching. US banks, in contrast to banks elsewhere, were numerous (for example, numbering more than 29,000 in 1920), undiversified, insulated from competition, and unable to coordinate their response to panics (US banks established clearing houses, which facilitated local responses to panics beginning in the 1850s, as emphasized by Gorton, 1985).

The structure of US banking explains why the United States uniquely had banking panics in which runs occurred despite the health of the vast majority of banks. The major US banking panics of the post-bellum era (listed above) all occurred at business cycle peaks, and were preceded by spikes in the liabilities of failed businesses and declines in stock prices; indeed, whenever a sufficient combination of stock price decline and rising liabilities of failed businesses occurred, a panic always resulted (Calomiris and Gorton, 1991). Owing to the US banking structure, panics were a predictable result of business cycle contractions that, in other countries, resulted in an orderly process of financial readjustment.

The United States, however, was not the only economy to experience occasional waves of bank failures before the First World War. Nor did it experience the highest bank failure rates, or bank failure losses. None of the US banking panics of the pre-First World War era saw nationwide banking distress (measured by the negative net worth of failed banks relative to annual GDP) greater than the 0.1 per cent loss of 1893. Losses were generally modest elsewhere, but Argentina in 1890 and Australia in 1893, where the most severe cases of banking distress occurred during this era, suffered losses of roughly ten per cent of GDP. Losses in Norway in 1900 were three per cent and in Italy in 1893 one per cent of GDP, but with the possible exception of Brazil (for which data do not exist to measure losses), there were no other cases in 1875–1913 in which banking loss exceeded one per cent of GDP.

Loss rates tended to be low because banks structured themselves to limit their risk of loss, by maintaining adequate equity-to-assets ratios, sufficiently low asset risk, and adequate asset liquidity. Market discipline (the fear that depositors would withdraw their funds) provided incentives for banks to behave prudently. The picture of small depositors lining up around the block to withdraw funds has received much attention, but perhaps the more important source of market discipline was the threat of an informed (often ‘silent’) run by large depositors (often other banks). Banks maintained relationships with each other through interbank deposits and the clearing of public deposits, notes and bankers’ bills. Banks often belonged to clearing houses that set regulations and monitored members’ behaviour. A bank
that lost the trust of its fellow bankers could not long survive.

Changing perceptions of banking instability

This perception of banks as stable, as disciplined by depositors and interbank arrangements to act prudently, and as unlikely to fail was common prior to the 1930s. The banking crises of the Great Depression changed this perception. US Bank failures resulted in losses to depositors in the 1930s in excess of three per cent of GDP. Bank runs, bank holidays (local and national government-decreed periods of bank closure to attempt to calm markets and depositors), and widespread bank closure suggested a chaotic and vulnerable system in need of reform. The Great Depression saw an unusual raft of banking regulations, especially in the United States, including restrictions on bank activities (the separation of commercial and investment banking, subsequently reversed in the 1980s and 1990s), targeted bank recapitalizations (the Reconstruction Finance Corporation), and limited government insurance of deposits.

Academic perspectives on the Depression fuelled the portrayal of banks as crisis-prone. The most important of these was the treatment of the 1930s banking crises by Milton Friedman and Anna Schwartz in their book, *A Monetary History of the United States* (1963). Friedman and Schwartz argued that many solvent banks were forced to close as the result of panics, and that fear spread from some bank failures to produce failures elsewhere. They saw the early failure of the Bank of United States in 1930 as a major cause of subsequent bank failures and monetary contraction. They lauded deposit insurance: ‘federal deposit insurance, to 1960 at least, has succeeded in achieving what had been a major objective of banking reform for at least a century, namely, the prevention of banking panics’. Their views that banks were inherently unstable, that irrational depositor runs could ruin a banking system, and that deposit insurance was a success, were particularly influential coming from economists known for their scepticism of government interventions.

Since the publication of *A Monetary History of the United States*, however, other scholarship (notably, the work of Elmus Wicker, 1996, and Charles Calomiris and Joseph Mason, 1997; 2003a) has led to important qualifications of the Friedman–Schwartz view of bank distress during the 1930s, and particularly of the role of panic in producing distress. Detailed studies of particular regions and banks’ experiences do not confirm the view that panics were a nationwide phenomenon during 1930 or early 1931, or an important contributor to nationwide distress until very late in the Depression (that is, early 1933). Regional bank distress was often localized and traceable to fundamental shocks to the values of bank loans. Not only does it appear that the failure of the Bank of United States had little effect on banks nationwide in 1930, one scholar has argued that there is evidence that the bank was, in fact, insolvent when it failed (Lucia, 1985).

Other recent research on banking distress during the pre-Depression era has also de-emphasized inherent instability, and focused on the historical peculiarity of the US banking structure and panic experience, noted above. Furthermore, recent research on the destabilizing effects of bank safety nets has been informed by the experience of the US Savings and Loan industry debacle of the 1980s, the banking collapses in Japan and Scandinavia during the 1990s, and similar banking system debacles occurring in 140 developing countries in the last quarter of the 20th century, all of which experienced banking system losses in excess of one per cent of GDP, and more than 20 of which experienced losses in excess of ten
per cent of GDP (data are from Caprio and Klingebiel, 1996, updated in private correspondence with these authors). Empirical studies of these unprecedented losses concluded that deposit insurance and other policies that protect banks from market discipline, intended as a cure for instability, have become instead the single greatest source of banking instability.

The theory behind the problem of destabilizing protection has been well known for over a century, and was the basis for US President Franklin Roosevelt's opposition to deposit insurance in 1933 (an opposition shared by many). Deposit insurance was seen as undesirable special interest legislation designed to benefit small banks. Numerous attempts to introduce it failed to attract support in Congress (Calomiris and White, 1994). Deposit insurance removes depositors' incentives to monitor and discipline banks, and frees bankers to take imprudent risks (especially when they have little or no remaining equity at stake, and see an advantage in ‘resurrection risk taking’). The absence of discipline also promotes banker incompetence, which leads to unwitting risk taking.

Empirical research on late 20th-century banking collapses has produced a consensus that the greater the protection offered by a country's bank safety net, the greater the risk of a banking collapse (see, for example, Caprio and Klingebiel, 1996, and the papers from a 2000 World Bank conference on bank instability listed in the bibliography). Empirical research on prudential bank regulation emphasizes the importance of subjecting some bank liabilities to the risk of loss to promote discipline and limit risk taking (Shadow Financial Regulatory Committee, 2000; Mishkin, 2001; Barth, Caprio and Levine, 2006).

Studies of historical deposit insurance reinforce these conclusions (Calomiris, 1990). The basis for the opposition to deposit insurance in the 1930s was the disastrous experimentation with insurance in several US states during the early 20th century, which resulted in banking collapses in all the states that adopted insurance. Government protection had played a similarly destabilizing role in Argentina in the 1880s (leading to the 1890 collapse) and in Italy (leading to its 1893 crisis). In retrospect, the successful period of US deposit insurance, from 1933 to the 1960s, to which Friedman and Schwartz referred, was an aberration, reflecting limited insurance during those years (insurance limits were subsequently increased), and the unusual macroeconomic stability of the era.

Models of banking crises followed trends in the empirical literature. The understanding of bank contracting structures, in light of potential crises, has been a consistent theme. Banks predominantly hold illiquid assets (‘opaque,’ non-marketable loans), and finance those assets mainly with deposits withdrawable on demand. Banks are not subject to bankruptcy preference law, but rather, apply a first-come, first-served rule to failed bank depositors (depositors who are first in line keep the cash paid out to them). These attributes magnify incentives to run banks. An early theoretical contribution, by Douglas Diamond and Philip Dybvig (1983), posited a banking system susceptible to the constant threat of runs, with multiple equilibria, where runs can occur irrespective of problems in bank portfolios or any fundamental demand for liquidity by depositors. They modelled deposit insurance as a means of avoiding the bad (bank run) equilibrium. Over time, other models of banks and depositor behaviour developed different implications, emphasizing banks’ abilities to manage risk effectively, and the beneficial incentives of demand deposits in motivating the monitoring of banks in the presence of illiquid bank loans (Calomiris and Kahn, 1991).

The literatures on banking crises also rediscovered an older line of thought emphasized by John Maynard Keynes (1931) and Irving Fisher (1933): market discipline implies links between increases in
bank risk, depositor withdrawals and macroeconomic decline. As banks respond to losses and increased risk by curtailing the supply of credit, they can aggravate the cyclical downturn, magnifying declines in investment, production, and asset prices, whether or not bank failures occur (Bernanke, 1983; Bernanke and Gertler, 1990; Calomiris and Mason, 2003b; Allen and Gale, 2004; Von Peter, 2004; Calomiris and Wilson, 2004). New research explores general equilibrium linkages among bank credit supply, asset prices and economic activity, and adverse macroeconomic consequences of ‘credit crunches’ that result from banks’ attempts to limit their risk of failure. This new generation of models provides a rational-expectations, ‘shock-and-propagation’ approach to understanding the contribution of financial crises to business cycles, offering an alternative to the endogenous-cycles, myopic-expectations view pioneered by Hyman Minsky (1975) and Charles Kindleberger (1978).

The distinctive function of banks is the transformation of short-term deposits into longer-term, less liquid and riskier loans (Fama, 1980; 1985; Diamond and Rajan, 2001; Gorton and Winton, 2003). By raising funds from depositors and providing credit, banks avoid the duplication of monitoring, which reduces the overall cost of transferring funds from capital suppliers to its users (Leland and Pyle, 1977; Diamond, 1984). At the same time, however, the greater liquidity of liabilities than of assets, which are typically longer-term and riskier, makes bank balance sheets vulnerable. Not only may banks fail if they are unable to obtain repayment of their loans, but depositors might even decide to withdraw their assets simply anticipating that others will do so. Such a ‘bank run’ can drive an otherwise sound bank to insolvency (Diamond and Dybvig, 1983). The need to protect depositors and so guarantee a stable monetary transaction system explains why the banking industry is so heavily regulated. It is harder for a depositor to protect his interests than for an average investor, because judging the financial condition of a bank is difficult and costly, even for specialists. For this reason, the typical instruments adopted by bank regulators include restrictions on the amount of risk that a bank can take, and compulsory deposit insurance schemes that prevent runs.

Regulatory intervention affects the shape of the banking industry and its degree of competition. Until the mid-1960s, governments deliberately limited competition in the interest of ‘safety and soundness’ by regulating deposit rates, entry, branching and mergers. The traditional view is of a trade-off between soundness and competition, with more intense competition reducing franchise values and increasing incentives to take on risky projects, since forgone future profits in the case of bankruptcy are lower.
By increasing the equity at risk, capital controls reduce (although perhaps not entirely) excessive risk-taking (Hellman, Murdock and Stiglitz, 2000). Recently, a more comprehensive view has been put forward, suggesting that regulation interacts dynamically with pervasive information asymmetries, and that the relationship between competition and stability is accordingly complex and multifaceted (Allen and Gale, 2003). The cost of acquiring information in order to mitigate moral hazard and adverse selection is a strong endogenous barrier to the entry of new banks, allowing incumbents to gain monopoly rents (Broecker, 1990), making competitive equilibria unsustainable (Dell'Ariccia, 2001; Dell'Ariccia, Friedman and Marquez, 1999), and forcing new entrants to take a higher-risk clientele (Shaffer, 1998).

The problems of information asymmetries can be attenuated if a bank deals repeatedly with the same customer, a practice known as ‘relationship lending’. However, as Sharpe (1990) and Rajan (1992) show, this gives relationship banks a monopoly on information about their borrowers, further reducing competition, especially in the short run (Petersen and Rajan, 1995). In this case, deregulation aimed at fostering inter-bank competition in transaction lending could have the effect of augmenting the scope for relationship banking, which permits banks to retain some monopoly power. As Boot and Thakor (2000) show, this is not the case if stronger competition comes from capital market financing, which drives some banks out of the market, reducing competition and consequently relationship lending.

Since the mid-1980s, the banking industry has been transformed by a series of events: deregulation of deposit accounts, which forced US banks to compete on interest rates; branching liberalization, which led to a sharp decline in the number of banks; the changes in capital requirements introduced with the Basel accords of 1988, which pushed banks towards newer and less regulated off-balance-sheet activities; the introduction of the euro, which created a unique wholesale banking market within Europe (Berger, Kashyap and Scalise, 1995); and the substantial repeal of the Glass–Steagall Act of 1933, allowing banks to supply financial services previously offered only by other intermediaries, such as investment firms and insurance companies.

One of most important consequences of deregulation has been the unprecedented numbers of mergers and acquisitions during the 1990s, which sharply reduced the number of banks in many industrial countries and often heightened concern over possible anti-competitive effects. However, there is no clear evidence that the consolidations have harmed consumers or diminished competition, as would have been predicted from the observed negative correlation between the degree of concentration in local banking markets and the level of deposit rates (Berger and Hannan, 1989). Rather, the available evidence indicates a positive effect stemming from the larger and more efficient banks taking over the smaller and less efficient (Berger, Kashyap and Scalise, 1995; Focarelli, Panetta and Salleo, 2002). And while there may be some contraction of credit to smaller clients due to consolidation, this effect appears to be largely offset by increased lending by other banks (Berger et al., 1998). Indeed, there is evidence that in the medium term mergers increase the efficiency of the target bank, benefiting depositors (Focarelli and Panetta, 2003).

The future of the banking industry is likely be determined by the interaction of three major forces: international competition, innovation in information technology and regulation. At present, all three factors are heightening competition in banking. International competition, while still limited, tends to display the same pattern as domestic consolidation, with larger and more efficient banks in more
developed countries taking over less efficient banks in financially less developed areas (Focarelli and Pozzolo, 2005). Technological innovation is lessening the importance of close lending relationships, enlarging the size of local credit markets and further reducing the role of small banks (Petersen and Rajan, 2002). Worldwide regulatory systems are moving to allow more competition and to assign a more important role to market evaluation (Basel Committee on Banking Supervision, 2005).

Banking School, Currency School, Free Banking School

Anna J. Schwartz
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The doctrines of the three 19th century schools differed. The Currency School believed that note issues should vary one-to-one with the Bank of England's gold reserves. The Banking School believed that real bills, needs of trade and the law of reflux should govern bank operations. The Free Banking School believed that competitive private banks would not overissue, whereas a monopoly issuer did so. Other issues were debated. Was a central bank needed? Should a central bank be subject to rules or allowed discretion? How should money be defined? No one point of view carried the day and several of the issues that divided the schools are still debated today.

Article

Historians of economic thought conventionally represent British monetary debates from the 1820s on as centred on the question of whether policy should be governed by rules (espoused by adherents of the Currency School), or whether authorities should be allowed discretion (espoused by adherents of the Banking School). In fact many other questions were in dispute, including those raised by neglected or misidentified participants in the debates – adherents of the Free Banking School.
Among the questions in dispute were the following: (1) Should the banking system follow the Currency School's principle that note issues should vary one-to-one with the Bank of England's gold holdings? (2) Were the doctrines of the Banking School – real bills, needs of trade and the law of reflux – valid? (3) Was a monopoly of note issue desirable or, as the Free Banking School contended, destabilizing? (4) Was overissue a problem and, if so, who was responsible? (5) How should money be defined? (6) Why do trade cycles occur? (7) Should there be a central bank? No, was the Free Banking School answer to the final question; yes, was the answer of the other two schools, with disparate views, as indicated, on the question of rules vs. authorities. What was not in dispute was the viability of the gold standard system with gold convertibility of Bank of England notes.

On what grounds did the schools oppose each other? Each of the first three questions identifies the central doctrines that the adherents of one of the schools shared; on the remaining questions, individual views within each school varied. Before establishing the positions of each school in the monetary debates, we introduce the institutional background and the principal participants.

Institutional background

The Bank of England, incorporated in 1694 as a private institution with special privileges, stood at the head of the British banking system at the time of the debates. Until 1826 the Bank's charter was interpreted to mean the prohibition of other joint stock banks in England. As a result banking establishments were either one-man firms or partnerships with not more than six members. Two types of banks predominated in England: the wealthy London private banks which had voluntarily surrendered their note-issuing privilege, and the country banks which depended almost exclusively on the business of note issues. Numerous failures among the country banks demonstrated that the effect of the Bank's charter was to foster the formation of banking units of uneconomical size.

Banking in Ireland was patterned on English lines. The Bank of Ireland, chartered in 1783 with the exclusive privilege of joint stock banking in Ireland, surrendered its monopoly in 1821 in places farther than fifty miles from Dublin. Joint-stock banking in the whole of Ireland was legalized in 1845.

The Bank of Scotland was founded in 1695 with privileges similar to those of the Bank of England, except that it was formed to promote trade, not to support the credit of the government. It lost its monopoly in 1716, and no further monopolistic banking legislation was enacted in Scotland. With free entry possible, many local private and joint stock banks, most of the latter well capitalized, were established, and a nationwide system of branch banking developed. Unlike the English system, overissue was not a problem in the Scottish system. The banks accepted each other's notes and evolved a system of note exchange. Shareholders of Scottish joint stock banks (except for three chartered banks) assumed unlimited liability. At the time of the debates banking in Scotland was at a far more advanced stage than in England.

Principals in the debates

The leading spokesmen for the Currency School side in the debates were McCulloch, Loyd (later Lord Overstone), Longfield, George Warde Norman, and Torrens. Norman, a director of the Bank of England for most of the years 1821–72, and of the Sun Insurance Company, 1830–64, was active in the timber trade with Norway. The principal Banking School representatives were Tooke, Fullarton, and John
Stuart Mill, while James Wilson held views that straddled Banking and Free Banking School doctrines. The most prominent members of the Free Banking School were Parnell (later Baron Congleton), James William Gilbart, and Poulett Scrope. Gilbart, a banker, was general manager of the London and Westminster Bank, the first of the joint stock banks authorized by the Bank Charter Act of 1833.

**Currency School principle**

The objective of the Currency School was to achieve a price level that would be the same whether the money supply were fully metallic or a mixed currency including both paper notes and metallic currency. According to Loyd, gold inflows or outflows under a fully metallic currency had the immediate effect of increasing or decreasing the currency in circulation, whereas a mixed currency could operate properly only if inflows or outflows of gold were exactly matched by an increase or decrease of the paper component. He and others of the Currency School regarded a rise in the price level and a fall in the bullion reserve under a mixed currency as symptoms of excessive note issues. They advocated statutory regulation to ensure that paper money was neither excessive nor deficient because otherwise fluctuations in the currency would exacerbate cyclical tendencies in the economy. They saw no need, however, to regulate banking activities other than note issue.

The Banking School challenged these propositions. Fullarton denied that overissue was possible in the absence of demand, that variations in the note issue could cause changes in the domestic price level, or that such changes could cause a fall in the bullion reserve ([1844] 1969, pp. 57, 128–9). Under a fully metallic as well as under a mixed currency bank, deposits, bills of exchange, and all forms of credit might influence prices. Moreover, inflows and outflows of gold under a fully metallic currency might change bullion reserves but not prices. If convertibility were maintained, overissue was not feasible and no statutory control of note issues was required. An adverse balance of payments was a temporary phenomenon that was self-correcting when, for example, a good harvest followed a bad one. According to the Free Banking School, the possibility of overissue and inflation applied only to Bank of England notes but could not occur in a competitive banking system.

**Banking School principle**

The Banking School adopted three principles that for them reflected the way banks actually operated as opposed to the Currency School principle which they dismissed as an artificial construct of certain writers (White, 1984, pp. 119–28).

The first Banking School principle was the doctrine that liabilities of deposits and notes would never be excessive if banks restricted their earning assets to real bills. One charge levelled by modern economists against the doctrine is that it leaves the quantity of money and the price level indeterminate, since it links the money supply to the nominal magnitude of bills offered for discount. Some members of the school may be exculpated from this charge if they regarded England as a small open economy, its domestic money stock a dependent variable determined by external influences. However, because it ignored the role of the discount rate in determining the volume of bills generated in trade, the doctrine was vulnerable. In addition, the Banking School confused the flow demand for loanable funds, represented by the volume of bills, with the stock demand for circulating notes, although the two magnitudes are non-
commensurable.

Free Banking School members who also adopted the real bills doctrine erroneously attributed overissue by the Bank of England to its purchase of assets other than real bills, when overissue was possible with a portfolio limited to real bills, acquired at an interest rate that led to a stock of circulating medium inconsistent with the prevailing price level (Gilbart, 1841, pp. 103–5; 119–20). The Currency School regarded the real bills doctrine as misguided since it could promote a cumulative rise in the note issue and hence in prices.

A second Banking School principle was the ‘needs of trade’ doctrine, to the effect that the note circulation should be demand-determined – curtailed when business declined and expanded when business prospered, whether for seasonal or cyclical reasons. An implicit assumption of the doctrine was that banks could either vary their reserve ratios to accommodate lower or higher note liabilities, or else offset changes in note liabilities by opposite changes in deposit liabilities. For non-seasonal increases in demand for notes, the doctrine implied that expanding banks could obtain increased reserves from an interregional surplus of the trade balance. The Currency School regarded an increase in the needs of trade demand to hold notes accompanying increases in output and prices as unsound because it would ultimately produce an external drain. The Free Banking School countered that such an objection by the Currency School was paradoxical since the virtue of a metallic currency according to the latter was that it accommodated the commercial wants of the country, and therefore for a mixed currency to respond to the needs of trade could not be a vice. The modern objection to the needs of trade doctrine as procyclical is an echo of the Currency School view.

The third Banking School principle was the law of the reflux according to which overissue was possible only for limited periods because notes would immediately return to the issuer for repayment of loans. This was a modification of the real bills doctrine that Tooke and Fullarton advanced, since adherence to the doctrine supposedly made overissue impossible. They made no distinction between the speed of the reflux for the Bank of England and for competitive banks of issue – a distinction at the heart of the Free Banking position. For the latter, reflux of excess notes was speedy only if the notes were deposited in rival banks. These would then return the notes to the issuing banks and accordingly bring an end to relative overissue by individual banks. The Bank of England, on the contrary, could overissue for long periods because it had no rivals. Fullarton, however, made the unwarranted assumption that notes would be returned to the Bank to repay previous loans at a faster rate than the Bank was discounting new loans, hence correcting the overissue. Moreover, he believed that if the Bank overissued by open market purchases, the decline in interest rates would quickly activate capital outflows, reducing the Bank's bullion and forcing it to retreat. Tooke was sounder in arguing for the law of reflux on the ground that excess issues would not be held if they did not match the preferences of holders for notes rather than deposits.

