Stochastic volatility (SV) is the main concept used in the fields of financial economics and mathematical finance to deal with the endemic time-varying volatility and codependence found in financial markets. Such dependence has been known for a long time; early commentators include Mandelbrot (1963) and Officer (1973). It was also clear to the founding fathers of modern continuous time finance that homogeneity was an unrealistic if convenient simplification; for example, Black and Scholes (1972, p. 416) wrote, ‘… there is evidence of non-stationarity in the variance. More work must be done to predict variances using the information available.’ Heterogeneity has deep implications for the theory and practice of financial economics and econometrics. In particular, asset pricing theory is dominated by the idea that higher rewards may be expected when we face higher risks, but these risks change through time in complicated ways. Some of the changes in the level of risk can be modelled stochastically, where the level of volatility and degree of codependence between assets is allowed to change over time. Such models allow us to explain, for example, empirically observed departures from Black–Scholes–Merton prices for options and understand why we should expect to see occasional dramatic moves in financial markets.

The outline of this article is as follows. In the first section I trace the origins of SV and provide links with the basic models used today in the literature. In the second section I briefly discuss some of the innovations in the second generation of SV models. In the third section I briefly discuss the literature on conducting inference for SV models. In the fourth section I talk about the use of SV to price options. In the fifth section I consider the connection of SV with realized volatility. An extensive review of this
literature is given in Shephard (2005).

The origin of SV models

The origins of SV are messy. I will give five accounts, which attribute the subject to different sets of people. Clark (1973) introduced Bochner's (1949) time-changed Brownian motion (BM) into financial economics. He wrote down a model for the log-price $M$ as

$$M_t = W_{\tau_t}, \quad t \geq 0,$$

where $W$ is Brownian motion (BM), $t$ is continuous time, $\tau$ is a time change, and $W_{\tau_t}$, where $\tau$ denotes independence. The definition of a time-change is a non-negative process with non-decreasing sample paths, although Clark also assumed $\tau$ has independent increments. Then $M_{\tau_t} \sim N(0, \tau_t)$. Further, so long (for each $t$) as $\mathbb{E}[\tau_t] < \infty$, then $M$ is a martingale (written $M \in \mathcal{M}$) for this is necessary and sufficient to ensure that $\mathbb{E}[\mathbb{H}[M]] < \infty$. More generally, if (for each $t$) $\tau_t < \infty$, then $M$ is a local martingale (written $M \in \mathcal{M}_{loc}$). Hence Clark was solely modelling the instantly risky component of the log of an asset price, written $Y$, which in modern semimartingale (written $Y \in \mathcal{S}\mathcal{M}$) notation we would write as

$$Y = \mathcal{A} + M.$$

The increments of $A$ can be thought of as the instantly available reward component of the asset price, which compensates the investor for being exposed to the risky increments of $M$. The $A$ process is assumed to be of finite variation (written $\mathcal{A} \in \mathcal{F}_t$).

To the best of my understanding, the first published direct volatility clustering SV paper is that by Taylor (1982). His discrete time model of daily returns, computed as the difference of log-prices

$$y_i = y_i - y_{i-1}, \quad i = 1, 2, \ldots,$$

where I have assumed that $t = 1$, represents one day to simplify the exposition. He modelled the risky part of returns, $m_i = m_i - m_{i-1}$, as a product process

$$m_i = \sigma_i \varepsilon_i,$$

(2)

Taylor assumed $\varepsilon$ has a mean of zero and unit variance, while $\sigma$ is some non-negative process, finishing the model by assuming $\varepsilon \sim \sigma$. Taylor modelled $\varepsilon$ as an autoregression and

$$\sigma_i = \exp(h_i / 2),$$
where $h$ is a non-zero mean Gaussian linear process. The leading example of this is the first order autoregression

$$h_{t+1} = \mu + \varphi(h_t - \mu) + \eta_t \, \eta_t \sim \text{NID}(0, \sigma^2).$$

(3)

In the modern SV literature the model for $\varepsilon$ is typically simplified to an i.i.d. process, for we deal with the predictability of asset prices through the $A$ process rather than via $M$. This is now often called the log-normal SV model in the case where $\varepsilon$ is also assumed to be Gaussian. In general, $M$ is always a local martingale.

A key feature of SV, which is not discussed by Taylor, is that it can deal with leverage effects. Leverage effects are associated with the work of Black (1976) and Nelson (1991), and can be implemented in discrete time SV models by negatively correlating the Gaussian $\varepsilon_i$ and $\eta_i$. This still implies that $M \in \mathcal{M}_{\text{loc}}$, but allows the direction of returns to influence future movements in the volatility process, with falls in prices associated with rises in subsequent volatility.

Taylor's discussion of the product process was pre-dated by a decade in the (until recently) unpublished Rosenberg (1972). Rosenberg introduces product processes, empirically demonstrating that time-varying volatility is partially forecastable and so breaks with the earlier work by Clark. He suggests an understanding of aggregational Gaussianity of returns over increasing time intervals and pre-dates a variety of econometric methods for analysing heteroskedasticity.

In continuous time the product process is the standard SV model

$$M_t = \int_0^t \sigma_s \, dW_s,$$

(4)

where the non-negative spot volatility $\sigma$ is assumed to have càdlàg sample paths (which means it can possess jumps). The squared volatility process is often called the spot variance.

The first use of continuous-time SV models in financial economics was, to my knowledge, by Johnson (1979), who studied the pricing of options using time-changing volatility models in continuous time (see also Johnson and Shanno, 1987; Wiggins, 1987). The best-known paper in this area is Hull and White (1987). Each of these authors desired to generalize the Black and Scholes (1973) approach to option pricing models to deal with volatility clustering. In the Hull and White approach, $\sigma^2$ follows the solution to the univariate SDE

$$d\sigma^2 = \alpha(\sigma^2) \, dt + \omega(\sigma^2) \, dB,$$

where $B$ is a second Brownian motion and $\omega(\cdot)$ is a non-negative deterministic function.

The probability literature has demonstrated that SV models and their time-changed BM relatives are fundamental. This theoretical development will be the fifth strand of literature that I think of as representing the origins of modern stochastic volatility research. Suppose we simply assume that
\( M \in M_{\text{loc}}^{c} \), a process with continuous local martingale sample paths. Then the celebrated Dambis–Dubins–Schwartz theorem shows that \( M \) can be written as a time-changed Brownian motion. Further, the time-change is the quadratic variation (QV) process

\[
[M]_t = \lim_{n \to \infty} \sum_{j=1}^{n} \left( M_{t_j} - M_{t_{j-1}} \right) \left( M_{t_j} - M_{t_{j-1}} \right)',
\]

for any sequence of partitions \( t_0 = 0 < t_1 < \ldots < t_n = t \) with \( \sup \{ t_j - t_{j-1} \} \to 0 \) for \( n \to \infty \). What is more, as \( M \) has continuous sample paths, so must \([M] \). Under the stronger condition that \([M] \) is absolutely continuous, then \( M \) can be written as a stochastic volatility process. This latter result, which is called the martingale representation theorem, is due to Doob (1953). Taken together, this implies that time-changed BMs are canonical in continuous sample path price processes, and SV models are special cases of this class. A consequence of the fact that, for continuous sample path time-change BM, \([M] = \tau \), is that in the SV case

\[
[M]_t = \int_0^t \sigma_s^2 \, ds.
\]

The SV framework has an elegant multivariate generalization. In particular, write a \( p \)-dimensional price process \( M \) as (4) but where \( \sigma \) is a matrix process whose elements are all càdlàg, \( W \) is a multivariate BM process. Further \([M]_t = \int_0^t \sigma_s \sigma_s^t \, ds \).

**Second-generation model building**

**Univariate models**

**General observations**

In initial diffusion-based models the volatility was Markovian with continuous sample paths. Research in the late 1990s and early 2000s has shown that more complicated volatility dynamics are needed to model either options data or high frequency return data. Leading extensions to the model are to allow jumps into the volatility SDE (for example, Barndorff-Nielsen and Shephard, 2001; Eraker, Johannes and Polson, 2003) or to model the volatility process as a function of a number of separate stochastic processes or factors (for example, Chernov et al., 2003; Barndorff-Nielsen and Shephard, 2001).

**Long memory**

In the SV literature considerable progress has been made on working with both discrete and continuous time long-memory SV. This involves specifying a long-memory model for \( \sigma \) in discrete or continuous time.

Breidt, Crato and de Lima (1998) and Harvey (1998) looked at discrete time models where the log of the volatility was modelled as a fractionally integrated process. In continuous time there is work on modelling the log of volatility as fractionally integrated Brownian motion by Comte and Renault (1998). More recent work, which is econometrically easier to deal with, is the square-root model driven by fractionally integrated BM introduced in an influential paper by Comte, Coutin and Renault (2003) and...
the infinite superposition of non-negative OU processes introduced by Barndorff-Nielsen (2001).

Jumps

In detailed empirical work a number of researchers have supplemented standard SV models by adding jumps to the price process or to the volatility dynamics. Bates (1996) was particularly important as it showed the need to include jumps in addition to SV, at least when volatility is Markovian. Eraker, Johannes and Polson (2003) deals with the efficient inference of these types of models. A radical departure in SV models was put forward by Barndorff-Nielsen and Shephard (2001), who suggested building volatility models out of pure jump processes called non-Gaussian OU processes. Closed form option pricing based on this structure is studied briefly in Barndorff-Nielsen and Shephard (2001) and in detail by Nicolato and Venardos (2003). All these non-Gaussian OU processes are special cases of the affine class advocated by Duffie, Pan and Singleton (2000) and Duffie, Filipovic and Schachermayer (2003).

Multivariate models

Diebold and Nerlove (1989) introduced volatility clustering into traditional factor models, which are used in many areas of asset pricing. In continuous time their type of model has the interpretation

\[ M_t = \sum_{j=1}^{J} \int \beta(j) \sigma(j) d\sigma(j) + \epsilon_t, \]

where the factors \( F(1), F(2), \ldots, F(J) \) are independent univariate SV models and \( G \) is correlated multivariate BM. Some of the related papers on the econometrics of this topic include King, Sentana and Wadhwani (1994) and Fiorentini, Sentana and Shephard (2004), who all fit this kind of model. These papers assume that the factor loading vectors are constant through time.

A more limited multivariate discrete time model was put forward by Harvey, Ruiz and Shephard (1994) who allowed \( M_t = \sum_{j=1}^{J} \sigma(j) dW_j \), where \( \sigma \) is a diagonal matrix process and \( C \) is a fixed matrix of constants with a unit leading diagonal. This means that the risky part of prices is simply a rotation of a \( p \)-dimensional vector of independent univariate SV processes.

Inference based on return data

Moment-based inference

The task is to carry out inference on \( \theta = (\theta_1, \ldots, \theta_K) \), the parameters of the SV model based on a sequence of returns \( y = (y_1, \ldots, y_T) \). Taylor (1982) and Melino and Turnbull (1990) calibrated their models using the method of moments. Systematic studies, using a GMM approach, of which moments to heavily weight in SV models was given in Andersen and Sørensen (1996), Genon-Catalot, Jeantheau and Larédo (2000), Sørensen (2000) and Hoffmann (2002).

A difficulty with using moment-based estimators for continuous time SV models is that it is not straightforward to compute the moments. In the case of no leverage, general results for the second order properties of \( y \) and their squares were given in Barndorff-Nielsen and Shephard (2001). Some quite general results under leverage are also given in Meddahi (2001).

In the discrete time log-normal SV models the approach advocated by Harvey, Ruiz and Shephard (1994) has been influential. Their approach was to remove the predictable part of the returns, so we
think of $y = M$ again, and work with $\log y_i^2 = h_i + \log \varepsilon_i^2$. If the volatility has short memory, then this form of the model can be handled using the Kalman filter, while long-memory models are often dealt with in the frequency domain. Either way, this delivers a Gaussian quasi-likelihood which can be used to estimate the parameters of the model. The linearized model is non-Gaussian due to the long left-hand tail of $\log \varepsilon_i^2$ which generates outliers when $\varepsilon_i$ is small.

Simulation-based inference

In the 1990s a number of econometricians started to use simulation-based inference to tackle SV models. To discuss these methods it will be convenient to focus on the simplest discrete time log-normal SV model given by (2) and (3).

MCMC allows us to simulate from $\theta, h|\gamma$, where $h = (h_1, \ldots, h_T)'$. Discarding the $h$ draws yields samples from $\theta|\gamma$. Summarizing yields fully efficient parametric inference. In an influential paper, Jacquier, Polson and Rossi (1994) implemented an MCMC algorithm for this problem. A subsequent paper by Kim, Shephard and Chib (1998) gave quite an extensive discussion of various MCMC algorithms. This is a subtle issue and makes a very large difference to the computational efficiency of the methods (see, for example, Jacquier, Polson and Rossi, 2004; Yu, 2005).

Kim, Shephard and Chib (1998) introduced the first filter using a so-called particle filter. As well as being of substantial scientific interest for decision making, the advantage of a filtering method is that it allows us to compute marginal likelihoods for model comparison and one-step-ahead predictions for model testing.

Although MCMC-based papers are mostly couched in discrete time, a key advantage of the general approach is that it can be adapted to deal with continuous time models by the idea of augmentation. This was fully worked out in Elerian, Chib and Shephard (2001), Eraker (2001) and Roberts and Stramer (2001).

A more novel non-likelihood approach was introduced by Smith (1993) and later developed by Gourieroux, Monfort and Renault (1993) and Gallant and Tauchen (1996) into what is now called indirect inference or the efficient method of moments. Here I briefly give a stylized version of this approach.

Suppose there is an auxiliary model for the returns (for example, GARCH) whose density, $g(\gamma, \psi)$, is easy to compute and, for simplicity of exposition, has $\dim(\psi) = \dim(\theta)$. Then compute its MLE, which we write as $\hat{\psi}$. We assume this is a regular problem so that $\partial \log g(\gamma, \psi) / \partial \psi = 0$, recalling that $y$ is the observed return vector. Simulate a very long process from the SV model using parameters $\theta$, which we denote by $y^+$, and evaluate the score using not the data but this simulation. This produces

$$\frac{\partial \log g(y^+; \psi)}{\partial \psi} \bigg|_{\psi = \hat{\psi}} = f(y, \theta).$$

Then move $\theta$ around until the score is again zero, but now under the simulation. Write the point where this happens as $\hat{\theta}$. It is called the indirect inference estimator.

Options

Models

SV models provide a basis for realistic modelling of option prices. We recall the central role played by
Johnson and Shanno (1987) and Wiggins (1987). The best-known paper in this area is by Hull and White (1987), who looked at a diffusion volatility model with leverage effects. They assumed that volatility risk was unrewarded and priced their options either by approximation or by simulation. Hull and White (1987) indicated that SV models could produce smiles and skews in option prices, which are frequency observed in market data. The skew is particularly important in practice, and Renault and Touzi (1996) proved that can be achieved in SV models via leverage effects.

The first analytic option pricing formulae were developed by Stein and Stein (1991) and Heston (1993). The only other closed form solution I know of is the one based on the Barndorff-Nielsen and Shephard (2001) class of non-Gaussian OU SV models. Nicolato and Venardos (2003) provided a detailed study of such option pricing solutions; see also the textbook exposition in Cont and Tankov (2004, ch. 15).

Slightly harder computationally to deal with is the more general affine class of models highlighted by Duffie, Filipovic and Schachermayer (2003).

Econometrics of SV option pricing

In theory, option prices themselves should provide rich information for estimating and testing volatility models. I discuss the econometrics of options in the context of the stochastic discount factor (SDF) approach, which has a long history in financial economics and is emphasized in, for example, Cochrane (2001) and Garcia, Ghysels and Renault (2006). For simplicity I assume interest rates are constant. We start with the standard Black–Scholes (BS) problem, which will take a little time to recall, before being able to rapidly deal with the SV extension. We model

\[ d \log Y = (r + \rho) dt + \sigma dW, \]

where \( \tilde{M} \) is the SDF process and \( r \) the riskless short rate, and \( \sigma, h, b \) and \( \rho \), the risk premium, are assumed constant for the moment.

We price all contingent payoffs \( g(Y_T) \) as \( C_t = \mathbb{E}(\frac{\tilde{M}_T}{\tilde{M}_t} g(Y_T) | \tilde{F}_t) \), the expected discounted value of the claim where \( T > t \). For this model to make financial sense we require that \( \tilde{M}_t Y_t \) and \( \tilde{M}_t \exp(\sigma^2/2) \) are local martingales, which is enough to mean that adding other independent BMs to the \( \log \tilde{M} \) process makes no difference to \( C \) or \( Y \), the observables. These two constraints imply, respectively, \( \rho + b \sigma = 0 \) and \( h = -r - \frac{1}{2} \sigma^2 \). This means that \( (C^{BS}, Y) \) is driven by a single \( W \).

When we move to the standard SV model we can remove this degeneracy. The functional form for the SV \( Y \) process is unchanged, but we now allow

\[ d \log \tilde{M} = h dt + \sigma dW + b dW, \]

where we assume that \( B = W \) to simplify the exposition. The SV structure means that \( \rho \) will have to change through time in response to the moving \( \sigma^2 \). \( B \) is again redundant in the SDF (but not in the volatility) so the usual SDF conditions again imply \( h = -r - \frac{1}{2} \sigma^2 \) and \( \rho + b \sigma = 0 \). This implies that the move to the SV case has little impact, except that the sample path of \( \sigma^2 \) \( W \). So the generalized BS (GBS) price is

---

http://www.dictionaryofeconomics.com/library/lemayne.edu/article?id=p... 2009-1-3
Now $C^{GBS}$ is a function of both $Y_t$ and $\sigma^2_t$, which means that $(C^{GBS}, \gamma)$ is not degenerate. From an econometric viewpoint this is an important step, meaning inference on options is just the problem of making inference on a complicated bivariate diffusion process. When we allow leverage back into the model, the analysis becomes slightly more complicated algebraically.

In some recent work econometricians have been trying to use data from underlying assets and option markets to jointly model the dynamics of $(C^{GBS}, \gamma)$. The advantage of this joint estimation is that we can pool information across data types and estimate all relevant effects which influence $Y_t$, $\sigma^2_t$ and $\bar{M}$. Relevant papers include Chernov and Ghysels (2000), Pastorello, Patilea and Renault (2003), Das and Sundaram (1999) and Bates (2000).

**Realized volatility**

The advent of very informative high-frequency data has prompted econometricians to study estimators of the increments of the quadratic variation (QV) process and then to use this estimate to project QV into the future in order to predict future levels of volatility. The literature on this starts with independent, concurrent papers by Andersen and Bollerslev (1998), Barndorff-Nielsen and Shephard (2001) and Comte and Renault (1998). Some of this work echoes earlier important contributions from, for example, Rosenberg (1972) and Merton (1980).

A simple estimator of $[Y]$ is the realized QV process

$$[Y]_t = \sum_{j=1}^{[t/\delta]} (Y_{j\delta} - Y_{(j-1)\delta})(Y_{j\delta} - Y_{(j-1)\delta})',$$

thus as $\delta \downarrow 0$ so $[Y]_t \rightarrow [Y]$. If $\mathcal{A} \in \mathcal{G} \mathcal{V}^\delta$, then $[Y] = [M]$, while if we additionally assume that $M$ is SV then $[Y]_t \rightarrow \int_0^t \sigma_s \sigma_s' d\delta$.

In practice it makes sense to look at the increments of the QV process. Suppose we are interested in analysing daily return data, but in addition have higher-frequency data measured at the time interval $\delta$.

The $i$-th daily realized QV is defined as

$$V(Y_{i\delta}) = \sum_{j=1}^{[1/\delta]} \left( (Y_{i\delta+\delta j} - Y_{i\delta+(j-1)\delta}) \times (Y_{i\delta+\delta j} - Y_{i\delta+(j-1)\delta})' \right)^{1/2}.$$
writing $F_t$ as the filtration generated by the continuous history of $Y$ up to time $t$ then

$$E(Y_t | \mathcal{F}_t) = E(Y_t | \mathcal{F}_{t-1}).$$

A review of some of this material is given by Barndorff-Nielsen and Shephard (2006a).

A difficulty with this line of argument is that the QV theory tells us only that $V(Y_t | \mathcal{F}_t)$; it gives no impression of the size of $V(Y_t)$. Jacod (1994) and Barndorff-Nielsen and Shephard (2002) have strengthened the consistency result to provide a univariate central limit theory

$$\frac{\delta^{-1/2}(\mathbb{E}[Y_t] - \mathbb{E}[Y])}{\sqrt{2\int_0^t \sigma_s^4 ds}} \overset{d}{\to} N(0, 1),$$

while giving a method for consistently estimating the integrated quarticity $\int_0^t \sigma_s^4 ds$ by using high-frequency data. This analysis was generalized to the multivariate case by Barndorff-Nielsen and Shephard (2004a). This type of analysis greatly simplifies parametric estimation of SV models, for we can now have estimates of the volatility quantities SV models directly parameterize. Barndorff-Nielsen and Shephard (2002), Bollerslev and Zhou (2002) and Phillips and Yu (2005) study this topic from different perspectives.

Recently there has been interest in studying the impact of market microstructure effects on the estimates of realized covariation. This causes the estimator of the QV to become biased. Leading papers on this topic are Zhou (1996), Fang (1996), Bandi and Russell (2003), Hansen and Lunde (2006) and Zhang, Mykland and Aït-Sahalia (2005). Further, one can estimate the QV of the continuous component of prices in the presence of jumps using the so-called realized bipower variation process. This was introduced by Barndorff-Nielsen and Shephard (2004b; 2006b).

stock price predictability

Wayne E. Ferson
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The question of predictability in stock returns has important and broad economic implications. Predictability relates directly to the efficiency of the capital markets in allocating resources to their highest valued uses. But the interpretation of predictability, and the evidence for its very existence, remain controversial. This article provides a review of the arguments and evidence for stock return predictability. The evidence for weak-form predictability, based on the information in past stock prices, is more fragile and less compelling than the evidence for semi-strong form predictability, based on publicly available information more generally.

Keywords

arbitrage; ARMA processes; asset pricing models; behavioral finance; capital markets; data mining; dividend–price ratio; efficient markets hypothesis; financial econometrics; finite sample bias; frictions; market inefficiency; martingales; momentum; multiple comparisons; predictability; regime shifts; selection bias; semi-strong form predictability; serial dependence; spurious regressions; standard error estimation; statistical econometrics; stock price predictability; stock market returns; strong-form predictability; structural breaks; trading strategies; variance ratio; weak-form predictability

Article

The interest in predicting stock prices or returns is probably as old as the markets themselves. Fama (1970) reviews early work and provides some organizing principles. This article concentrates selectively on developments following Fama's review. In that review, Fama describes increasingly fine information sets in a way that is useful in organizing the discussion. Weak-form predictability uses the information in past stock prices. Semi-strong form predictability uses variables that are obviously publicly available, and strong form uses anything else. While there is a literature characterizing strong-form predictability (for example, analysing the profitability of corporate insiders' trades), this article concentrates on the first two categories of information. Early studies, reviewed by Fama (1970), concluded that a martingale or random walk was a good model for stock prices, values or their logarithms. Thus, the best forecast of the future price was the current price. However, predicting price or value changes, and thus rates of return, is more challenging and controversial. The current financial economics literature reflects two, often-competing, views about predictability in stock returns. The first argues that predictability represents exploitable inefficiencies in the way capital markets function. The second view argues that predictability is a natural outcome of an efficient capital market. The exploitable inefficiencies view of return predictability argues that, in an efficient market, traders would bid up the prices of stocks with predictably high returns, thus lowering the future return and removing any predictability at the new price (for example, Friedman, 1953; Samuelson, 1965). However, market frictions or human imperfections are assumed to impede such price-correcting, or 'arbitrage' trading. Predictable patterns can thus emerge when there are important market
imperfections, like trading costs, taxes, or information costs, or important human imperfections in processing or responding to information, as studied in behavioural finance. These predictable patterns are thought to be exploitable in the sense that an investor who could avoid the friction or cognitive imperfection could profit from the predictability at the expense of other traders.

The ‘efficient markets’ view of predictability is described by Fama (1970) and has an entry in this dictionary. According to this view returns may be predictable if required expected returns vary over time in association with changing interest rates, risk or investors’ risk aversion. Predictability may be expected in an efficient capital market. If the required expected returns vary over time, there may be no abnormal trading profits and thus no incentive to exploit the predictability. Write the return as $R = E(R|Ω) + u$, where $Ω$ is the information at the beginning of the period and $u$ is the unexpected return. Since $E(u|Ω) = 0$, the unexpected return cannot be predicted ahead of time. Thus, predictability, in the efficient markets view, rests on systematic variation through time in the expected return. Modelling and testing for this variation is the focus of the conditional asset pricing literature (reviewed by Ferson, 1995).

While this article focuses on stock return predictability, not all of the predictability associated with stock prices involves predicting the levels of returns. A large literature models predictable second moments of returns (for example, using ARCH and GARCH-type models; see Engle, 2004, or stochastic volatility models). Predictability studies have also examined the third moments (for example, Harvey and Siddique, 2001).

**Weak-form predictability**

Much of the literature on weak-form predictability can be characterized through an autoregression. Let $R_t$ be the continuously compounded rate of return over the shortest measurement interval ending at time $t$. Let $r(t, t + H) = \sum_{j=1}^{H} R_{t+j}$. Then,

$$r(t, t + H) = a_H + \rho_H r(t - H, t) + \epsilon(t, t + H)$$

is the autoregression, $\rho_H$ is the autocorrelation, and $H$ is the return horizon. Studies can be grouped according to the return horizon. An alternative to the autoregression is the variance ratio statistic: $\var(r(t, t + H)) / \text{Var}(R_t)$, proposed by Working, 1949, and studied for stock returns by Lo and MacKinlay, 1988, and others. Cochrane, 1988, shows that the variance ratio is a function of the autocorrelation in returns. Kaul, 1996, provides an analysis of various statistics that have been used to evaluate weak-form predictability, showing how they can be viewed as combinations of autocorrelations at different lags, with different weights assigned to the lags.

Many studies measure small but statistically significant serial dependence in daily or intra-daily stock return data. Serial dependence in daily returns can arise from end-of-day price quotes that fluctuate between bid and ask (Roll, 1984) or from non-synchronous trading of the stocks in an index (for example, Fisher, 1966; Scholes and Williams, 1977). These effects do not represent predictability that can be exploited with any feasible trading strategy. Spurious predictability due to such data problems should clearly not be attributed to time variation in the expected discount rate for stocks. On the other hand, much of the literature on predictability allows that high-frequency serial dependence may reflect changing conditional means. For example, Lo and MacKinlay (1988) and Conrad and Kaul (1988) model expected returns within the month as following an autoregressive processes.

Conrad and Kaul (1988; 1989) study serial dependence in weekly stock returns. They point out that, if the expected returns, $E(R|Ω)$, follow an autoregressive process, the actual returns would be described by the sum of an autoregressive process and a white noise, and thus follow an ARMA process. The autoregressive and moving average coefficients would be expected to have the opposite signs: if current expected returns increase, it may signal that future expected returns are higher, but
stock prices fall in the short run because the future cash flows are discounted at a new, higher rate. The two effects offset and returns could have small autocorrelations. Estimating ARMA models, Conrad and Kaul find that the autoregressive coefficients for weekly returns on stock portfolios are positive, near 0.5, and can explain up to 25 per cent of the variation in the returns on a portfolio of small-firm stocks.

Even with weekly returns, however, some of the measured predictability can reflect non-synchronous trading effects. Lo and MacKinlay (1990) use statistical models that attempt to separate out the various effects in measured portfolio returns. Boudoukh, Richardson and Whitelaw (1994) use stock index futures contracts, which are not subject to non-synchronous trading, and find little evidence for weak-form predictability at a weekly frequency.

Much of the literature on weak-form predictability studies broad stock-market indexes or portfolios of stocks, grouped according to the market capitalization (size) or other characteristics of the firms. But another significant stream of the literature studies relative predictability. Stocks have relative predictability if the future returns of one group of stocks is predictably higher than the returns of another group. Thus, if a trader could buy the stocks in the high-return group and sell short the stocks in the low-return group, the trader can profit even if both groups go up (or down). In a weak-form version of relative predictability, past stock prices or returns are used to form the groups. If past winner (loser) stocks have predictably higher (lower) returns, we have continuation or ‘momentum’. If past winner stocks can be predicted to have lower future returns, we have reversals. Relative predictability can be evaluated by viewing eq. (1) as a cross-sectional regression, an approach taken by Jegadeesh (1990), who finds continuation in monthly returns. Lehman (1990) finds some evidence for reversals in the weekly returns of US stocks.

Jegadeesh and Titman (1993) find that relatively high-return stocks over the previous year tend to repeat their performance over future three- to twelve-month horizons. They study US data for 1927–89 but focus on the 1965–89 period. The magnitude of the effect is striking. The top 20 percent winner stocks over the last six months can outperform the loser stocks by about one percent per month for the next six months. This momentum effect has spawned a huge subsequent literature which is largely supportive of the momentum effect but which has not reached a consensus about its causes. The efficient markets view of predictability suggests that momentum trading strategies should be subject to greater risk exposures which justify their high returns. Most efforts at explaining the effect by risk adjustments have failed. (There are some partial successes. For example, Ang, Chen and Xing, 2006, associate some of the momentum strategy profits with high exposure to ‘downside risk’, that is, likely negative returns to the strategy when the market return is negative.) The momentum effect has inspired a number of behavioural models, suggesting that momentum may occur because markets under-react to news in the pricing of stocks. For example, one argument (Daniel, Hirshleifer and Subrahmanyam, 1998) is that traders have ‘biased self attribution’, meaning that they think their private information is better than it really is. As a result they do not react fully to public news about the value of stocks, so the news takes time to get impounded in market prices, resulting in momentum. In another argument, traders suffer a ‘disposition effect’, implying that they tend to hold on to their losing stocks longer than they should, which can lead to momentum. These arguments suggest that traders who can avoid these cognitive biases may profit from momentum trading strategies. However, Lesmond, Schill and Zhou (2004) and Korajczyk and Sadka (2004) measure the trading costs of momentum strategies and conclude that the apparent excess returns to the strategies are consumed by trading costs.

Perhaps the most controversial evidence of weak-form predictability involves long-horizon returns. Fama and French (1988) use autoregressions like (1) to study predictability in portfolio returns, measured over one-month to multi-year horizons. They find U-shaped patterns in the autocorrelations as a function of the horizon, with negative serial dependence, or mean reversion, at four- to five-year horizons. Mean reversion can be consistent with either view of predictability. If expected returns are stationary (reverting to a constant unconditional mean) but time-varying, mean reversion can occur in an efficient market. Mean reversion would also be expected if stock values depart temporarily from the fundamental, or correct prices, but are drawn back to that level. DeBondt and Thaler (1985) find that past high-return stocks perform poorly over the next five years and vice versa – a form of relative predictability. They interpret reversals in long-horizon relative returns as indicating that the market overreacts to news about stock values, and then eventually
corrects the mistake. The reversal effect was shown to occur mainly in the month of January by Zarowin (1990) and Grinblatt and Moskowitz (2003), which is interpreted as related to ‘tax loss selling’. In this story investors sell loser stocks at the end of the year for tax reasons, thus depressing their prices, and buy them back in the new year, subsequently raising their prices. McLean (2006) finds that reversals are concentrated in stocks with high idiosyncratic risks, which is thought to present a deterrent to arbitrage traders who might otherwise correct temporary errors in the market prices.

Like momentum, behavioural models attempt to explain reversals as the result of cognitive biases. Models of Barberis, Shleifer and Vishny (1998), Daniel, Hirshleifer and Subrahmanyam (1998) and Hong and Stein (1999) argue that both short-run momentum and long-term reversals can reflect under- and overreaction to news about stock values. Research in this area continues, and it is fair to say that the jury is still out on the issue of weak-form predictability.

**Semi-strong form predictability**

Studies of semi-strong form predictability can be described with the regression:

\[ r(t, t+H) = \alpha + \beta_H Z_{t+H} + \nu(t, t+H), \]

(2)

where \( Z_t \) is a vector of variables that are publicly available by time \( t \). Many predictor variables have been analysed in published studies, and it is useful to group them into categories. The first category of predictor variables comprises ‘valuation ratios’, which are measures of cash flows divided by the stock price. Keim and Stambaugh (1986) use a constant numerator in the ratio and ‘detrend’ the price. Rozeff (1984), Campbell and Shiller (1988) and Fama and French (1989) use dividend–price ratios, Pontiff and Schall (1998) and Kothari and Shanken (1997) use the book value of equity divided by price. Boudoukh et al. (2007) add share repurchases and other non-cash payouts, respectively, to the dividend measure. Lettau and Ludvigson (2001) propose a macroeconomic variation on the valuation ratio: Aggregate consumption divided by a measure of aggregate wealth. All of these studies find the regression coefficients \( \beta_H \) to be significant.

Rozeff (1984) and Berk (1995) argue that valuation ratios should generally predict stock returns. Consider the simplest model of a stock price, \( P \), as the discounted value of a fixed flow of expected future cash flows or dividends: \( P = c / R \), where \( c \) is the expected cash flow and \( R \) is the expected rate of return. Then, \( R = c / P \), and the dividend price ratio is the expected return of the stock. If predictability is attributed to the expected return, as in the efficient markets view, then a valuation ratio should be a good predictor variable.

Predictability of stock returns with valuation ratios is also related to the expected growth rates of future dividends or cash flows. Consider the Gordon (1962) constant-growth model for a stock price: \( P = c / (R - g) \), where \( g \) is the future growth rate. Then, \( c / P = R - g \). This suggests that if dividend–price ratios vary, either across stocks or over time, then expected returns should vary, and/or expected cash flow growth rates should vary, and the dividend–price ratio should be able to predict one or the other. Campbell and Shiller (1988) show that the intuition from this example holds to a good approximation in models where the growth rates and expected returns are not held fixed over time. They find that market dividend–price ratios do not significantly predict future cash flow growth rates. Cochrane (2006) uses this result to re-evaluate the empirical evidence for stock return predictability using dividend–price ratios. He essentially argues that, if you know that the dividend–price ratio does not forecast future cash flow growth, then it must forecast future stock returns. Studies of semi-strong form predictability in stock index returns typically report regressions with small R-squares, as the fraction of the variance in returns that can be predicted with the lagged variables is small – say, 10–15 percent or less for monthly to annual return horizons. The R-squares are larger for longer-horizon returns – up to 40 percent or more for four- to five-year horizons. This...
is interpreted as the result of expected returns that are more persistent than returns themselves, as would be expected if returns are expected returns plus noise. Thus, the variance of the sum of the expected returns accumulates with longer horizons faster than the variance of the sum of the returns, and the R-squares increase with the horizon (for example, Fama and French, 1989). However, small R-squares can mask economically important variation in the expected returns.

Stocks are long ‘duration’ assets, so a small change in the expected return can lead to a large change in the asset value. To illustrate, consider another example using the Gordon model, where the dividend is \( c = \frac{E}{k} \), \( E \) is the earnings and \( k \) is the dividend–payout ratio. The price–earnings ratio, \( P / E = 15 \), the payout ratio, \( k = 0.6 \), and the expected growth rate, \( g = 3\% \). The expected return is \( R = 7\% \). Suppose there is a shock to the expected return, ceteris paribus. A change of one per cent in \( R \) leads to approximately a 20 per cent change in the asset value. Of course, this overstates the effect to the extent that a shock that changes the required return also changes the expected future cash flows. But the example suggests that small changes in expected returns can produce economically significant changes in asset values. Consistent with this argument, studies such as Kandel and Stambaugh (1996), Campbell and Viceira (2002) and Fleming, Kirby and Ostdiek (2001) show that optimal portfolio decisions can be affected to an economically significant degree by return predictability, even when the amount of predictability, as measured by R-squared, is small.

The second category of semi-strong form predictor variables for stock returns includes calendar and seasonal effects. The list of effects that have been related to stock returns and the list of studies are too long to cite here. (See Haugen and Lakonishok, 1988, and Schwert, 2003, for reviews.) Some examples include the season (winter versus summer), the month of the year (especially, high returns in January), the time of the month (first versus second half), holidays, the day of the week (low returns on Mondays), the time of the day, the amount of sunlight (as in seasonal affective disorder), and even the frequency of geomagnetic storms.

The third category of predictor variables in eq. (2) is a catch-all, ‘other’ variables. Prominent among these are bond yields and yield spreads. Fama and Schwert (1977) were among the first to observe that the level of short-term Treasury yields predicts returns in eq. (2) with a negative coefficient. They interpreted the short-term yield as a measure of expected inflation. Ferson (1989) argues that the regressions imply that the systematic risk of stocks that determines the expected returns must vary over time with changes in interest rates. Keim and Stambaugh (1986) study the yield spreads of low-quality over high-quality bonds and find predictive ability for stock returns, and Campbell (1987) studies a number of yield spreads in shorter-term Treasury securities. Another interesting set of predictor variables includes measures of the conditional variance or volatility of stock returns (for example, Merton, 1980). Fama and French (1989) assemble a list of variables from studies in the 1980s and describe their relations with US business cycles. Of course, many other semi-strong form predictor variables have been proposed, and more will doubtless be proposed in the future. Some recent variables include the fraction of equity issues in new issues of corporate securities (Baker and Wurgler, 2000), firms’ investment plans (Lamont, 2000), the average ‘idiosyncratic’ or firm-specific component of past return volatility (Goyal and Santa-Clara, 2003), the level of corporate cash holdings, the aggregate rate of dividend initiation (Baker and Wurgler, 2000), share issuance, and the political party currently in office (Santa-Clara and Valkanov, 2003).

**Methodological issues**

Even though the regressions (1) and (2) seem pretty straightforward, interpreting the predictability evidence for stock returns based on these regressions is not. It can be argued that one of the greatest contributions of the literature on stock return predictability is the methodological lessons it has taught researchers in the field. Perhaps the most difficult issues involve selection bias and data mining. Additional issues that have been addressed in the literature include small sample biases in the coefficients, standard error estimation, multiple comparisons, efficient estimation, regime shifts, spurious regression and the interactions among these effects.

Selection bias and data mining are serious concerns. Data mining refers to sifting through the data in search of predictive or associative patterns. There are two kinds of data mining. Sophisticated data mining accounts for the number of searches undertaken when evaluating the statistical significance.
of the finding (for example, White, 2000). This is important because, if 100 independent variables are examined, we expect to find five that are ‘significant’ at the five per cent level, even if there is no predictive relation. Naive data mining does not account for the number of searches. The big problem, given the strong interest in predicting stock returns among academics and practitioners, and the many studies using the same data, is that it is difficult to account for the number of searches. There probably have been at least as many regressions run using the Center for Research in Security Prices (CRSP) database as there are numbers in the database. Compounding this problem are various selection biases. Perhaps most difficult is the fact that only ‘significant’ results get circulated and published in academic papers. No one knows how many insignificant regressions were run before those results were found.

A reasonable response to these concerns is to see whether the predictive relations hold out of sample. This kind of evidence is mixed. Some studies find support for predictability in step-ahead or out-of-sample exercises (for example, Fama and French, 1989; Pesaran and Timmerman, 1995). Semi-strong form variables show some ability to predict returns outside of the US data where they were originally studied (for example, Harvey, 1991; Solnik, 1993; Ferson and Harvey, 1993; 1999). Other studies conclude that predictability using many of the semi-strong form variables does not hold outside of the original samples (for example, Goyal and Welch, 2003; Simin, 2008). Even this evidence is difficult to interpret, because a variable could have real predictive power yet still fail to outperform a naive benchmark when predicting out of sample (Campbell and Thompson, 2005).

A large literature has addressed statistical issues in predictive regressions. Boudoukh and Richardson (1994) provide an insightful review. Ferson, Sarkissian and Simin (2003) study the interaction between data mining and spurious regression effects. The interaction among the various statistical issues with predictive regressions has received relatively little research to date, and this is likely to be an active field in the future.

Perspective

Does the current body of evidence lead to the conclusion that there actually is predictability in stock returns? I think there are good reasons to be sceptical of predictability and good reasons to believe in predictability.

Why should we be sceptical? First, the logic of the older efficient markets literature is compelling to many. In that view, traders would bid up the prices of stocks with predictably high returns, thus lowering their returns and removing any predictability at the new price. Furthermore, data mining and selection bias conspire to make us see predictable patterns where none may exist.

For one example, studies of relative predictability, such as momentum, have sliced and diced common stocks into portfolios based on many characteristics of the data, at which point the effect often retreats into subsets of stocks, sub-periods of time, phases of the business cycle or other parts of the data. Studies find momentum to be concentrated according to industries, the size of the firm (more momentum in large stocks), the price of the share (more when the price is above five dollars per share), and so on. The effect does not appear prior to 1940, appears stronger after 1968, and appears stronger during economic expansions than contractions.