The Banking School had no legislative programme for reform of the monetary system. Good bank management, in the view of the school, could not be legislated.

**Free Banking School principle**

As the name suggests, the principle the Free Banking School advocated was free trade in the issue of currency convertible into specie. Members of the school favoured a system like the Scottish banking system, where banks competed in all banking services, including the issue of notes, and no central bank
held a monopoly of note issue. They argued that in such a system banks did not issue without limit but
indeed provided a stable quantity of money. Although the costs of printing and issuing were minimal, to
keep notes in circulation required restraint in their issue. The profit-maximizing course for competitive
banks was to maintain public confidence in their issues by maintaining convertibility into specie on
demand, which required limiting their quantity.

Loyd's response to the argument for free trade in currency was that unlike ordinary trades, what was
sought was not the greatest quantity at the cheapest price but a regulated quantity of currency. The Free
Banking School denied that free banking would debase the currency, and contended that the separation
of banking from note issue, the Banking School proposal, was impractical. Scrope (1833a, pp. 32–3)
asked why the Currency School objected to unregulated issue of notes but not to that of deposits,
questioning Loyd's assumption that an issuing bank's function was to produce money, when in fact its
function was to substitute its bank notes for less well-known private bills of exchange that were the
bank's assets. Scrope and other Free Banking adherents (Parnell, 1827, p. 143) neglected the distinction
between a banknote immediately convertible into gold and a commercial bill whose present value varied
with time to maturity and the discount rate. Contrary to Loyd, they reasoned that free trade and
competition were applicable to currency creation because the business of banks was to produce the
scarcely good of reputation.

Loyd's second disagreement with the argument for free trade in banking was that miscalculations by the
issuers were borne not by them but by the public. Moreover, individuals had no choice but to accept
notes they received in ordinary transactions, and trade in general suffered as a result of overissue. The
Free Banking School answer to this externality argument turned on the ability of holders to refuse
notes of issuers without reputation. Protection against loss could also be provided if joint stock banks
were allowed to operate in place of country banks limited to six or fewer partners. In addition, if banks
were required to deposit security of government bonds or other assets, noteholders would be further
protected (Scrope, 1832, p. 455; 1833b, p. 424; Parnell, 1827, pp. 140–4). Free Banking School
members who argued in this vein failed to recognize that they were thereby acknowledging a role for
government intervention in currency matters.

In the 1820s the Free Banking School championed joint stock banking both in the country bank industry
and in direct competition in note issue with the Bank of England in London. Although the six-partner
rule for banks of issue at least 65 miles from London was repealed in 1826 after a spate of bank failures,
the Bank retained its monopoly of note circulation in the London area. In addition, the Bank was
permitted to establish branches anywhere in England. The Parliamentary inquiry in 1832 on renewal of
the Bank's character was directed to the question of prolonging the monopoly. The Act of 1833 eased
entry for joint stock banks within the 65-mile limit but denied them the right of issue and made the
Bank's notes legal tender for redemption of country bank notes, in effect securing the Bank's monopoly.
The doom of the Free Banking cause was finally pronounced by the Bank Charter Act of 1844. It
restricted note issues of existing private and joint stock banks in England and Wales to their average
circulation during a period in 1843. Note issue by banks established after the Act was prohibited.

Was overissue a problem?

Participants in the debates understood overissue to mean a stock of notes, whether introduced by a single
issuer or banks in aggregate, in excess of the quantity holders voluntarily chose to keep as assets, given
the level of prices determined by the world gold standard. Was overissue of a convertible currency possible? According to the Free Banking School, interbank note clearing by competitive banks operated to eliminate excess issued by a single bank. The check to excess issues by the banking system as a whole was an external drain through the price-specie flow mechanism. In this respect the school acknowledged that the result of overissue by a competitive banking system as a whole was the same as for a monopoly issuer. However, they held that overissue was a phenomenon that the monopoly of the Bank of England encouraged but a competitive system would discourage.

The Currency School, on the other hand, regarded both the Bank of England and the Scottish and country banks as equally prone to overissue and did not grant that a check to overissue by a single bank or banks in the aggregate was possible through the interbank note clearing mechanism. For them, regulation of a monopoly issuer promised a stable money supply that was not attainable with a plural banking system.

The Free Banking School's explanation of the Bank of England's ability to overissue rested on the absence of rivals for the Bank's London circulation, so no interbank note clearing took place; the absence of competition in London from interest-bearing demand deposits; and the fact that London private banks held the Bank's notes as reserves. Hence the demand for its notes was elastic. The Free Banking and Currency Schools agreed that there was a substantial delay before an external drain checked overissue, so the Bank's actions inescapably inflicted damage on the economy. Scrope (1830, pp. 57–60), who attributed the Bank's willingness to overexpand its note issues to its monopoly position, advocated abrogating that legal status.

The Banking School dismissed the question of overissue as irrelevant, for noteholders could easily exchange unwanted notes by depositing them. What they failed to examine was the possibility that a broader monetary aggregate could be in excess supply resulting in an external drain.

**How should money be defined?**

Currency School members favoured defining money as the sum of metallic money, government paper money, and bank notes (Norman, 1833, pp. 23, 50; McCulloch, 1850, pp. 146–7). The Free Banking School, like the Currency School, focused on bank notes as the common medium of exchange, ignoring demand deposits that were not usually subject to transfer by check outside London. The Banking School definition of money is sometimes represented as broader than that of the other schools, but in fact was narrower – money was restricted to metallic and government paper money. Bank notes and deposits were excluded, since they were regarded as means of raising the velocity of bank vault cash but not as adding to the quantity of money (Tooke [1848] 1928, pp. 171–83; Fullarton [1844] 1969, pp. 29–36; Mill [1848] 1909, p. 523). In the short run, the school held that all forms of credit might influence prices, but only money as defined could do so in the long run, because the domestic price level could deviate only temporarily from the world level of prices determined by the gold standard.

**Why do trade cycles occur?**

The positions of the three schools on the impulses initiating trade cycles were not dogma for their members. In general the Currency and Banking Schools held that nonmonetary causes produced trade
cycles, whereas the Free Banking School pointed to monetary causes, but individual members did not invariably hew to these analytical lines. McCulloch (1837, p. 63), Loyd (1857, p. 317), and Longfield (1840, pp. 222–3) essentially attributed cycles to waves of optimism and pessimism to which the banks then responded by expanding and contracting their issues. Banks accordingly never initiated the sequence of expansion and contraction. Hence the Currency School principle of regulating the currency to stabilize prices and business did not imply that cycles would thereby be eliminated. Cycles would, however, no longer be amplified by monetary expansion and contraction, if country banks were denied the right to issue and the Bank of England's circulation were governed by the ‘currency principle’.

Torrens (1840, pp. 31, 42–3), unlike other Currency School members, attributed trade cycles to actions of the Bank of England. That was also the position of the Free Banking School, although in an early work Parnell (1827, pp. 48–51) of that school held that cycles were caused by nonmonetary factors. For the Banking School, however, nonmonetary factors accounted for both the origin and spread of trade cycles. Tooke (1840, pp. 245, 277), for example, believed that overoptimism would prompt an expansion of trade credit for which the banks were in no way responsible. Collapse of optimism would then lead to shrinkage of trade credit. For Fullarton ([1844] 1969, p. 101) nonmonetary causes produced price fluctuations to which changes in note circulation were a passive response. Proponents of the nonmonetary theory of the onset of trade cycles provided no explanation of the waves of optimism and pessimism themselves. For the Free Banking School the waves were precipitated by the Bank of England's expansion and ultimate contraction of its liabilities. Initially, the Bank's actions depressed interest rates and ultimately forced them up, as loanable funds increased in supply and then decreased. The Bank's monopoly position enabled it to create such monetary disturbances, whereas competitive country banks had no such power.

Should there be a central bank?

The Currency and Banking Schools were in agreement that a central bank with the sole right of issue was essential for the health of the economy. McCulloch (1831, p. 49) regarded a system of competitive note issuing institutions as one of inherent instability. Tooke (1840, pp. 202–7) favoured a monopoly issuer as promoting less risk of overissue and greater safety because it would hold sufficient reserves. The two schools differed on the need for a rule to regulate note issues, the Currency School pledged to a rulebound authority, the Banking School to an unbound authority. The Free Banking School disapproved of both a rule and a central bank authority, instead favouring a competitive note-issuing system that it held to be self-regulating. For that school proof that centralized power was inferior to a competitive system was revealed by cyclical fluctuations that had been caused by errors of the Bank of England.

A continuing debate

The Bank Charter Act of 1844 ended the right of note issue for new banks in England and Wales. Scottish banks, however, were treated differently from Irish banks by the Act of 1845 and from English provincial banks by the Act of 1844. Like the latter, authorized circulation for the Scottish banks was determined by the average of a base period, but they could exceed the authorized circulation provided they held 100 per cent specie reserves against the excess – a provision also imposed on the Bank of
England.
The Free Banking School thus lost its case for an end of the note issue monopoly of the Bank of England. The death of Parnell in 1842, a leading Parliamentary spokesman, had hurt the cause. Others of the school were mainly country and joint stock bankers. The Acts conferred benefits on them by restricting entry into the note-issuing industry and by freezing market shares (White, 1984, pp. 78–9). Their voices were not raised in opposition. Only Wilson was critical of the privileges the Bank of England was accorded ([1847] 1859, pp. 34–66).
The Banking School objected not only to the Act but claimed vindication for its point of view by the necessity to suspend it in 1847, 1857 and 1866. The Currency School responded that the suspensions were of no great significance (Loyd, 1848, pp. 393–4). The recommendations of the Currency School prevailed to set a maximum for country bank note issues and the eventual transfer of their circulation to the Bank of England.
The monetary debates that were initiated in the 1820s were not conclusive. No point of view carried the day. Long after the original participants had passed from the scene, the doctrines of the schools found supporters. Even the Free Banking School position in opposition to monopoly issue of hand-to-hand currency that seemed to be buried has recently been revived by new adherents (White, 1984, pp. 137–50). The debate on all the questions in dispute in the 19th century continues to be live.

Article

Bankruptcy is the legal process whereby financially distressed firms, individuals, and occasionally governments resolve their debts. The bankruptcy process for firms plays a central role in economics, because competition tends to drive inefficient firms out of business, thereby raising the average efficiency level of those remaining. Consumers benefit because the remaining firms produce goods and services at lower costs and sell them at lower prices. The legal mechanism through which most firms exit the market is bankruptcy. Bankruptcy also has an important economic function for individual debtors, since it provides them with partial consumption insurance and supplements the government-provided safety net. Local governments occasionally also use bankruptcy to resolve their debts, and there has been discussion of establishing a bankruptcy procedure for financially distressed countries (see White, 2002).
Bankruptcy law

For both corporate and individual debtors, bankruptcy law provides a collective framework for simultaneously resolving all debts when debtors’ assets are less valuable than their liabilities. This includes both rules for determining which of the debtor’s assets must be used to repay debt and rules for dividing the assets among creditors. Thus bankruptcy is concerned with both the size of the pie – the total amount paid to creditors – and how the pie is divided.

For financially distressed corporations, both the size and the division of the pie depend on whether the corporation liquidates or reorganizes in bankruptcy, and bankruptcy law also includes rules for deciding whether reorganization or liquidation will occur. When corporations liquidate under Chapter 7 of US bankruptcy law, the pie includes all of the firm’s assets but none of its owners’ other assets. This reflects the doctrine of limited liability, which exempts owners of equity in corporations from personal liability for the corporation’s debts beyond loss of the value of their shares. The corporation’s assets are liquidated and the proceeds are used to repay creditors according to the absolute priority rule (APR). The APR carries into bankruptcy the non-bankruptcy rule that debt must be repaid in full before equity receives anything. The APR also determines how the pie is divided among creditors. Classes of creditors are ranked and each class receives full payment of its claims until funds are exhausted.

When corporations reorganize under Chapter 11 of US bankruptcy law, the reorganized corporation retains most or all of its assets and continues to operate – generally under the control of its pre-bankruptcy managers. Bankruptcy law again provides a procedure for determining both the size and the division of the pie in reorganization, but the procedure involves a negotiation process rather than a formula.

Funds to repay creditors come from the firm’s future earnings rather than from liquidating its assets. The rule for the division of the pie in reorganization is also different. Instead of creditors receiving either full payment or nothing, most classes of creditors receive partial payment regardless of their rank, and pre-bankruptcy equity receives some of the reorganized firm’s new shares. This priority rule is referred to as ‘deviations from the APR’ since equity receives a positive payoff even though creditors are repaid less than 100 per cent. Creditors and equity negotiate a reorganization plan that specifies what each group will receive, and the plan must be adopted by a super-majority vote of each class of creditors and equity.

For individuals in financial distress, bankruptcy law also includes both rules for determining which of the individual’s assets must be used to repay debt (the size of the pie) and rules for dividing the assets among creditors (the division of the pie). In determining the size of the pie, personal bankruptcy law plays a role similar to that of limited liability for corporate equity-holders, since it limits the amount of assets that individual debtors must use to repay. It does this by specifying exemptions, which are maximum amounts of both financial wealth and post-bankruptcy earnings that individual debtors are allowed to keep. Only amounts in excess of the exemption levels must be used to repay. An important feature of US bankruptcy law is the 100 per cent exemption for post-bankruptcy earnings, known as the ‘fresh start’, which greatly limits individual debtors’ obligation to repay. (Note that in 2005 Congress adopted limits on the availability of the fresh start.) In personal bankruptcy, the rule for dividing repayment among creditors is also the APR.

An important difference between personal and corporate bankruptcy law is that, while corporations may either liquidate or reorganize in bankruptcy, individuals can only reorganize (even though the most
commonly used personal bankruptcy procedure in the United States is called liquidation). This is because part of individual debtors’ wealth is their human capital, and the only way to liquidate human capital is to sell debtors into slavery – as the Romans did. Since slavery is no longer used as a penalty for bankruptcy, all personal bankruptcy procedures are forms of reorganization in which individual debtors keep their human capital and the right to decide whether to use it.

**Economic objectives**

The economic objectives are similar in corporate and personal bankruptcy. One important objective of bankruptcy is to require sufficient repayment that lenders will be willing to lend – not necessarily to the bankrupt debtor but to other borrowers. Reduced access to credit makes debtors worse off because businesses need to borrow in order to grow and individuals benefit from borrowing to smooth consumption. On the other hand, repaying more to creditors harms debtors by making it more difficult for financially distressed firms to survive and by reducing financially distressed individuals’ incentive to work. Both the optimal size and the division of the pie in bankruptcy are affected by this trade-off. A second important objective of both types of bankruptcy is to prevent creditors from harming debtors by racing to be first to collect. When creditors think that a debtor is in financial distress, they have an incentive to collect their debts quickly, since the debtor will be unable to repay all creditors in full. But aggressive collection efforts by creditors may force debtor firms to shut down even when the best use of their assets is to continue operating, and may cause individual debtors to lose their jobs (if creditors repossess their cars or garnish their wages). A third objective of personal bankruptcy law that has no counterpart in corporate bankruptcy is to provide individual debtors with partial consumption insurance. If consumption falls substantially, long-term harm may occur, including debtors’ children leaving school prematurely in order to work or debtors’ medical conditions going untreated and becoming disabilities. Discharging debt in bankruptcy when debtors’ consumption would otherwise fall reduces these costs. An additional objective that applies only to corporate bankruptcy is to reduce filtering failure. Financially distressed firms may be economically either efficient or inefficient, depending on whether the best use of their assets is the current use or some alternative use. Filtering failure in bankruptcy occurs when efficient but financially distressed firms shut down and when inefficient financially distressed firms reorganize and continue operating. The cost of filtering failure is either that the firm’s assets remain tied up in an inefficient use or that they move to an alternative use when the current one is the most efficient. Many researchers have argued that reorganization in Chapter 11 tends to save economically inefficient firms that should shut down.

Research on corporate and personal bankruptcy is discussed separately below. Small-business bankruptcy is included with personal bankruptcy, because small businesses are often unincorporated and therefore their debts are legal liabilities of the business owner. When these businesses fail, their owners can file for bankruptcy and both their business and personal debts will be discharged. (Note that most of the research on bankruptcy is focused on US law and US data. For a longer survey of research on corporate and personal bankruptcy that includes many references, see White, 2006.)

**Corporate bankruptcy**

**Theory**
A central theoretical question in corporate bankruptcy is how priority rules affect the efficiency of decisions made by managers (who are assumed to represent the interests of equity), particularly whether the firm invests in safe or risky projects and whether and when it files for bankruptcy. Inefficient investment decisions lower the firm's return, and inefficient bankruptcy decisions result in filtering failure. Both reduce creditors' returns and cause them to raise interest rates or to reduce the amount they are willing to lending.

Bebchuk (2002) compares the efficiency of corporate investment decisions when the priority rule in bankruptcy is the APR with those when deviations from the APR occur, where use of the APR represents liquidation in bankruptcy and deviations from the APR represent reorganization in bankruptcy. A well-known result in finance is that equity prefers risky to safe investment projects, because equity gains disproportionately when risky projects succeed and bears only limited losses when risky projects fail. If the priority rule in bankruptcy is changed from the APR to deviations from the APR, then equity's preference for risky projects becomes even stronger. This is because equity now receives a positive return rather than nothing when risky projects fail, and the same high return when risky projects succeed. This change makes risky projects even more attractive relative to safe ones, since the latter rarely fail and so their return is unaffected by the change in the priority rule. Thus, when the bankruptcy regime is reorganization rather than liquidation, investment decisions become less efficient because equity over-invests in risky projects.

But Bebchuk argues that the results are reversed when firms are already in financial distress. Here, deviations from the APR reduce rather than increase equity's bias towards choosing risky investment projects. This is because, when the project is likely to fail and the firm to file for bankruptcy, equity's main return comes from the share that it receives of the firm's value in bankruptcy – the deviations from the APR. And since safe projects have higher downside returns, they generate more for equity. Thus the overall result is that neither priority rule in bankruptcy always leads to efficient investment incentives. Similar models have shown that none of the standard priority rules always leads to efficient bankruptcy decisions.

Bankruptcy law also affects other economically important decisions, including whether managers default strategically, whether they reveal important information about the firm's condition to creditors, and how much effort they expend. Strategic default occurs when firms default on their debt even though they are financially solvent. In the financial contracting literature, there is a trade-off between strategic default and filtering failure (see Bolton and Scharfstein, 1996). Suppose a firm borrows $D$ in period 0 to finance an investment project. The firm will either succeed or fail. If it succeeds, it earns $R_1 > D$ in period 1 and an additional $R_2 > L$ in period 2. If it fails, then its period 1 earnings are zero, but it still earns $R_2$ in period 2. Regardless of whether the firm succeeds or fails, the liquidation value of its assets is $L$ in period 1 and 0 in period 2. The firm's earnings are assumed to be observable but unverifiable. The loan contract calls for the firm to repay $D$ in period 1 and it gives lenders the right to liquidate the firm in period 1 and collect $L$ if default occurs. The contract does not call for any repayment in period 2, since promises to repay are not credible when the firm's liquidation value is zero. Liquidating the firm in period 1 is inefficient, since the firm would earn more than $L$ if it continued to operate. Under these assumptions, the firm's owners always repay in period 1 when the firm is successful, since they benefit from retaining control and collecting $R_2$ in the following period. But if the firm fails, then its owners
default and creditors liquidate it. Thus there is no strategic default, but filtering failure occurs since there is inefficient liquidation. If lenders instead allowed owners to remain in control following default, then there would be no filtering failure but a high level of strategic default. Because of incomplete information, strategic default and filtering failure cannot both be eliminated.

Bankruptcy law also affects managers’ choice of how much effort to expend and whether to delay filing for bankruptcy. Povel (1999) analyses a model in which managers make an effort-level decision and also receive an early signal on whether the firm will succeed. When the signal is bad, managers decide whether to file for bankruptcy or continue operating outside of bankruptcy. Filing for bankruptcy is assumed to be economically efficient in this situation, since it allows creditors to rescue the firm. Neither the effort-level decision nor the signal is observed by creditors. Povel considers two different bankruptcy laws: reorganization and liquidation. In the model, if the bankruptcy procedure is reorganization, the result is that managers choose low effort and file for bankruptcy when the signal is bad. Filing for bankruptcy is economically efficient, but low effort by managers is inefficient. Conversely, if the bankruptcy procedure is liquidation, the result is that managers choose high effort and avoid bankruptcy when the signal is bad. This trade-off suggests that the better bankruptcy procedure could be either reorganization or liquidation, depending on parameter values. See Berkovitch, Israel and Zender (1998) for a similar model that explores the efficiency of auctions as an alternative bankruptcy procedure.

There is a large literature on reforms of bankruptcy law. Most studies start from the premise that too many firms reorganize in bankruptcy under current law, since reorganization under Chapter 11 has both high transactions costs and high costs of filtering failure. One proposal is to auction all bankrupt firms and use the proceeds to repay creditors according to the APR. This procedure has the dual advantages that it would be quick and that the new owners would make efficient decisions on whether to save or liquidate each firm (see Baird, 1986). Another proposal is to use options to divide the value of firms in reorganization (Bebchuk, 1988). Both auctions and options would establish a market value of the firm’s assets, so that creditors could be repaid according to the APR and deviations from the APR could be eliminated. Another proposal, called bankruptcy contracting, would allow debtors and creditors to adopt their own bankruptcy procedure when they write their loan contracts, rather than requiring them to use the state-supplied mandatory bankruptcy procedure. Schwartz (1997) showed that bankruptcy contracting could improve efficiency in particular circumstances. But whether bankruptcy contracting or any of the other reform proposals would work well in a general model that takes account of other complications – such as the existence of multiple creditor groups and strategic default – has not been established.

**Empirical research**

Now we turn to empirical research on corporate bankruptcy. It has focused on measuring the costs of bankruptcy and the size and frequency of deviations from the APR. Studies of the costs of bankruptcy include only the legal and administrative costs of the bankruptcy process; that is, the costs of bankruptcy-induced disruptions are excluded. Most studies have found that bankruptcy costs as a fraction of the value of firms’ assets are higher in liquidation than in reorganization, but this may reflect the fact that bankruptcy costs are subject to economies of scale and larger firms tend to reorganize rather than
liquidate in bankruptcy. Unsecured creditors generally receive nothing in liquidation, but are repaid one-third to one-half of their claims in reorganization. This higher return in reorganization could be due to selection bias, if firms that reorganize are in relatively better financial condition. Other studies provide evidence that Chapter 11 filings are associated with an increase in managers’ and directors’ turnover, suggesting that the process is very disruptive. In addition, many firms that reorganize in Chapter 11 end up requiring additional financial restructuring within a short period. This is consistent with the theoretical prediction that too many financially distressed firms reorganize. Deviations from the APR have been found to occur in around three-quarters of all reorganization plans of large corporations in bankruptcy (see Bris, Welch and Zhu, 2006, for a recent study and references).

Personal bankruptcy

When an individual or a married couple files for bankruptcy under Chapter 7 (the most commonly used procedure), most unsecured debts are discharged. Debtors are obliged to use their non-exempt assets to repay debt, but their future earnings are entirely exempt under the ‘fresh start’. Exemption levels, unlike other features of US bankruptcy law, differ across states. The most important exemption is the ‘homestead’ exemption for equity in owner-occupied homes, which varies widely from zero to unlimited. Because debtors can convert non-exempt assets such as bank accounts into home equity before filing for bankruptcy, high homestead exemptions protect all types of wealth for debtors who are homeowners.

There is also a second personal bankruptcy procedure, Chapter 13, under which debtors’ assets are completely exempt, but they must use some of their future earnings to repay their debt. Until recently, debtors had the right to choose between the two procedures and, since most debtors have few non-exempt assets, Chapter 7 was almost always the more favourable. It was also the more heavily used – about 70 per cent of all personal bankruptcy filings were under Chapter 7. Those debtors who filed under Chapter 13 often repaid only token amounts, since the value of their non-exempt assets was zero. However, in late 2005 bankruptcy reforms went into effect that will force some debtors having higher incomes to file for bankruptcy under Chapter 13 and to repay more.

Theory

From an economic standpoint, the main reason for having a personal bankruptcy procedure is to provide individual debtors with consumption insurance by discharging debt when the obligation to repay would cause a substantial reduction in their consumption levels. This is because sharp falls in consumption can have permanent negative effects – debtors may become homeless, their illnesses may become disabilities for lack of medical care, and their children may leave school prematurely and have lower future earnings. Consumption insurance is mainly provided by the public sector in the form of the social safety net – welfare payments, food stamps and health insurance for the poor. But bankruptcy reduces the cost to the public sector of providing the safety net, since discharge of debt in bankruptcy frees up funds for consumption that debtors might otherwise use to repay debt.

The higher the exemption levels for wealth and earnings in bankruptcy, the more the consumption insurance that bankruptcy provides. Theoretical research on personal bankruptcy has focused on deriving optimal exemption levels. Higher levels of both exemptions benefit debtors by providing them...
with extra consumption insurance, but harm those who repay their debts by reducing the availability of credit and increasing interest rates. However, the two exemptions have differing effects on debtors’ incentives to work after bankruptcy. A higher wealth exemption is likely to have little effect on work incentives, while a higher earnings exemption increases debtors’ incentive to work as long as the positive substitution effect outweighs the negative income effect. The model suggests that the optimal earnings exemption is 100 per cent – that is, the ‘fresh start’ – while the optimal wealth exemption is an intermediate level. This is because a higher earnings exemption both encourages debtors to work more after bankruptcy and provides better consumption insurance than a higher wealth exemption. See White (2005).

An important feature of personal bankruptcy law is that it encourages opportunistic behaviour by debtors. Although bankruptcy debt relief is intended for debtors whose consumption has fallen sharply due to factors such as job loss or illness, in fact debtors’ incentive to file is hardly affected by these adverse events. Debtors’ financial benefit from bankruptcy equals the amount of debt discharged minus the sum of non-exempt assets that must be used to repay plus the costs of bankruptcy. White (1998b) calculated that at least one-sixth of US households would benefit financially from filing for bankruptcy, and this figure rose to more than one-half if households were assumed to pursue various strategies, such as borrowing more on an unsecured basis, converting non-exempt assets into exempt home equity, and moving to states with high homestead exemptions. White (1998b) also found that these calculations underestimate the proportion of households that would benefit from bankruptcy, since some households that would not benefit from filing immediately could benefit from filing in the future. She calculated the value of the option to file for bankruptcy and found that it is particularly valuable for high-wealth households and those in high-exemption states. These features of bankruptcy law are probably responsible for high filing levels (more than 1.6 million US households filed for bankruptcy in 2003) and for the fact that the US Congress recently changed Chapter 7 to make bankruptcy less attractive to many debtors.

**Empirical research**

Most of the empirical research on personal bankruptcy makes use of the variation in exemption levels that causes bankruptcy law to differ across US states. Gropp, Scholz and White (1997) found that, if households live in states with high rather than low exemptions, they are more likely to be turned down for credit, they borrow less, and they pay higher interest rates. They also found that in high-exemption states credit is redistributed from low-asset to high-asset households. Households in high-exemption states demand more credit because borrowing is less risky, but lenders respond by offering larger loans to high-asset households while rationing credit more tightly to low-asset households. Fay, Hurst and White (2002) found that households are more likely to file for bankruptcy when their financial benefit from filing is higher. Since households’ financial benefit from filing is positively related to the size of the exemption, this means that households are more likely to file if they live in states with higher bankruptcy exemptions. Fay, Hurst and White did not find that recent job loss or health problems were significantly related to whether households filed for bankruptcy. But they found that households were more likely to file when they live in regions that have higher average bankruptcy filing rates – which suggests the existence of network effects.
Personal bankruptcy exemption levels also affect small businesses, since business debts often are personal obligations of the business owner and these debts are discharged in bankruptcy. Fan and White (2003) found that individuals are more likely to own or start businesses in states with higher exemption levels, presumably because the additional consumption insurance in these states makes going into business more attractive by lowering the cost of failure. But Berkowitz and White (2004) found that small businesses are more likely to be turned down for credit and to pay higher interest rates if they are located in states with higher exemption levels. Overall, higher exemption levels have mixed effects on small business.

Finally, since higher exemption levels provide households with additional consumption insurance, the variance of household consumption is predicted to be smaller in states that have higher exemption levels. Grant (2006) found macro-level support for this hypothesis using data on the variance of consumption across state-years.

Abstract

Bankruptcy is the formal procedure to resolve the disputes among creditors, shareholders, and managers of a company in financial distress. Countries have designed bankruptcy procedures that differ in the control that is given to the existing management relative to creditors. These differences determine the incentives that are given to the parties before, during, and after the bankruptcy proceedings. They also determine how expensive the bankruptcy process is. Ultimately, bankruptcy costs are borne by firms’ shareholders.

Article

Bankruptcy is the legal procedure whereby the assets of a debtor are distributed among its creditors. The debtor can be either an individual or a firm. In corporations, bankruptcy happens when either the firm or its creditors delegate a third party – be it a judge or other public official – to determine the amount of the creditors’ claims, as well as the way to distribute the firm's assets among them. In essence, bankruptcy results from financial distress, which happens when the market value of the assets is insufficient to satisfy the debt claims, or when the firm does not generate enough cash flow to meet the coupon and interest payments. An alternative to bankruptcy is an informal reorganization, or workout, whereby creditors relax debt covenants, possibly exchanging their claims for a package of new claims. Bankruptcy is an old European institution that derives its name from the Italian ‘banca rotta’ (broken bench). It refers to the boards from which traders in medieval towns traded coins, and which they broke whenever they defaulted on their payments. Nowadays, countries have implemented different procedures to deal with the distribution of the assets of a firm that cannot meet its debt obligations. In the United States, firms and creditors can opt into two forms of restructuring. Under a Chapter 7
liquidation, assets are sold piecemeal and the proceeds distributed according to the absolute priority rule (APR), whereby debt and equity are paid according to a predetermined order: secured debt first, then unsecured claims, and finally common stock. The distinction between senior and junior claims refers to the priority of secured debt (senior) over unsecured debt (junior). The firm ceases to exist after a Chapter 7. Under a Chapter 11 reorganization, shareholders and creditors agree on a reorganization plan, which allows the company to continue. When the company enters a Chapter 11, the firm becomes a ‘debtor-in-possession’, a term that recognizes that the management retains control of the company's operations, under court supervision. In a Chapter 11, APR may be violated if secured creditors give up part of their claims in favour of unsecured debtors, or if shareholders receive some interest in the restructured firm at the expense of debtholders (Herbert, 1998).

Under the absolute priority rule, unsecured claims are classified into priority claims and general unsecured claims. Priority claims are further classified into three groups: administrative claims, wages and employee benefits, and taxes. This means that, under APR – which is always upheld in Chapter 7 cases – wages cannot be paid unless administrative expenses (compensation of lawyers and other professionals) have been satisfied in full. Moreover, tax claims include only those taxes that the firm owes at the time it files for bankruptcy.

The practice in the United States is to reimburse administrative expenses incurred by the committee of unsecured creditors. A Chapter 11 creditors’ committee is composed of creditors ‘that hold the seven largest claims against the debtor of the kinds represented on such committee’ (Bankruptcy Code §1102(b)(1)). The bankruptcy court is authorized to reimburse a substantial portion of the expert expenses that juniors incur. However, the United States code does not authorize the bankruptcy court to compensate the expenses of creditors whom it defines as ‘senior.’ This cost allocation fails to encourage the seniors to spend on activities that increase the value of the firm, but encourages the juniors to spend on activities that maximize only the value of their own claims.

In the United States the debtor has an exclusivity period of 120 days to file a plan of reorganization. This period can be, and usually is, extended upon the debtor's requests. In the plan, each class of creditors is classified as impaired or unimpaired. An unimpaired class of creditors is paid in full, and does not vote on the reorganization plan. The plan requires the approval of each impaired class of creditors and equity security holders. Approval requires dual majority: more than one-half of the votes, and more than two-thirds of the amount of the claims.

In the United Kingdom and other countries with British legal traditions, such as Canada, Australia and New Zealand, bankrupt companies are restructured via an administrative receivership. White (1996) and Franks and Davydenko (2006) provide a comparison between the bankruptcy codes in the United States and some European countries. Under an administrative receivership, the secured creditors appoint an expert (the administrative receiver) whose objective is to obtain sufficient funds to repay the secured creditors. To do that, the receiver can either liquidate some assets or sell the company as a going concern. The receiver does not have any obligation with respect to other creditors or shareholders, as long as absolute priority is respected. Unlike with a United States Chapter 11, in a receivership control is transferred from the management to the secured creditors.

Under the old French system neither the firm nor the creditors retained control. The court appointed an administrator who managed the day-to-day operations of the firm, and whose objectives were, first, to preserve the estate and employment, and then to satisfy creditors. Most systems in Continental Europe have followed this tradition. In the new Loi de Sauvegarde des Enterprises enacted in 2005, France has
moved towards the Chapter 11 system in the United States. In Germany, the system introduced in 1999 establishes an automatic stay of three months, which means that creditors cannot dispose of the firm's assets during that period. Moreover, and similar to a Chapter 7 in the United States, the court appoints an administrator who monitors the process and determines a plan of reorganization.

Auctions are a very efficient alternative to court-administered procedures. In Sweden, the court appoints an independent trustee who is in charge of selling the firm's assets to the highest bidder. The winning bidder can pay only in cash, as described in Thorburn (2000), and the trustee distributes the proceeds respecting the APR. Stromberg (2000) shows that in one out of three cases in Sweden the assets are sold back to the incumbent managers (because they have the highest valuation of the assets), and the remaining cases are liquidated.

**Controversy over Chapter 11**

In recent years, there has been a convergence in bankruptcy laws towards a Chapter 11-type reorganization. Countries in western and eastern Europe, Asia and Latin America have enacted regulations that allow managers to retain control of defaulted firms. Regulators have moved from a system that favours liquidations to a legal procedure that tends to maximize the probability of firm survival. However, the efficiency of Chapter 11 has been questioned by scholars like Bebchuk (1988), Adler (1993), Schwartz (1998), Baird and Rasmussen (2002), and Baird and Morrison (2005). They promote a *contractual approach* to bankruptcy, or a formal scheme of bargained bankruptcy. Under this view, the parties should be free to bargain in advance over a set of rules that will govern their rights in the event of bankruptcy, with Chapter 11 being only a default system. Bebchuk (1988), for instance, proposes that firms can issue derivative securities, contingent on the firm being in default. The contractual view attacks the Chapter 11 system on several fronts, first of all on the grounds that it leads to inefficient outcomes (Baird and Morrison, 2005; Franks and Loranth, 2006). In particular, Franks and Loranth show that Chapter 11 in Hungary is biased in favour of inefficient going concerns. The argument is that most bankrupt firms should be liquidated rather than reorganized. Chapter 11 is also attacked because it is considered a more lengthy process than other systems (Stromberg, 2000; Thorburn, 2000). Additionally, it is extremely expensive (Bris, Welch and Zhu, 2006).

The opponents of such a private bankruptcy system (Warren and Westbrook, 2005) make two important arguments to defend Chapter 11. In principle, a private system would have only redistributive effects, with some creditors (secured and large creditors) shifting risks to others. Also, Chapter 11 is a mechanism by which benevolent large creditors give up part of their claims in favour of small, empowered creditors. Therefore it has a positive redistributive effect. Finally, a private system is inefficient because of the duplication of transaction costs.

Most of the theoretical and empirical research on bankruptcy addresses the conflicts that arise among creditors, shareholders, firm managers and bankruptcy specialists. These conflicts arise during the bankruptcy proceedings, but also when the company is in financial distress and before it files for bankruptcy. The design of the bankruptcy system can affect the interaction among all these agents, the efficiency of the bankruptcy process and, therefore, the costs of bankruptcy.
Incentives before filing for bankruptcy

Financial distress may lead to bankruptcy if either the firm management or the creditors opt into a legal procedure to resolve their disputes. But, if the distressed firm is economically viable, managers have an incentive to delay filing for bankruptcy and to maintain operations, especially if the legal procedure gives control to a third party. Self-interested managers will then preserve their jobs at the expense of shareholders and creditors. Jensen and Meckling (1976) show that in distressed firms there is a debt overhang problem. Managers have an incentive to bypass positive net present value (NPV) projects (a problem known as underinvestment) because they benefit only current creditors (Myers, 1977). Instead, when choosing between less and more risky projects managers prefer to invest in more risky projects because managers act on behalf of shareholders, and shareholders, because of limited liability, are interested only in the upside of the investments (excess risk taking or overinvestment). These incentives in turn reduce the value of the debtor's claims and ultimately the value of the firm because creditors take them into account when pricing their securities.

Recently, Adler, Capkun and Weiss (2005) have shown that a change in regulation in the United States around 2000, which gave more control to creditors during the filing period, induced managers to delay the bankruptcy filing. Indeed, they show that after 2000 firms that file for Chapter 11 in the United States display a worse financial and operating condition. This can explain why, in countries with secured creditor control of the bankruptcy process, the number of bankruptcy filings is much lower, and firm managers prefer liquidation (Claessens and Kappler, 2005).

Conversely, and depending on the debt structure, managers may have an incentive to default strategically even if the firm is still economically viable. Bolton and Scharfstein (1996) argue that managers will always prefer to default strategically so as to divert cash to themselves. In order to avoid that distortion, creditors should have the right to liquidate the firm in case of default. However, this induces inefficient liquidations because the value of the firm as a going concern may exceed its liquidation value. Bolton and Scharfstein (1996) show that borrowing from multiple creditors solves the problem by increasing the liquidation value of the firm.

Incentives during bankruptcy proceedings

The efficiency of the bankruptcy process and a firm's capital structure are closely related because, for a firm with multiple creditors, bankruptcy results in coordination problems among creditors, as well as conflicts between secured and unsecured, or between senior and junior, claimants. Regarding coordination problems, and in contrast to Bolton and Scharfstein (1996), Bris and Welch (2005) argue that, when competing for the firm's assets, multiple creditors (similar to public bonds) waste the firm's resources in fighting with each other; hence, it is more efficient to issue highly concentrated debt (bank debt). Indeed, Welch (1997) shows that bank debt should be senior because a single creditor fights better with shareholders, thereby increasing the ex ante value of the debt.

Conflicts between secured and unsecured creditors depend on the bankruptcy system and the priority rules. If unsecured creditors can extract rents at the expense of more senior debtors (that is, if absolute priority can be violated), then a firm may prefer to liquidate its assets because unsecured creditors will expend the firm's resources in order to satisfy part of their claim. Eberhart, Moore and Roenfeldt (1990)
and Franks and Torous (1994) show that APR is often violated under Chapter 11. Firms in bankruptcy are allowed sometimes to issue new financing that can be senior to the already outstanding debt (debtor-in-possession, DIP, financing). The ability to raise DIP financing is priced \textit{ex ante} by the firm's creditors. Therefore, it increases the value of the firm \textit{ex post} but it reduces shareholder value \textit{ex ante}. This trade-off has been extensively considered in the literature.

\textbf{Life after bankruptcy}

The design of the bankruptcy process can also affect the performance of firms when they emerge from Chapter 11. Hotchkiss (1995) reports that over 40 per cent of the firms in her sample still experience operating losses in the three years following the bankruptcy case, while another 32 per cent re-file for bankruptcy or restructure their debt.

\textbf{Bankruptcy costs}

Bankruptcy costs encompass not only the explicit payments made to bankruptcy specialists (lawyers, trustees, accountants, investment bankers) but also the indirect costs of being in default. Among the latter, we can include loss of customers when the company is in financial distress, adverse payment terms enforced by suppliers when the viability of the firm is not guaranteed, loss of key personnel and waste of management time. Measuring the indirect costs of bankruptcy is very difficult. Altman (1984) uses forgone profits as a proxy, while Opler and Titman (1994) focus on losses of trade credit. However, because of the nature of the indirect costs, any proxy tends to underestimate their extent. Other researchers have used the length of the proceedings as a proxy for indirect bankruptcy costs, under the assumption that, the longer the firm stays in bankruptcy, the larger the collateral effects (Franks and Torous, 1994). Bris, Welch and Zhu (2006) show that both liquidations under Chapter 7 and reorganizations under Chapter 11 take about two years to resolve. In exploring the Swedish system, Thorburn (2000) shows that the Swedish auction system is much faster than the United States Chapter 11 process, since auctions take only two months on average.

The evidence on direct costs is more extensive. Warner (1977) finds that the direct costs of bankruptcy are about four per cent of the market value of the firm one year prior to the default. This result is based on a sample of 11 bankrupt railroads. Altman (1984) calculates these costs to be about 7.5 per cent of firm value, using a broader sample of 19 bankrupt companies from 1974 to 1978. Using 105 Chapter 11 cases, Ang, Chua and McConnell (1982) report that administrative fees are about 7.5 per cent of the total liquidating value of the bankrupt corporation's assets. Lubben (2000) calculates in his sample of 22 firms from 1994 that the cost of legal counsel in Chapter 11 bankruptcy represents 1.8 per cent of the distressed firm's total assets, and in some cases more than five per cent. In his average case, the debtor spends $500,000 on lawyers, and creditors spend $230,000. LoPucki and Doherty (2004) study a sample of 48 cases from 1998 to 2002, mostly from Delaware and New York. They report that professional fees were 1.4 per cent of the debtors' total assets at the beginning of the bankruptcy case. Bris, Welch and Zhu (2006) compare the costs of bankruptcy for Chapter 7 and Chapter 11 cases. They report that the
mean ratio of total expenses to assets is 9.5 per cent for Chapter 11, and 8.1 per cent for Chapter 7. However, they warn against simple averages because cost measures depend on the value of the assets (pre-bankruptcy or post-bankruptcy) one uses.

**Conclusion**

The design of a bankruptcy system is very important because it determines shareholder value for all firms, whether or not they are in financial distress. The reason is that any conflict that can arise among creditors of different classes, and any coordination problem in the bankruptcy proceedings among creditors in a similar class, are both priced in the debt securities that a company issues. Moreover, the bankruptcy system can impose distortions on a firm's policies when it is in financial distress; in particular it can induce managers to make suboptimal decisions at the expense of shareholders. Countries' legal systems differ in terms of who controls the firm's assets during bankruptcy. Because control shapes the conflicts set out above, this feature of the bankruptcy system is one of the most important considered by the academic literature. Additionally, scholars have studied the issue of bankruptcy costs in detail. While we have extensive evidence on the direct costs of bankruptcy, the indirect costs of being in distress are very difficult to measure.

Banks, Jeffrey Scot (1958–2000)

David Austen-Smith

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
adverse selection; agency models; Banks Set; Banks, J.; divinity; incomplete information; industrial organization; moral hazard; Nash equilibrium; pretrial bargaining; social choice; spatial theory of elections; subgame perfection

Article

Jeff Banks received his BA from University of California, Los Angeles, in 1982 and his Ph.D. from California Institute of Technology in 1986. He arrived as a new assistant professor of political science and economics at the University of Rochester with two significant and influential publications in hand, reflecting his principal interests in social choice theory (1985) and game theory (1987) respectively. By the time he died of complications from treating leukemia, Banks had published (or had forthcoming) more than 50 papers in economics, game theory and formal political theory, edited one conference volume, published a review monograph and coauthored two books.

In the 1985 paper, Banks completely characterized the set of subgame perfect Nash equilibrium outcomes achievable through an amendment agenda on a voting tournament. In effect, this set (which came to be called the Banks Set through no fault of its author) defines the consequential limits of an agenda-setter's power under the amendment procedure. Banks went on to write a series of influential papers on a variety of topics in social choice theory (for example, 1995; 1996; 2000; 2006) and in more applied positive political theory (for example, 1988; 1989; 1990a; 1990b). Indeed, it is difficult to identify any area within the field to which Banks did not make some significant contribution.