The evidence for long-term return reversals has a similar problem. Reversals have been found to be concentrated in small stocks, low-priced stocks, the month of January, and high idiosyncratic risk stocks, and to be more pronounced in earlier samples than in more recent data. For each approach to slicing and dicing the data there is a clever story. That is not all bad. By digging into subsamples it should be possible, in principle, to isolate what is driving an effect. But many of the patterns, especially those documented in the weak-form predictability literature, appear to be sample-specific. Finding results that vary with the sample period stimulates research featuring structural breaks and regime shifts. This reader is left more with concerns about naive data mining, improper multiple comparisons and statistical issues than with an understanding of why and where these weak-form effects occur systematically.

Predictive regressions are also subject to a host of statistical issues. There are finite sample biases and problems associated with structural breaks and regime shifts. It is hard to get reliable standard errors for the regressions. There are potential spurious regression problems. And, as we are now beginning to understand, these effects can interact with each other. If semi-strong form predictability...
is spurious, as a result of statistical bias and naive data mining, we would expect predictor variables to appear in the empirical literature, and then to fail to work with fresh data. To some extent, the literature has evolved in this way.

There are also many good reasons to believe that stock returns are predictable. First of all, theory suggests that some amount of predictability is likely. If expected returns vary over time with some degree of persistence, predictability is expected. Most people find it easy to believe that expected stock returns and risks might be different coming out of a recession, for example, than going into one, and the predictability evidence tends to confirm such common-sense patterns. Studies find that predictability using lagged variables is largely explained by asset pricing models if they allow the risk premiums to vary over time (for example, Ferson and Harvey, 1991; Ferson and Korajczyk, 1995; Avramov and Chordia, 2006). The behavioural models of predictability are compelling to many, as we see ourselves making the same cognitive errors as those made by the agents in those models.

The momentum effect has been found to hold out of sample relative to the original study of Jegadeesh and Titman (1993). Jegadeesh and Titman (2001) find momentum in data for 1990–98. Momentum is also found in stock markets outside the United States.

The evidence of semi-strong form predictability has also survived a number of out-of-sample tests, working in other countries and over different time periods. Many of the variables identified as predictors for stock returns also seem to have some predictive power for other types of securities such as bonds and futures, and also for the growth rates in ‘fundamental’ macroeconomic data. The evidence for semi-strong form predictability has survived corrections for a host of statistical and data problems.

Some studies that find semi-strong form stock market predictability, measured directly using lagged variables, has weakened in recent samples. It may be that the predictability was never really there, or that it was ‘real’ when first publicized but diminished as traders attempted to exploit it. Ferson, Heuson and Su (2005) examine semi-strong form predictability by regressing individual stocks on firm-specific predictors, then measuring the average covariances of the fitted values. It can be shown that the variance of the expected return on a large portfolio is approximately the average covariance. They find no evidence that predictability, measured in this way, is weaker in recent sub-periods. As the firm-specific predictors have not been examined extensively in the literature, they may be less subject to naive data mining biases. Campbell and Thompson (2005), using step-ahead tests, also find that semi-strong form predictability holds up in recent data.

Conclusion

The issue of predictability in stock returns has important and broad economic implications. For example, it relates to the efficiency of capital markets in allocating resources to their highest-valued uses. But the interpretation of predictability, and the evidence for its very existence, remain controversial. This reader finds the evidence for weak-form predictability (using the information in past stock prices) to be more fragile and less compelling than the evidence for semi-strong form predictability (using publicly available information more generally).

For the field of financial economics and asset pricing in particular, allowing for the possibility of predictability in stock returns through time-variation in expected returns, risk measures and volatility, has been one of the most significant developments since the mid-1980s. Such conditional asset pricing models provide a rich setting for the study of the dynamic behaviour of asset markets and problems such as the evaluation of portfolio manager performance. The issue of predictability has stimulated numerous advances in the statistical and econometric methods of financial economics. Research on predictability in asset markets is likely to continue, and remain both useful and controversial, for a long time.

**How to cite this article**

Volatility is a measure of asset price variability over some period of time, which typically describes the standard deviation of an investment's return in a particular context. The measurement and prediction of volatility is important when designing an equity portfolio. It is also important for risk managers, particularly when they calculate 'value at risk'.

Volatility has been defined in at least five different ways. The simplest of these regards volatility as a constant numerical parameter $\sigma$, associated with the assumption that investment returns during identical durations of time have both identical standard deviations and independent distributions. This assumption is contradicted for stock prices by substantial changes in price variability as time progresses. These changes are often referred to as the phenomenon of volatility clustering; as first noted by Mandelbrot (1963, p. 418), this is the property of prices that ‘large changes tend to be followed by large changes – of either sign – and small changes tend to be followed by small changes’.

A second definition of volatility views it as a stochastic process, whose dynamic properties and parameters can be estimated from historical time series (see stochastic volatility models). This entry covers realized volatility, conditional volatility and implied volatility, and it concludes with observations about forecasting methods. Chapters about all of these topics and stochastic volatility are included in Taylor (2005).

An answer to the fundamental question ‘Why does stock price volatility change?’ has proved elusive. Occasional crises explain some of the higher observed levels of volatility. These crises may be economic, political or financial, examples being the Great Depression, the Watergate tapes episode and the crash of 19 October 1987. Macroeconomic variables, such as inflation, unemployment and GNP, have an impact upon equity volatility. Scheduled announcements about these variables usually coincide with a very short period of higher volatility, but at other times macro variables explain only a small proportion of the variability of volatility. Stock volatility depends partially on the level of the market. When prices fall, the value of firm equity relative to debt increases, financial leverage increases and it is observed that volatility increases on average. Volatility is positively correlated with trading volume, but this does not imply a causal relationship.
between these two variables. Instead, information flows are likely to have a common impact upon both volatility and volume – as the amount and the importance of information increase both volatility and volume should theoretically increase.

Realized volatility

Investment returns can be defined by changes in the logarithms of stock prices, with appropriate adjustments for dividend payments. The standard deviation of a set of \( n \) returns calculated from the latest price and \( n \) previous prices provides a simple measure of realized or historical volatility. These standard deviations are often calculated from daily closing prices and scaled to provide an annualized quantity. The conversion from daily to annual volatility requires multiplication by \( \sqrt{N} \), with \( N \) the number of daily returns available in one year. A typical level in the United States of the annualized volatility is 15 per cent for a diversified stock index, 30 per cent for a large firm and 45 per cent for a randomly selected firm.

More accurate realized volatilities can be calculated from more frequent price observations. Andersen et al. (2001) essentially evaluate standard deviations for five-minute returns, for each stock in the Dow Jones Industrial Average index. They show that realized volatility has an approximate lognormal distribution and a long-memory property. The distribution of daily returns, conditional upon their realized volatility, is approximately normal. This contrasts with the high peaks, fat tails and excess kurtosis of the unconditional distribution of returns, all of which are created by the stochastic behaviour of volatility.

Conditional volatility

A conditional variance for a future return can be calculated from historical returns and a time series model, whose structure and parameters can respectively be identified and estimated from previous returns. A massive literature on autoregressive conditional heteroscedasticity (ARCH) commences with Engle (1982). The most appropriate simple choice for the conditional variance \( h_t \) of the daily stock return \( r_t \) during period \( t \) is given by the following recursive equation of Glosten, Jagannathan and Runkle (1993):

\[
\begin{align*}
    h_t &= \omega + (\alpha + \gamma d_{t-1}) (r_{t-1} - \mu)^2 + \beta h_{t-1} \\
    d_{t-1} &= 1 \text{ if } r_{t-1} < \mu \text{ and } d_{t-1} = 0 \text{ otherwise.}
\end{align*}
\]

The expected return \( \mu \) and the volatility parameters \( \omega, \alpha, \beta \text{ and } \gamma \) can all be estimated easily by maximizing the log-likelihood function for some historical set of returns. The dummy variable \( d_{t-1} \) in (2) is important when modelling stock indices. It is required to accommodate the asymmetric tendency for volatility to rise more sharply when stock market prices fall significantly than when they rise by the same percentage amount. Most US estimates of the asymmetry ratio, \( \alpha + \gamma / \alpha \), exceed three, and values as high as nine have been estimated from recent data. Possibly the best explanation for the asymmetric effect is that the correlations between the returns from different firms tend to increase when the market falls. The duration of volatility shocks is characterized by the persistence parameter, \( \varphi = \alpha + \beta + 0.5 \gamma \) for
(1), that is often estimated above 0.97 for series of daily returns. Volatility does not appear to be a unit-root process. Typical estimates of the half-life parameter, $H = \log(0.5) / \log(\varphi)$ trading periods, vary from a few months to one year. Typical annualized standard deviations for the above model can be calculated from daily S&P 100 index returns between 1991 and 2000: they vary from 7 per cent to 47 per cent, with interquartile range from 10 per cent to 18 per cent, and median equal to 13 per cent. The average level rises from 11 per cent for 1991–95 to 18 per cent for 1996–2000, reflecting the dotcom bubble, and it has fallen since 2000.

We note that many other ARCH models have been proposed for stock volatility. Including a long-memory component often appears to improve the statistical fit, although the calculations and the mathematical structure are then far more complicated.

**Implied volatility**

Option markets provide a rich source of information about market beliefs concerning future volatility. The Black–Scholes formula for a European call option assumes that stock prices follow a special continuous-time process that has constant volatility $\sigma$. The formula provides a theoretical price $c(S, T, K, r, q, \varphi)$ that depends on the unknown quantity $\sigma$ and five observable variables: the current stock price $S$, the time until expiry of the option $T$, the strike price $K$, the risk-free interest rate $r$ and the dividend yield $q$ (here assumed constant for expositional convenience). As the theoretical price is an increasing function of $\sigma$, for any market price $c_M$ that excludes arbitrage profits there is a unique value of $\sigma$ that solves the equation $c(S, T, K, r, q, \sigma) = c_M$. This unique solution is called the implied volatility. Similar definitions apply to put and to American options.

At any moment in time a matrix of implied volatilities can be calculated, with the rows and columns respectively defined by the two contractual parameters, $T$ and $K$. The entries in an empirical matrix are not identical as predicted by Black–Scholes theory, primarily because their assumed continuous-time process oversimplifies reality. The mean-reverting, stochastic behaviour of volatility creates term effects – for a fixed $K$, the implied volatilities tend to increase (decrease) as $T$ increases when their level is below (above) the long-run average. The deviation of future price distributions from the lognormal shape and the level of the correlation $\rho$ between price and volatility shocks creates so-called smile effects – for a fixed $T$, implied volatilities decrease as $K$ increases for stock indices (as $\sigma < 0$) but can define a U-shaped function for individual securities (as $\rho$ can be near to zero) (see also stochastic volatility models).

Implied volatilities are on average slightly higher than realized or conditional volatilities. One explanation is that option prices incorporate risk premia that compensate their owners for bearing the risk that volatility changes and/or prices jump.

**Volatility forecasts**

Historical information about prices can be converted into forecasts of future volatility, from the current time until any chosen future time, by using time-series methods to extrapolate from current and past values of either realized or conditional volatilities. Implied volatilities can also be converted into forecasts. Conceptually they have the advantage that they can incorporate beliefs about volatility changes arising from future events. Set against this are two issues: (a) the necessity of extracting a single number from a matrix of candidate values, which refer to option lifetimes that rarely match the forecast horizon, and (b) the tendency of unadjusted implied volatilities (that embed risk-neutral probabilities) to be biased predictors of future realized volatilities.

A high proportion of the empirical evidence shows that option-based forecasts of realized index volatility are more accurate than historical forecasts, particularly when the forecast horizon is at least one month. Blair, Poon and Taylor (2001) show that an option-based forecast calculated from a weighted average of several implied volatilities outperforms historical forecasts that utilize daily and more frequent returns. Jiang and Tian (2005) obtain the same conclusion when they use a model-free measure of implied volatility, which provides a theoretically optimal method for extracting the market's risk-neutral variance expectation from a complete set of option prices.

Article

The Stockholm School existed between the years 1927 and 1937 as a separate and distinctive school of economics. The School was given its name by Ohlin in his review of the General Theory (see Ohlin, 1937). A ‘School’ is here defined as an interrelated development of a common theme among its members, who included Myrdal, Lindahl, Hammarskjöld, Ohlin and Lundberg. The common theme is the development of dynamic methods, which refer to notions such as temporary equilibrium and intertemporal equilibrium.

The development of dynamic methods is an original contribution. There is no evidence that the members were influenced in any significant way by other contemporary economists. After 1937 there are clear indications that the Swedish economists took up ideas from Hicks and Samuelson (cf. Hansen, 1951). The Stockholm School generally applied their concepts to macroeconomic problems and there are similarities to Keynes's General Theory, but they did not construct the principle of effective demand (Hansson, 1982; Landgren, 1960; Patinkin, 1982; Steiger, 1971).

Equilibrium approaches

The first contribution to the development of dynamic method is Myrdal's dissertation from 1927, Prisbildningsproblemet och föränderligheten (The problem of price formation and change). His method includes anticipations, that is, among the data or the immediate determinants of relative prices. The direct stimulus to this idea seemed to have come from what Myrdal considered to be Cassel's incomplete handling of the dynamic problem.

The inclusion of anticipations implies that future anticipated changes have effects on the economic process long before they actually take place. The theoretical determination of an equilibrium has therefore to include the anticipated consequences of probable changes. Myrdal's method of putting the anticipated effects alongside the other data has been called ‘the method of expectation’, which means the inclusion of expectations as explicit variables in a formal equilibrium theory (cf. Hicks, 1973, p. 143 n. 11).

Lindahl's construction of intertemporal and temporary equilibrium are both examples of an equilibrium approach, which means that for each individual and commodity the anticipated price achieves a balance of demand and supply and all expectations are therefore fulfilled. Lindahl also considered the assumption of perfect foresight a necessary condition for the determination of a price situation as a state of equilibrium.

Lindahl's aim in the article ‘The Place of Capital in the Theory of Price’ (1929) was to analyse the effects of including capital goods in the determination of a static equilibrium. Intertemporal
equilibrium emerges from the shortcomings of comparative statics in handling some of the problems related to this analysis and it is not aimed at solving macro-theoretical problems. Hayek had already constructed intertemporal equilibrium in 1928 but there is no evidence that Lindahl at this time was aware of Hayek's contribution.

Intertemporal equilibrium can analyse dynamic conditions, since there is a movement in the system. However, the mathematical formulation shows that there is no 'movement' in any meaningful sense, since it is a simultaneous determination of prices, quantities and interest rates for all periods under the assumption of equilibrium within each period. Lindahl's development of temporary equilibrium grew out of this inadequacy of intertemporal equilibrium. He looked for a method which should include the analysis both of relative prices in each period and of the price relations between different periods, and temporary equilibrium was meant to solve this problem.

The notion of a period plays an important role both in intertemporal and temporal equilibrium as methods to analyse dynamic conditions. The principal difference between dynamic and stationary conditions is that in the former case the factors determining the prices – the data – are constantly changing. The dynamic case implies practically continuous changes in data but Lindahl assumed for analytical reasons that:

In order to analyse such a dynamic process, we imagine it to be subdivided into periods of time short that the factors directly affecting prices, and therefore also the prices themselves, can be regarded as unchanged in each period. All such changes are therefore assumed to take place at the transition points between periods. The development of prices can then be expressed as a series of successive price situations. (Lindahl, 1930, p. 158)

To divide the dynamic process into periods was in the beginning just introduced as an heuristic device, but later on Hammarskjöld gave it an analytical base.

The application of temporary equilibrium implies that for each period the prices are in equilibrium states in the sense that there will be equality between supply and demand during the period; the determination of prices is expressed as a system of equations for each period. The dynamic process is then analysed as a series of temporary equilibria. It shows that temporary equilibrium was developed before the publication of Hicks's Value and Capital (1939).

Lindahl's analysis was almost immediately criticized by both Lundberg and Myrdal. Lundberg's criticism relates only to intertemporal equilibrium but his critique is also valid for temporary equilibrium. The main weakness is that the accommodations to the disturbances are unexplained and outside the model, and the successive sequence of equilibria is therefore not explained (cf. Lundberg, 1930, p. 157; Myrdal, 1939, p. 122). The missing element is an analysis of the accommodation process, that is to say to explain the 'link' between consecutive periods. In fact, Lindahl himself later described his method as introducing 'dynamical problems within the static framework' (Lindahl, 1939a, p. 10), since this method could employ the entire static apparatus for the analysis of a dynamic sequence.

**Disequilibrium approaches**

In Monetary Equilibrium (1931) Myrdal attempted a critical reconstruction of Wicksell's normal rate of interest; the starting-point was Lindahl's analysis in The Rate of Interest and the Price Level. However, the most important contribution to the School is the construction of the famous ex ante/ex post calculus. The ex ante anticipations are the driving force in the dynamic process, but the ex post results do still play a role since they are a basis for the forthcoming ex ante calculations.

The method is constructed in such a way that there is always an ex post balance. But the interesting problem is to analyse the changes during the period which are required to bring about the ex post balance. These changes must be the result of inconsistent anticipations or due to exogenous changes during the period. It was precisely Lindahl's insufficient analysis of the balancing changes that was criticized by Myrdal and by Lundberg: the intervening changes could not be explained because time is divided into a number of short equilibrium periods during which no changes occur. However, with
the application of *ex ante* and *ex post*, which makes a proper analysis of the intervening changes, it is possible to be released from the straitjacket of the equilibrium approach implied by temporary equilibrium.

Hammarskjöld was the first within the Stockholm School to give an explicit explanation of the means by which two periods may be connected in a disequilibrium approach. Both Lindahl and Myrdal held, with greater or lesser clarity, that unexpected changes in the price level and the concomitant income changes would keep the process going, but their equations have no formal connections with plans in subsequent periods. Before Hammarskjöld nobody within the Stockholm School had shown that there was a relation between fixed plans and the length of the period, but after his contribution it was generally assumed that the duration of unchanged plans determines the length of the unit period.

Like the other members of the Stockholm School, Ohlin was interested in explaining changes in the price level, but he also wanted to give the most general analysis of the driving force behind price movements. His explanation is a restatement of an old Wicksellian idea. An explanation of price changes must look at the factors influencing the demand and supply of both consumption goods and investment goods. It is therefore not surprising that Ohlin found the idea of the disequilibrium in the capital market as representing the driving force – the hallmark of the Wicksellian approach – as a too narrow explanation. In particular, since he could construct examples where a disequilibrium in the consumer goods market was the main factor behind a price movement.

Ohlin's specific extension of Wicksellian macro-theory was his explicit treatment of autonomous changes in consumption, which seemed to have been Ohlin's own evaluation of his contribution to the Stockholm School (cp. Steiger, 1976, p. 356 n.22). But he made no significant contribution to the dynamic method.

**Sequence analysis**

Lindahl's ‘Note on the dynamic pricing problem’, a short (four pages) and privately circulated paper from 1934, lays the foundation of sequence analysis. His unpublished manuscript ‘Introduction to the theory of price movements in a closed community’ (1935) gives his idea on a general dynamic approach, which should be the basis for all theories, and most of these ideas were later reproduced in ‘The Dynamic Approach to Economic Theory’ (1939b).

To define a determinate sequence it is necessary to prove that certain human actions will necessarily follow from a definite situation at a given point of time. However, human actions or the results of human actions are not deterministic and can not be explained in the same way as events in the physical world, but this is only a problem for the empirical relevance of the theory and it does not show that the theory is inconsistent. The construction of a dynamic theory ‘solves’ the problem. To develop his general dynamic approach Lindahl had to postulate that individual actions represent the fulfillment of certain plans, which at the beginning of the period are determined according to explicit principles. It obviously takes a certain amount of time to realize these actions and a period of time is resolved. As far as changes in plans are concerned, Lindahl assumed that these take place at the transition point between two consecutive periods. It is implied that a period is defined by unchanged plans, which was already hinted at by Hammarskjöld. The notion of plan had played a central role within the Stockholm School almost from its beginning, but now it is explicitly stated as the pivot for the dynamic method.

To develop sequence analysis Lindahl assumed: at an arbitrary point in time \( t \) the plans for production and consumption are given for a certain period of time \( t \) to \( t+1 \), which means that if the prices are known then the individual actions are determined for the period; the supply prices are given during the period and all changes in prices and plans take place at the transition point between two consecutive periods, that is, a *fixprice* method. The problem to be solved is then the following:

the analysis of what happens during the said period, that is, the determination of the situation at the point \( t+1 \) as it results from the situation at the point \( t \). When this problem is solved, the situation at the point \( t+2 \) can in the same manner be explained as it results from the situation at the point \( t+1 \), and so on. The solution of this problem implies,
therefore, [...], the solution of the whole dynamic problem. (Lindahl, 1934, p. 204)

This solution contributes to the ‘whole dynamic problem’ in the sense that the same method could be employed for the period \((t+1)\) to \(t+2)\) at point \(t+1). This is an example of a single-period analysis, which shows that is going to happen during one single period; how certain \textit{ex ante} plans at the beginning of the period lead to determinate \textit{ex post} results at the end of the period. But it does not determine the whole dynamic process (from \(t\) to \(t+1\) and onwards) at point \(t\). It is also necessary to have a \textit{continuation analysis} to show the effects of the \textit{ex post} results in the current period on the plans for the subsequent period. It is obvious that both parts are necessary components in a sequence analysis which is supposed to determine a process spanning several consecutive periods.