In (1987), Banks addressed the equilibrium refinement problem. Their proposed refinement, ‘divinity’, is on out-of-equilibrium beliefs and is closely related to the Cho and Kreps (1987) D1 refinement. Like D1, a virtue of divinity (in particular of its stronger variant, universal divinity) is that it is widely applicable and easy to compute, especially in games with a continuum of types and actions. Banks was a pioneer in developing strategic theories of collective decision-making under incomplete information, and his (1990a) paper is both the seminal contribution to the spatial theory of elections under incomplete information and the first application of divinity to an applied problem. Subsequently, the refinement has
been used profitably by others on a variety of problems in industrial organization, pretrial bargaining and so forth. Along with incomplete information, Banks contributed some of the earliest formal papers dealing with problems of time and dynamics in politics. For example, he explored dynamic agency models that exhibit both moral hazard and adverse selection simultaneously (1993; 1998). Such environments are notoriously complicated and, as a step towards developing an appropriate toolbox for handling them, Banks (1992) made an important contribution to theory of denumerably armed bandits.

Banks’s professional career barely spanned 15 years, yet the footprint he has left on (especially) positive political theory is considerable. He was a fine teacher and a remarkable colleague; he is, and will continue to be, much missed.

Baran, Paul Alexander (1910–1964)

Paul M. Sweezy

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Baran, P. A.; capitalism; feudalism; India, economics in; Japan, economics in; monopoly capitalism; potential surplus; surplus; surplus value; Sweezy, P. M.; underdevelopment

Article

Paul Baran, the eminent Marxist economist, was born on 8 December 1910 in Nikolaev, Russia, the son of a medical doctor who was a member of the Menshevik branch of the Russian revolutionary movement. After the October Revolution the family moved to Germany, where Baran's formal education began. In 1925 the father was offered a position in Moscow and returned to the USSR. Baran began his studies in economics at the University of Moscow the following year. Both his ideas and his politics were deeply and permanently influenced by the intense debates and struggles within the Communist Party in the late 1920s. Offered a research assignment at the Agricultural Academy in Berlin in late 1928, he enrolled in the University of Berlin, and when his assignment at the Agricultural Academy ended he accepted an assistantship at the famous Institute for Social Research in Frankfurt. This experience too had a lasting influence on his intellectual development.

Leaving Germany shortly after Hitler's rise to power, Baran sought without success to find academic employment in France. He therefore moved to Warsaw, where his paternal uncles had a flourishing international lumber business. During the next few years he travelled widely as a representative of his uncles’ business, ending up in London in 1938. With the approach of World War II, however, he decided to take what savings he had been able to accumulate, move to the United States, and resume his interrupted academic career.

Arriving in the United States in the fall of 1939, he was accepted as a graduate student in economics at Harvard. From there he went to wartime Washington, where he served in the Office of Price Administration, the Research and Development branch of the Office of Strategic Services, and the United States Strategic Bombing Survey, ending in 1945–6 as Deputy Chief of the Survey's mission to Japan. Back in the United States, he took a job at the Department of Commerce and gave lectures at George Washington University before being offered a position in the Research Department of the
Federal Reserve Bank of New York. After three years in New York, he accepted an offer to join the economics faculty at Stanford University and was promoted to a full professorship in 1951, a position he retained until his death of a heart attack on 26 March 1964.

Baran was not a prolific writer, but his two main books, *The Political Economy of Growth* (1957) and (in collaboration with Paul M. Sweezy) *Monopoly Capital: An Essay on the American Economic and Social Order* (1966), are generally considered to be among the most important works in the Marxian tradition of the post-World War II period.

*The Political Economy of Growth* is concerned with the processes and condition of economic growth (or development, the terms are used interchangeably) in both industrialized and underdeveloped societies, with a special emphasis throughout on the ways the two relate to and interact with each other. It is at once an outstanding work of scholarship weaving an intricate pattern of theory and history, and a passionate polemic against mainstream economics. Its chief (innovative) analytical concept is that of ‘potential surplus’, defined as ‘the difference between the output that could be produced in a given natural and technological environment with the help of employable productive resources, and what might be regarded as essential consumption’. (This concept presupposes Marx's ‘surplus value’, extending and modifying it for the particular purposes of the study in hand.) Two long chapters, totalling 90 pages, apply the concepts of surplus and potential surplus to the analysis of monopoly capitalism in ways that would later be refined and elaborated in *Monopoly Capital*. Three chapters (115 pages) follow on ‘backwardness’ (also called underdevelopment), and it is for these that the book has become famous, especially in the Third World.

Baran begins this analysis with a question which may be said to define the focus of the whole work: ‘Why is it that in the backward capitalist countries there has been no advance along the lines of capitalist development that are familiar from the history of other capitalist countries, and why is it that forward movement there has been slow or altogether absent?’ His answer, in briefest summary, is as follows: all present-day capitalist societies evolved from precapitalist conditions which Baran for convenience labels ‘feudal’ (explicitly recognizing that a variety of social formations are subsumed under this heading). Viable capitalist societies could have emerged in various parts of the world; actually the decisive breakthrough occurred in Western Europe (Baran speculates on the reasons, but in any case they are not crucial to the subsequent history). Having achieved its headstart, Europe proceeded to conquer weaker precapitalist countries, plunder their accumulated stores of wealth, subject them to unequal trading relations, and reorganize their economic structures to serve the needs of the Europeans. This was the origin of the great divide in the world capitalist system between the developed and the underdeveloped parts. As the system spread into the four corners of the globe, new areas were added, mostly to the underdeveloped part but in a few cases to the developed (North America, Australia, Japan). One of the highlights of Baran's study is the brilliant historical sketch of the contrasting ways India and Japan were incorporated into the world capitalist system, the one as a hapless dependency, the other as a strong contender for a place at the top of the pyramid of power. Baran's message to the Third World was loud and clear: once trapped in the world capitalist system, there is no hope for genuine progress; only a revolutionary break can open the road to a better future. The message has been widely heard. Most of the revolutionary movements of the Third World have been deeply influenced, directly or indirectly, by Paul Baran's *Political Economy of Growth*.

The economic analysis of *Monopoly Capital* is a development and systematization of ideas already contained in *The Political Economy of Growth* and Paul Sweezy's *The Theory of Capitalist Development*.
The central theme is that in a mature capitalist economy dominated by a handful of giant corporations the potential for capital accumulation far exceeds the profitable investment opportunities provided by the normal *modus operandi* of the private enterprise system. This results in a deepening tendency to stagnation which, if the system is to survive, must be continuously and increasingly counteracted by internal and external factors. In the authors’ estimation – not always shared, or even understood by critics – the new and original contributions of *Monopoly Capital* had to do mainly with these counteracting factors and their far-reaching consequences for the history, politics, and culture of American society during the period from roughly the 1890s to the 1950s when the book was written. They intended it, in other words, as much more than a work of economics in the usual meaning of the terms.

Nicholas Barbon, son of Praisegod Barbon, a London leather merchant, was born in 1637 (or 1640), and after studying medicine at Leyden and Utrecht and taking the MD at Utrecht in 1661, was admitted an Honorary Fellow of the College of Physicians at London in 1664. He was elected a Member of Parliament in 1690 and 1695. His successful career in various mercantile activities is reported in the autobiography of Roger North, the brother, biographer, and co-author of Sir Dudley North. He was engaged in the building trade in London following the great fire of 1666, and in 1685 he published a pamphlet *Apology for the Builder: or a Discourse showing the Cause and Effects of the Increase of Building*. In 1681 he established the first fire insurance company, and in 1684 published an *Account of two insurance offices*. Barbon also established a large financial venture in banking. With John Asgill he operated a land bank in 1695 and in the same year published *An Account of the Land Bank, showing the design and manner of the settlement*, and prepared a scheme for a national land bank which did not, however, come into existence.

Barbon's place in the history of economics is due to his *Discourse of Trade* (1690) and his more important *Discourse concerning coining the new money lighter: An answer to Mr Locke's Considerations about raising the value of money*. Taking the same position as Josiah Child and arguing, against Locke, for a legal reduction of the maximum rate of interest, he published in 1694 An *Answer to ... reasons against reducing interest to four per cent*. His argument against trade restrictions and for international free trade principles places him in the front rank of anticipators of the doctrines that developed in the following century. He exhibited clearly the connection between the supply of money and the effective level of trade. Against the proposals to recoin the currency at the old standard he pointed out the potential deflationary effects of the reduction in the money supply that would result, ‘the consequence whereof will be that trade will be at a stand’.

Barbon's concern with the ‘disorder … that attends a nation that want money to drive their trade and
commerce’ and the ‘prejudice to the state by making money scarce’ led him to argue, in contexts that
elevated to priority the functional significance of money, that ‘it is not absolutely necessary that money
should be made of gold or silver’. ‘Banks of credit … are of great advantage to trade.’ ‘Money is the
instrument and measure of commerce and not silver.’ Barbon held a supply and demand theory of
market price, based on a logically prior notion of use values, and what he called ‘time and place’ value.
He argued that ‘interest is the rent of stock and is the same as the rent of land’, claiming that a lower
interest rate would raise capital values, indirectly by remedying ‘the decay of trade’ and directly by
increasing the capitalized value of income streams.
Consumption expenditures, Barbon argued, provided employment. In his argument that ‘prodigality is a
vice that is prejudicial to the man but not to trade … covetousness is a vice prejudicial to both man and
trade’, he anticipated the prodigality and employment-creating expenditure argument of the following
century.

bargaining

Roberto Serrano

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article is a survey on bargaining theory. The focus is the game theoretic approach to bargaining, both on its axiomatic and strategic counterparts. The application of bargaining theory to large markets and its connections with competitive allocations are also discussed.

Keywords

Article

In its simplest definition, ‘bargaining’ is a socio-economic phenomenon involving two parties, who can cooperate towards the creation of a commonly desirable surplus, over whose distribution the parties are in conflict. The nature of the cooperation in the agreement and the relative positions of the two parties in the status quo before agreement takes place will influence the way in which the created surplus is divided. Many social, political and economic interactions of relevance fit this definition: a buyer and a seller trying to transact a good for money, a firm and a union sitting at the negotiation table to sign a labour contract, a couple deciding how to split the intra-household chores, two unfriendly countries trying to reach a lasting peace agreement, or out-of-court negotiations between two litigating parties. In all these cases three basic ingredients are present: (a) the status quo, or the disagreement point, that is, the arrangement that is expected to prevail if an agreement is not reached; (b) the presence of mutual gains from cooperation; and (c) the multiplicity of possible cooperative arrangements, which split the
resulting surplus in different ways. If the situation involves more than two parties, matters are different, as set out in von Neumann and Morgenstern (1944). Indeed, in addition to the possibilities already identified of either disagreement or agreement among all parties, it is conceivable that an agreement be reached among only some of the parties. In multilateral settings, we are therefore led to distinguish pure bargaining problems, in which partial agreements of this kind are not possible because subcoalitions have no more power than individuals alone, from coalitional bargaining problems (or simply coalitional problems), in which partial agreements become a real issue in formulating threats and predicting outcomes. An example of a pure bargaining problem would be a round of talks among countries in order to reach an international trade treaty in which each country has veto power, whereas an example of a coalitional bargaining problem would be voting in legislatures. In this article we concentrate on pure bargaining problems, leaving the description of coalitional problems to other articles in the dictionary. We are likewise not concerned with the vast informal literature on bargaining, which conducts case studies and tries to teach bargaining skills for the ‘real world’ (for this purpose, the reader is referred to Raiffa, 1982).

Approaches to bargaining before game theory

Before the adoption of game theoretic techniques, economists deemed bargaining problems (also called bilateral monopolies at the time) indeterminate. This was certainly the position adopted by important economic theorists, including Edgeworth (1881) and Hicks (1932). More specifically, it was believed that the solution to a bargaining problem must satisfy both individual rationality and collective rationality properties: the former means that neither party should end up worse than in the status quo and the latter refers to Pareto efficiency. Typically, the set of individually rational and Pareto-efficient agreements is very large in a bargaining problem, and these theorists were inclined to believe that theoretical arguments could go no further than this in obtaining a prediction. To be able to obtain such a prediction, one would have to rely on extra-economic variables, such as the bargaining power and abilities of either party, their state of mind in negotiations, their religious beliefs, the weather and so on. A precursor to the game theoretic study of bargaining, at least in its attempt to provide a more determinate prediction, is the analysis of Zeuthen (1930). This Danish economist formulated a principle whereby the solution to a bargaining problem was dictated by the two parties’ risk attitudes (given the probability of breakdown of negotiations following the adoption of a tough position at the bargaining table). The reader is referred to Harsanyi (1987) for a version of Zeuthen's principle and its connection with Nash's bargaining theory. The remainder of this article deals with game theoretic approaches to bargaining.

The axiomatic theory of bargaining

Nash (1950) and Nash (1953) are seminal papers that constitute the birth of the formal theory of bargaining. Two assumptions are central in Nash's theory. First, bargainers are assumed to be fully rational individuals, and the theory is intended to yield predictions based exclusively on data relevant to them (in particular, the agents are equally skilful in negotiations, and the other extraneous factors mentioned above do not play a role).
Second, a bargaining problem is represented as a pair $\langle S, d \rangle$ in the utility space, where $S$ is a compact and convex subset of $\mathbb{R}^2$ – the feasible set of utility pairs – and $d \in \mathbb{R}^2$ is the disagreement utility point. Compactness follows from standard assumptions such as closed productions sets and bounded factor endowments, and convexity is obtained if one uses expected utility and lotteries over outcomes are allowed. Also, the set $S$ must include points that dominate the disagreement point, that is, there is a positive surplus to be enjoyed if agreement is reached and the question is how this surplus should be divided. As in most of game theory, by ‘utility’ we mean von Neumann–Morgenstern expected utility; there may be underlying uncertainty, perhaps related to the probability of breakdown of negotiations. We shall normalize the disagreement utilities to 0 (this is without loss of generality if one uses expected utility because any positive affine transformation of utility functions represents the same preferences over lotteries). The resulting bargaining problem is called a normalized problem.

With this second assumption, Nash is implying that all information relevant to the solution of the problem must be subsumed in the pair $\langle S, d \rangle$. In other words, two bargaining situations that may include distinct details ought to be solved in the same way if both reduce to the same pair $\langle S, d \rangle$ in utility terms. In spite of this, it is sometimes convenient to distinguish between feasible utility pairs (points in $S$) and feasible outcomes in physical terms (such as the portions of a pie to be created after agreement). Following the two papers by Nash (1950; 1953), bargaining theory is divided into two branches, the so-called axiomatic and strategic theories. The axiomatic theory, born with Nash (1950), which most authors identify with a normative approach to bargaining, proposes a number of properties that a solution to any bargaining problem should have, and proceeds to identify the solution that agrees with those principles. Meanwhile, the strategic theory, initiated in Nash (1953), is its positive counterpart: the usual approach here is the exact specification of the details of negotiation (timing of moves, information available, commitment devices, outside options and threats) and the identification of the behaviour that would occur in those negotiation protocols. Thus, while the axiomatic theory stresses how bargaining should be resolved between rational parties according to some desirable principles, the strategic theory describes how bargaining could evolve in a non-cooperative extensive form in the presence of common knowledge of rationality. Interestingly, the two theories connect and complement one another.

The Nash bargaining solution

The first contribution to axiomatic bargaining theory was made by John Nash in his path-breaking paper published in 1950. Nash wrote it as a term paper in an international trade course that he was taking as an undergraduate at Carnegie, at the age of 17. At the request of his Carnegie economics professor, Nash mailed his term paper to John von Neumann, who had just published his monumental book with Oskar Morgenstern. John von Neumann may not have paid enough attention to a paper sent by an undergraduate at a different university, and nothing happened with the paper until Nash arrived in Princeton to begin studying for his Ph.D. in mathematics.

According to Nash (1950), a solution to bargaining problems is simply a function that assigns to each normalized utility possibility set $S$ one of its feasible points (recall that the normalization of the disagreement utilities has already been performed). The interpretation is that the solution dictates a specific agreement to each possible bargaining situation. Examples of solutions are: $(a)$ the disagreement solution, which assigns to each normalized bargaining problem the point $(0,0)$, a rather pessimistic
solution; and (b) the dictatorial solution with bargainer 1 as the dictator, which assigns the point in the Pareto frontier of the utility possibility set in which agent 2 receives 0 utility. Surely, neither of these solutions looks very appealing: while the former is not Pareto efficient because it does not exploit the gains from cooperation associated with an agreement, the latter violates the most basic fairness principle by being so asymmetric.

Nash (1950) proceeds by proposing four desirable properties that a solution to bargaining problems should have.

1. **Scale invariance or independence of equivalent utility representations.** Since the bargaining problem is formulated in von Neumann–Morgenstern utilities, if utility functions are re-scaled but they represent the same preferences, the solution should be re-scaled in the same fashion. That is, no fundamental change in the recommended agreement will happen following a re-normalization of utility functions; the solution will simply re-scale utilities accordingly.

2. **Symmetry.** If a bargaining problem is symmetric with respect to the 45 degree line, the solution must pick a point on it: in a bargaining situation in which each of the threats made by one bargainer can be countered by the other with exactly the same threat, the two should be equally treated by the solution. This axiom is sometimes called ‘equal treatment of equals’ and it ensures that the solution yields ‘fair’ outcomes.

3. **Pareto efficiency.** The solution should pick a point of the Pareto frontier. As elsewhere in welfare economics, efficiency is the basic ingredient of a normative approach to bargaining; negotiations should yield an efficient outcome in which all gains from cooperation are exploited.

4. **Independence of irrelevant alternatives (IIA).** Suppose a solution picks a point from a given normalized bargaining problem. Consider now a new normalized problem, a subset of the original, but containing the point selected earlier by the solution. Then, the solution must still assign the same point. That is, the solution should be independent of ‘irrelevant’ alternatives: as in a constrained optimization programme, the deleted alternatives are deemed irrelevant because they were not chosen when they were present, so their absence should not alter the recommended agreement.

With the aid of these four axioms, Nash (1950) proves the following result:

**Theorem 1:** There is a unique solution to bargaining problems that satisfies properties (1–4): it is the one that assigns to each normalized bargaining problem the point that maximizes the product of utilities of the two bargainers.

Today we refer to this solution as the ‘Nash solution’. Although some of the axioms have been the centre of some controversy – especially his fourth, IIA, axiom – the Nash solution has remained as the fundamental piece of this theory, and its use in applications is pervasive.

Some features of the Nash solution ought to be emphasized. First, the theory can be extended to the multilateral case, in which there are \( n \geq 3 \) parties present in bargaining: in a multilateral problem, it continues to be true that the unique solution that satisfies (1–4) is the one prescribing that agreement in which the product of utilities is maximized. See Lensberg (1988) for an important alternative axiomatization.

Second, the theory is independent of the details of the negotiation-specific protocols, since it is
formulated directly in the space of utilities. In particular, it can be applied to problems where the utilities are derived from only one good or issue, as well as those where utility comes from multiple goods or issues.

Third, perhaps surprisingly because risk is not explicitly part of Nash's story, it is worth noting that the Nash solution punishes risk aversion. All other things equal, it will award a lower portion of the surplus to a risk-averse agent. This captures an old intuition in previous literature that risk aversion is detrimental to a bargainer: afraid of the bargaining breakdown, the more risk-averse a person is, the more he will concede in the final agreement. For example, suppose agents are bargaining over how to split a surplus of size 1. Let the utility functions be as follows: \( u_1(x_1) = x_1^\alpha \) for \( 0 < \alpha \leq 1 \), and \( u_2(x_2) = x_2 \), where \( x_1 \) and \( x_2 \) are the non-negative shares of the surplus, which add up to 1. The reader can calculate that the Pareto frontier of the utility possibility set corresponds to the agreements satisfying the equation \( u_1^1/\alpha + u_2 = 1 \). Therefore, the Nash solution awards the utility vector \((u_1^*, u_2^*) = ((\frac{\alpha}{\alpha+1})^\alpha, \frac{1}{\alpha+1})\), corresponding to shares of the surplus \((x_1, x_2) = (\frac{\alpha}{\alpha+1}, \frac{1}{\alpha+1})\). Note how the smaller \( \alpha \) is, the more risk-averse bargainer 1 is.

Fourth, Zeuthen's principle turns out to be related to the Nash solution (see Harsanyi, 1987): in identifying the bargainer who must concede next, the Nash product of utilities of the two proposals plays a role. See Rubinstein, Safra and Thomson (1992) for a related novel interpretation of the Nash solution.

Fifth, the family of asymmetric Nash solutions has also been used in the literature as a way to capture unequal bargaining powers. If the bargaining power of player i is \( \beta_i \in [0, 1], \sum_i \beta_i = 1 \), the asymmetric Nash solution with weights \((\beta_1, \beta_2)\) is defined as the function that assigns to each normalized bargaining problem the point where \( u_1^\beta_1 u_2^\beta_2 \) is maximized.

The Kalai–Smorodinsky bargaining solution

Several researchers have criticized some of Nash's axioms, IIA especially. To see why, think of the following example, which begins with the consideration of a symmetric right-angled triangle \( S \) with legs of length 1. Clearly, efficiency and symmetry alone determine that the solution must be the point \((1/2,1/2)\). Next, chop off the top part of the triangle to get a problem \( T \subset S \), in which all points where \( u_2 > 1/2 \) have been deleted. By IIA, the Nash solution applied to the problem \( T \) is still the point \((1/2,1/2)\).

Kalai and Smorodinsky (1975) propose to retain the first three axioms of Nash's, but drop IIA. Instead, they propose an individual monotonicity axiom. To understand it, let \( a_i(S) \) be the highest utility that agent \( i \) can achieve in the normalized problem \( S \), and let us call it agent \( i \)'s aspiration level. Let \( a(S) = (a_1(S), a_2(S)) \) be the utopia point, typically not feasible.

1. **Individual monotonicity.** If \( T \subset S \) are two normalized problems, and \( a_j(T) = a_j(S) \), the solution must award \( i \) a utility in \( S \) at least as high as in \( T \).