To solve the single-period analysis Lindahl assumed that the spending plans are assumed to be realized as far as quantities are concerned; it is implied that there are enough unemployed factors of production and sufficient stocks of goods and therefore all adjustments during a period can take place via changes in stocks. The role of this assumption is to show that the actions during the period can be directly deduced from the plans once the prices are given at the beginning of the period.

Hence, the result of the period is a necessary outcome of the \textit{ex ante} plans for the current period. To determine the \textit{ex post} results from the given \textit{ex ante} plans at time \(t\) does not imply that the ongoing process after time \(t+1\) can be determined at \(t\) without further assumptions. The crucial assumption of the continuation analysis concerns the relation between \textit{ex ante} plans for the forthcoming period and the \textit{ex post} results for the current period. Lindahl now assumed: if the plans are fulfilled, and there are no changes in the exterior events, then it is possible to postulate a simple functional relation between the \textit{ex ante} plans for the next period and the \textit{ex post} results of the current period. The application of this assumption for several periods gives as a result that the whole dynamic process can be deduced from the data given at the beginning of the first period. Thus, in Lindahl's analysis each single period is in equilibrium and this type of sequence analysis can be interpreted as a sort of moving equilibrium. Lundberg left out the postulate that the plans have to be fulfilled within each period, which is the difference between equilibrium and disequilibrium sequence analysis.

Lundberg's development of sequence analysis, in \textit{Studies in the Theory of Economic Expansion} (1937), used a disequilibrium approach but at the same time it is an equilibrium process. It is this two-sided character of disequilibrium and equilibrium in Lundberg's sequence analysis which is important to understand.

Lundberg criticized static equilibrium but such equilibrium notions might still be useful to explain the development of aggregate relations. In fact, if a sequence analysis should be possible then some equilibrium relations must hold even out of equilibrium, and equilibrium constructions play therefore a fundamental role in sequence analysis. The question is to what extent equilibrium constructions may be used in a sequence analysis which starts with aggregate categories. Lundberg's analysis is a disequilibrium sequence analysis, while Lindahl in 1934 pursued an equilibrium sequence analysis.

In Lundberg's analysis the equilibrium notion is represented by the fixed response functions – an expectation function of a constant form – which is presupposed for the existence of equilibrium through time (cf. Hahn, 1952, p. 804). Sequence analysis belongs therefore to the class of equilibrium processes, since constant expectation functions imply that behaviour is invariant over a certain period of time which is a crucial aspect of a general notion of equilibrium. Hence, disequilibrium sequence analysis is an equilibrium process, but, at the same time, it is a disequilibrium approach since expectations are not fulfilled within each period.

**Assessment**

After the late 1930s there was almost no contribution to the development of dynamic method from the original members of the School. Most of them had also left the world of pure academics: Myrdal worked on the problem of black people in the United States in the early 1940s and was later minister for trade in the social democratic government; Hammarskjöld was already in the mid-1930s a prominent civil servant; Ohlin became leader of the Liberal Party in the early 1940s; Lundberg was in 1937 appointed as the first director of the Swedish Business Cycle Research Institute; Lindahl was
the only one who pursued a pure academic career and now and then he would dwell on his original ideas, but there was no further development.

The essence of stock–flow analyses of individual or market behaviour is an explicit recognition of the interdependence of current production, consumption and asset-holding plans. The term ‘stock–flow analysis’ is used here generically to refer to any theories dealing simultaneously with the economic activities of production, consumption and asset-holding. At a market level this implies a distinction between plans to purchase a good in the current period in order to consume it during the current period (flow demand) and for the purpose of holding it at the end of the current period as an asset (stock demand), and an analogous distinction between plans to supply the good from current production (flow supply) and past production (inventories, or stock supply). In this article we review the nature of the distinction between stocks and flows and then illustrate the importance of the distinction for alternative theories of market price determination. Detailed references to the folklore of the stock–flow literature may be found in Burstein (1982), Bushaw and Clower (1957), Clower (1968) and Harrison (1980). We focus here on markets: see Archibald and Lipsey (1958), Clower (1963), Clower and Burstein (1960), Hadar (1965; 1971, ch. 11) and Johnson (1971) for important contributions to theories of individual behaviour in a stock–flow environment.

Whether acknowledged or not, there are three respects in which stocks and flows are commonly distinguished. We shall refer to these, for convenience, as the dimensional, behavioural and heuristic distinctions. It is crucial to keep these conceptually separate. For purposes of exposition we shall discuss the analytical characterization of the trading and exchange processes pertaining to a market period of given length. For convenience and familiarity presume that market-price determination occurs instantaneously at discrete points of time spaced equally apart in calendar time. Hicks (1946; ch. 9) chose to visualize this point at the beginning of each ‘week’. Providing we do explicitly identify some such reference date, there is no reason to visualize it at any particular point during the week. For the sake of tradition we follow Hicks's vision of traders coming together at the beginning of the week. Their trading plans, which we shall characterize precisely in a moment, are presumed to be coordinated in some fashion by the activities of an auctioneer in setting a particular price vector that is to prevail until the next meeting at the Bourse (the beginning of the week). For present purposes we shall assume that prices are set so as to satisfy the Hicksian temporary equilibrium condition that planned purchases equal planned sales.

By viewing what happens at the Bourse as happening at a point in time we are led to characterize trading plans, for whatever purpose, dimensionally as stocks. At a given price a trader plans to buy or sell a particular quantity of a good; when the auctioneer cries out a particular price for a particular good, the traders each respond with no more than a positive or negative number (positive for purchase offers and negative for sales offers, let us presume). The auctioneer is not in the least interested in what the trader plans to do with the bottle of whisky he bid for – for all he cares, the trader may sip it continuously for the ensuing week, gulp it down completely at some instant during
the week, or just add it to his stockpile. It is only his trading plans that are relevant to the price determination that occurs at the Bourse, and they are unambiguously measured at the instant the Bourse is open. Thus we have the first stock–flow distinction – trading plans are dimensionally stocks (measured at some reference date) and not flows (measured per some market period).

The illustration of the opening of the Bourse is just one of many possible characterizations. Such a conception permits us to focus on the important implications of a behavioural stock–flow distinction implicit in many writings. Referring to his own temporary equilibrium condition, Hicks argues (1965; p. 85) that:

> As long as we hold to the principle of price determination by ‘equilibrium of demand and supply’, on which that theory is based, we have no call to attend to anything but transactions. We do not need to distinguish between stocks and flows; for stocks and flows enter into the determination of equilibrium in exactly the same way.

There can, in competitive conditions, be no more than one price for the same commodity at the same time; and even in conditions that are only partially competitive, it does not have one price at stock and another as flow. The supply and demand that are equated, in the single period of Temporary Equilibrium theory, may (and probably will) contain stock elements as well as flow elements. Supply comes partly from stock carried over, partly from new production; demand is partly a demand for carry-forward. Expectations of futures prices affect both elements; interest affects both elements. The analysis does not require that stock and flow should be separated into compartments. It is not the case that there is one stock equilibrium and one flow equilibrium. There is one ‘stock–flow’ equilibrium of the single period; and that is all.

The stock–flow distinction implicit in Hicks's discussion is the behavioural one that calls the activities of current period production and consumption ‘flow activities’ and the activity of asset-holding a ‘stock activity’. It cannot be emphasized too strongly that the terms stock and flow are in this respect merely euphemisms for asset-holding and production/consumption behaviour, respectively. Thus we shall distinguish those trading plans related to asset-holding plans from those trading plans related to current production and/or consumption plans. We may refer to the former as excess stock demand and the latter as excess flow demand.

There are two important reasons for wanting to make such a behavioural distinction. The first concerns the alternative ways in which we may then choose to characterize trading plans as being ‘coordinated’. In terms of the Hicksian temporary equilibrium condition, market price is set such that at that price excess market demand (the sum of excess stock and excess flow demand) is zero. In terms of the Marshallian temporary equilibrium condition, market price is set such that excess stock demand is zero. Indeed, a failure to recognize the behavioural stock–flow distinction has led some authors to fail to see that these (and other) price determination conditions are alternatives; these implications of the behavioural stock–flow distinction are taken up below.

The second reason for making the behavioural distinction is that it raises the important difference between temporary (current period) market equilibrium and full (stock–flow, stationary, long-run static) market equilibrium. Clower (1968) argues that this may be the only reason for adopting a stock–flow analysis of market behaviour. This point may be put more accurately by saying that a recognition of stock and flow trading plans leads to a non-trivial explicit dynamic model of market behaviour from period to period. The overwhelming majority of received theory is written in terms of stock or flow trading plans; in such cases, a Hicksian temporary equilibrium in any period is, ceteris paribus, a full equilibrium. To account for observed non-stationary time series of market prices and/or inventories, recourse in such cases must be had either to persistent exogenous shocks to the system and/or ‘ad hoc’ adjustment lags in production or expectations formation.

We now highlight the point of separating the dimensional and behavioural stock–flow distinctions. When describing the Hicksian temporary equilibrium condition, we shall talk about flow trading plans rather than production and consumption plans. The reason for doing so is that we may wish to visualize the latter plans as being dimensionally flows. Similarly, we may wish to visualize asset-holding plans as being dimensionally stocks – we may accordingly choose to reference-date stock demand as planned holdings as at the end of the period and stock supply as existing inventory at the
beginning of the period. The point is that ‘... we have no call to attend to anything but transactions’, and all trading plans are dimensionally comparable, obviously leaving the theorist great scope in terms of the ‘real’ economic processes he may wish to discuss in terms of this scenario of market price determination. This scope is, however, often restricted by a third heuristic stock–flow distinction in common use.

The heuristic distinction asserts that current production and consumption are economic activities occurring in ‘real time’, while portfolio formation plans are not. It is often an implicit presumption, based intuitively but not necessarily on the behavioural stock–flow distinction. The rate at which whisky may be currently consumed at some price is, let us say, fixed in terms of calendar time units by taste considerations. Hence, it is argued, the number representing flow demand trading plans at that price varies directly with the market period length adopted. At all prices I, for example, like to sip one bottle of whisky a day; if the market opens once a week my (perfectly inelastic) flow demand is seven; if it opens daily, it is one. In each case my planned purchases remain dimensionally a stock. With respect to asset–holding behaviour it is argued conversely that the number representing (end of market period) stock demand is invariant to the market period length adopted. One thinks perhaps of speculators who are only concerned with inter-period price changes. It makes no difference to them, so it is argued, if the price changes daily or weekly (storage costs aside). The argument is far less plausible in the case of whisky retailers, however. The heuristic stock–flow distinction involves, in Patinkin’s words,

implicitly defining a ‘flow’ not as a quantity whose dimensions are 1/T, but as a quantity whose magnitude is directly proportionate to $h$ [the length of the market/planning period]; similarly, the implicit definition of a ‘stock’ is that a quantity whose magnitude is independent of $h$. Clearly such ‘stocks’ and ‘flows’ can be added together. (Patinkin, 1965, p. 521)

We might just add at the end of this quote: ‘... for a period of given, fixed length with respect to the conceptual experiments underlying these relations’. An obvious extension to this received presumption is to consider the factors influencing the cost of adjustment of portfolios in real time (cf. Clower and Howitt, 1978). With respect to production, consumption and portfolio formation, we may think of transaction costs (as distinct from learning by doing and indigestion) as common to all three activities. This extension implies, for the time being, an elaboration rather than refinement of the basic price theory under discussion here. It does clarify, however, the basis (such as it is) of a stock–flow dichotomy in the literature, focusing on price determination at an instant (for example, the approach of Tobin, 1969, may be viewed as an application of the Marshallian temporary equilibrium condition along with the explicit assumption of a perfectly elastic flow supply schedule). Knowing this, one would hardly wish to make this received presumption an article of modelling faith.

We now consider the importance of the behavioural stock–flow distinction for alternative theories of market price determination. For expository purposes consider an isolated market model for some good which is, with respect to the market period length adopted, capable of being produced, consumed and held as an asset. Such a good is referred to as a stock–flow good. A perishable good which may only be currently produced and currently consumed is called a pure flow good and a non-augmentable durable a pure stock good. Define the following notation with respect to any market period $t$: $D_t$: planned stock demand to hold the good at the end of the current period; $S_t$: existing stock supply of inventory of the good at the beginning of the current period; $d_t$: planned flow demand to consume the good over the current period; $s_t$: planned flow supply of current period production of the good; $p_t$: money-price of one unit of the good in the current market period; $x_t$: excess flow demand $= d_t - s_t$; and $X_t$: excess stock demand $= D_t - S_t$. Stock supply in period $t$ is defined as the accumulated sum of past excess flow supply: $S_t = x_t - x_{t-1} - x_{t-2} - ... - x_0$. The alternative temporary equilibrium conditions introduced earlier are defined as follows:
It is clear from these specifications of the two temporary equilibrium conditions that they do not in general predict that the current market price will be the same value. Moreover, the periodic rate of accumulation of inventory also depends on the theory employed. This accumulation process feeds back on the market price in period $t+1$, due to an induced shift of the excess stock demand schedule. The properties of the first-order difference equations implied by the alternative theories are well known: Bushaw and Clower (1957, chs 3 and 4) discuss the Hicksian condition, and Clower (1954a) the Marshallian condition.

A full (or stationary, or stock flow) equilibrium sequence in this market is characterized not only by a stationary market price from period to period, but also by zero accumulation of inventory holdings from period to period. The three conditions defining such a static equilibrium sequence (only two of which are independent) are

$$x_t + X_t = 0 \quad X_t = 0 \quad x_t = 0.$$

These conditions define the static equilibrium for both Hicksian and Marshallian theories of market behaviour. Presuming linear functional forms for the basic trading relations, the alternative theories are illustrated in Figures 1 and 2 and, their common static equilibrium in Figure 3. Note that $S_{t+1}$ in Figures 1 and 2 will be located to the right of $S_t$ by the amount of net new production shown. The market supply schedule $S_{t+1} + S_{t+1}$ correspondingly shifts to the right implying, *ceteris paribus*, a new temporary equilibrium price $p_{t+1}$ and further net new production. In Figures 1 and 2 current period excess flow supply is shown by the amount $q_1 - q_2$. In Figure 3, $S^*$ and $p^*$ denote static equilibrium values of these endogenous variables.

Figure 1
Hicksian temporary equilibrium
Figure 2
Marshallian temporary equilibrium
Figure 3
Full equilibrium (Hicksian and Marshallian)
Taken at face value, these stock–flow models may be used to generate sequences of non-stationary temporary equilibria that eventually converge on some full equilibrium (presuming the system to be stable). Indeed Clower (1954a; 1954b) and Bushaw and Clower (1957, pp. 63–75) illustrate these deterministic paths at length. What of the dynamic behaviour of the basic stock–flow model, however, when economic agents have some form of rational expectations (RE) about the future
course of the system?
Muth (1961, pp. 321–9) presented a model of an isolated market with certain stock–flow characteristics. If we amend that model to include flow supply as a function of the current period price, it can be shown that Muth’s derivation of the RE equilibrium remains essentially valid. Using our notation, the system is:

\[\sigma_t = -\beta p_1 D_t = \kappa [E(p_{t+1}) - p_t] s_t = \gamma p_t + \epsilon_t D_t + \sigma_t = S_t + s_t,\]

where \(E(p_{t+1})\) denotes the price expected in period \(t\) to prevail in period \(t+1\), this expectation based on all information about the history of this system up to and including period \(t\). The first three equations refer to the deviations of endogenous variables from their full equilibrium values in the absence of any stochastic influences (following Muth). The form of this stock demand equation may be rationalized along several lines (for example, the ‘supply of storage’ literature uses a similar relation to explain spot/futures differentials); for current purposes we need not pursue these. It can be shown that, if we accept the RE hypothesis that \(E(p_{t+1}) = \lambda p_t\), the expected price is given by \(E(p_{t+1}) = \lambda p_t\). The parameter \(\lambda\) in this case depends on the coefficients of flow demand, flow supply, and stock demand in a very specific way (see McCallum, 1972). It can also be shown that the use of RE in the simple stock–flow model leads to more robust dynamic market behaviour when compared to alternative expectations schemes.

These results, however, are not intuitively appealing. Stock–flow analysis emphasizes the distinction between temporary and full equilibrium, and the study of the stability (or otherwise) of sequences of temporary equilibria. The notion of rational expectations postulates that agents know the nature of the market they operate in, and pattern their current behaviour on expectations based on that knowledge. Why, then, do agents in Muth (1961, section 4) only consider the current temporary equilibrium of their market? It would seem more logical for speculators to be concerned with expectations of the full equilibrium of the market (note that the first model introduced by Muth, 1961, p. 317, is a pure flow market with a one-period supply lag; in this case it may seem more appropriate to focus on the expected price next period, given that producers are facing a point-input point-output decision problem). Burstein (1982) recognizes this point, arguing correctly that under rational expectations, transactors, knowing the structure of the economy and the structure of the sub-economies in which they operate, will optimize relative to ‘best estimates’ of future data; under characteristic formulations of stock–flow disequilibrium, transactors do not optimize even relative to data-sequences ground out by deterministic models; in the non-stochastic world of standard stock–flow theory, ‘rational’ transactors would achieve an equilibrium at the onset of the process – one spanning the phase space of the system. The upshot would support the basic insights of earlier stock–flow analysts but would require a quite different paradigm of market behavior.

In the amended stock–flow model with RE, a similar derivation with the added full equilibrium condition leads to the result \(E(p_{t+1})=0\). Recall that we are specifying the basic structural model in deviation form (thus a zero here implies that expected price is equal to the expected full equilibrium price). There are many ways to relax this result formally, as evidenced in recent literature on exchange rate dynamics. One major determinant of dynamics in stock–flow models is therefore the assumed ‘term-structure’ of expectations (rational or otherwise).

Richard Stone was a great British empiricist. He and James Meade developed a systematic double-entry approach to national income accounting that later became the basis of the UN's System of National Accounts and for which he received the Nobel Memorial Prize in 1984. His work on the analysis of consumer behaviour is an outstanding example of how to use theory in the service of measurement, and contains perhaps the first case of the econometric estimation of the parameters of preferences. He was founding director of Cambridge's Department of Applied Economics and, through it, the father of a generation of applied econometricians.

Article
Sir Richard Stone, knighted in 1978 and Nobel Laureate in economics in 1984, was the outstanding

figure in post-war British applied econometrics. His work in social accounting has had a profound influence on the way that measurement is carried out in economics, and his econometric model building changed the way that economists analyse those measurements. In contrast to many of his British contemporaries, he was a scientist and scholar whose command of methodology and theory was always at the service of the interpretation and measurement of the evidence. He was the inheritor of the British empiricist tradition in economics that saw its first flowering among the ‘political arithmeticians’ of the English Restoration, men such as William Petty, Gregory King and Charles Davenant. To a large extent, he abstained from providing short-term policy advice, preferring to concentrate on the advancement of his science. But his contributions have had an incalculable effect on economic policy and his career provides eloquent testimony to the long-run social value of scientific scholarship in economics and a contrast to the sometimes unenviable record of his contemporaries who involved themselves in the day-to-day conduct of British economic policy.

Richard Stone was born in 1913, attended Westminster School, and set out to follow his father's profession by reading law at Gonville and Caius College, Cambridge. He moved to economics midway through his undergraduate career, and came under the influence of Colin Clark, who was then lecturing in statistics to the economists and who was himself deeply involved in the measurement of national income (see particularly Clark, 1937). Stone's interest in modelling, in measurement and in estimation was immediate. During the summer prior to his graduation from Cambridge, he set out to estimate a two-factor Cobb–Douglas production function, a pioneering effort, the results of which excited little interest or understanding from 'the Prof', as Pigou was known, perhaps the first evidence of a Cambridge attitude to econometrics that was later to be reinforced by Maynard Keynes's reactions to Tinbergen's work (Keynes, 1939) and was to be maintained long after similar perceptions had died out elsewhere.