We can now state the Kalai–Smorodinsky theorem:
Theorem 2: There is a unique solution to bargaining problems that satisfies properties (1, 2, 3, 5): it is the one that assigns to each normalized bargaining problem the intersection point of the Pareto frontier and the straight line segment connecting 0 and the utopia point.

Note how the Kalai–Smorodinsky solution awards the point (2/3, 1/3) to the problem T of the beginning of this subsection. In general, while the Nash solution pays attention to local arguments (it picks out the point of the smooth Pareto frontier where the utility elasticity \( (\frac{du_2}{u_2})/(\frac{du_1}{u_1}) \) is 1), the Kalai–Smorodinsky solution is mostly driven by ‘global’ considerations, such as the highest utility each bargainer can obtain in the problem.

Other solutions

Although the two major axiomatic solutions are Nash's and Kalai–Smorodinsky's, authors have derived a plethora of other solutions also axiomatically (see, for example, Thomson, 1994, for an excellent survey). Among them, one should perhaps mention the egalitarian solution, which picks out the point of the Pareto frontier where utilities are equal. This is based on very different principles, much more tied to ethics of a certain kind and less to the principles governing bargaining between two rational individuals. In particular, note how it is not invariant to equivalent utility representations, because of the strong interpersonal comparisons of utilities that it performs.

The strategic theory of bargaining

Now we are interested in specifying the details of negotiations. Thus, while we may lose the generality of the axiomatic approach, our goal is to study reasonable procedures and identify rational behaviour in them. For this and the next section, some major references include Osborne and Rubinstein (1990) and Binmore, Osborne and Rubinstein (1992).

Nash's demand game

Nash (1953) introduces the first bargaining model expressed as a non-cooperative game. Nash's demand game, as it is often called, captures in crude form the force of commitment in bargaining. Both bargainers must demand simultaneously a utility level. If the pair of utilities is feasible, it is implemented; otherwise, there is disagreement and both receive 0. This game admits a continuum of Nash equilibrium outcomes, including every point of the Pareto frontier, as well as disagreement. The first message that emerges from Nash's demand game is the indeterminacy of equilibrium outcomes, commonplace in non-cooperative game theory. In the same paper, advancing ideas that would be developed a couple of decades later, Nash proposed a refinement of the Nash equilibrium concept based on the possibility of uncertainty around the true feasible set. The result was a selection of one Nash equilibrium outcome, which converges to the Nash solution agreement as uncertainty vanishes.

The model just described is referred to as Nash's demand game with fixed threats: following an incompatible pair of demands, the outcome is the fixed disagreement point. Nash (1953) also analysed a variable threats model. In it, the stage of simultaneous demands is preceded by another stage, in which bargainers choose threats. Given a pair of threats chosen in the first stage, the refinement argument is
The alternating offers bargaining procedure

The following game elegantly describes a stylized protocol of negotiations over time. It was studied by Stahl (1972) under the assumption of an exogenous deadline (finite horizon game) and by Rubinstein (1982) in the absence of a deadline (infinite horizon game). Players 1 and 2 are bargaining over a surplus of size 1. The bargaining protocol is one of alternating offers. In period 0, player 1 begins by making a proposal, a division of the surplus, say \((x, 1-x)\), where \(0 \leq x \leq 1\) represents the part of the surplus that she demands for herself. Player 2 can then either accept or reject this proposal. If he accepts, the proposal is implemented; if he rejects, a period must elapse for them to come back to the negotiation table, and at that time (period 1) the roles are reversed so that player 2 will make a new proposal \((y, 1-y)\), where \(0 \leq y \leq 1\) is the fraction of surplus that he offers to player 1. Player 1 must then either accept the new proposal, in which case bargaining ends with \((y, 1-y)\) as the agreement, or reject it, in which case a period must elapse before player 1 makes a new proposal. In period 2, player 1 proposes \((z, 1-z)\), to which player 2 must respond, and so on. The \(T\)-period finite horizon game imposes the disagreement outcome, with zero payoffs, after \(T\) proposals have been rejected. On the other hand, in the infinite horizon version, there is always a new proposal in the next period after a proposal is rejected. Both players discount the future at a constant rate. Let \(\delta \in [0, 1)\) be the per period discount factor. To simplify, let us assume that utility is linear in shares of the surplus. Therefore, from a share \(x\) agreed in period \(t\), a player derives a utility of \(\delta^{t-1} x\). Note how utility is increasing in the share of the surplus (monotonicity) and decreasing in the delay with which the agreement takes place (impatience).

A strategy for a player is a complete contingent plan of action to play the game. That is, a strategy specifies a feasible action every time a player is called upon to act in the game. In a dynamic game, Nash equilibrium does little to restrict the set of predictions: for example, it can be shown that in the alternating offers games, any agreement \((x, 1-x)\) in any period \(t, 0 \leq t \leq T < \infty\), can be supported by a Nash equilibrium; disagreement is also a Nash equilibrium outcome.

The prediction that game theory gives in a dynamic game of complete information is typically based on finding its subgame perfect equilibria. A subgame perfect equilibrium (SPE) in a two-player game is a pair of strategies, one for each player, such that the behaviour specified by them is a best response to each other at every point in time (not only at the beginning of the game). By stipulating that players must choose a best response to each other at every instance that they are supposed to act, SPE rules out incredible threats: that is, at an SPE players have an incentive to carry out the threat implicit in their equilibrium strategy because it is one of the best responses to the behaviour they expect the other player to follow at that point.

In the alternating offers games described above, there is a unique SPE, in both the finite and the infinite horizon versions. The SPE in the finite horizon game is found by backward induction. For example, in the one-period game, the so-called ultimatum game, the unique SPE outcome is the agreement on the split \((1,0)\): since the outcome of a rejection is disagreement, the responder will surely accept any share of
\( \epsilon > 0 \), which implies that in equilibrium the proposer ends up taking the entire surplus. Using this intuition, one can show that the outcome of the two-period game is the immediate agreement on the split \((1 - \delta, \delta)\): anticipating that if negotiations get to the final period, player 2 (the proposer in that final period) will take the entire surplus, player 1 persuades him not to get there simply by offering him the present discounted value of the entire surplus, that is, \( \delta \), while she takes the rest. This logic continues and can be extended to any finite horizon. The sequence of SPE outcomes so obtained as the deadline \( T \to \infty \) is shown to converge to the unique SPE of the infinite horizon game. This game, more challenging to solve since one cannot go to its last period to begin inducting backwards, was studied in Rubinstein (1982). We proceed to state its main theorem and discuss the properties of the equilibrium (see Shaked and Sutton, 1984, for a simple proof).

**Theorem 3:** Consider the infinite horizon game of alternating offers, in which both players discount the future at a per period rate of \( \delta \in [0, 1) \). There exists a unique SPE of this game: it prescribes immediate agreement on the division \( \left( \frac{1}{1+\delta}, \frac{\delta}{1+\delta} \right) \).

The first salient prediction of the equilibrium is that there will not be any delay in reaching an agreement. Complete information – each player knows the other player's preferences – and the simple structure of the game are key factors to explain this.

The equilibrium awards an advantage to the proposer, as expressed by the discount factor: note how the proposer's share exceeds the responder's by a factor of \( 1/\delta \). Given impatience, having to respond to a proposal puts an agent in a delicate position, since rejecting the offer entails time wasted until the next round of negotiations. This is the source of the proposer's advantage. Of course, this advantage is larger, the larger the impatience of the responder: note how if \( \delta = 0 \) (extreme impatience), the equilibrium awards all the surplus to the proposer because her offer is virtually an ultimatum; on the other hand, as \( \delta \to 1 \), the first-mover advantage disappears and the equilibrium tends to an equal split of the surplus.

To understand how the equilibrium works and in particular how the threats employed in it are credible, consider the SPE strategies. Both players use the same strategy, and it is the following: as a proposer, each player always asks for \( 1/(1+\delta) \) and offers \( \delta/(1+\delta) \) to the other party; as a responder, a player accepts an offer as long as the share offered to the responder is at least \( \delta/(1+\delta) \). Note how rejecting a share lower than \( \delta/(1+\delta) \) is credible, in that its consequence, according to the equilibrium strategies, is to agree in the next period on a split that awards the rejecting player a share of \( 1/(1+\delta) \), whose present discounted value at the time the rejection occurs is exactly \( \delta/(1+\delta) \).

To appreciate the difference from Nash equilibrium, let us argue, for example, that the split \((0,1)\) cannot happen in an SPE. This agreement happens in a Nash equilibrium, supported by strategies that ask player 1 to offer the whole pie to player 2, and player 2 to reject any other offer. However, the threat embodied in player 2's strategy is not credible: when confronted with an offer \( (\epsilon, 1 - \epsilon) \) for \( \delta < 1 - \epsilon < 1 \), player 2 will have to accept it, contradicting his strategy. Can the reader argue why the Nash equilibrium split \((1,0)\) is not an SPE outcome either (because to do so one would need to employ non-credible threats)? Rubinstein (1982) shows that the same non-credible threats are associated with any division of the pie other than the one identified in the theorem.

The Rubinstein–Stahl alternating offers game provides an elegant model of how negotiations may take place over time, and its applications are numerous, including bargaining problems pertaining to international trade, industrial organization, or political economy. However, unlike Nash's axiomatic theory, its predictions are sensitive to details. This is no doubt one of its strengths because one can
calibrate how those details may influence the theory's prediction, but it is also its weakness in terms of lack of robustness in predictive power.

Incomplete information

In a static framework, Chatterjee and Samuelson (1983) study a double auction. A buyer and a seller are trying to transact a good. Each proposes a price, and trade takes place at the average of the two prices if and only if the buyer's price exceeds the seller's. Each trader knows his own valuation for the good. However, there is incomplete information on each side concerning the other side's valuation. It can be shown that in any equilibrium of this game there are inefficiencies: given certain ex post valuations of buyer and seller, there should be trade, yet it is precluded because of incomplete information, which leads traders to play 'too tough'.

Let us now turn to bargaining over time. As pointed out above, one prediction of the Rubinstein–Stahl model is immediate agreement. This may clash with casual observation; one may simply note the existence of strikes, lockouts and long periods of disagreement in many actual negotiations. As a consequence, researchers have suggested the construction of models in which inefficiencies, in the form of delay in agreement, occur in equilibrium. The main feature of bargaining models with this property is incomplete information. (For delay in agreement that does not rely on incomplete information, see Fernandez and Glazer, 1991, Avery and Zemsky, 1994, and Busch and Wen, 1995.)

If parties do not know each other's preferences (impatience rate, per period fixed cost of hiring a lawyer, profitability of the agreement, and so on), the actions taken by the parties in the bargaining game may be intended to elicit some of the information that they do not have, or perhaps to reveal or misrepresent some of the information privately held.

One technical remark is in order. The typical approach is to reduce the uncertainty to a game of imperfect information through the specification of types in the sense of Harsanyi (1967–8). In such games, SPE no longer constitutes an appropriate refinement of Nash equilibrium. The relevant equilibrium notions are perfect Bayesian equilibrium and sequential equilibrium, and in them the off-equilibrium path beliefs play an important role in sustaining outcomes. Moreover, these concepts are often incapable of yielding a determinate prediction in many games, and authors have in these cases resorted to further refinements. One problem of the refinements literature, however, is that it lacks strong foundations. Often the successful use of a given refinement in a game is accompanied by a bizarre prediction when the same concept is used in other games. Therefore, one should interpret these findings as showing the possibilities that equilibrium can offer in these contexts, but the theory here is far from giving a determinate answer.

Rubinstein (1985) studies an alternating offers procedure in which there is one-sided incomplete information (that is, while player 1 has uncertainty regarding player 2's preferences, player 2 is fully informed). Suppose there are two types of player 2: one of them is 'weaker' than player 1, while the other is 'stronger' (in terms of impatience or per period costs). This game admits many equilibria, and they differ as a function of parameter configurations. There are pooling equilibria, in which an offer from player 1 is accepted immediately by both types of player 2. More relevant to the current discussion, there are also separating equilibria, in which player 1's offer is accepted by the weak type of player 2, while the strong type signals his true preferences by rejecting the offer and imposing delay in
equilibrium. These equilibria are also used to construct other equilibria with more periods of delay in agreement. Some authors (Gul and Sonnenschein, 1988) argue that long delays in equilibrium are the product of strong non-stationary behaviour (that is, a player behaves very differently in and out of equilibrium, as a function of changes in his beliefs). They show that imposing stationary behaviour limits the delay in agreement quite significantly. One advantage of stationary equilibria is their simplicity, but one problem with them is that they impose stationary beliefs (players hold beliefs that are independent of the history of play).

The analysis is simpler and multiplicity of equilibrium is less of a problem in games in which the uninformed party makes all the offers. Consider, for example, a version of the model in Sobel and Takahashi (1983). The two players are a firm and a union. The firm is fully informed, while the union does not know the true profitability of the firm. The union makes all offers in these wage negotiations, and there is discounting across periods. In equilibrium, different types of the firm accept offers at different points in time: firms whose profitability is not very high can afford to reject the first high wage offers made by the union to signal their private information, while very profitable firms cannot because delay in agreement hurts them too much.

Most papers have studied the case of private values asymmetric information (if a player knows her type, she knows her preferences), although the correlated values case has also been analysed (where knowing one's type is not sufficient to know one's utility function); see Evans (1989) and Vincent (1989). The case of two-sided asymmetric information, in which neither party is fully informed, has been treated, for example, in Watson (1998). In all these results, one is able to find equilibria with significant delay in agreement, implying consequent inefficiencies. Uncertainty may also be about the rationality of the opponent: for example, one may be bargaining with a ‘behavioural type’ who has an unknown threshold below which he will reject all proposals (see Abreu and Gul, 2000).

A more general approach is adopted by studies of mechanism design. The focus is not simply on explaining delay as an equilibrium phenomenon in a given extensive form. Rather, the question is whether inefficiencies are a consequence of equilibrium behaviour in any bilateral bargaining game with incomplete information. The classic contribution to this problem is the paper by Myerson and Satterthwaite (1983). In a bilateral trading problem in which there is two-sided private values asymmetric information and the types of each trader are drawn independently from overlapping intervals, there does not exist any budget-balanced mechanism satisfying incentive compatibility, interim individual rationality and \textit{ex post} efficiency. All these are desirable properties for a trading mechanism. Budget balance implies that payoffs cannot be increased with outside funds. Incentive compatibility requires that each type has no incentive to misrepresent his information. Interim individual rationality means that no type can be worse off trading than not trading. Finally, \textit{ex post} efficiency imposes that trade takes place if and only if positive gains from trade exist. This impossibility result is a landmark of the limitations of bargaining under incomplete information, and has generated an important literature that explores ways to overcome it (see for example Gresik and Satterthwaite, 1989, and Satterthwaite and Williams, 1989).

\textbf{Indivisibilities in the units}

One important way in which Rubinstein's result is not robust happens when there is only a finite set of
possible offers to be made (see van Damme, Selten and Winter, 1990, and Muthoo, 1991). Indivisibilities make it impossible for an exact adjustment of offers to leave the responder indifferent; as a result, multiple and inefficient equilibria appear. The issue concerns how fine the grid of possible instantaneous offers is with respect to the time grid in which bargaining takes place. If the former is finer than the latter, Rubinstein's uniqueness goes through; otherwise it does not. There will be circumstances for which one or the other specification of negotiation rules will be more appropriate.

**Multi-issue bargaining**

The following preliminary observation is worth making: if offers are made in utility space or all issues must be bundled in every offer, Rubinstein's result obtains. Thus, the literature on multi-issue bargaining has looked at procedures that depart from these assumptions.

The first generation of papers with multiple issues assumed that the agenda – that is, the order in which the different issues are brought to the table – was exogenously given. Since each issue is bargained over one at a time, Rubinstein's uniqueness and efficiency result obtains, simply proceeding by backward induction on the issues. Fershtman (1990; 2000) and Busch and Horstmann (1997) study such games, from which one learns the comparative statics of equilibrium when agendas are exogenously fixed. The next group of papers studies more realistic games where the agenda is chosen endogenously by the players. The main lesson from this line of work is that restricting the issues that a proposer can bring to the table is a source of inefficiencies. Inderst (2000) and In and Serrano (2003) study a procedure where agenda is totally unrestricted, that is, the proposer can make offers on any subset of remaining issues and, by exploiting trade-offs in the marginal rates of substitution between issues, Rubinstein's efficiency result is also found. In contrast, Lang and Rosenthal (2001) and In and Serrano (2004) construct multiple and inefficient equilibria (including those with arbitrarily long delay in agreement) when agenda restrictions are imposed. Finally, Weinberger (2000) considers multi-issue bargaining when the responder can accept selectively subsets of proposals and also finds inefficiencies if issues are indivisible.

**Multilateral bargaining**

Even within the case of pure bargaining problems, one needs to make a distinction between different ways to model negotiations. The first extension of the Rubinstein game to this case is due to Shaked, as reported in Osborne and Rubinstein (1990, p. 63); see also Herrero (1985). Today we refer to the Shaked/Herrero game as the ‘unanimity game’. In it, one of the players, say player 1, begins by making a public proposal to the others. A proposal is a division of the unit of surplus available when agreement is reached. Players 2, •…, • then must accept or reject this proposal. If all agree, it is implemented immediately. If at least one of them rejects it, time elapses and in the next period another player, say player 2, will make a new proposal, and so on. Note how these rules reduce to Rubinstein's when there are only two players. However, the prediction emerging from this game is dramatically different. For values of the discount factor that are sufficiently high (if \( \delta \geq 1 / (n - 1) \)), every feasible agreement can be supported by an SPE and, in addition, equilibria with an arbitrary number of periods of delay in agreement show up. The intuition for this extreme result is that the unanimity required by the rules in
order to implement an agreement facilitates a plethora of equilibrium behaviours. For example, let us see how in the case of \( n = 3 \) it is possible to sustain an agreement where all the surplus goes to player 3. If player 2 rejects it, the same split will be repeated in the continuation, so it is pointless to reject it. If player 1 changes her proposal to try to obtain a gain, it will be rejected by that responder who in the proposal receives less than 1/2 (there must be at least one). This rejector can be bribed with receiving the entire surplus in the continuation, whose present discounted value is at least 1/2 (recall \( \delta \geq 1 / 2 \)), thereby rendering his rejection credible. Of course, the choice of player 3 as the one receiving the entire surplus is entirely arbitrary and, therefore, one can see how extreme multiplicity of equilibrium is a phenomenon inherent to the unanimity game. This multiplicity relies on non-stationary strategies, as it can be shown that there is a unique stationary SPE.

An alternative extension of the Rubinstein rules to multilateral settings is given by exit games; see Jun (1987), Chae and Yang (1994), Krishna and Serrano (1996). As an illustration, let us describe the negotiation rules of the Krishna–Serrano game. Player 1 makes a public proposal, a division of the surplus, and the others must respond to it. Those who accept it leave the game with the shares awarded by the proposer, while the rejectors continue to bargain with the proposer over the part of the surplus that has not been committed to any player. A new proposal comes from one of the rejectors, and so on. These rules also reduce to Rubinstein's if \( n = 2 \), but now the possibility of exiting the game by accepting a proposal has important implications for the predictive power of the theory. Indeed, Rubinstein's uniqueness is restored and the equilibrium found inherits the properties of Rubinstein's, including its immediate agreement and the proposer's advantage (the equilibrium shares are \( 1/(1+(n-1)\delta) \) for the proposer and \( \delta / [1+(n-1)\delta] \) for each responder). Note how, given that the others accept, each responder is de facto immersed in a two-player Rubinstein game, so in equilibrium he receives a share that makes him exactly indifferent between accepting and rejecting: this explains the ratio \( 1/\delta \) between the proposer's and each responder's equilibrium shares. The sensitivity of the result to the exact specification of details is emphasized in other papers. Vannetelbosch (1999) shows that uniqueness obtains in the exit game even with a notion of rationalizability, weaker than SPE; and Huang (2002) establishes that uniqueness is still the result in a model that combines unanimity and exit, since offers can be made both conditional and unconditional to each responder. Baliga and Serrano (1995; 2001) introduce imperfect information in the unanimity and exit games (offers are not public, but made in personalized envelopes), and multiplicity is found in both, based on multiple off-equilibrium path beliefs. Merlo and Wilson (1995) propose a stochastic specification and also find uniqueness of the equilibrium outcome. In a model often used in political applications, Baron and Ferejohn (1989) study a procedure with random proposers in which the proposals are adopted if approved by simple majority (between the unanimity and exit procedures described).

Bargaining and markets

Bargaining theory provides a natural approach to understand how prices may emerge in markets as a consequence of the direct interaction of agents. One can characterize the outcomes of models in which the interactions of small groups of agents are formulated as bargaining games, and compare them with market outcomes such as competitive equilibrium allocations. If a connection between the two is found, one is giving an answer to the long-standing question of the origin of competitive equilibrium prices.
without having to resort to the story of the Walrasian auctioneer. If not, one can learn the importance of the frictions in the model that may be preventing such a connection. Both kinds of results are valuable for economic theory.

Small markets

Models have been explored in which two agents are bargaining, but at least one of them may have an outside option (see Binmore, Shaked and Sutton, 1988). Thus, the bargaining pair is part of a larger economic context, which is not explicitly modelled. In the simplest specification, uniqueness and efficiency of the equilibrium is found. In the equilibrium, the outside option is used if it pays better than the Rubinstein equilibrium; otherwise it is ignored. Jehiel and Moldovanu (1995) show that delays may be part of the equilibrium when the agreement between a seller and several buyers is subject to externalities among the buyers: a buyer may have an incentive to reject an offer in the hope of making a different buyer accept the next offer and free-ride from that agreement. In general, these markets involving a small number of agents do not yield competitive allocations because market power is retained by some traders (see Rubinstein and Wolinsky, 1990).