After a brief spell in the City of London, during which he devoted his spare time to producing a monthly bulletin of current economic trends, Stone moved at the outset of the Second World War to Whitehall, where eventually he came to work, with James Meade and initially under his direction, on the construction of wartime national accounts. At Keynes's instigation, their results were published in the 1941 government White Paper, An Analysis of the Sources of War Finance and an Estimate of the National Income and Expenditure in 1938 and 1940. In 1945, and again under Keynes's stimulus, the Cambridge Department of Applied Economics was founded and Richard Stone was appointed its first director with an indefinite tenure in the position. Stone brought enormous distinction and worldwide recognition to the department until he was manoeuvred out of the directorship by the Cambridge 'Keynesians' in the mid-1950s; he remained in Cambridge as the P.D. Leake Chair of Finance and Accounting until his retirement in 1980. The 1984 Nobel Prize in economics is perhaps the greatest of many professional honors bestowed on Sir Richard. He was a Fellow of King's College, Cambridge from 1945 and of the Econometric Society from 1946. He was president of the Econometric Society in 1955 and President of the Royal Economic Society from 1978 to 1980.

The work for which Stone received the 1984 Nobel Prize in economics was his ‘fundamental contributions to the development of national accounts’ that ‘greatly improved the basis for empirical economic analysis’. The full history of the development of modern national income accounting remains to be written, and any attempt is beyond the scope of an article such as this. It is of course not true that Stone was responsible for the basic concepts of national product, consumption, investment and so on, nor that he provided the first estimates of these magnitudes for the United Kingdom or anywhere else (see, for example, Stone's brief history of the subject in his Nobel Memorial Lecture: Stone, 1984a).
What Stone (along with Meade, whose original vision Stone developed and made his own) should be credited with is the construction of an interlocking system of balanced national accounts, and the implementation of that system on a worldwide basis. Stone's system of national accounts, the SNA, published by the United Nations Statistical Office in 1953 with several subsequent revisions, is not simply a set of tables containing the national income magnitudes, but a set of interlocking accounts in which the principles of double-entry bookkeeping are scrupulously maintained. Each outlay for each agent must be matched somewhere else by an inflow for some other agent, so that each entry in each account must appear somewhere else in some other account. Of course, this is of value only because each account, whether for production, accumulation, consumption or international trade, is independently filled in so that in the end the whole system provides its own complete set of internal consistency checks. Of course, there are always errors and omissions, and some magnitudes cannot be independently measured from both sides of the account, but the credibility and usefulness of each of the numbers hinge on the systematic framework in which they are set. It was Richard Stone, first with James Meade in the Cabinet Office in London, and later on the world stage at the United Nations and the Organization for European Co-operation and Development, who was largely responsible for the way in which national accounts are today collected and presented throughout the world (Stone, 1947; OEEC, 1952).

Stone always favored the presentation of his national accounts in a matrix format, so that each account appears as the row (incomings) and column (outgoings) of a single matrix. In this social accounting matrix (SAM), the standard magnitudes such as national product, consumption or the balance of trade all have their place, but the detailed entries provide a rich picture of the structure and functioning of the economy. For example, the Leontief input–output matrix of inter-industry transactions is the sub-matrix corresponding to the detail of the production accounts. Demand patterns of households appear in the sub-matrix with industries in the rows and households in the columns, while the incomes generated in production flow into households through the value added sub-matrix. Such social accounting matrices can be disaggregated to show any amount of data, and they can be supplemented by balance sheet data (the opening and closing stocks corresponding to the national income flows); and they can be related to socio-demographic variables in a set of demographic accounts. For a typically elegant and lucid account of this with simple examples, see again Stone (1985). One of the most important features of such ‘tableaux économiques’ is that it is almost impossible to look at them for long without being led into attempts to model the behaviour that they reveal. For some cases, the SAM is close to being a model; the input–output matrix can be thought of both as a record of transactions, and as a succinct description of the technology of production. Similarly, the links between production, accumulation and consumption lead naturally to models of the allocation of household income between saving and the purchases of goods and services. Together with his first wife, Stone had published one of the very first empirical papers on the marginal propensity to consume (Stone and Stone, 1938), and his work on modelling, particularly of consumer behaviour, continued along with his work on national accounts through the late 1940s and 1950s.

Perhaps Stone's greatest work lies in his empirical analysis of consumer behaviour and the contributions to econometric methodology that came with it. In a series of papers (Stone, 1945; 1948; 1951; Stone and Prais, 1953) that culminated in 1954 in a book, *The Measurement of Consumers’ Expenditure and Behaviour in the United Kingdom, 1920–38*, which to this day remains one of the classics of applied econometrics, Stone presented models that analysed the determination of consumers’ expenditures. The
book contains a dazzling display of all of the elements of the econometrician's art as of the mid-1950s, and there is very much that can be learned from it even today. There is a great deal of very careful and painstaking description of the data, not tucked away where the details cannot be seen, but proudly and prominently displayed for readers to see and quarrel with should they choose. There is a masterly exposition of the theory of demand and of revealed preference, and there is a chapter on econometric methodology that reads like a text until one realizes that this is where the texts originated. The standard matrix algebra formulation of the general linear model $y = X\beta + u$ appears in its modern form, together with such now standard diagnostics as the Durbin–Watson test, then just invented in the Department of Applied Economics by two young statisticians.

For each of the commodities that he analyses, Stone begins with a loglinear formulation in which the logarithm of the quantity of the good is related to the logarithm of income and the logarithms of other prices, together with a number of other factors that vary from commodity to commodity. For example, the demand for beer is influenced by the average strength of beer as measured by its specific gravity. Stone's major practical problem is lack of degrees of freedom; with only 19 annual observations, disentangling the separate effects of prices, income, and other influences requires generous application of theory and/or of prior information. Stone uses both. In the first place, he uses the Slutsky decomposition to absorb the income effects of prices into the income term through what is now known as a Stone index, thus converting the latter into real rather than money income. Second, he uses zero degree homogeneity to convert prices to relative prices, saving one degree of freedom. Third, he uses elasticities estimated from Engel curve analysis on cross-sectional household budget data to estimate the income elasticities so that, with these imposed, the time-series data are liberated to estimate as many price effects as precisely as possible. Fourth, Stone recognizes the difficulties presented by strong positive autocorrelation in the residuals and to counteract them takes first differences of model and data prior to estimation. Stone's recognition of the non-stationarity of his data, and his first-differencing procedure, though less than perfect, is much superior to and less misleading than the ignoring of the problem that characterized most applied work for the quarter-century after Stone's book. His general procedure set up, Stone then goes on to analyse commodities one by one, reporting results and testing alternative specifications with a care and conviction that has been a model for generations of those of us who have tried to follow him.

The other work of Stone's that is of lasting importance is his paper on the linear expenditure system that appeared in the *Economic Journal* in 1954, the same year that the book appeared. The transition from the models of the book to the model in the paper is in some respects one of the most important transitions in modern applied econometrics, and the methodological issues that are involved are still far from settled. In Stone's book, the influence of the theory of demand is pervasive throughout the discussion of specification and interpretation, but the functional form of the demand equations is essentially ad hoc, the double logarithmic form having been widely adopted because of its convenient parameterizations of the elasticities which are routinely used to describe demand behaviour. The consequences of using such an equation, and of treating demand equations one by one, is that certain aspects of the theory cannot be used nor easily tested. In particular, the symmetry of the compensated substitution effects could not be imposed within the analysis of the book, much as it would have been desirable to do so to gain degrees of freedom and precision of estimation. In the *EJ* paper, Stone comes up with a solution. Starting from a *system* of expenditure equations that are linear in prices and total expenditure, the theoretical requirements of adding-up, homogeneity, and symmetry are imposed.
algebraically to yield a set of estimating equations, the linear expenditure system, that is fully consistent with demand theory. Although the model cannot be estimated by linear methods, Stone invents an iterative Gauss–Seidel procedure that allows him to obtain estimates for a small system using the interwar data. There are many things to admire in this paper, and many things that can be criticized, especially with the benefit of hindsight. The linear expenditure system is a rather primitive model, and Stone's estimation technique was a poor one; similar things could no doubt be said about many great innovations. It is also true that Stone did not solve out for the linear expenditure system utility function, even though the theory of the model had been fully analysed some years before in papers by Klein and Rubin (1947–8), Samuelson (1947–8), and Geary (1950–1). The real originality and importance of the paper lie elsewhere. Nowhere is the previous literature had anyone ever had the extraordinary idea that it might be possible to use economic theory to confront the data so directly; demand equations had been estimated before, but no one had ever attempted to estimate the parameters of a utility function.

Economic theory might be used as a general guide as to what to look for, but not to yield estimating equations directly. The two main currents in applied econometrics today, structural estimation of ‘deep’ parameters versus more eclectic, atheoretical, or implicitly theoretical estimation, can be seen in Stone's paper and book of 1954. Today, when structural estimation is so familiar, it is easy to forget that ‘taking theory to the data’ is a relatively young methodology. I believe that Stone's linear expenditure system is a major landmark along the route that leads to where we are now.

In an article of this length it is impossible to give any detail on more than a tiny fraction of Stone's contributions to economics, although see my own more detailed (and somewhat more personal) memoir (Deaton, 1993). In addition to his work on the detail of commodity expenditures, there is a set of important papers on savings behaviour (Stone and Rowe, 1962; Stone, 1964a; 1966; 1973) and on the development of the stock-adjustment model for explaining the dynamic demands for durable goods (Stone and Rowe, 1957; 1958; 1960). A fuller appreciation of this work and other papers on demand analysis can be found in Johansen (1985) and in Houthakker (1985). Stone published important work on the theory of price indexes (1956), on seasonal adjustment (1970), and on methods of handling errors of measurement in national accounts (Champernowne, Stone and Meade, 1942; Stone, 1984b). He was one of the first to use principal components analysis as a practical data reduction procedure in economics (Stone, 1947). Over many years, he supervised the construction of the Cambridge Growth Model, in which social accounting matrices and behavioural equations for demand and production were integrated so as to provide a tool for planning and policy evaluation (see in particular Stone and Brown, 1962a; Stone 1964b). He also extended his work on economic accounting to incorporate demographic accounts (Stone, 1971; 1975; Stone and Weale, 1986). At the very end of his life, he acknowledged his debts to his predecessors in a set of quantitative biographies of 12 British empiricists in the social sciences, William Petty, Charles Davenant, Gregory King, William Fleetwood, Arthur Young, Patrick Colquhoun, John Graunt, Edmond Halley, William Farr, Frederick Morton Eden, Florence Nightingale, and Charles Booth (Stone, 1997).

There is another very great contribution that Stone has made to economics and econometrics that is not reflected in his own published work, but in that of those who have been associated with him over the years. Stone was never really a teacher in the conventional way. He was a reluctant lecturer, especially to students, and he participated very little in the routine of Cambridge instruction over more than 30 years of formal attachment to the faculty. However, his personal influence has been extraordinarily strong, partly because of the compelling lucidity of his writings, but also by the example he set to the
stream of economists and statisticians who spent time in the Department of Applied Economics with him. That stream flowed for many years, but there is no doubt that the best years were at the beginning, in the late 1940s and early 1950s, when Stone himself was working on demand and on the econometric techniques of estimating demands. I have no complete list of those who passed through, but a partial list of those who were there for extended periods includes Brumberg working on life-cycle models, Houthakker working on revealed preference and applied demand analysis, Prais working on family budgets, and Tobin working on demand analysis and on rationing. On the more statistical side, Durbin, Watson, Cochrane, Orcutt and Anderson spent time in the Department working on autocorrelation in economic time series, early visitors included Tintner and Duesenberry, Geary, Klein, Leontief, Samuelson, Koopmans, Wold, Frisch, Ruggles and Hoffman. Farrell began his academic life in Stone's department and did fine empirical work on dynamic demands and on aggregation theory. Prest worked on demand analysis and on time-series problems. Alan Brown worked on Engel curves and wrote a distinguished book with Aitchison on the uses of lognormal distribution (Aitchison and Brown, 1957). Afriat began his work on price indexes in the department. Not only did all of this work owe much to Stone's presence and to the existence of the Department of Applied Economics, but the joint output of all of these people represents an explosion of econometric and economic knowledge that has never been exceeded in the history of the subject and has perhaps been equalled only by the work of the Cowles Commission.

strategic and extensive form games

Martin J. Osborne
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The basic theory of strategic and extensive games is described. Strategic games, Bayesian games, extensive games with perfect information, and extensive games with imperfect information are defined and explained. Among the solution concepts discussed are Nash equilibrium, correlated equilibrium, rationalizability, subgame perfect equilibrium, and weak sequential equilibrium.

Keywords

Article

1 Introduction

Game theory is a collection of models designed to understand situations in which decision-makers interact. This article discusses models that focus on the behaviour of individual decision-makers. These models are sometimes called ‘non-cooperative’.

2 Strategic games

2.1 Definition

The basic model of decision-making by a single agent consists of a set of possible actions and a preference relation over this set. The simplest theory of the agent's behaviour is that she chooses a member of the set that is best according to the preference relation.

The model of a strategic game extends this model to many agents, who are referred to as players. Each player has a set of possible actions and a preference relation over action profiles (lists of actions, one for each player).

Definition 1: A strategic game with deterministic preferences consists of

- a set \( N \) (the set of players)
A strategic game \((N, (A_i, \succeq_i))\) is **finite** if the set \(N\) of players and the set \(A_i\) of actions of each player \(i\) are finite.

The fact that each player's preferences are defined over the set of action profiles allows for the possibility that each player cares not only about her own action but also about the other players' actions, distinguishing the model from a collection of independent single-agent decision problems.

Notice that the model does not have a temporal dimension. An assumption implicit in the solution notions applied to a game is that each player independently commits to an action before knowing the action chosen by any other player. Notice also that no structure is imposed on the players' sets of actions. In the simplest cases, a player's set of actions may consist of two elements; in more complex cases, it may consist, for example, of an interval of real numbers, a set of points in a higher dimensional space, a set of functions from one set to another, or a combination of such sets. In particular, an action may be a contingent plan, specifying a player's behaviour in a variety of possible circumstances, so that the model is not limited to 'static' problems (see Section 3.1.1). Thus, although the model has no temporal dimension, it may be used to study 'dynamic' situations under the assumption that each player chooses her plan of action once and for all.

A few examples give an idea of the range of situations that the model encompasses. The most well-known strategic game is the **Prisoner's Dilemma**. In this game, there are two players (1, 2, say), each player has two actions, Quiet and Fink, and each player's preference relation ranks the action pair in which she chooses Fink and the other player chooses Quiet highest, then (Quiet, Quiet), then (Fink, Fink), and finally the action profile in which she chooses Quiet and the other player chooses Fink. In this example, as in most examples, working with payoff representations of the players' preference relations is simpler than working with the preference relations themselves. Taking a payoff function for each player that assigns the payoffs 3, 2, 1, and 0 to the four outcomes, we may conveniently represent the game in the table in Figure 1. (Any two-player strategic game in which each player has finitely many actions may be represented in a similar table.)

**Figure 1**

The Prisoner's Dilemma

<td>1, 1</td>
</tr>
</tbody>
</table>

This game takes its name from the following scenario. The two players are suspected of joint involvement in a major crime. Sufficient evidence exists to convict each one of a minor offence, but conviction of the major crime requires at least one of them to confess, thereby implicating the other (that is, one player 'finks'). Each suspect may stay quiet or may fink. If a single player finks, she is rewarded by being set free, whereas the other player is convicted of the major offence. If both players fink, then each is convicted but serves only a moderate sentence.

The game derives its interest not from this specific interpretation but because the structure of the players' preferences fits many other social and economic situations. The combination of the desirability of the players' coordinating on an outcome and the incentive on the part of each player individually to deviate from this outcome is present in situations as diverse...
as duopolists setting prices and countries involved in an arms race.

Another example of a strategic game models oligopoly as suggested by Cournot (1838). The players are the $n$ firms, each player's set of actions is the set of possible outputs (the set of non-negative real numbers), and the preference relation of player $i$ is represented by its profit, given by the payoff function $u_i$ defined by

$$u_i(q_1, \ldots, q_n) = q_iP\left(\sum_{j=1}^{n} q_j\right) - C_i(q_i),$$

where $q_i$ is player $i$'s output, $C_i$ is its cost function, and $P$ is the inverse demand function, giving the market price for any total output. Another strategic game that models oligopoly, associated with the name of Bertrand, differs from Cournot's model in taking the set of actions of each player to be the set of possible prices (which requires profit to be defined as a function of prices).

A strategic game that models competition between candidates for political office was suggested by Hotelling (1929). The set of players is a finite set of candidates; each player's set of actions is the same subset $X$ of the line, representing the set of possible policies. Each member of a continuum of citizens (who are not players in the game) has single-peaked preferences over $X$. Each citizen votes for the candidate whose position is closest to her favourite position. A density function on $X$ represents the distribution of the citizens' favourite policies. The total number of votes obtained by any player is the integral with respect to this density over the subset of $X$ consisting of points closer to the player's action (chosen policy) than to the action of any other player. A player's preferences are represented by the payoff function that assigns 1 to any action profile in which she obtains more votes than every other player, $1/k$ to any action profile in which she obtains at least as many votes as any other player and $k \geq 2$ players tie for the highest number of votes, and 0 to any action profile in which she obtains fewer votes than some other player.

### 2.2 Nash equilibrium

Which action profile will result when a strategic game is played? Game theory provides two main approaches to answering this question. One isolates action profiles that correspond to stable 'steady states'. This approach leads to the notion of Nash equilibrium, discussed in this section. The other approach, discussed in Section 2.5, isolates action profiles that are consistent with each player's reasoning regarding the likely actions of the other players, taking into account the other players' reasoning about each other and the player in question.

Fix an $n$-player strategic game and suppose that for each player in the game there exists a population of $K$ individuals, where $K$ is large. Imagine that, in each of a long sequence of periods, $K$ sets of $n$ individuals are randomly selected, each set consisting of one individual from each population. In each period, each set of $n$ individuals plays the game, the individual from population $i$ playing the role of player $i$, for each value of $i$. The selected sets change from period to period; because $K$ is large, the chance that an individual will play the game with the same opponent twice is low enough not to enter her strategic calculations. If play settles down to a steady state in which each individual in each population $i$ chooses the same action, say $a_i^*$, whenever she plays the game, what property must the profile $a^*$ satisfy?

In such a (deterministic) steady state, each individual in population $i$ knows from her experience that every individual in every other population $j$ chooses $a_j^*$, $j \neq i$. Thus we can think of each such individual as being involved in a single-person decision problem in which the set of actions is $A_i$ and the preferences are induced by player $i$'s preference relation in the game when the action of every other player $j$ is fixed at $a_j^*$. That is, $a_j^*$ maximizes $i$'s payoff in the game given the actions of all other players. Or, looked at differently, $a^*$ has the property that no player $i$ can increase her payoff by changing her action $a_i^*$ given the other players' actions. An action profile with this property is a Nash equilibrium. (The notion is due to Nash, 1950; the underlying idea goes back at least to Cournot, 1838.) For any action profile $b$, denote by $(a_i, b_{-i})$ the action profile in which player $i$'s action is $a_i$ and the action of every other player $j$ is $b_j$.

**Definition 2:** A Nash equilibrium of the strategic game $\langle N, (A_i), (\succeq_j) \rangle$ is an action profile $a^*$ for which

$$a^* \succeq_j (a_i, a_{-i}^*) \quad \text{for all } a_i \in A_i.$$
By inspection of the four action pairs in the Prisoner's Dilemma (Figure 1) we see that the action pair (Fink, Fink) is the only Nash equilibrium. For each of the three other action pairs, a player choosing Quiet can increase her payoff by switching to Fink, given the other player's action.

The games in Figure 2 immediately answer three qsts. Does every strategic game necessarily have a Nash equilibrium? Can a strategic game have more than one Nash equilibrium? Is it possible that every player is better off in one Nash equilibrium than she is in another Nash equilibrium? The left-hand game, which models the game ‘Matching pennies’, has no Nash equilibrium. The right-hand game has two Nash equilibria, (B,B) and (C, C), and both players are better off in (C, C) than they are in (B, B).