Large markets under complete information

The standard model assumes a continuum of agents who are matched at random, typically in pairs, to perform trade of commodities. If a pair of agents agrees on a trade, they break the match. In simpler models, all traders leave the market after they trade once. In the more general models agents may choose either to leave and consume, or to stay in the market to be matched anew. Some authors have studied steady-state versions, in which the measure of traders leaving the market every period is offset exactly by the same measure of agents entering the market. In contrast, non-steady state models do not keep the measure of active traders constant (one prominent class of non-steady state models is that of one-time entry, in which after the initial period there is no new entry; certain transacting agents exit every period, so the market size dwindles over time). The analysis has been performed with discounting (where $\delta$ is the common discount factor that is thought of as being near 1) or without it: in both cases the idea is to describe frictionless or almost frictionless conditions (for example, Muthoo, 1993, considers several frictions and the outcomes that result when some, but not all, of them are removed).

The first models were introduced by Diamond and Maskin (1979), Diamond (1981), and Mortensen (1982), and they used the Nash solution to solve each bilateral bargaining encounter. Later each pairwise meeting has been modelled by adopting a procedure from the strategic theory.

The most general results in this area are provided by Gale (1986a; 1986b; 1986c; 1987). First, in a partial equilibrium set-up, a market for an indivisible good is analysed in Gale (1987), under both steady state and non-steady-state assumptions. The result is that all equilibrium outcomes yield trade at the competitive price when discounting is small: in all equilibria trade tends to take place at only one price, and that price must be the competitive price because it is the one that maximizes each trader's expected surplus. This generalizes a result of Binmore and Herrero (1988) and clarifies an earlier claim made by Rubinstein and Wolinsky (1985). Rubinstein and Wolinsky analysed the market in steady state and claimed that the market outcome was different from the competitive one. Their claim is justified if one...
measures the sets of traders in terms of the stocks present in the market, but Gale (1987) argues convincingly that, given the steady state imposed on the solution concept, it is the flow of agents into the market every period, not the total stock, that should comprise the relevant demand and supply curves. When this is taken into account, all prices are competitive because the measure of transacting sellers is the same as that of the transacting buyers.

In a more general model, Gale (1986a; 1986b; 1986c) studies an exchange economy with an arbitrary number of divisible goods. Now there is no discounting and agents can trade in as many periods as they wish before they leave the market place. Only after an agent rejects a proposal can he leave the market. Under a number of technical assumptions, Gale shows once again that all the equilibrium outcomes of his game are Walrasian:

Theorem 4: At every market equilibrium, each agent leaves the market with the bundle $x_k$ with probability 1, where the list of such bundles is a Walrasian allocation of the economy.

Different versions of this result are proved in Gale (1986a; 1986c) and in Osborne and Rubinstein (1990). Also, Kunimoto and Serrano (2004) obtain the same result under substantially weaker assumptions on the economy, thereby emphasizing the robustness of the connection between the market equilibria of this decentralized exchange game and the Walrasian allocations of the economy. There are two key steps in this argument: first, one establishes that, since pairs are trading, pairwise efficiency obtains, which under some conditions leads to Pareto efficiency; and second, the equilibrium strategies imply budget balance so that each agent cannot end up with a bundle that is worth more than his initial endowment (given prices supporting the equilibrium allocation, already known to be efficient).

Dagan, Serrano and Volij (2000) also show a Walrasian result, but in their game the trading groups are coalitions of any finite size: in their proof, the force of the core equivalence theorem is exploited. One final comment is pertinent at this point. Some authors (for example, Gale, 2000) question the use of coalitions of any finite size in the trading procedure because the ‘large’ size of some of those groups seems to clash with the ‘decentralized’ spirit of these mechanisms. On the other hand, one can also argue that for the procedure to allow trade only in pairs, some market authority must be keeping track of this, making sure that coalitions of at least three agents are ‘illegal’. Both trading technologies capture appealing aspects of decentralization, depending on the circumstances, and the finding is that either one yields a robust connection with the teachings of general equilibrium theory in frictionless environments. This is one more instance of the celebrated equivalence principle: in models involving a large number of agents, game theoretic predictions tend to converge, under some conditions, to the set of competitive allocations.

Large markets under incomplete information

If the asymmetric information is of the private values type, the same equivalence result is obtained between equilibria of matching and bargaining models and Walrasian allocations. This message is found, for example, in Rustichini, Satterthwaite and Williams (1994), Gale (1987) and Serrano (2002). In the latter model, for instance, some non-Walrasian outcomes are still found in equilibrium, but they can be explained by features of the trading procedure that one could consider as frictions, such as a finite set of prices and finite sets of traders’ types.

The result is quite different when asymmetric information goes beyond private values. For example,
Wolinsky (1990) studies a market with pairwise meetings in which there is uncertainty regarding the true state of the world (which determines the true quality of the good being traded). Some traders know the state, while others do not, and there are uninformed traders among buyers and sellers (two-sided asymmetric information). The analysis is performed in steady state. To learn the true state, uninformed traders sample agents of the opposite side of the market. However, each additional meeting is costly due to discounting. The relevant question is whether information will be transmitted from the informed to the uninformed when discounting is removed. Wolinsky's answer is in the negative: as the discount factor $\delta \to 1$, a non-negligible fraction of uninformed traders transacts at a price that is not ex post individually rational. It follows that the equilibrium outcomes do not approximate those given by a fully revealing rational expectations equilibrium (REE). The reason for this result is that, while as $\delta \to 1$ sampling becomes cheaper and therefore each uninformed trader samples more agents, this is true on both sides, so that uninformed traders end up trying to learn from agents that are just as uninformed as they are. Serrano and Yosha (1993) overturn this result when asymmetric information is one-sided: in this case, although the noise force behind Wolinsky's result is not operative because of the absence of uninformed traders on one side, there is a negative force that works against learning, which is that misrepresenting information becomes cheaper for informed traders as $\delta \to 1$. The analysis in Serrano and Yosha's paper shows that, under steady state restrictions, the learning force is more powerful than the misrepresentation one, and convergence to REE is attained. Finally, Blouin and Serrano (2001) perform the analysis without the strong steady-state assumption, and show that with both information structures (one-sided and two-sided asymmetries) the result is negative: Wolinsky's noise force in the two-sided case continues to be crucial, while misrepresentation becomes very powerful in the one-sided model because of the lack of fresh uninformed traders. In these models, agents have no access to aggregate market signals; information is heavily restricted because agents observe only their own private history. It would be interesting to analyse other procedures where information may flow more easily.

Barone was born in Naples on 22 December 1859 and died in Rome on 14 May 1924. His education provided him with a solid grounding in the classics and in mathematics, with a view to embarking on a military career. He was appointed in 1894 to the Officers’ Training School, where he was ‘teacher in charge of military history’. He remained in this position until 1902, when he became the head of the historical office of the General Staff, and was given the rank of colonel.

He resigned in 1906, having already published an excellent series of biographical and historical military studies which altered the traditional concept of historical study in that field, by applying to it a method of successive approximation to which his growing interest in economics had introduced him.

His acquaintance with Maffeo Pantaleoni and Vilfredo Pareto provided him with the opportunity of collaborating with the Giornale degli Economisti. This association proved to be extremely valuable and productive and was to last from 1894 right up to the year of his death. It was in this periodical that in September/October 1908 he published the article ‘Il Ministro della Produzione nello Stato Collettivista’. This article was for a long time considered to be a mere ‘curiosum’. However, after its publication in English in a volume edited by Hayek in 1935, it was destined to place its author, together with von Wieser and Pareto, alongside the founders of the pure theory of a socialist economy.

The whole discussion on collective economic planning, as it had developed since the 1920s, had ideological motivations and implications. These were totally excluded from Barone's article. The paper was, above all, a very ingenious illustration of one of Barone's deep beliefs: the usefulness of mathematical tools in clarifying questions which otherwise remain intricate and obscure. In fact it was Barone's use of equations which established the formal equivalence of the basic economic categories between a society based on private ownership in perfectly competitive conditions and a socialist society,
Barone, Enrico (1859–1924) : The New Palgrave Dictionary of Economics

in which the distinct need to establish the relative distribution of income was recognized. As Samuelson writes, the innovative meaning of Barone's contribution was that 'by avoiding all mention of utility and indeed without introducing even the notion of indifference curves, Barone was able to break new ground along lines which have in recent years become associated with the economic theory of index numbers'. The importance of Barone's arguments in the 1930s debate on the economics of socialism in which he used the idea of a Pareto optimum and improved its application, was also not fully appreciated. It remained for Samuelson's Foundations of Economic Analysis (1948) to give a complete acknowledgement of Barone's development (adding different products after they have been weighted by their respective prices through a process of tâtonnement) of the Paretoian optimum conditions as they relate to the planning of production under collectivism.

In addition to his connections with the economists already mentioned, Barone was acquainted with the famous academics of the time, both Italian and foreign (in particular, Walras) and they all in various ways underlined the enormous potential of Barone's intellect, his clever use of analytical tools, and the extreme clarity of his graphics. Walras, for example, wrote to him saying that

Providence has singled you out to write the historical review of the various attempts made at mathematical economics over the last centuries, which promise to offer a doctrine which will become generally accepted in the next century. I strongly urge you to recognize this as your vocation and I hope that circumstances will allow you to undertake the task.

Alongside this appreciation, however, is the impression that Barone was overstretching his interests, a feeling which was stated in no uncertain terms by Luigi Einaudi: ‘Because of the various vicissitudes of a life torn between activity, journalism, learning and the cinema … Barone, who was not inclined to laborious and painstaking research, produced far fewer fruits than his supporters had anticipated.’ The comment on the cinema refers to the fact that Barone, pressed by financial necessity and using his historical and military background, prepared treatments for the booming early Italian film industry. This division of interests delayed until 1910 Barone's appointment to a chair in political economy at the Advanced Institute of Economics and Commerce in Rome, which later became the Faculty of Economics and Commerce. But with hindsight it cannot be said that Barone's admirers were justified in ‘asking for more’. It is nearer the truth to say that he had not taken the trouble to put together his often very original and therefore extremely important papers on various subjects. As often happens, however, the very fact that his work on the pure theory of socialism received so much international acclaim was the cause for inadequate recognition of his other notable contributions. Of these, the much revised Principi di Economia Politica (1908) was an excellent textbook, which, together with the booklet Moneta e Risparmio (1920), indicated that dynamic market forces constituted the main area of his intellectual interest. See also his works entitled Economia coloniale (1912), ‘I Costi Connessi e l'Economia dei Trasporti’ (1921), and ‘Sindacati (Cartelli e Trust’) (1921). Of comparable importance are Barone's investigations in the field of financial studies, demonstrating an approach different from that of De Viti de Marco and Einaudi. Barone assumed an autonomous position in as much as he availed himself of Pareto's contributions on the stability of the distribution of incomes, using it as the basis of the distribution of taxes amongst the members of the community. There have been numerous criticisms of the statistical foundation of the Paretoian income curve, and even Barone admitted that its shape could
undergo change according to variations in social composition. Nevertheless, using its formulation, he provided an inductive basis for the study of a central issue in public finance. Barone's other research of recognized theoretical relevance was on the adverse welfare effects of indirect taxes on taxpayers as compared with direct taxes, for the same given tax returns. Barone was also a severe critic of the alternative versions of the financial theories of savings, in particular that of Edgeworth on minimum saving.

Although Barone was at the centre of the major theoretical debates of his time, he suffered from a conflicting loyalty to the two main formulators of general equilibrium theory, Walras and Pareto. Having been one of the first to grasp the logical aspects of general equilibrium theory, Barone was able to suggest ideas which Walras used to improve his formulation of the production function and the theory of distribution. When Pareto criticized the Walrasian formulation, Barone refrained from taking sides between the two exponents of general equilibrium theory, and as a result Walras refused to recognize the suggestions Barone had given him. Barone himself confided to Wicksell that much of his work had aimed at ‘bringing peace’ between the two great antagonists. He considered their ‘heated disputes’ to be ‘utterly and completely’ deplorable. In spite of this show of fidelity, Barone should not be thought of merely as a follower of Walras and Pareto. As Gustavo del Vecchio, an excellent judge of both Italian and international economic thought, observed,

Barone understood the deep systematic and critical significance of general equilibrium theory, but because he had been brought up on philosophy and history, he was able to fully appreciate how great were the writers who followed the partial approach, of whom Marshall was pre-eminent. For them, economic science existed only where it could be related to concrete and immediate reality by means of our instruments of observation.

Abstract

The precise definition of barriers to entry is controversial; different versions have been proposed over the years. The issue is not one of pure semantics, since evidence of barriers to entry plays an important role in merger review and other areas of antitrust policy. One definition that seems to reflect current thought and practice is as follows: barriers to entry are structural, institutional and behavioural conditions that allow established firms to earn economic profits for a significant length of time.

Keywords

absolute cost advantage; antitrust; asymmetric information; barriers to entry; collusion; contracts as barriers to entry; excess capacity; game theory; limit pricing; merger analysis; oligopolistic competition; patents; predatory pricing; product differentiation; scale economies; sunk costs

Article

Scholars usually debate theories, proofs, frameworks and the like. Rarely does controversy arise over a definition, as it does in the case of ‘barriers entry’. Economists tend to agree on the relevant issues, for example, what the market outcome is given a set of assumptions regarding costs, demand, and the nature of competition. So why so much argument over a definition? One answer is that words and definitions play an important role in antitrust analysis. For example, the Federal Trade Commission and U.S. Department of Justice's Antitrust Guidelines for Collaborations Among Competitors (2000) suggests that evidence of substantial barriers to entry leads to closer scrutiny of the practice being challenged. Entry conditions play a similar role in other areas of antitrust policy (for example, merger analysis) in the United States, the European Union and other parts of the world. So, like it or not, we must address the issue of what barriers to entry are.

Bain (1956) defined an entry barrier as the set of technology or product conditions that allow incumbent firms to earn economic profits in the long run. Bain identified three sets of conditions: economies of
barriers to entry: The New Palgrave Dictionary of Economics

scale, product differentiation, and absolute cost advantages of established firms. Stigler (1968) criticized this approach, especially the idea of scale economies as a barrier to entry. He offered an alternative definition: a production cost that must be borne by an entrant but not by an incumbent. Both of these approaches are incomplete, as a simple example will show. I will consider a series of different markets with the same structural conditions: a demand $D(p)$ and a technology that consists of a fixed cost $F$ and zero variable costs. In market A, potential entrants sequentially decide whether to pay $F$, which is sunk; and then active firms compete à la Bertrand. Market B is like market A, but entrants collude at the monopoly price. Market C differs from market A in that potential entrants simultaneously decide whether to pay the fixed cost $F$, and moreover $F$ is committed only for a short period of time. Finally, in market D potential entrants first simultaneously commit to their price level for a given short period, and then decide whether to pay the fixed cost $F$, to which they are committed during the same period as they are committed to price.

All of these scenarios feature the same structural conditions, and so the Bain and Stigler tests would yield the same answer. Under the Bain approach, there would be barriers to entry, namely, the scale economies implied by the fixed-cost technology. Under the Stigler definition, there would be no barriers to entry, since all firms face the same cost conditions. But both approaches would miss the substantial differences between the various markets. In market A, the equilibrium is for the first potential entrant to become a monopolist. In market B, firms will enter to the point where each firm makes zero profits (I am ignoring here the integer constraint). In market C there are multiple Nash equilibria. A reasonable equilibrium is for firms to enter with a probability such that their expected profit is zero. However, with positive probability the outcome of this equilibrium is for one firm to be a monopolist, just as in market A. Finally, in market D the equilibrium is for one firm to enter with a price equal to average cost.

The above example, while simplistic, shows the importance of looking beyond costs and demand to include behavioural conditions. What is the timing of moves – that is, what are firms committed to and for how long? The toughness of oligopolistic competition, one of the key differences across the cases in the above example, is largely the result of the assumed timing of moves. The length of time over which costs are committed (how sunk costs are) is also a crucial factor. In fact, the issue of time reveals an additional limitation of the Bain approach, with its emphasis on the long-run equilibrium. What use is it to know that the long-run equilibrium is a symmetric duopoly if it takes years for an entrant to catch up with an established firm?

If we take these considerations into account, and bear in mind the practical antitrust use of the concept of barriers to entry, a reasonable definition seems to be: the set of structural, institutional and behavioural conditions that allow incumbent firms to earn economic profits for a significant length of time. Admittedly, this is a fairly general definition, but necessarily so: the problem with other definitions is that, in attempting to be more specific, they become incomplete and potentially misleading.

**Strategic entry deterrence**

In the analysis of entry conditions and barriers to entry, a greater emphasis was initially placed on structural (or exogenous) entry conditions, such as economies of scale or incumbent cost advantages. The game theory ‘revolution’ of the 1970s and 1980s, however, shifted the focus to firm behaviour. This led to a coherent story of why structural conditions may turn into barriers to entry. Consider, for example, market A in the above example. If two firms imply zero prices, as the Bertrand assumption and
zero variable costs imply, then the equilibrium outcome is for one firm to enter and set a monopoly price, no matter how low $F$ is. However, if price competition is not vigorous (market B), then no matter how high $F$ is incumbent firms never earn economic profits. More generally, it's the combination of entry cost levels, the irreversibility assumption and the oligopolistic competition assumption that, together, lead to a barrier to entry.

Once the game theory apparatus was developed, the number of applications blossomed, frequently with particular models formalizing particular instances of entry barriers endogenously created by incumbents. So in the 1970s DuPont increased its capacity in the titanium dioxide industry as a way to preempt entry or expansion by rival firms. From the 1950s to the 1970s, established firms in the ready-to-eat breakfast cereal industry rapidly increased the number of brands they offered, possibly as an entry pre-emption strategy. In the late 1960s and early 1970s, Xerox developed hundreds of patents that it never used (‘sleeping patents’), their purpose being allegedly to make it more difficult for an entrant to challenge its plain-paper photocopy monopoly. Before the expiry of its patent on aspartame, Monsanto signed exclusive contracts with its major customers of Nutrasweet (Coke and Pepsi), effectively reducing the residual demand to a potential entrant. And so on.

Gilbert (1989) provides an excellent, if slightly dated, survey of the game-theoretic work in this area. What is common to all of these examples of strategic entry deterrence is a prior action by incumbents that decreases the probability of subsequent entry. This may result from an increase in entry costs (Xerox's sleeping patents, Nutrasweet's contracts) or a decrease in the entrant's post-entry profits (Dupont's excess capacity, excess number of cereal brands). In fact, it suffices that the entrant's beliefs regarding costs and profits shift in the appropriate direction, even if there is no direct effect. In a world of asymmetric information, a low price by the incumbent may be interpreted as an absolute cost advantage and thus discourage entry; and repeated aggressive reaction to past entry episodes may increase the expectation of aggressive reaction to future entry. So the strategies of limit pricing or predatory pricing may also create barriers to entry.

Conclusion

The game theory revolution had the benefit of revealing the rich interaction between structural conditions and behavioural conditions. But it also complicated the task of deriving a simple, general definition of barriers to entry. In other parts of the field of industrial organization, the reaction to the ‘embarrassment of riches’ created by game theory has been to focus on particular industries. I believe a similar approach must be taken with respect to the concept of barriers to entry and its application.

barter in transition

Barry W. Ickes
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

One of the striking features of the transition in Russia was the enormous growth in the use of barter and other non-monetary means of payment. The transition from command initially led to a monetization of the economy, but a subsequent re-demonetization was a surprise. Barter was a passing phase in most transition economies but became endemic in Russia. Barter proliferated as inflation was tamed and reached its zenith prior to the August 1998 financial crisis. Various theories of why barter exploded in Russia are discussed and empirical findings are assessed.

Keywords

arrears; barter; barter in transition; contract enforcement; credit rationing; double coincidence of wants; hold-up problem; inflation; institutional trap; liquidity constraints; market power; multilateral barter; natural monopoly; price discrimination; relational capital; tax evasion; tax offsets; trust; virtual economy.

Article

One of the striking features of the transition in Russia was the enormous growth in the use of barter and other non-monetary means of payment. In addition to conventional barter – goods exchanged for goods – non-monetary transactions were also prevalent in this period. These involved non-monetary IOUs, veksels, which were claims on goods from other enterprises or offsets on future taxes. (The literature often treats these as equivalent, and indeed, they do arise from similar causes, but the nature of the transactions is clearly distinct.) What was a passing phase of transition in Central Europe became, by 1997, an endemic feature of the Russian situation. The explosion in barter culminated in the August 1998 Russia crisis, and since then the importance of barter has declined.

The growth in the use of barter has been characterized as ‘re-demonetization’ (Ickes, Murrell and Ryterman, 1997). The Soviet economy (with the partial exception of the household sector) was essentially a non-monetary economy. Central planners’ decisions, not purchasing power, determined the
production and allocation of goods and services. Money was mainly a record-keeping instrument. A main objective of economic reform was to transform the economy from a partially demonetized planned economy to a monetized market economy. Hence the growth in barter represented a return to a non-monetary economy, or a re-demonetization. By 1997 barter accounted for nearly half of all enterprise transactions: see Aukutsionek (1998), Commander and Mummsen (2000) and Noguera and Linz (2006).

Not only was barter used in payments between enterprises (estimates of the share of barter in inter-enterprise transactions ranged from 30 per cent to 80 per cent) but it was also widely used in paying taxes to local, regional, and even federal governments. Even wages were occasionally paid in kind.

The emergence of barter in Russia in the mid-1990s presents a challenge to economic theory. Textbook analysis suggests that barter is inferior to monetary exchange. Barter requires a double coincidence of wants and hence is more costly than monetary transactions. Moreover, in Russia barter exploded as inflation was declining. Hence, the growth of barter was not the result of a flight from money as its store-of-value services declined. Indeed, one indication of this is the fact that this explosion in barter was almost exclusively within the enterprise and budget sectors of the economy. Households were typically involved only to the extent they received wages in kind. This suggests that the growth of barter had something to do with what was happening to enterprises.

Explanations of the prevalence of barter in Russia and other transition economies tend to divide into two types. One group of explanations focuses on circumstances external to the firm and views barter as an involuntary decision. The other group of explanations views the use of barter as a strategic decision by the enterprise to reduce its costs or increase its profitability (survivability).

**Barter as a passive response**

A leading argument of the passive theory views barter as the result of a lack of liquidity. Enterprises engage in barter because they simply lack the cash to use money. This could be due to underdeveloped financial systems (Hendley, Ickes and Ryterman, 1998) or to the effects of macroeconomic tightening (Commander and Mummsen, 2000; Noguera and Linz, 2006). In either case, the premise is that barter will only be used by enterprises that cannot afford to pay with cash; that is, barter is the result of a liquidity constraint. Hence, as argued in Woodruff (1999), barter is an instrument for cutting prices to enterprises that cannot pay the nominal price for inputs using money. Barter thus allows production to continue for those enterprises that are liquidity constrained. Barter is thus an instrument used to price discriminate. Models with this feature are developed by Ericson and Ickes (2001) and Guriev and Kvasov (2004). The liquidity explanation of barter has the advantage of getting the timing right: barter began to increase as real interest rates rose in response to the switch in policy from monetization to borrowing to finance fiscal deficits. Most of the empirical support for the theory, however, comes from survey responses of directors who state that they accept barter because their customers lack liquidity. That is, the information on the buyers’ lack of liquidity stems from surveys of sellers. A problem with this evidence, however, is that, if it is advantageous to the buyer to pay with goods rather than with money, then buyers will act strategically. That is, they will pretend to be liquidity constrained when they may not be, in order to qualify for barter. What sellers observe is the financial condition that the buyers want the sellers to believe. Hence, the liquidity of an enterprise may be endogenous. If enterprises act strategically, then the seller's information may not be the most accurate indicator of the liquidity position.
of the buyer.

Some empirical evidence that casts doubt on the liquidity hypothesis comes from a study by Guriev and Ickes (2000) that avoids the problem of uninformed sellers and strategic buyers. To get around the problem of strategic signalling, Guriev and Ickes matched data on the proportions of revenues in cash and non-cash form taken from a survey of directors with the Goskomstat database of Russian enterprises, which contains the financial accounts of all large and medium-size industrial enterprises in Russia. This allowed them to compare the share of non-cash payments with the enterprise's financial position. They could find no discernible relationship between the use of barter and the financial condition of the enterprise. The only explanatory variable they found that predicted barter was share of export sales. (This also, perhaps, explains why barter fell dramatically when the ruble depreciated and exports increased.) Most interestingly, they found that the best predictor of whether an enterprise would use barter was lagged barter. This suggests that barter was an institutional trap. Once non-cash payments became a widespread phenomenon, it became part of the strategies of all agents. As barter proliferated it became a ‘normal’ way of doing business.

**Barter as a choice**

The notion that barter is a choice that an enterprise makes presumes that it results in a lowering of its net costs of production or an increase in its net revenues. Employing barter clearly increases the costs of transactions, so it must have some other offsetting benefits. For example, it may afford the buyer the opportunity to pay an effectively lower price, or it may enable enterprises to avoid taxation or reduce the cost of paying taxes. This still begs the question of why the seller is willing to accept lower-priced goods. Presumably, the key reason is the ability to pass these off for payment in taxes. This begs the further question of why governments are willing to allow tax offsets. The prevalence of tax offsets, especially at the regional level, is an accepted fact. But the motivation is more complex. (See Gaddy and Ickes, 2002 for a discussion.) Barter may also be used as a means of hiding revenues and avoiding restructuring (see virtual economy).

If we suppose that the effective price of purchasing inputs is cheaper using barter, it follows that enterprises will prefer to pay with barter than with money. There must be some way for sellers to limit the use of barter. One method would be to limit barter to enterprises with which there are good relations (see virtual economy for a discussion of relational capital and its importance in the Russian economy). Indeed, as it may be more difficult to enforce contracts using barter, a high level of relational capital or trust may be needed to enable barter to occur. An alternative method is price discrimination by those with market power.

**Barter and tax evasion**

One reason why enterprises may prefer to use barter is that it reduces the effective burden of taxation. In Russia, the traditional banking system served as a key part of the tax collection system. An enterprise in tax arrears would have its bank account blocked, and all receipts would go directly to the tax service. Such an enterprise thus faced 100 per cent marginal tax rates on revenues paid with money. Monetary transactions between enterprises in Russia were required by law to operate through the banking system.
Cash withdrawals could only be made for payment of wages and other incidental uses. Using barter allowed a seller in tax arrears to receive payment and circumvent the tax authorities. Hence, for such enterprises sufficient surplus would be generated by barter to offset the costs. Evidence on the role of tax evasion as a motivation for barter is mixed. Some studies (for example, Hendley, Ickes and Ryterman, 1998) find survey evidence in favour of the tax-evasion hypothesis, while others do not (for example, Commander and Mummsen, 2000). But in most cases these studies focus the question too narrowly. They typically ask whether enterprises use barter to evade taxes. A more appropriate question would ask whether enterprises use barter to reduce the effective tax burden. Enterprises often use barter not to evade taxes but in order to pay taxes, only in a way advantageous to the enterprise. This is the practice of tax offsets.

The practice of using tax offsets as a means of reducing tax incidence became widespread prior to the 1998 crisis and was a key feature of the virtual economy (see virtual economy). Consider, for example, an enterprise that is able to supply the local government with services in lieu of taxes. The enterprise could pay its tax liability in money, but this would require selling its output for cash. Alternatively, the enterprise can negotiate with the government to supply some service as an offset for taxes. If the enterprise has resources that are not fully utilized, the latter alternative is likely to reduce the effective tax burden on the enterprise. Gaddy and Ickes (2002) provide an abundance of examples of the use of tax offsets.

Any comprehensive theory of barter in Russia in the 1990s must also explain one particularly vexing question: why governments are willing to accept tax payments in kind. It is easy to understand why enterprises would want to pay taxes in kind: this lowers the burden of their payments. It is harder to understand why governments would be willing to accept in-kind payments of taxes.

One explanation for the government's willingness to participate in barter is the virtual economy thesis. The proliferation of tax offsets is a mechanism for the distribution of subsidies in a non-transparent manner. Although more costly than a cash distribution of subsidies, non-transparency provides a more durable means of providing subsidies. They are less likely to be attacked as wasteful. This is especially true when subsidies are distributed through production, by keeping open enterprises that ought to be shut down. Thus it may be in the interest of government officials to keep subsidies non-transparent (see virtual economy).

**Multilateral barter**

A key problem with barter is the difficulty in finding a double coincidence of wants. It is thus interesting that in Russia multilateral barter chains appeared. Barter was often not bilateral, but part of a chain (see Humphrey, 2000). As one report described it:

> The barter chain itself turned out to be a special kind of consumer of the output. But its needs differed from the needs of liquid demand. The barter chains frequently reminded one of the ‘production for production's sake’ of the [Soviet] planned economy, when a quasi-cooperation gave rise to closed autonomous systems that served only themselves. In a number of enterprises which we surveyed, the share of output necessary simply to support the viability of the chain itself was as high as 30 per cent. (Institute of the
Thus enterprises engaged in production of goods that were useful for maintaining the barter chain. The network character of barter also means that a web of relationships is crucial to maintaining it. This implies that barter was a conservative force, preserving relationships among enterprises.

Barter and market power

A robust finding among students of barter in Russia is that the large natural monopolies (Gazprom, UES, and the State Railways system, *tri tolstayaka*, ‘The Three Fat Boys’) were heavily involved with barter. This suggests that price discrimination may be a motive for barter. Guriev and Kvasov (2004) develop a model where firms can choose to pay in cash or in barter, and natural monopolies use barter to engage in price discrimination across customers. Unlike the model of Ericson and Ickes (2001) the Guriev–Kvasov model does not require the natural monopolies to receive any benefit from the government in exchange for the lower prices it charges to low-profitability purchasers. Rather, barter simply facilitates price discrimination and is thus profitable for monopolists. Barter allows enterprises with market power to extract higher prices from those that can afford to pay more. Of course, such discrimination can only occur if markets are not competitive.

Guriev and Ickes (2000) tested the predictions of this model and found that the use of barter increases with concentration. Industries where market concentration is very low display lower prevalence of barter than in other industries. Similarly, larger enterprises that operate in concentrated industries (and do not sell to foreign markets) are much more likely to engage in barter. Similar findings with respect to Russia (but not to Central Europe) were found in an EBRD study (Carlin et al., pp. 247–8).

Barter and efficiency

As barter is costly it is often assumed that the welfare effects of widespread barter are negative. Barter is typically viewed as a means of avoiding restructuring. An enterprise that successfully restructures may be unable to credibly signal that it is in distress, and thus it may be forced to use cash instead of barter. Ericson and Ickes (2001) developed a general equilibrium model where a restructuring trap exists: enterprises refuse to restructure because they are afraid of losing the benefits of cheap energy supplied via barter. Indeed, a form of this mechanism is at work in most price discrimination models of barter (for example, Guriev and Kvasov). Guriev and Ickes (2000) found empirical support for this hypothesis: in their sample an increase in the share of barter resulted in a decrease in labour productivity.

If barter is the result of liquidity problems external to the enterprise then access to this technology can be welfare enhancing (Noguera and Linz, 2006). The basic idea is that in a credit-rationing equilibrium higher interest rates do not provide access to capital; so cash-poor firms that have no access to barter may have to reduce production when real interest rates rise due to crowding out. With access to barter, however, they can maintain production. Of course, to evaluate the welfare consequences one must examine why the enterprises are cash poor in the first place. If this is purely external to the firm then higher production is welfare improving. If the reason they are cash poor is that they produce goods that
It has also been argued that barter enhances efficiency in an environment of weak contract enforcement. Marin, Kaufmann and Gorochowskiiy (2000) argue that barter creates ‘deal-specific collateral’. They argue that this alleviates the hold-up problem that appears when credit enforcement is prohibitively costly. In such environments transactions that are mutually beneficial take place via barter but would not take place if cash were required. They argue that barter ‘is a self-enforcing arrangement which makes intermediate producers along the chain of production lose from reneging on the contract’ (2000, p. 222). The main difficulty with this theory, however, is to understand how barter creates deal-specific collateral. Presumably, an enterprise can always pledge collateral, and a promise to trade the good to a supplier to is no more credible than a promise to deliver the good if a loan cannot be repaid. The key point is that relational capital among enterprises supports barter, but barter itself does not create relational capital (see Gaddy and Ickes, 2002). The agreement between a buyer and a seller to engage in barter does not preclude the buyer from defecting anymore than a pledge of collateral to a supplier would. Thus, it is not easy to see how barter enhances transactions possibilities (though one can see how this might work with veksels: see below).

**Veksels**

As barter is costly, Russian enterprises developed an alternative institution, the use of non-monetary IOUs, or veksels. These were claims on output or offsets of future taxes, and their use proliferated prior to the August 1998 crisis. These promissory notes, issued by commercial banks, governments and enterprises, serve as an alternative medium of exchange. The use of veksels has become widespread: by one estimate the outstanding stock of these instruments had grown by the spring of 1997 to be roughly two-thirds of the value of all rubles in circulation (ruble M2) (OECD, 1997, p. 178). Enterprise veksels are issued by large established firms (for example, Gazprom, UES). These notes circulate among chains of enterprises that owe goods to the issuer. Eventually the note is redeemed by some customer of the issuer. Veksels had two important characteristics that were similar to conventional barter. First, by operating out of the normal channels of the banking system they enabled enterprises to avoid taxation. Second, the use of veksels had the effect of keeping enterprises as part of a chain of production. The value of a veksel would be much lower outside the chain; hence, they had the effect of keeping enterprises from defecting. A veksel, for example, would be issued by a bank to support transactions among suppliers in a chain of production. If one of the suppliers chose not to produce the inputs but defect with the credit the discount on the paper may be quite large. If the credit had been issued in cash, on the other hand, it would be much easier to defect from the production chain. Hence, veksels may have served as a means of preserving production relations and extending credit with weak contract enforcement possibilities (Hendley, Ickes and Ryterman, 1998).

**Consequences of barter**

Barter raises the private costs of transactions for those engaged in it. Barter becomes prevalent when the institutional and macroeconomic environment is such that it is profitable for enterprises to bear these
costs. Hence, it is not barter per se, but the institutional and environmental constraints that generate it that are the problem. The fact that barter locks enterprises into a chain of production and inhibits restructuring is costly to the economy. But it is not the barter that is the cause of the problem, but rather a result of the peculiar economic conditions that make such an equilibrium sustainable.

After the Russian crisis, as the ruble depreciated in real terms and oil prices recovered, the barter equilibrium seems to have broken down. Cash transactions became less costly than they were prior to the crisis. Enhanced government revenues, due to tax reforms and export revenues, led to a decline in tax offsets. Hence, the relative cost of barter increased. The economy re-monetized. Whether barter will return if economic conditions return to their mid-1990s setting is an open question.

**How to cite this article**

Barter is a simultaneous exchange of commodities, whether goods or labour services, with bargaining and without using money. It is thus a form of trade in which credit is absent or weak, where buyers and sellers compete and rates are not fixed, and which lacks an abstract measure of value in exchange or payment.

There is no economy known to ethnographers in which barter is the only means of exchange; but there are some in which it is dominant (for example, Humphrey, 1985); and many marginal areas where barter plays a significant role alongside varieties of primitive trade and money transactions. Moreover barter is a major component of international trade, especially between east and west; it is an indispensable business tool of many modern corporations; and, with the rise of computerized exchange in the USA, it has begun to worry the Internal Revenue Service.

None of these contemporary examples, however, captures the interest of economists in barter. For it is as a central plank in the origin myth of classical and neoclassical economics that barter owes its prominence in modern thought. Adam Smith traced the ‘wealth of nations’ to division of labour:

> This division of labour, from which so many advantages are derived, is not originally the effect of any human wisdom! It is the necessary, though very slow and gradual, consequence of a certain propensity in human nature which has in view no such extensive utility; the propensity to truck, barter and exchange one thing for another. (Smith, 1776, I. ii, p. 13)

Linking this propensity to the faculties of reason and speech, Smith draws a line between ourselves and the animals: ‘Nobody ever saw a dog make a fair and deliberate exchange of one bone for another with another dog’ (1776, I. ii, p. 13). Given such a predisposition, mankind took advantage of differences in
geography and skill to establish interdependence through primitive barter. Eventually the difficulties inherent in barter led to the emergence of certain commodities as normal means of exchange and eventually to money proper. Barter, as an expression of a natural human tendency, is thus the forerunner of modern markets based on money. It follows that these markets should be allowed to be self-regulating and spared the interventions of political agents claiming to possess superior ‘wisdom’.

The founders of marginalist economics (Menger, Jevons) likewise traced the origins of money to the inefficiency of an earlier stage of barter. Most modern writers on money follow their example. In this they all echo a tradition first established by Plato and Aristotle. The Greek philosophers, however, imagined that, for money to come to express proportionate needs in a complementary division of labour, law rather than nature was required. To sum up the standard economists’ myth, a natural propensity to exchange led human beings to establish a division of labour articulated by individualized barter in local markets; eventually long-distance trade evolved and with it more efficient markets based on money. The absence of a guiding political agency is an important feature of this story.

The most elegant refutation of such a construct is made by Polanyi in *The Great Transformation* (1944). He suggests that a more plausible historical sequence is the reverse of the above. Starting from a geographically based division of labour, highly placed political agents trade goods over long distances and routinize means of payment in a process leading to the establishment of money. Local markets are sometimes a spinoff of these channels of *grand commerce*, ‘thus eventually, but no means necessarily, offering to some individuals an occasion to indulge in their alleged propensity for bargaining and haggling’ (Polanyi, 1944, p. 58). Clearly, evolutionary parables should be treated with caution, especially when they fall under one pole or the other of an ideological struggle between liberalism and socialism. Barter is invariably found in an economic context marked by several institutions of exchange. What matters is to identify its structural features in juxtaposition with alternative mechanisms. In the following discussion the evidence for barter in primitive or backward economies will be reviewed, before turning briefly to its revival in capitalist economies. The principal conclusion is that an understanding of barter requires a synthetic approach combining politics and markets.

Grierson’s classic article on the silent trade (1903) is a compilation of evidence for barter without face-to-face contact which captures the early fascination of armchair anthropology with the subject. The first modern fieldwork monograph in anthropology was also devoted to institutions of exchange. In *Argonauts of the Western Pacific* (1922), Malinowski set out to challenge what he took to be prevailing models of ‘economic man’. His focus was the *kula*, a system of gift-exchange in the islands near New Guinea, involving armshells and necklaces. Under the cover of such an exchange between local leaders, the common people bartered for goods whose uneven distribution owed much to a geographically based division of labour. In addition maritime and inland villages exchanged fish for vegetables, sometimes through a formal rationing system organized by community leaders, sometimes through individual barter. Malinowski emphasized the contrast of styles and status honour between ceremonial exchange and ordinary barter, although in the first case cited they were spatially united and in the second were institutional alternatives. The Melanesians were as anxious as the ethnographer to stress their absolute antipathy to confusion of the two extreme forms of exchange. Gift-giving was formal, characterized by generosity and delay of a return (implying credit and trust); barter was informal, characterized by conflict in bargaining and immediacy of return (implying no projection of the relationship into the future). One conferred high social standing, the other low status. In practice, ceremonial exchange is a means of establishing a fragile political order for trade through a transfer of tokens of alliance between
leaders whose communities are on a footing akin to war, whereas individual barter and the appearance of hostility intrinsic to price negotiations can only be tolerated in a situation marked by peace and stable social order. Whatever the imputed social psychology, ceremonial exchange is a direct political intervention in the market, barter a manifestation of relatively free commodity exchange. Societies lacking states and money cannot rely exclusively on one form or the other. They must combine gift-exchange and barter pragmatically in response to variable degrees of ‘peace for the trade’.

More recently, Humphrey (1985) has linked barter to economic disintegration in the periphery. Her case study of a people living near the Nepal–Tibet border accounts for the dominance of barter by the low supply of money. Being very poor, they cannot afford to keep much wealth in the form of money, preferring to satisfy demand immediately in the one-to-one transactions of barter. Under these circumstances money itself becomes an item of barter. Humphrey relates this temporary phenomenon to a collapse of the local political order which has left the population in a fragmented and individuated state. They have a high level of mutual tolerance but no hierarchy through which to organize inter-local trade as they once did. There is sometimes ‘delayed barter’ involving more valuable items and the extension of credit between trading partners. But this looks like a weak version of that more formalized trade based on trust which perhaps ought not to be confused with barter. Delay in making a return and associated relations of credit/debt are antithetical to barter; for bargaining is impossible if either party does not have the option of withdrawing from the negotiation.

Recent anthropological research has focused on the tendency of bartered goods to fall into distinct ‘spheres of exchange’. In a classic article Bohannan (1955) argues that the Tiv of Nigeria prefer to exchange goods of the same broad category and look down on transactions across the boundaries between such spheres. Subsistence items are distinguished from prestige goods like cattle, slaves, metal bars and cloth. The highest level of exchange involves marriageable women only. In the colonial period money destroyed this compartmentalization of exchange by making conversion between spheres easier. Cultural disruption was the result.

This argument confuses several levels of analysis. First, as Marshall pointed out, utilities are never wholly commensurate: subsistence, luxury and prestige goods cannot be equalized simply by sharing a monetary medium of evaluation. It does not make any sense to ask how many sacks of potatoes an Eton education is worth, even though they both have a money price. Second, there are clearly problems of conversion in barter between low-bulk, high-value items and high-bulk, low-value items, typically between long-distance trade goods and small agricultural surpluses. Livestock and poultry offer one ready means of conversion, however. Again, nobody likes to sell a hi-fi set in order to pay the groceries bill, but such conversions are known to occur. Third – and most damaging – the main force restricting exchange to separate spheres is political and ideological, not economic in the technical sense. Tiv elders control commerce with the outside world and hold their junior kinsmen on the farm through a monopoly of marriageable women. Colonialism – not money as a fetishized abstraction – undermined that control by introducing markets for the young men's goods and labour.

The absence of money does not in itself present an insurmountable obstacle to efficient exchange. Much the most important precondition for barter lies in the forms of political order (or the lack of it); and it is this which is undermined by modern markets and by the states whose power is essential to their functioning. With this in mind we should consider briefly the survival of barter in the trading institutions of the advanced economies.

Much of the trade between the West and the Communist bloc took the form of barter for the obvious
reason that the East could not accumulate hard currency reserves. The end of Communism was also associated with substantial intra-country barter; see barter in transition. Third World countries, such as some West African states, barter the products of an ecological division of labour (meat for grain) owing to a general lack of cash. Such activities are similar to the early trade between political agents emphasized by Polanyi. The multinational corporations have treasuries larger than those of many nations, yet they often choose to barter commodities they would normally be unable to sell in open markets – so many thousand gallons of paint for several months’ lease of a Bahamas hotel chain.

The laissez-faire economist's myth of barter as an expression of mankind’s innate propensity to exchange ought to be replaced by a more complex historical appraisal of the institution's significance. Barter is an extremely widespread phenomenon, occurring in many times and places as a partial and often temporary solution to the problem of exchange. It is not abolished by money and indeed sometimes transforms money itself into an item of barter; and, if recent trends are a reliable indicator, it may now be undergoing a revival in the West. It was always a mistake to suppose that markets expanded without definite political conditions for their maintenance. Barter too rests on variable political conditions which are as much contemporary as they are primitive.

Barton is remembered in the history of economic thought for an early critical discussion of the impact of machinery on employment. A Sussex landowner, he combined an interest in statistical observation with a special concern for the impact of industrial and agrarian change on the condition of the labourer. He was the author of two important books, *Observations on the Circumstances which Influence the Condition of the Labouring Classes of Society* (1817) and *An Inquiry into the Causes of the Progressive Depreciation of Agricultural Labour in Modern Times* (1820). Later, in the 1830s, he wrote several tracts on the Corn Laws and on population and colonization. He was elected a fellow of the London Statistical Society in 1847 and read a paper in 1849, ‘The Influence of the Subdivision of the Soil on the Moral and Physical Well-being of the People of England and Wales’. His early manuscript essays show a wide and careful grounding in political economy based on Hume, Smith and Ricardo. His first books were, however, written as interventions in the contemporary debates on the Poor Laws. Barton's primary purpose in writing both the *Observations* and the *Inquiry* was to challenge Malthusian population theory, and the prevailing opinion that the cause of excess population and falling wages was the support offered by the Old Poor Law. Barton combined abstract reasoning with statistical data in a critique of Malthus and Ricardo that so impressed Schumpeter that he judged it ‘a remarkable performance … far above the rest of the literature that currently criticized the class leaders for their lack of realism, actual or supposed’.