In some games, especially ones in which each player has a continuum of actions, Nash equilibria may most easily be found by first computing each player's best action for every configuration of the other players' actions. For each player \(i\), let \(u_i\) be a payoff function that represents player \(i\)'s preferences. Fix a player \(i\) and define, for each list \(a_{-i}\) of the other players’ actions, the set of actions that maximize \(i\)'s payoff:

\[
B_i(a_{-i}) = \{ a_i \in A_i: a_i \text{ maximizes } u_i(a_i, a_{-i}) \text{ over } a_i \in A_i \}.
\]

Each member of \(B_i(a_{-i})\) is a best response of player \(i\) to \(a_{-i}\); the function \(B_i\) is called player \(i\)'s best response function. (Note that it is set-valued.) An action profile \(a^*\) is a Nash equilibrium if and only if

\[
a_i^* \in B_i(a_{-i}^*) \text{ for every player } i.
\]

In some games, the set \(B_i(a_{-i})\) is a singleton for every player \(i\) and every list \(a_{-i}\). For such a game, denote the single element by \(b_i(a_{-i})\). Then the condition for the action profile \(a^*\) to be a Nash equilibrium may be written as

\[
a_i^* = b_i(a_{-i}^*) \text{ for every player } i,
\]

a collection of \(n\) equations in \(n\) unknowns.

Consider, for example, a two-player game in which each player's set of actions is the set of non-negative real numbers and the preference relation of each player \(i\) is represented by the
payoff function \( u_i \) defined by

\[ a_j(c + a_j - a_j) \]

where \( c > 0 \) is a constant. In this game each player \( i \) has a unique best response to every action \( a_j \) of the other player \((j)\), given by

\[ b_j(a_j) = \frac{1}{2}(c + a_j) \]

The two equations

\[ a_1 = \frac{1}{2}(c + a_2) \quad \text{and} \quad a_2 = \frac{1}{2}(c + a_1) \]

immediately yield the unique solution \((a_1, a_2) = (c, c)\), which is thus the only Nash equilibrium of the game.

2.3 Mixed strategy Nash equilibrium

In a steady state modelled by the notion of Nash equilibrium, all individuals who play the role of a given player choose the same action whenever they play the game. We may generalize this notion. In a stochastic steady state, the rule used to select an action by individuals in the role of a given player is probabilistic rather than deterministic. In a polymorphic steady state, each individual chooses the same action whenever she plays the game, but different individuals in the role of a given player choose different deterministic actions.

In both of these generalized steady states an individual faces uncertainty: in a stochastic steady state because the individuals with whom she plays the game choose their actions probabilistically, and in a polymorphic steady state because her potential opponents, who are chosen probabilistically from their respective populations, choose different actions. Thus, to analyse the players’ behaviour in such steady states, we need to specify their preferences regarding lotteries over the set of action profiles. The following extension of Definition 1 assumes that these preferences are represented by the expected value of a payoff function. (The term ‘vNM preferences’ refers to von Neumann and Morgenstern, 1944, pp. 15–31; 1947, pp. 204–221, who give conditions on preferences under which such a representation exists.)

Definition 3: A strategic game (with vNM preferences) consists of

- a set \( N \) (the set of players)
- for each player \( i \in N \)
  - a set \( A_i \) (the set of player \( i \)’s possible actions)
  - a function \( u_i : A_i \times \bigcup_{j \in N \setminus \{i\}} A_j \to \mathbb{R} \) (player \( i \)’s payoff function, the expected value of which represents \( i \)’s preferences over the set of lotteries over action profiles).

A probability distribution over \( A_i \), the set of actions of player \( i \), is called a mixed strategy of player \( i \). The notion of a mixed strategy Nash equilibrium corresponds to a stochastic steady state in which each player chooses her mixed strategy to maximize her expected payoff, given the other players’ mixed strategies.

Definition 4: A mixed strategy Nash equilibrium of the strategic game \((N, (A_i), (u_i))\) is a profile \( \alpha^* \) in which each component \( \alpha_i^* \) is a probability distribution over \( A_i \) that satisfies

\[ U_j(\alpha^*) \geq U_j(\alpha_i^*, a_i^*) \]

for every player \( i \in N \), where \( U_j(\alpha) \) is the expected value of \( u_j(a) \) under \( \alpha \).

Suppose that each player’s set of actions is finite and fix the mixed strategy of every player \( j \neq i \) to be \( \alpha_j \). Then player \( i \)’s expected payoff when she uses the mixed strategy \( \alpha_i \) is a weighted average of her expected payoffs to each of the actions to which \( \alpha_i \) assigns positive probability. Thus, if \( \alpha_i \) maximizes player \( i \)’s expected payoff given \( \alpha_{-i} \), then so too do
all the actions to which \( a_i \) assigns positive probability. This observation has two significant consequences. First, a mixed strategy Nash equilibrium corresponds not only to a stochastic steady state but also to a polymorphic steady state. (The equilibrium probability \( \bar{a}_i (a_i) \) is the fraction of individuals in population \( i \) that choose \( a_i \).) Second, the fact that in a mixed strategy Nash equilibrium each player is indifferent between all the actions to which her mixed strategy assigns positive probability is sometimes useful when computing mixed strategy Nash equilibria. To illustrate the notion of a mixed strategy Nash equilibrium, consider the games in Figure 2. In the game on the left, a player's expected payoff is the same (equal to 0) for her two actions when the other player chooses each action with probability \( \frac{1}{2} \), so that the game has a mixed strategy Nash equilibrium in which each player chooses each action with probability \( \frac{1}{2} \). The game has no other mixed strategy Nash equilibrium because each player's best response to any mixed strategy other than the one that assigns probability \( \frac{1}{2} \) to each action is either the action \( B \) or the action \( C \), and we know that the game has no equilibrium in which neither player randomizes. The game on the right of Figure 2 has three mixed strategy Nash equilibria. Two correspond to the Nash equilibria of the game in which randomization is not allowed: each player assigns probability 1 to \( B \), and each player assigns probability 1 to \( C \). In the third equilibrium, each player assigns probability \( \frac{2}{3} \) to \( B \) and probability \( \frac{1}{3} \) to \( C \). This strategy pair is a mixed strategy Nash equilibrium because each player's expected payoff to each of her actions is the same (equal to \( \frac{2}{3} \) for both players). The notion of mixed strategy Nash equilibrium generalizes the notion of Nash equilibrium in the following sense.

- If \( a^* \) is a Nash equilibrium of the strategic game \( (N, \{A_i\}, \{u_i\}) \); then the mixed strategy profile in which each player \( i \) assigns probability 1 to \( a_i^* \) is a mixed strategy Nash equilibrium of any strategic game with vNM preferences \( (N, \{A_i\}, \{u_i\}) \) in which, for each player \( i \), \( u_i \) represents \( u_i \).
- If \( a^* \) is a mixed strategy Nash equilibrium of the strategic game with vNM preferences \( (N, \{A_i\}, \{u_i\}) \) in which for each player \( i \) there is an action \( a_i^* \) such that \( u_i^*(a_i^*) = 1 \), then \( a^* \) is a Nash equilibrium of the strategic game \( (N, \{A_i\}, \{u_i\}) \) in which, for each player \( i \), \( u_i \) is the preference relation represented by \( u_i \).

The following result gives a sufficient condition for a strategic game to have a mixed strategy Nash equilibrium.

**Definition 5:** A strategic game with vNM preferences \( (N, \{A_i\}, \{u_i\}) \) in which the set \( N \) of players is finite has a mixed strategy Nash equilibrium if either (a) the set \( A_i \) of actions of each player \( i \) is finite or (b) the set \( A_i \) of actions of each player \( i \) is a compact convex subset of a Euclidean space and the payoff function \( u_i \) of each player \( i \) is continuous.

Part (a) of this result is due to Nash (1950, 1951) and part (b) is due to Glicksberg (1952).

In many games of economic interest the players' payoff functions are not continuous. Several results giving conditions for the existence of a mixed strategy Nash equilibrium in such games are available; see, for example, Section 5 of Reny (1999).

As I have noted, in any mixed strategy Nash equilibrium in which some player chooses an action with positive probability less than 1, that player is indifferent between all the actions to which her strategy assigns positive probability. Thus, she has no positive reason to choose her equilibrium strategy: any other strategy that assigns positive probability to the same actions is equally good. This fact shows that the notion of a mixed strategy equilibrium lacks robustness. A result of Harsanyi (1973) addresses this issue. For any strategic game \( G \), Harsanyi considers a game in which the players' payoffs are randomly perturbed by small amounts from their values in \( G \). In any play of the perturbed game, each player knows her own payoffs, but not (exactly) those of the other players. (Formally the perturbed game is a Bayesian game, a model described in Section 2.6.) Typically, a player has a unique optimal action in the perturbed game, and this game has an equilibrium in which no player randomizes. (Each player's equilibrium action depends on the value of her own payoffs.) Harsanyi shows that the limit of these equilibria as the perturbations go to zero defines a mixed strategy Nash equilibrium of \( G \), and almost any mixed strategy Nash equilibrium of \( G \) is associated with the limit of such a sequence. Thus we can think of the players' strategies in a mixed strategy Nash equilibrium as approximations to collections of strictly optimal actions.

### 2.4 Correlated equilibrium

One interpretation of a mixed strategy Nash equilibrium is that each player conditions her action on the realization of a random variable, where the random variable observed by each player is independent of the random variable observed by every other player. This interpretation leads naturally to the question of how the theory changes if the players may observe random variables that are not independent.

To take a simple example, consider the game at the right of Figure 2. Suppose that the players observe random variables that are perfectly correlated, each variable taking one value,
say $x$, with some probability $p$, and another value, say $y$, with probability $1 - p$. Consider the strategy that chooses the action $B$ if the realization of the player's random variable is $x$ and the action $C$ if the realization is $y$. If one player uses this strategy, the other player optimally does so too: if the realization is $x$, for example, she knows the other player will choose $B$, so that her best action is $B$. Thus the strategy pair is an equilibrium.

More generally, the players may observe random variables that are partially correlated. Equilibria in which they do so exist for the game at the right of Figure 2, but the game in Figure 3 is more interesting.

Figure 3
A strategic game

Consider the random variable that takes the values $x$, $y$, and $z$, each with probability $\frac{1}{3}$. Player 1 observes only whether the realization is in $\{x, y\}$ or is $z$ (but not, in the first case, whether it is $x$ or $y$), and player 2 observes only whether it is in $\{x, z\}$ or is $y$. Suppose that player 1 chooses $B$ if she observes $\{x, y\}$ and $C$ if she observes $z$, and player 2 chooses $B$ if she observes $\{x, z\}$ and $C$ if she observes $y$. Then neither player has an incentive to change her action, whatever she observes. If, for example, player 1 observes $\{x, y\}$, then she infers that $x$ and $y$ have each occurred with probability $\frac{1}{2}$, so that player 2 will choose each of her actions with probability $\frac{1}{2}$. Thus her expected payoff is $4$ if she chooses $B$ and $\frac{7}{2}$ if she chooses $C$, so that $B$ is optimal. Similarly, if player 1 observes $z$, she infers that player 2 will choose $B$, so that $C$ is optimal for her. The outcome is $(B, B)$ with probability $\frac{1}{3}$, $(B, C)$ with probability $\frac{1}{3}$, and $(C, B)$ with probability $\frac{1}{3}$, so that each player's expected payoff is $5$.

An interesting feature of this equilibrium is that both players' payoffs exceed their payoffs in the unique mixed strategy Nash equilibrium (in which each player chooses $B$ with probability $\frac{2}{3}$ and obtains the expected payoff $\frac{14}{3}$).

In general, a correlated equilibrium of a strategic game with vNM preferences consists of a probability space and, for each player, a partition of the set of states and a function associating an action with each set in the player's partition (the player's strategy) such that, for each player and each set in the player's partition, the action assigned by her strategy to that set maximizes her expected payoff given the probability distribution over the other players' actions implied by her information. (The notion of correlated equilibrium is due to Aumann, 1974.)

The appeal of a correlated equilibrium differs little from the appeal of a mixed strategy equilibrium. In one respect, in fact, most correlated equilibria are more appealing: the action specified by each player's strategy for each member of her partition of the set of states is strictly optimal (she is not indifferent between that action and any others). Nevertheless, the notion of correlated equilibria has found few applications.

2.5 Rationalizability

The outcome $(Fink, Fink)$ of the Prisoner's Dilemma is attractive not only because it is a Nash equilibrium (and hence consistent with a steady state). In addition, for each player, $Fink$ is optimal and Quiet is suboptimal regardless of the other player's action. That is, we may argue solely on the basis of a player's rationality that she will select Fink; no reference to her belief about the other player's action is necessary.

We say that the mixed strategy $\boldsymbol{\alpha}_i$ of player $i$ is rational if there exists a probability distribution over the other players' actions to which it is a best response. (The probability
distribution may entail correlation between the other players’ actions; we do not require it to be derived from independent mixed strategies. With this terminology, the only rational action for each player in the Prisoner’s Dilemma is Fink.

This definition of rationality puts no restriction on the probability distribution over the other players’ actions that justifies a player’s mixed strategy. In particular, an action is rational even if it is a best response only to a belief that assigns positive probability to the other players’ not being rational. For example, in the game on the left of Figure 4, Q is rational for player 1, but all the mixed strategies of player 2 to which Q is a best response for player 1 assign probability of at least \( \frac{1}{2} \) to Q, which is not rational for player 2. Such beliefs are ruled out if we assume that each player is not only rational, but also believes that the other players are rational. In the game on the left of Figure 4 this assumption means that player 1’s beliefs must assign positive probability only to player 2’s action F, so that player 1’s only optimal action is F. That is, in this game the assumptions that each player is rational and that each player believes the other player is rational isolate the action pair (F, F).

Figure 4
Two variants of the Prisoner’s Dilemma

<table>
<thead>
<tr>
<th></th>
<th>Q</th>
<th>F</th>
</tr>
</thead>
<tbody>
<tr>
<td>Q</td>
<td>3, 2</td>
<td>0, 3</td>
</tr>
<tr>
<td>F</td>
<td>2, 0</td>
<td>1, 1</td>
</tr>
</tbody>
</table>

We may take this argument further. Consider the game on the right of Figure 4. Player 1’s action Q is consistent with player 1’s rationality and also with a belief that player 2 is rational (because both actions of player 2 are rational). It is not, however, consistent with player 1’s believing that player 2 believes that player 1 is rational. If player 2 believes that player is rational, her belief must assign probability 0 to player 1’s action X (which is not a best response to any strategy of player 2), so that her only optimal action is F. But if player 2 assigns positive probability only to F, then player 1’s action Q is not optimal.

In all of these games — the Prisoner’s Dilemma and the two in Figure 4 — player 1’s action F survives any number of iterations of the argument: it is consistent with player 1’s rationality, player 1’s belief that player 2 is rational, player 1’s belief that player 2 believes that player 1 is rational, and so on. An action with this property is called rationalizable, a notion developed independently by Bernheim (1984) and Pearce (1984). (Both Bernheim and Pearce discuss a slightly different notion, in which players are restricted to beliefs that are derived from independent probability distributions over each of the other player’s actions. Their notion does not have the same properties as the notion described here.)

The set of action profiles in which every player’s action is rationalizable may be given a simple characterization. First define a strictly dominated action.

**Definition 6:** Player i’s action \( a_i \) in the strategic game with vNM preferences \( \langle N, (A_i), (u_i) \rangle \) is **strictly dominated** if for some mixed strategy \( \alpha_i \) of player i we have

\[
U_j(\alpha_i, a_{-i}) > U_j(a_i, a_{-i}) \quad \text{for every } a_{-i} \in A_{-i} \times \bigcap_{j \in N \setminus \{i\}} A_j,
\]

where \( U_j(\alpha_i, a_{-i}) \) is player j’s expected payoff when she uses the mixed strategy \( \alpha_i \) and the other players’ actions are given by \( a_{-i} \).

Note that the fact that \( \alpha_i \) in this definition is a mixed strategy is essential: some strictly dominated actions are not strictly dominated by any action. For example, in the variant of the game at the left of Figure 4 in which player 1 has an additional action, say Z, with \( U_1(Z, Q) = 0 \) and \( U_1(Z, F) = 5 \), the action F is not strictly dominated by any action, but is strictly dominated by the mixed strategy that assigns probability \( \frac{3}{4} \) to Q and probability \( \frac{1}{4} \) to Z.

We may show that an action in a finite strategic game is not rational if and only if it is strictly dominated. Given this result, it is not surprising that actions are rationalizable if they...
survive the iterated elimination of strictly dominated actions, defined precisely as follows.

Definition 7: Let \( G = (N, (A_i), (\psi_i)) \) be a strategic game. For each \( j \in N \), let \( X^j_1 = A_j \), and for each \( j \in N \) and each \( t \geq 1 \) let \( X^{j_t+1}_j \) be a subset of \( X^j_t \) with the property that every member of \( X^j_1 \) is strictly dominated in the game \( \{N, (X^j_t), (\psi^j_t)\} \), where \( \psi^j_t \) denotes the restriction of the function \( \psi_j \) to \( \times j \in N X^j_t \). If no member of \( X^j_T \) for any \( j \in N \) is strictly dominated, then the set \( \times j \in N X^j_T \) survives iterated elimination of strictly dominated actions.

The procedure specified in this definition does not pin down exactly which actions are eliminated at each step. Only strictly dominated actions are eliminated, but not all such actions are necessarily eliminated. Thus the definition leaves open the question of the uniqueness of the set of surviving action profiles. In fact, however, this set is unique; it coincides with the set of profiles of rationalizable actions.

Proposition 8: In a finite strategic game the set of action profiles that survives iterated elimination of strictly dominated actions is unique and is equal to the set of profiles of rationalizable actions.

Every action of any player used with positive probability in a correlated equilibrium is rationalizable. Thus the set of profiles of rationalizable actions is the largest ‘solution’ for a strategic game that we have considered. In many games, in fact, it is very large. (If no player has a strictly dominated action, all actions of every player are rationalizable, for example.) However, in several of the games mentioned in the previous sections, each player has a single rationalizable action, equal to her unique Nash equilibrium action. This property holds, with some additional assumptions, for Cournot’s and Bertrand’s oligopoly games with two firms and Hotelling’s model of electoral competition with two candidates. The fact that in other games the set of rationalizable actions is large has limited applications of the notion, but it remains an important theoretical construct, delineating exactly the conclusion we may reach by assuming that the players take into account each others’ rationality.

2.6 Bayesian games

In the models discussed in the previous sections, every player is fully informed about all the players’ characteristics: their actions, payoffs, and information. In the model of a Bayesian game, players are allowed to be uncertain about these characteristics. We call each configuration of characteristics a state. The fact that each player’s information about the state may be imperfect is modelled by assuming that each player does not observe the state but rather receives a signal that may depend on the state. At one extreme, a player may receive a different signal in every state; such a player has perfect information. At another extreme, a player may receive the same signal in every state; such a player has no information about the state. In between these extremes are situations in which a player is partially informed; she may receive the same signal in states \( \omega_1 \) and \( \omega_2 \), for example, and a different signal in state \( \omega_2 \).

To make a decision, given her information, a player needs to form a belief about the probabilities of the states between which she cannot distinguish. We assume that she starts with a prior belief over the set of states, and acts upon the posterior belief derived from this prior, given her signal, using Bayes’s Law. If, for example, there are three states, \( \omega_1, \omega_2, \) and \( \omega_3 \), to which her prior belief assigns probabilities \( \frac{1}{4}, \frac{1}{3}, \) and \( \frac{1}{2} \), and she receives the same signal, say \( X \), in states \( \omega_1 \) and \( \omega_2 \), and a different signal, say \( Y \), in state \( \omega_3 \), then her posterior belief assigns probability \( \frac{3}{5} \) to \( \omega_1 \) and probability \( \frac{2}{5} \) to \( \omega_2 \) when she receives the signal \( X \) and probability \( \frac{1}{2} \) to \( \omega_3 \) when she receives the signal \( Y \).

In summary, a Bayesian game is defined as follows. (The notion is due to Harsanyi, 1967/68.)

Definition 9: A Bayesian game consists of

- a set \( N \) (the set of players)
- a set \( \Omega \) (the set of states)

and for each player \( i \in N \)

- a set \( A_i \) (the set of player \( i \)'s possible actions)
- a set \( T_i \) (the set of signals that player \( i \) may receive) and a function \( \tau_i: \Omega \to T_i \), associating a signal with each state (player \( i \)'s signal function)
- a probability distribution \( p_i \) over \( \Omega \) (player \( i \)'s prior belief), with \( p_i(\tau_i^{-1}(t_i)) > 0 \) for all \( t_i \in T_i \)
- a function \( u_i: (\times j \in N A_j) \times \Omega \to \mathbb{R} \) (player \( i \)'s payoff function, the expected value of which represents \( i \)'s preferences over the set of lotteries on the set \( (\times j \in N A_j) \times \Omega \).

This definition allows the players to hold different prior beliefs. In many applications every player is assumed to hold the same prior belief.