Barton drew on population figures from the 16th to the 18th century to challenge Malthusian propositions of the dependence of population growth on levels of capital accumulation. Using data gathered from the agricultural districts, he also challenged assumptions of flexible supplies of labour in...
response to wage changes. His data provided no support for those who feared that population growth would follow on high wages. Custom and employment prospects, not changing wage rates, were the most important determinant of the age of marriage. Barton dissected the gap between population and labour supply, analysing age structure, apprenticeship, skills and labour immobility. His demographic work impressed Sismondi and induced McCulloch to give up Malthusianism.

The most influential analysis of the Observations, however, was Barton's critique of Ricardo's and Malthus’ early optimistic assumptions of the impact of capital accumulation and machinery on the working classes. Another reason why high wages could not be blamed for inducing population growth, he argued, was that capital accumulation did not necessarily entail increases in employment. Capital had to be disaggregated into fixed (technological) and circulating (wage goods) capital before its impact on the labour market could be assessed. The demand for labour was dependent on circulating, not fixed, capital. And if wage rates rose relative to commodity prices, employers would substitute machinery for labour. The process of capital accumulation could, therefore, entail the release of rather than the demand for labour, and the amount of labour employed in the construction and repair of new machinery would provide only small compensation.

Barton's Observations was read by political economists and policy-makers – Huskisson and Malthus noted it, Sismondi praised it and McCulloch reviewed it. It was said to have induced Ricardo to make an about-turn in the third edition of his Principles and so to write his controversial chapter on machinery accepting the idea that the introduction of machinery could hurt the interests of manual labour. But Ricardo did not introduce this change until the third edition in 1821, and his analysis was rather different. Accepting Barton's point that the introduction of machinery might be induced by wage increases, he added his own novel analysis of autonomous technical change. It is likely that Ricardo changed his views on machinery not because he read Barton but because of contemporary political concern over the machinery issue combined with a timely reminder of Barton's work in a recent correspondence he had with McCulloch.

Barton's later pamphlets and newspaper articles of the 1830s and 1840s extended his early analysis into a general critique of industrialism. He defended the Corn Laws, arguing that labour thrown out of agriculture could not be transferred easily to manufacturing, and that the extension of manufacturing and machinery only concentrated wealth in fewer hands. He drew attention to an Adam Smith forgotten by his contemporaries – the Smith who conducted a radical critique of the monopoly spirit of merchants and manufacturers. John Barton's critique of industrialism and the introduction of machinery was a striking example of a special early 19th-century combination of traditional landed opinion with a radical concern for the condition of labour.

Bastiat, Claude Frédéric (1801–1850)

R.F. Hébert

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Bastiat, C. F.; Cobden, R.; Dupuit, A.-J.-E. J.; free trade; Harmonism; service theory of value

Article

French economist and publicist, born at Bayonne on 30 June 1801, the son of a merchant in the Spanish trade; died in Italy, at Rome, on 24 December 1850. Orphaned at the age of nine, Bastiat nevertheless received an encyclopedic education before entering his uncle's business firm in 1818. By 1824 he was expressing dissatisfaction with his employment. Upon inheriting his grandfather's estate in 1825, he left business and became a gentleman farmer at Mugron, but showed no more aptitude for agriculture than he had for commerce. So he became a provincial scholar, establishing a discussion group in his village and reading voraciously. His later writings show familiarity with the works of French, British, American and Italian authors, among them Say, Smith, Quesnay, Turgot, Ricardo, Mill, Bentham, Senior, Franklin, H.C. Carey, Custodi, Donato and Scialoja.

Bastiat left France in 1840 to study in Spain and in Portugal, where he tried unsuccessfully to establish an insurance company. Returning to Mugron, he learned (in the course of seeking information for his study club) of Cobden's Anti-Corn Law League and became an ardent free-trader (the 'French Cobden'). As a complete unknown in economics, he submitted a stirring article to the Journal des économistes in 1844, dealing with the influence of protectionism on France and England. It created an immediate sensation and raised a clamour for more from the editors. This response encouraged Bastiat's Economic Sophisms, which quickly sold out upon its publication in 1845, and was soon thereafter translated into English and Italian. In 1846 Bastiat moved to Paris, where he established the Association for Free Trade and quickened his literary activity, endangering his frail health in the process. A torrent of articles, pamphlets and books now flowed from his talented pen, undoubtedly made possible in such short order by the preceding 20 years of practically uninterrupted reflection. Some scholars say the frenzy produced more heat than light, yet on the whole, economics is better off for Bastiat's Herculean efforts.

Bastiat was one of several writers (Quesnay, Smith, Say and Carey were the others) who formed the doctrine of Harmonism, or the optimistic idea that class interests naturally and inevitably coincide so as...
to promote economic development. The major challenge to this view came from Ricardo and Malthus, whose theories cast a sinister shadow over the prospect of economic progress. As against Ricardo’s system, Bastiat erected a theory of value based on the idea of service. He distinguished between utility and service, identifying the former as insufficient, of itself, to establish value, because certain free goods (sun, air, water) have utility. Bastiat considered all commercial transactions as exchanges of service, with value measured in terms of the trouble a buyer saves by making the purchase.

J.E. Cairnes complained that this merely confounded what Ricardo had sought to delineate, namely those cases in which value is proportioned to effort and sacrifice from those in which it is not. A more fundamental criticism is that Bastiat’s theory, notwithstanding denials to the contrary, is simply a labour theory in different guise. It is noteworthy, however, that Bastiat’s idea bears a close resemblance to the notion of ‘public utility’ which Dupuit applied so successfully to the measure of gain from transport improvements, and in which reduction of costs effected by the improved service became the central issue. Yet any connection between the two, tenuous as it may be, must be considered to run from Dupuit to Bastiat rather than the reverse, since Dupuit published his famous article on public works and marginal utility before Bastiat abandoned his earlier polemics in favour of more ‘constructive’ attempts at theory. Bastiat's theory of rent, also clearly aimed against Ricardo, denied the notion of unearned income, again advancing the view that the value of land (always in the absence of government interference) derives entirely from the services it renders.

Generally, judgement on Bastiat has been that he made no original contributions to economic analysis. Cairnes, Sidgwick and Böhm-Bawerk discounted his pure economics completely. Marshall said that he understood economics hardly better than the socialists against whom he declaimed. And Schumpeter declared that Bastiat was not a bad theorist, he was simply no theorist at all. Schumpeter also described Bastiat as ‘the most brilliant economic journalist who ever lived’, and so weighty a thinker as Edgeworth praised Bastiat's genius for popularizing, in the best sense of the term, the economic discoveries of his predecessors. Almost all commentators agree that Bastiat was unrivalled at exposing economic fallacies wherever he found them, and he found them everywhere. He was quite simply a genius of wit and satire, frequently described as a combination of Voltaire and Franklin. He had the habit of exposing even the most complex economic principles in amusing parables that both charmed and educated his readers. His writings retain their currency, even today. And as Hayek has reminded us in his introduction to Bastiat's Selected Essays, his central idea continues to command attention: the notion that if we judge economic policy solely by its immediate and superficial effects, we shall not only not achieve the good results intended, but certainly and progressively undermine liberty, thereby preventing more good than we can ever hope to achieve through conscious design. This principle is exceedingly difficult to elaborate in all of its profundity, but it is one which has galvanized the thought of contemporary economists, Hayek and Friedman.

Over the long haul, Bastiat’s influence has waxed and waned. In his own day he received the ready support of Dunoyer, Blanqui, Chevalier and Garnier. Francis A. Walker introduced his doctrines into America at about the time of the Civil War. Pre-First World War French liberals such as Leroy-Beaulieu, Molinari and Guyot relied on his authority. Bastiat’s ideas subsequently went into a long decline, only to become resurgent in the late 20th century among libertarian economists dissatisfied with Keynesian orthodoxy and Marxist alternatives. Ironically, Bastiat's originality is exhibited most in his contribution to political theory, which has drawn surprisingly little attention to this day.

Baudeau, Nicolas (1730–c1792)

Peter Groenewegen

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Baudeau, N.; free trade; Gournay, Marquis de; hoarding; luxury; Mirabeau, V. R., Marquis de; monopoly; net product; Physiocracy; productive vs. unproductive expenditure; sumptuary laws; surplus

Article

Born at Amoise, Baudeau entered the church, becoming a canon and professor of theology at the Chancelade Abbey. He was subsequently called to Paris in the service of Archbishop de Beaumont. In 1765, Baudeau founded the periodical *Ephémérides*, becoming its first editor till late 1768 and again during its two subsequent revivals. Converted to Physiocracy by Mirabeau in 1768, he became one of its most active propagandists through the many articles, pamphlets and books he produced. He died insane in Paris circa 1792 (Coquelin and Guillaumin, 1854, I, p. 148). Daire (1846, pp. 652–4) provides a bibliography of the economic writings and reprints his long introduction to economic philosophy (Baudeau, 1771) and his explanations of the *Tableau économique* (Baudeau, 1767–8), which Marx (1962, p. 324) found helpful for clarifying some of its more difficult points and which remains a most useful introduction to Physiocracy and the *Tableau’s* intricacies. Baudeau (1771) is noteworthy for its concise definition of monopoly as ‘everything which by force limits the numbers and competition of buyers and sellers’ (p. 327) and its direct attribution to Gournay of the phrase, *laissez les faire* (p. 323). Perhaps the most interesting of Baudeau's many writings is his systematic exposition and development of the Physiocratic theory of luxury (Baudeau, 1767), the most complete version of that doctrine and as such wrongly ignored (Dubois, 1912, pp. v–vi). Inspired by the Swedish sumptuary laws of 1767, and bearing in mind the Physiocratic division of output between necessary expenses and disposable net product, the essay clearly defines luxury as ‘that subversion of the natural and essential order of national expenditure which increases the total of unproductive expenditure to the detriment of that which is used in production and at the same time to the detriment of production itself’ (Baudeau, 1767, p. 14). In other words, disposal of the net product when in direct agricultural investment or in spending which directly or indirectly enhances the demand for agricultural produce is productive: other uses of the surplus are...
wasteful, luxury spending. For example, hoarding which detracts from demand for agricultural produce, is luxury; importing commodities from abroad, if this increases overseas demand for domestic produce and thereby augments productive expenses, is not. Sumptuary laws are therefore not appropriate for curtailing luxury; free trade and a more simple pattern of consumption channelling more demand to the agricultural sector, are much more effective. In short, ostentation in consumption is to be preferred to ostentation in display and ornament, since the former creates a greater market for agricultural produce and hence for all production. As Meek (1962, p. 318) points out, this ‘theory of luxury, with its distinction between productive and unproductive expenditure out of revenue, was much more useful to Smith and Ricardo than it was to the underconsumptionists’, despite its emphasis on consumption spending as a factor in stimulating production.

Keywords
Bauer, P.T.; capital accumulation; central planning; democracy; development economics; economic freedom; foreign aid; free trade; freedom of contract; gains from trade; institutional economics; limited government; poverty; poverty traps; property rights; total factor productivity

Article

Peter (Lord) Bauer, one of the pioneers of early post-Second World War development economics, stood almost alone in the 1940s and 1950s in questioning the prevailing orthodoxy. Born in Budapest on 6 November 1915, he was the son of a bookmaker. Bauer left Hungary in 1934 to study at Cambridge University, where he earned a first-class degree in economics from Gonville and Caius College in 1937. He returned home to complete his law degree at Budapest University, and then took a job in London with the trading firm of Guthrie & Company. In 1947 he was appointed a lecturer in agricultural economics at London University. From 1948 to 1956 he was a lecturer in economics at Cambridge University, and then became Smuts Reader in Commonwealth Studies. In 1960 Bauer accepted a professorship at the London School of Economics, and took emeritus status in 1983. Prime Minister Margaret Thatcher elevated Bauer to the House of Lords, as a life peer, in 1982. Lord Bauer was a fellow of the British Academy and of Gonville and Caius College. He was the first recipient of the Milton Friedman Prize for Advancing Liberty, a $500,000 prize awarded every two years by the Cato Institute. The award cited Bauer's ‘tireless and pioneering scholarly contributions to understanding the role of property and free markets in wealth creation’. Peter Bauer died on 2 May 2002 at the age of 86.

In the early post-war era, orthodox development economists held that there was a ‘vicious circle of poverty’. They assumed that low incomes in less developed countries would prevent sufficient domestic saving and capital accumulation, which were seen as essential for growth. Moreover, poor people were assumed to be incapable of readily responding to market incentives or to have the foresight to save and invest, investment opportunities were seen as narrowly limited, and external trade was viewed as ineffective or even harmful. Poverty was therefore regarded as self-perpetuating. The only escape was to generate a ‘big push’ by comprehensive central planning and by relying on external assistance.
Bauer's first-hand observations during his extensive work in south-east Asia and in British West Africa in the 1940s and 1950s led him to question the conventional wisdom. In his classic studies of the rubber industry in Malaya (Bauer, 1948) and small traders in West Africa (Bauer, 1954), he found strong evidence that poor people can lift themselves out of poverty by hard work, entrepreneurial activities, and internal and external trade – provided they have the freedom to do so. He was fond of saying, ‘If the notion of the vicious circle of poverty were valid, mankind would still be living in the Old Stone Age’.

Rather than advocate a state-led development model, which was in high fashion at the time, Bauer argued that investment planning, compulsory saving, protectionist trade policies, marketing boards, and government-to-government transfers (foreign aid) would politicize economic life, empower the ruling class, and perpetuate poverty. His views have been vindicated by the failure of comprehensive economic planning and by the ineffectiveness of official aid to spur development.

For Bauer, the essence of economic development is to increase ‘the range of effective alternatives open to people’—that is, to increase economic freedom. Until recently, this classical-liberal view was largely invisible. Bauer was among the first to downplay the importance of physical capital accumulation as a precondition for growth. His focus was on institutions and incentives, and especially on the dynamic gains from trade. Total factor productivity is a black box that must be opened to understand the underlying forces of the development process. Bauer was sceptical that those forces could be precisely modelled or that there could be a general theory of development. The process was much too complex.

The primary role of government, in Bauer's view, is to protect private property rights and freedom of contract so that individuals are free to choose and to trade. Conditions will then be conducive to develop and to prosper. Limited government is more important than democracy, in this respect. Hong Kong has few natural resources but has limited government and free trade, and was able to escape the ‘poverty trap’—without comprehensive planning or foreign aid.

Bauer, like Ronald Coase, relied on direct observation, an understanding of institutions and history, and sound economic logic to overturn conventional wisdom. When nearly everyone was focusing on capital accumulation as the primary determinant of growth, Bauer (1957a, p. 119) argued, ‘It is more meaningful to say that capital is created in the process of development, rather than that development is a function of capital’.

In his final book, *From Subsistence to Exchange and Other Essays* (2000), Bauer summarized his market-liberal vision of the development process:

- ‘Economic performance depends on personal, cultural, and political factors, on people's attitudes, motivations, and social and political institutions.’
- ‘Contacts through traders and trade are prime agents in the spread of new ideas, modes of behavior, and methods of production.’
- ‘Development aid is thus clearly not necessary to rescue poor societies from a vicious circle of poverty. Indeed, it is far more likely to keep them in that state.’

Those ideas were controversial for many years, but are now more readily accepted in the field of development economics. Bauer deserves much credit for that reversal.

Bayes, Thomas (1702–1761)

D.V. Lindley
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
Bayes, T.; De Finetti, B.; expectations; Inference; Laplace, P. S.; Price, R.; probability; subjective probability

Article

The Rev. Thomas Bayes was the eldest son of Joshua Bayes, a minister in the nonconformist church. He was probably educated at Coward's Academy. After assisting his father as pastor in Hatton Garden, London, he became, in 1731, Presbyterian minister at Mount Sion, Tunbridge Wells where he remained until his death on 17 April 1761. His fame today rests entirely on one paper, found by his friend Richard Price amongst Bayes’ effects after his death and presented to the Royal Society (Bayes, 1763; a convenient recent reference is Bayes, 1958). The paper appears to have aroused little interest at the time and a proper appreciation was left to Laplace. Even today there is much discussion over just what Bayes meant, but the fact that so much interest is taken in a paper over 200 years old testifies to the importance of the problem and the brilliance of Bayes’ argument.

The problem was this (as stated at the beginning of the paper): ‘Given the number of times in which an unknown event has happened and failed: Required the chance that the probability of its happening in a single trial lies somewhere between any two degrees of probability that can be named.’
Bayes’ solution depended on two original ideas. The first, in the modern notation where $p(A|B)$ means the probability of $A$ given $B$, says

$$p(B|A) = p(A|B) \cdot p(B) / p(A)$$

and is always known as Bayes’ theorem. The second idea is more controversial and open to many interpretations. The question is what ‘rule is the proper one to be used in the case of an event concerning
the probability of which we absolutely know nothing antecedently to any trials made concerning it’?
To solve the problem Bayes took \( A \) to be the event of \( r \) happenings and \( s \) failures; \( B \) to be the unknown value \( \theta \) of ‘its happening in a single trial’ so that \( p(r, s|\theta) = \theta^r(1 - \theta)^s \), and supposed

\( p(r, s) = (r + s)^{-1} \) as a solution to the second question. This is equivalent to taking \( p(\theta) \) as constant.

The importance of Bayes’ ideas goes beyond the initial problem. Let \( A \) be any particular event and \( B \) some general proposition. Then his theorem enables one to pass from the probability of the particular given the general, \( p(A|B) \), which, as above, is often straightforward, to the difficult probability of the general given the particular, \( p(B|A) \). As such it provides a solution to the central problem of induction or inference, enabling us to pass from a particular experience to a general statement. This Bayesian inference applies generally in science, economics and law. A special case with statistical problems is called Bayesian Statistics. It has been shown by Ramsey (1931), De Finetti (1974/5) and others that this is the only coherent form of inference. Despite this, eminent philosophers like Popper (1959) still misunderstand Bayes and deny probabilistic induction.

Bayes’ solution to the second question has not been generally accepted and the probability to be assigned to the general proposition before the particular is observed, \( p(B) \), has been the subject of much discussion. Solutions by Jeffreys (1985), and by Jaynes (1983) using entropy ideas, have all met with difficulties. The best solution currently available is to accept that all probabilities are subjective so that, in particular, \( p(B) \) is the subject's probability for the general proposition. This view is primarily due to De Finetti. Enough data (in the form of particular events) enable subjects, despite differences in \( p(B) \), to have close agreement on \( p(B|A) \).

An interesting feature of Bayes’ approach is that he defines probability in terms of expectation. The amount you would pay for the expectation of one unit of currency were \( B \) to occur is \( p(B) \). Because of its confusion with utility concepts, this approach has not been much used.

It is hard to think of a single paper that contains such important, original ideas as does Bayes’. His theorem must stand with Einstein’s \( E = mc^2 \) as one of the great, simple truths.

Bayesian econometrics

Dale J. Poirier
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

‘Bayesian econometrics’ consists of the tools of Bayesian statistics applicable to economic phenomena. The Bayesian paradigm interprets ‘probability’ as a measure of ‘uncertainty’ or ‘degree of belief’ associated with the occurrence of a particular uncertain event, given the available information and any accepted assumptions. It prescribes how an individual should act in the face of such uncertainty in order to avoid undesirable inconsistencies. The coherence of the Bayesian approach contrasts sharply with conventional statistical methods which sometimes advocate negative estimators of positive quantities to ensure unbiasedness, and confidence intervals which may be null or consist of the whole parameter space.

J.; statistical inference; subjective probability; uncertainty

Article

‘Bayesian econometrics’ consists of the tools of Bayesian statistics applicable to economic phenomena. Bayesian statistics traces its roots back to Reverend Thomas Bayes (born circa 1702 and died in 1761) who was an ordained nonconformist minister in England. His ideas appear to have been independently developed by James Bernoulli, and later popularized independently by Pierre Laplace later in the 18th century. After more than a century of neglect, a rebirth of Bayesian statistics occurred in the 1930s at the hands of Sir Harold Jeffreys and Bruno de Finetti, and momentum built in the 1950s as a result of the efforts of I.J. Good, Dennis Lindley and Leonard J. Savage. Bayesian econometrics started in the 1960s with the work of Jaques Dreze and Arnold Zellner. With the computational revolution sparked by Markov chain Monte Carlo (MCMC) techniques in the 1980s and 1990s, many computational constraints were removed, and Bayesian analysis was flourishing in a wide variety disciplines as the new millennium began.

The Bayesian paradigm interprets ‘probability’ as a measure of ‘uncertainty’ or ‘degree of belief’ associated with the occurrence of a particular uncertain event, given the available information and any accepted assumptions. It prescribes how an individual should act in the face of such uncertainty in order to avoid undesirable inconsistencies.

Consider an individual asked to quote probabilities on a set of uncertain events, and required to accept any wagers about these events. According to Bruno de Finetti’s coherency principle, such an individual should never assign probabilities so that someone else can select stakes that guarantee a sure loss (Dutch book) for the individual whatever the eventual outcome. This simple principle implies the usual axioms of probability except that the additivity of probability for unions of disjoint events is required to hold only for finite unions.

Expected utility maximization (or loss minimization) provides a basis for rational decision making, and Bayes’ theorem describes how beliefs evolve as data are obtained. There are numerous axiomatic formulations leading to the central unifying Bayesian prescription of maximizing expected subjective utility as the guiding principle of Bayesian statistical analysis. Bernardo and Smith (1994, ch. 2) is a valuable introduction to this vast literature. While the descriptive accuracy of the Bayesian approach in capturing
the actual behaviours of individuals is questioned by many opponents, Bayesians claim that the Bayesian view provides only normative guidelines for behaviour.

The subjective interpretation of probability is based on an individual's personal assessment of a situation. For evidence of the use of subjectivity by history's most illustrious scientists, see Press and Tanur (2001). Accordingly, probability is a property of an individual's perception of reality. In contrast, according to objective interpretations, probability is a property of reality itself. For subjectivists there are no 'true unknown probabilities' in the world to be discovered. Instead, 'probability' is in the eye of the beholder. In de Finetti's words, 'Probability does not exist'.