A widely studied class of Bayesian games models auctions. An example is a single-object auction in which each player knows her own valuation of the object but not that of any other player and believes that every player’s valuation is independently drawn from the same distribution. In a Bayesian game that models such a situation, the set of states is the set of profiles of valuations and the signal received by each player depends only on her own valuation, not on the valuation of any other player. Each player holds the same prior belief, which is derived from the assumption that each player’s valuation is drawn independently from the same distribution.

The desirability for a player of each of her actions depends in general on the signal she receives. Thus a candidate for an equilibrium in a Bayesian game is a profile of functions, one for each player; the function for player \(i\) associates an action (member of \(A_i\)) with each signal she may receive (member of \(T_i\)). We refer to player \(i\) after receiving the signal \(t_i\) as type \(t_i\) of player \(i\). A Nash equilibrium of a Bayesian game embodies the same principle as does a Nash equilibrium of a strategic game: each player’s action is optimal given the other players’ actions. Thus, in an equilibrium, the action of each type of each player maximizes the payoff of that type given the action of every other type of every other player. That is, a Nash equilibrium of a Bayesian game is a Nash equilibrium of the strategic game in which the set of players is the set of pairs \((i, t_i)\), where \(i\) is a player in the Bayesian game and \(t_i\) is a signal that she may receive.

**Definition 10:** A Nash equilibrium of a Bayesian game \((N, \Omega, (\varepsilon_i), (T_i), (\tau_i), (\varphi_i), (u_i))\) is a Nash equilibrium of the following strategic game.

- The set of players is the set of all pairs \((i, t_i)\) such that \(i \in N\) and \(t_i \in T_i\).
- The set of actions of player \((i, t_i)\) is \(A_i\).
- The payoff of player \((i, t_i)\) when each player \((j, t_j)\) chooses the action \(a(j, t_j)\) is

\[
\sum_{\omega \in \Omega} \varphi^r(\omega | t_i) u_i((a_j, \widetilde{a}_{-j}(\omega)), \omega),
\]

where \(\widetilde{a}_{j}(\omega) = a(j, \tau_j(\omega))\) for each \(j \in N\).

To illustrate this notion, consider the two-player Bayesian game in which there are two states, each player has two actions (\(B\) and \(C\)), player 1 receives the same signal in both states, player 2 receives a different signal in each state, each player’s prior belief assigns probability \(\frac{1}{3}\) to state 1 and probability \(\frac{2}{3}\) to state 2, and the payoffs are those shown in Figure 5. A Nash equilibrium of this Bayesian game is a Nash equilibrium of the three-player game in which the players are player 1 and the two types of player 2 (one for each state). I claim that the strategy profile in which player 1 chooses \(B\), type 1 of player 2 (that is, player 2 after receiving the signal that the state is 1) chooses \(C\), and type 2 of player 2 chooses \(B\) is a Nash equilibrium. The actions of the two types of player 2 are best responses to the action \(B\) of player 1. Given these actions, player 1’s expected payoff to \(B\) is \(\frac{2}{3}\) (because with probability \(\frac{1}{3}\) the state is 1 and player 2 chooses \(C\) and with probability \(\frac{2}{3}\) the state is 2 and player 2 chooses \(B\)) and her expected payoff to \(C\) is \(\frac{1}{3}\). Thus player 1’s action \(B\) is a best response to the actions of the two types of player 2.

**Figure 5**

A Bayesian game
Although situations in which players choose their actions sequentially may be modelled as strategic games, they are more naturally modelled as extensive games. In Section 3.1 I discuss a model in which each player, when choosing an action, knows the actions taken previously. In Section 3.2 I discuss a more complex model that allows players to be imperfectly informed. (The notion of an extensive game is due to von Neumann and Morgenstern, 1944, and Kuhn, 1950; 1953.) The formulation in terms of histories is due to Ariel Rubinstein.)

### 3.1 Extensive games with perfect information

An *extensive game with perfect information* describes the sequential structure of the players’ actions. It does so by specifying the set of sequences of actions that may occur and the player who chooses an action after each subsequence. A sequence that starts with an action of the player who makes the first move and ends when no move remains is called a *terminal history*.

**Definition 11:** An *extensive game with perfect information* consists of

- a set $N$ (the set of players)
- a set $H$ of sequences (the set of terminal histories) with the property that no sequence is a proper sub-history of any other sequence
- a function $P$ (the player function) that assigns a player to every proper subsequence of every terminal history

and for each player $i \in N$

- a preference relation $\succsim_i$ over the set $H$ of terminal histories.

The restriction on the set $H$ is necessary for its members to be interpreted as terminal histories: if $(x,y,z)$ is a terminal history then $(x,y)$ is not a terminal history, because $z$ may be chosen after $(x,y)$. We refer to subsequences of terminal histories as *histories*.

The sets of actions available to the players when making their moves, while not explicit in the definition, may be deduced from the set of terminal histories. For any history $h$, the set of actions available to $P(h)$, the player who moves after $h$, is the set of actions $a$ for which $(h,a)$ is a history. We denote this set $A(h)$.

Two simple examples of extensive games with perfect information are shown in Figure 6. In the game on the left, the set of terminal histories is $\{(X, w), (X, x), (Y, y), (Y, z)\}$ and the player function assigns player 1 to the empty history (a subsequence of every terminal history) and player 2 to the histories $X$ and $Y$. The game begins with player 1’s choosing either $X$ or $Y$. If she chooses $X$, then player 2 chooses either $w$ or $x$; if she chooses $Y$, then player 2 chooses either $y$ or $z$. In the game on the right, the set of terminal histories is $\{(W, x, y), (W, x, z), (W, y, x)\}$ and the player function assigns player 1 to the empty history and the history $(W, x)$, and player 2 to the history $W$.

<td>1, 0</td>
<td>0, 1</td>
</tr>
</tbody>
</table>
Two extensive games with perfect information. \textit{Note:} Player 1’s payoff is the first number in each pair.

Another example of an extensive game with perfect information is a sequential variant of Cournot’s model of oligopoly in which firm 1 chooses an output, then firm 2 chooses an output, and so on. In this game, the set of terminal histories is the set of all sequences \((q_1, \ldots, q_n)\) of outputs for the firms; the player function assigns player 1 to the empty history and, for \(k = 1, \ldots, n-1\), player \(k+1\) to every sequence \((q_1, \ldots, q_k)\). (Because a continuum of actions is available after each non-terminal history, this game cannot easily be represented by a diagram like those in Figure 6.)

A further example is the bargaining game of alternating offers. This game has terminal histories of infinite length (those in which every offer is rejected).

### 3.1.1 Strategies

A key concept in the analysis of an extensive game is that of a \textit{strategy}. The definition is very simple: a strategy of any player \(j\) is a function that associates with every history \(h\) after which player \(j\) moves a member of \(A(h)\), the set of actions available after \(h\).

\textit{Definition 12:} A \textit{strategy} of player \(j\) in an extensive game with perfect information \((N, H, P, (\geq \cdot))\) is a function that assigns to every history \(h\) (subsequence of \(H\)) for which \(P(h) = j\) an action in \(A(h)\).

In the game at the left of Figure 6, player 1 has two strategies, \(X\) and \(Y\). Player 2 has \textit{four} strategies, which we may represent by \(wY, wz, wy,\) and \(xz\), where the first component in each pair is the action taken after the history \(X\) and the second component is the action taken after the history \(Y\). This example illustrates that a strategy is a complete plan of action, specifying the player’s action in every eventuality. Before the game begins, player 2 does not know whether player 1 will choose \(X\) or \(Y\); her strategy prepares her for both eventualities.

The game at the right of Figure 6 illustrates another aspect of the definition. Player 1 in this game has \textit{four} strategies, \(WY, WZ, XY,\) and \(XZ\). In particular, \(XY\) and \(XZ\) are distinct strategies. (Remember that a player’s strategy assigns an action to \textit{every} history after which she moves.) I discuss the interpretation of strategies like these in Section 3.1.3.

### 3.1.2 Nash equilibrium

A key concept in the analysis of an extensive game is that of a \textit{strategy}. The definition is very simple: a strategy of any player \(j\) is a function that associates with \textit{every} history \(h\) after which player \(j\) moves a member of \(A(h)\), the set of actions available after \(h\).

\textit{Definition 12:} A \textit{strategy} of player \(j\) in an extensive game with perfect information \((N, H, P, (\geq \cdot))\) is a function that assigns to every history \(h\) (subsequence of \(H\)) for which \(P(h) = j\) an action in \(A(h)\).

In the game at the left of Figure 6, player 1 has two strategies, \(X\) and \(Y\). Player 2 has \textit{four} strategies, which we may represent by \(wY, wz, wy,\) and \(xz\), where the first component in each pair is the action taken after the history \(X\) and the second component is the action taken after the history \(Y\). This example illustrates that a strategy is a complete plan of action, specifying the player’s action in every eventuality. Before the game begins, player 2 does not know whether player 1 will choose \(X\) or \(Y\); her strategy prepares her for both eventualities.

The game at the right of Figure 6 illustrates another aspect of the definition. Player 1 in this game has \textit{four} strategies, \(WY, WZ, XY,\) and \(XZ\). In particular, \(XY\) and \(XZ\) are distinct strategies. (Remember that a player’s strategy assigns an action to \textit{every} history after which she moves.) I discuss the interpretation of strategies like these in Section 3.1.3.
A Nash equilibrium of an extensive game with perfect information is defined in the same way as a Nash equilibrium of a strategic game: it is a strategy profile with the property that no player can increase her payoff by changing her strategy, given the other players’ strategies. Precisely, first define the outcome \( O(S) \) of a strategy profile \( s \) to be the terminal history that results when the players use \( s \). (The outcome \( O(X,wy) \) of the strategy pair \((X,wy)\) in the game on the left of Figure 6, for example, is the terminal history \((X,w)\).)

**Definition 13:** A Nash equilibrium of the extensive game with perfect information \( \{N, H, P, (\succeq, \geq)\} \) is a strategy profile \( s^* \) for which

\[
O(s^*) \geq O(s_i, s_{-i}^*) \text{ for all } s_i \in S_i
\]

for every player \( i \in N \), where \( S_i \) is player \( i \)'s set of strategies.

As an example, the game on the left of Figure 6 has three Nash equilibria, \((X,wy), (X,wz)\) and \((Y,xy)\). (One way to find these equilibria is to construct a table like the one in Figure 1 in which each row is a strategy of player 1 and each column is a strategy of player 2.)

For each of the last two equilibria, there exists a history \( h \) such that the action specified by player 2's strategy after \( h \) is not optimal for her in the rest of the game. For example, in the last equilibrium, player 2's strategy specifies that she will choose \( x \) after the history \( X \), whereas only \( w \) is optimal for her after this history. Why is such a strategy optimal? Because player 1’s strategy calls for her to choose \( Y \), so that the action player 2 plans to take after the history \( X \) has no effect on the outcome: the terminal history is \((Y,y)\) regardless of player 2's action after the history \( X \).

I argue that this feature of the strategy pair \((Y,xy)\) detracts from its status as an equilibrium. Its equilibrium status depends on player 1’s believing that if she deviates to \( X \) then player 2 will choose \( x \). Given that only \( w \) is optimal for player 2 after the history \( X \), such a belief seems unreasonable.

Suppose that player 1 forms her belief on the basis of her experience. If she always chooses \( Y \), then no amount of experience will enlighten her regarding player 2’s choice after the history \( X \). However, in a slightly perturbed steady state in which she very occasionally erroneously chooses \( X \) at the start of the game and player 2 chooses her optimal action whenever called upon to move, player 1 knows that player 2 chooses \( w \), not \( x \), after the history \( X \).

If player 1 bases her belief on her reasoning about player 2’s rational behaviour (in the spirit of rationalizability), she reaches the same conclusion. (Note, however, that this reasoning process is straightforward in this game only because the game has a finite horizon and one player is indifferent between two terminal histories if and only if the other player is also indifferent.)

In either case, we conclude that player 1 should believe that player 2 will choose \( w \), not \( x \), after the history \( X \). Similarly, the Nash equilibrium \((X,wz)\) entails player 1’s unreasonable belief that player 2 will choose \( z \), rather than \( y \), after the history \( Y \).

We now extend this idea to all extensive games with perfect information.

### 3.1.3 Subgame perfect equilibrium

A subgame perfect equilibrium is a strategy profile in which each player’s strategy is optimal not only at the start of the game, but also after every history. (The notion is due to Selten, 1965.)

**Definition 14:** A subgame perfect equilibrium of the extensive game with perfect information \( \{N, H, P, (\succeq, \geq)\} \) is a strategy profile \( s^* \) for which

\[
O_h(s^*) \geq O_h(s_i, s_{-i}^*) \text{ for all } s_i \in S_i
\]

for every player \( i \in N \) and every history \( h \) after which it is player \( i \)'s turn to move (that is, \( P(h) = i \), where \( S_i \) is player \( i \)'s set of strategies and \( O_h(s) \) is the terminal history consisting of \( h \) followed by the sequence of actions generated by \( s \) after \( h \).)

For any non-terminal history \( h \), define the subgame following \( h \) to be the part of the game that remains after \( h \) has occurred. With this terminology, we have a simple result: a strategy profile is a subgame perfect equilibrium if and only if it induces a Nash equilibrium in every subgame. Note, in particular, that a subgame perfect equilibrium is a Nash equilibrium of the whole game. (The function \( O \) in Definition 2 is the same as the function \( O_\emptyset \) in Definition 3, where \( \emptyset \) denotes the empty history.) The converse is not true, as we have seen: in the game at the left of Figure 6, player 2’s only optimal action after the history \( X \) is \( w \) and her only optimal action after the history \( Y \) is \( y \), so that the game has a single subgame perfect
Now consider the game at the right of Figure 6. Player 1’s only optimal action after the history \((W, x)\) is \(Y\); given that player 1 chooses \(Y\) after \((W, x)\), player 2’s only optimal action after the history \(W\) is \(x\); and given that player 2 chooses \(x\) after the history \(W\), player 1’s only optimal action at the start of the game is \(X\). Thus the game has a unique subgame perfect equilibrium, \((X, Y, x)\).

Note, in particular, that player 1’s strategy \(XZ\), which generates the same outcome as does her strategy \(XY\) regardless of player 2’s strategy, is not part of a subgame perfect equilibrium. That is, the notion of subgame perfect equilibrium differentiates between these two strategies even though they correspond to the same ‘plan of action’. This observation brings us back to a question raised in Section 3.1.1: how should the strategies \(XZ\) and \(XY\) be interpreted?

If we view a subgame perfect equilibrium as a model of a perturbed steady state in which every player occasionally makes mistakes, the interpretation of player 1’s strategy \(XY\) is that she chooses \(X\) at the start of the game, but, if she erroneously chooses \(W\) and player 2 subsequently chooses \(x\), she chooses \(Y\). More generally, a component of a player’s strategy that specifies an action after a history \(h\) precluded by the other components of the strategy is interpreted to be the action the player takes if, after a series of mistakes, the history \(h\) occurs. Note that this interpretation is strained in a game in which some histories occur only after a long series of mistakes, and thus are extremely unlikely.

In some finite horizon games, we may alternatively interpret a subgame perfect equilibrium to be the outcome of the players’ calculations about each other’s optimal actions. If no player is indifferent between any two terminal histories, then every player can deduce the actions chosen in every subgame of length 1 (at the end of the game); she can use this information to deduce the actions chosen in every subgame of length 2; and she can similarly work back to the start of every subgame at which she has to choose an action. Under this interpretation, the component \(Y\) of the strategy \(XY\) in the game at the right of Figure 6 is player 2’s belief about player 1’s action after the history \((W, x)\) and also player 1’s belief about the action player 2 believes player 1 will choose after the history \((W, x)\). (This interpretation makes sense also under the weaker condition that, whenever one player is indifferent between the outcomes of two actions, every other player is also indifferent – a sufficient condition for each player to be able to deduce her payoff when the other players act optimally, even if she cannot deduce the other players’ strategies.)

This intp., like the previous one, is strained in some games. Consider the game that differs from the one at the right of Figure 6 only in that player 1’s payoff of 3 after the history \((W, y)\) is replaced by 1. The unique subgame perfect equilibrium of this game is \((XY, x)\) (as for the original game). The equilibrium entails player 2’s belief that player 1 will choose \(Y\) if player 2 chooses \(x\) after player 1 chooses \(W\). But choosing \(W\) is inconsistent with player 1’s acting rationally: she guarantees herself a payoff of 2 if she chooses \(X\), but can get at most 1 if she chooses \(W\). Thus it seems that player 2 should either take player 1’s action \(W\) as an indication that player 1 believes the game to differ from the game that player 2 perceives, or view the action as a mistake. In the first case the way in which player 2 should form a belief about player 1’s action after the history \((W, x)\) is unclear. The second case faces difficulties in games with histories that occur only after a long series of mistakes, as for the interpretation of a subgame perfect equilibrium as a perturbed steady state.

The subgame perfect equilibria of the games in Figure 6 may be found by working back from the end of the game, isolating the optimal action after any history given the optimal action in the following subgame. This procedure, known as *backward induction*, may be used in any finite horizon game in which no player is indifferent between any two terminal actions. A modified version that deals appropriately with indifference may be used in any finite horizon game.

### 3.2 Extensive games with imperfect information

In an extensive game with perfect information, each player, when taking an action, knows all actions chosen previously. To capture situations in which some or all players are not perfectly informed of past actions we need to extend the model. A general extensive game allows arbitrary gaps in players’ knowledge of past actions by specifying, for each player, a partition of the set of histories after which the player moves. The interpretation of this partition is that the player, when choosing an action, knows only the member of the partition in which the history lies, not the history itself. Members of the partition are called *information sets*. When choosing an action, a player has to know the choices available to her; if the choices available after different histories in a given information set were different, the player would know the history that had occurred. Thus for an information partition to be consistent with a player’s not knowing which history in a given information set has occurred, for every history \(h\) in any given information set, the set \(A(h)\) of available actions must be the same. We denote the set of actions available after the information set \(I_1\) by \(A(I_1)\).

**Definition 15**: An extensive game consists of

- a set \(N\) (the set of players)
- a set \(H\) of sequences (the set of terminal histories) with the property that no sequence is a proper subhistory of any other sequence
- a function \(P\) (the player function) that assigns a player to every proper subsequence of every terminal history

and for each player \(i \in N\)
A strategy for any player $j$ in an extensive game associates with each of her information sets $I_j$ a member of $A(I_j)$.

Definition 16: A strategy of player $j$ in an extensive game $(N, H, P, (\mathcal{G}_j), (\succeq_i))$ is a function that assigns to every information set $I_j \in \mathcal{G}_j$ of player $j$ an action in $A(I_j)$.

Given this definition, a Nash equilibrium is defined exactly as for an extensive game with perfect information (Definition 2) — and, as before, is not a satisfactory solution. Before discussing alternatives, we need to consider the possibility of players’ randomizing.

In an extensive game with perfect information, allowing players to randomize does not significantly change the set of equilibrium outcomes. In an extensive game with imperfect information, the same is not true. A straightforward way of incorporating the possibility of randomization is to follow the theory of strategic games and allow each player to choose her strategy randomly. That is, we may define a mixed strategy to be a probability distribution over (pure) strategies. An approach more directly suited to the analysis of an extensive game is to allow each player to randomize independently at each information set. This second approach involves the notion of a behavioural strategy, defined as follows.

Definition 17: A behavioural strategy of player $j$ in an extensive game $(N, H, P, (\mathcal{G}_j), (\succeq_i))$ is a function that assigns to each information set $I_j \in \mathcal{G}_j$ a probability distribution over the actions in $A(I_j)$, with the property that each probability distribution is independent of every other distribution.

For a large class of games, mixed strategies and behavioural strategies are equivalent: for every mixed strategy there exists a behavioural strategy that yields the same outcome.
regardless of the other players' strategies, and vice versa. (This result is due to Kuhn, 1950; 1953.) In the discussion that follows, I work with behavioural strategies.

The notion of subgame perfect equilibrium for an extensive game with perfect information embodies two conditions: whenever a player takes an action, (a) this action is optimal given her belief about the other players' strategies and (b) her belief about the other players' strategies is correct. In such a game, each player needs to form a belief only about the other players' future actions. In an extensive game with imperfect information, players need also to form beliefs about the other player's past actions. Thus, in order to impose condition (b) on a strategy profile in an extensive game with imperfect information, we need to consider how a player choosing an action at an information set containing more than one history forms a belief about which history has occurred and what it means for such a belief to be correct.

Consider the game in Figure 7. If player 1's strategy is \( X \) or \( Y \), then the requirement that player 2's belief about the history be correct is easy to implement: if player 1's strategy specifies \( X \) then she believes \( X \) has occurred, whereas if player 1's strategy specifies \( Y \) then she believes \( Y \) has occurred. If player 1's strategy is \( Z \), however, this strategy gives player 2 no basis on which to form a belief — we cannot derive from player 1's strategy a belief of player 2 about player 1's action. The main approach to defining equilibrium avoids this difficulty by specifying player 1's belief as a component of an equilibrium. Precisely, we define a belief system and an assessment as follows.

**Definition 18:** A **belief system** is a function that assigns to every information set a probability distribution over the set of histories in the set. An **assessment** is a pair consisting of a profile of behavioural strategies and a belief system.

We may now define an equilibrium to be an assessment satisfying conditions \( a \) and \( b \). To do so, we need to decide exactly how to implement \( b \). One option is to require consistency of beliefs with strategies only at information sets reached if the players follow their strategies, and to impose no conditions on beliefs at information sets not reached if the players follow their strategies. The resulting notion of equilibrium is called a weak sequential equilibrium. (The name ‘perfect Bayesian equilibrium’ is sometimes used, although the notion with this name defined by Fudenberg and Tirole, 1991, covers a smaller class of games and imposes an additional condition on assessments.)

**Definition 19:** An assessment \((\beta, \mu)\), where \( \beta \) is a behavioural strategy profile and \( \mu \) is a belief system, is a **weak sequential equilibrium** if it satisfies the following two conditions.

- **Sequential rationality:** Each player's strategy is optimal in the part of the game that follows each of her information sets, given the other players' strategies and her belief about the history in the information set that has occurred. Precisely, for each player \( i \) and each information set \( I_i \) of player \( i \), player \( i \)'s expected payoff to the probability distribution over terminal histories generated by her belief \( \mu_i \) at \( I_i \) is at least as large as her expected payoff to the probability distribution over terminal histories generated by her belief \( \mu_i \) at \( I_i \) and the behaviour prescribed subsequently by the strategy profile \( \beta \) is at least as large as her expected payoff to the probability distribution over terminal histories generated by her belief \( \mu_i \) at \( I_i \) and the behaviour prescribed subsequently by the strategy profile \((\gamma \beta - i)\), for each of her behavioural strategies \( Y_i \).

- **Weak consistency of beliefs with strategies:** For every information set \( I_i \) reached with positive probability given the strategy profile \( \beta \), the probability assigned by the belief system to each history \( h \) in \( I_i \) is the probability of \( h \) occurring conditional on \( I_i \) being reached, as given by Bayes' law.

Consider the game in Figure 7. Notice that player 2's action \( x \) yields her a higher payoff than does \( y \) regardless of her belief. Thus in any weak sequential equilibrium she chooses \( x \) with probability 1. Given this strategy, player 1's only optimal strategy assigns probability 1 to \( Y \). Thus the game has a unique weak sequential equilibrium, in which player 1's strategy is \( Y \), player 2's strategy is \( x \), and player 2's belief assigns probability 1 to the history \( Y \).

Now consider the game in Figure 8. I claim that the assessment in which player 1's strategy is \((\frac{1}{2}, \frac{1}{2}, 0)\), player 2's strategy is \((\frac{1}{2}, \frac{1}{2})\), and player 2's belief assigns probability \( \frac{1}{2} \) to \( X \) and probability \( \frac{1}{2} \) to \( Y \) is a weak sequential equilibrium. Given her beliefs, player 2's expected payoffs to \( x \) and \( y \) are both 2, and given player 2's strategy, player 1's expected payoffs to \( X \) and \( Y \) are both \( \frac{5}{2} \) and her payoff to \( Z \) is 2. Thus each player's strategy is sequentially rational. Further, player 2's belief is consistent with player 1's strategy. This game has an additional weak sequential equilibrium in which player 1's strategy is \( Z \), player 2's strategy is \( y \), and player 2's belief assigns probability 1 to the history \( Y \). Note that the consistency condition does not restrict player 2's belief in this equilibrium, because player 1 chooses neither \( X \) nor \( Y \) with positive probability.

**Figure 8**
An extensive game with imperfect information
In some games the notion of weak sequential equilibrium yields sharp predictions, but in others it is insufficiently restrictive. Some games, for example, have weak sequential equilibria that do not satisfy a natural generalization of the notion of subgame perfect equilibrium. In response to these problems, several ‘refinements’ of the notion of a weak sequential equilibrium have been studied, including sequential equilibrium (due to Kreps and Wilson, 1982) and perfect Bayesian equilibrium (due to Fudenberg and Tirole, 1991).

strategic trade policy

Barbara J. Spencer and James A. Brander
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Strategic trade policy refers to trade policy that affects the outcome of strategic interactions between firms in an actual or potential international oligopoly. A main idea is that trade policies can raise domestic welfare by shifting profits from foreign to domestic firms. A well-known application is the strategic use of export subsidies, but import tariffs as well as subsidies to R&D or investment for firms facing global competition can also have strategic effects. Since intervention by more than one government can lead to a Prisoner's Dilemma, the theory emphasizes the importance of trade agreements that restrict such interventions.

Article

International trade policy is one of the oldest subject areas in economics, having generated serious academic debate at least as far back as the classical period of ancient Greece, well over two thousand years ago. A very informative description of classical Greek and Roman thought on international trade and trade policy is provided by Irwin (1996, ch. 1). Interestingly, for example, both Plato and Aristotle were at best ambivalent about the virtues of open trade. Our modern understanding of international trade policy is based largely on the principle of comparative advantage as developed by David Ricardo (1807) and has been the focus of much political as well as academic debate in the two centuries since Ricardo. Consideration of strategic trade policy is a relatively recent addition to the trade policy debate, having started in the early 1980s. Although definitions of the term differ slightly, we believe the following definition captures the important concepts:

Definition: Strategic trade policy refers to trade policy that affects the outcome of strategic interactions between firms in an actual or potential international oligopoly.

As the definition suggests, the term ‘strategic’ in this context arises from consideration of the strategic interaction between firms. It does not refer to military objectives or the importance of an industry. Strategic interaction requires that firms recognize that their payoffs in terms of profit or other objectives are directly affected by the decisions of rivals or potential rivals. As a result, firms recognize that their own choices concerning such variables as output, price and investment depend on the decisions of other firms. The existence of strategic interaction is the defining characteristic of oligopoly.

The term ‘trade policy’ is interpreted broadly here as any policy directed primarily at the level or pattern of trade. In particular, policies that change the incentives for investment or research and development (R&D) in the context of international oligopoly represent an important application in the literature.

The requirement that the oligopoly be ‘international’ implies that production is actually or potentially carried out in two or more countries. Trade policy instruments set by one country then tend to affect the strategic choices of firms located in that country differently from firms located abroad. Strategic trade policy typically exploits these differential effects so as to achieve a domestic objective at the expense of welfare in other countries. In much of the literature the domestic objective is to maximize aggregate domestic welfare, but there is nothing that rules out political economy objectives, such as the use of trade policy to reward special interest groups that provide large donations to the government.
A brief history of the origins of strategic trade policy

Strategic trade policy was one of the early applications of oligopoly theory in international economics. Formal treatment of oligopoly (and monopolistic competition) in international trade theory did not become well-established until the 1980s. Perhaps the first formal application was by Brander (1981), who explained intra-industry trade in identical commodities. Prior to the 1980s, most trade theory relied on the assumption of perfect competition, although monopoly also received some attention. There was an early ‘distortions literature’ that concerned second-best policies in imperfectly competitive markets, but strategic interaction between firms was not modelled (see, for example, Bhagwati, Ramaswami and Srinivasan, 1969). In the light of the empirical importance of competition between large firms in world markets, the introduction of oligopoly into international trade was a significant step forward in improving the relevance of international trade theory. Oligopoly turned out to be central for understanding and explaining a number of important phenomena that could not be understood in a perfectly competitive framework. In addition to strategic trade policy, these included intra-industry trade, intra-firm trade, multinational corporations, and the role of economies of scale, R&D and technology transfer in international trade.

In applying strategic trade policy, one key difference between oligopoly and other market structures is the existence of profits (or ‘rents’) that can be shifted from one firm to another in a given industry by altering the strategic interactions between firms. Under monopoly, profit-shifting between firms does not arise as there is only one firm. In standard models of perfect competition and monopolistic competition, long-run profits are zero so there are no profits to shift. There are variations of the basic models of perfect competition or monopolistic competition in which firms are heterogeneous, only marginal firms earn zero profits, and infra-marginal firms can earn positive profits. However, such firms are not explicitly engaged in strategic interactions or ‘games’ with one another, so altering the outcome of strategic interactions is not an issue. As the previous paragraph suggests, application of basic game theory is a feature of strategic trade policy that distinguishes it from much of the previous work in international economics. In addition to considering games between firms, strategic trade policy places particular emphasis on the sequential structure of decision-making, making it one of the first areas of application of game theory where the implications of sequential rationality were clearly understood.

Two papers often cited as pioneering contributions to strategic trade policy are Spencer and Brander (1983) and Brander and Spencer (1985). Both papers assume an international duopoly in which a domestic and a foreign firm compete based on Cournot oligopoly in a third-country market. Spencer and Brander (1983) develops a three-stage game in which a subsidy to R&D (or the combination of an R&D tax and an export subsidy) can increase domestic welfare by shifting profits from the foreign to the domestic firm. The R&D subsidy makes it credible for the domestic firm to commit to a higher level of R&D, causing the foreign firm to reduce its R&D and exports. Brander and Spencer (1985) uses a simpler two-stage game so as to emphasize the profit-shifting role of export subsidies in a more standard international trade setting in which a second good is used to achieve trade balance. However, an earlier paper, Brander and Spencer (1981), may in fact be the first application of strategic trade policy. In Brander and Spencer (1981) a foreign firm chooses between entry deterrence based on the model of Dixit (1979) and Stackelberg leader–follower competition with a domestic entrant. The paper sets out cost conditions under which the domestic country can gain by increasing its import tariff above the entry-inducing level. The optimum tariff shifts sufficient profits from the foreign to the domestic firm so as to more than offset the loss in consumer surplus and tariff revenue. A drawback of the paper is that the game theory structure of the entry-deterrence model does not satisfy sequential rationality: it is not subgame perfect. The foreign firm prevents entry by setting its exports to the domestic country at a level that reduces domestic profits to zero. This is not subgame perfect since, if the domestic firm were to enter, the foreign firm would maximize profits by reducing its exports so as to accommodate entry. In a sequentially rational structure the domestic firm would be aware of this reaction and entry would not be deterred. In a subsequent paper, Brander and Spencer (1984) examine the strategic use of a tariff to shift profits to a domestic firm in a sequentially rational structure in which a domestic and foreign firm engage in Cournot competition. Other early contributions to strategic trade policy include Krugman (1984), Dixit (1984) and Eaton and Grossman (1986).

Numerical examples

We first illustrate the idea that governments can use trade policy instruments to shift profits from foreign to domestically owned firms, thereby raising national economic welfare at the expense of other countries. The example draws on Brander (1986) and Krugman (1987).

Suppose that only two firms, Boeing, an American firm, and Airbus, a European firm, are capable of producing a certain type of passenger aircraft. To focus on profit-shifting, we abstract from effects on consumer welfare in Europe and America by assuming that the aircraft are all exported to a third country. The profit earned by each country’s firm minus the...
cost of any subsidy is then the appropriate measure of each country’s national benefit. Consider an initial situation where the third-country market is profitable if there is only one producer, but both firms would make losses if they both enter and must share the market. The European government is considering whether to subsidize the entry of Airbus.

Figure 1 shows the profits of each firm depending on whether or not each firm enters. The game tree on the left illustrates profits if there is no intervention or ‘free trade’, while the game tree on the right illustrates profits if Europe commits to pay a subsidy of 6 to Airbus in the event that it enters. The box diagrams show Boeing’s profit as the first number in each cell, while the second number is the profit of Airbus.

Figure 1

<table>
<thead>
<tr>
<th></th>
<th>Boeing</th>
<th>Airbus</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Enter</strong></td>
<td>0, 50</td>
<td>50, 0</td>
</tr>
<tr>
<td><strong>Not enter</strong></td>
<td>0, 56</td>
<td>0, 0</td>
</tr>
</tbody>
</table>

The outcome of the game in Figure 1 is indeterminate under non-intervention. If either firm enters, the other firm loses from entry. Thus, if Boeing enters while Airbus does not, then Boeing earns 50, but both Boeing and Airbus lose 5 if Airbus enters. By contrast, if Airbus is given a subsidy of 6 when it enters, the outcome is a Nash equilibrium in which Airbus enters and Boeing does not. The subsidy makes entering a dominant strategy for Airbus. If Boeing enters, Airbus earns 1 from entry, which is better than the zero it gets if it does not enter. If Boeing does not enter, then Airbus gains 56 by entering. Given that Airbus enters, Boeing will not enter, for it will lose 5.

To move back one stage to Europe's subsidy decision, it is clear that Europe is made better off by the subsidy. If Boeing would have entered under no intervention, Europe gains 50 by preventing the entry of Boeing: Airbus earns 56, but Europe's payoff is reduced by 6 due to the cost of the subsidy to taxpayers. If there is a 50 per cent chance that Airbus would have captured the market in the absence of intervention, the expected gain to Europe is 25 from intervention. It is notable that a small subsidy can give rise to a large payoff as a result of the effect of the subsidy in changing the outcome of the strategic interaction between firms.

As this example illustrates, strategic trade policy requires that governments have the ability to commit to policy: that is, government policy must be ‘credible’. This requirement is captured in the game-theoretic structure by the order in which parties make decisions. Credibility of policy requires that the government move first by committing to its policy, prior...
strategic trade policy: The New Palgrave Dictionary of Economics

Commitment means that the government cannot subsequently change its policy. If Boeing did not believe that Europe would follow through on its subsidy, then the subsidy would not have any effect.

Having established the advantage to Europe from a subsidy, the obvious next question is whether the US government would also have an incentive to subsidize the entry of Boeing. In this example, the outcome of the policy game is indeterminate. Both countries lose if both countries subsidize leading to the entry of both firms, but each country has an incentive to subsidize if the other does not. Consequently, to gain a richer insight, we slightly change the example so that each government is considering an export subsidy in a situation where, without intervention, both firms earn profits from exports to the third-country market.

Figure 2 illustrates the payoffs to each country in a symmetric game in which both Airbus and Boeing earn 25 in the absence of intervention (bottom-right cell). If Europe subsidizes exports, say by 6, and the US does not, the profits of Airbus are assumed to increase by 16, so that, net of the subsidy, Europe earns 35 (bottom-left cell). The subsidy makes it credible that Airbus expands its sales at the expense of Boeing, which then earns 5. Due to the overall expansion in sales, the buyers of aircraft enjoy lower prices and the net industry profit (after the European subsidy is subtracted) falls from 50 to 40. Consequently, for the subsidy to benefit Europe, the shift in sales from Boeing to Airbus must be sufficient to offset the fall in price. The same situation applies to the United States if it subsidizes exports but Europe does not. If both countries subsidize exports, the expansion of sales by both firms reduces net industry profit to 20, with each country gaining 10 (top-left cell).

This policy game involves a Prisoner's Dilemma. In a non-cooperative one-shot game in which countries move simultaneously, the dominant strategy is for each country to subsidize its exports. Consequently, at the Nash equilibrium, both countries use strategic trade policy with a payoff of 10 each (upper-left cell). However, both countries would be better off if they could cooperate so as to achieve the higher payoff of 25 (bottom-right cell). As pointed out by Spencer and Brander (1983), one means of cooperation would be to negotiate a trade agreement that binds the countries to free trade. Also, if the game is repeated through time, a government might hope that current cooperation (that is, choosing not to intervene) might induce future cooperation from the other government.
The analysis of strategic trade policy provides a helpful framework for understanding the incentives facing governments in trade policy negotiations. In particular, strategic trade policy provides a rationale for the Prisoner's Dilemma mentality that pervades real-world trade policy negotiations. Under perfect competition, countries would not use export subsidies since they would simply benefit foreign consumers. In a world of strategic trade policy it makes sense that each government might reasonably view reducing or eliminating its own subsidies or tariffs as 'giving up' something, but might be willing to do so if other countries do the same. Each country faces a unilateral incentive to use activist trade policy but all can benefit if they can collectively agree to abandon such policies.

A formal model of the role of export subsidies

In the examples given so far, payoffs to firms and countries have been specified as convenient numbers. For a convincing analysis, it is important to model the underlying structure that gives rise to these payoffs. In this section we provide an algebraic demonstration of the argument for the profit-shifting effects of an export subsidy.

As in Brander and Spencer (1985), a domestic and a foreign firm are assumed to act as Cournot competitors in exporting to a third-country market. Entry barriers, such as high fixed costs, prevent entry. Let \( x \) and \( y \) represent the exports of the domestic and foreign firm, \( c \) and \( c^* \) their respective marginal costs, and \( p = p(x + y) \) the price of the homogeneous product. If an export subsidy, \( s \), is applied per unit of domestic exports, the profit functions of the domestic and foreign firm are:

\[
\pi(x, y, s) = xp(x + y) - cx + sx \quad \text{and} \quad \pi^*(x, y, s) = yp(x + y) - cy
\]

At the Cournot–Nash equilibrium, each firm sets output to maximize its profit given the output level of its rival. The first order conditions are \( \pi_x = 0 \) and \( \pi_y = 0 \), where subscripts denote partial derivatives. From total differentiation of the first order conditions with respect to \( x \), \( y \) and \( s \), and use of Cramer's rule, it follows that a domestic subsidy always raises domestic exports: that is, \( \frac{dx}{Ds} = -\frac{\pi_{yy}}{D} > 0 \) where \( \pi_{yy} < 0 \) and \( D / \pi_{xx} \pi_{yy} - \pi_{xy} \pi_{yx} > 0 \) from the second order and stability conditions. To ensure that a domestic export subsidy reduces the output of the foreign firm (that is, \( \frac{dy}{Ds} = \pi_{yx} / D < 0 \)), an important assumption identified by Brander and Spencer (1985) is

\[
\pi_{yx} = p' + yp'' < 0 \quad \text{and} \quad \pi_{xy} = p' + xp'' < 0
\]

where prime and double prime represent first and second derivatives. Condition (2) is now known as the requirement that \( x \) and \( y \) be 'strategic substitutes': an increase in \( x \) reduces the rival firm's marginal profit from an increase in \( y \) and vice versa. Given Cournot competition, this holds for linear demand (since \( p'' = 0 \)) and, more generally, if the inverse demand curve is not too convex.

The effect of the export subsidy is illustrated in Figure 3 showing the best response or reaction functions of each firm. Since domestic marginal cost falls, the subsidy increases domestic exports for any given level of the rival's exports, as shown by the outward shift in the best-response function of the domestic firm. As a result, the subsidy moves the Cournot–Nash equilibrium from point N to point S, reducing the output of the foreign firm.

Figure 3

A domestic export subsidy
The optimal subsidy is determined by maximizing domestic welfare with respect to \( s \). As there is no domestic consumption, welfare, denoted \( W \), consists only of the profit of the domestic firm minus the cost of the subsidy:

\[
W(s) = \pi(x(s), y(s); s) - s\alpha(s) = \pi(x + y) - Cs.
\]

The domestic firm’s best-response functions and the foreign firm’s best-response function are illustrated in the diagram. The domestic firm’s iso-profit contour is also shown, indicating the range of exports that maximize profit for different levels of subsidy. The diagram helps visualize the strategic interactions between the domestic and foreign firms in the context of trade policy.
Setting $\frac{dW}{ds} = \pi(y) / \frac{dy}{ds} - \pi(y) = 0$, yields $s = -\frac{\pi(y)}{\pi''(y)} \pi''(y) > 0$. Consequently, an export subsidy increases domestic profits by more than the subsidy payment leading to a rise in domestic welfare. But why is it that we need government intervention to do this?

At the initial Cournot–Nash equilibrium, domestic profits are lower than they would be if the domestic firm were able to somehow act first as a Stackelberg leader so as to take into account the reaction of the foreign firm. Government commitment to an export subsidy makes it credible for the domestic firm to expand within the confines of a Cournot–Nash equilibrium in which no one firm has the ability to act first. Indeed, if only one government intervenes, the optimal export subsidy increases domestic exports to the (unsubsidized) Stackelberg-leader level. As illustrated in Figure 3, the profits of a domestic leader-firm (and domestic welfare) are maximized at $S$, which is the point of tangency between the domestic firm's iso-profit curve and the foreign firm's reaction function.

Further analysis of this case shows that both governments have a unilateral incentive to subsidize exports. There is a domestic profit-shifting gain even if the foreign government also subsidizes exports. The outcome is a Prisoner's Dilemma in which both are made worse off than if they could agree not to use export subsidies. Thus, as previously discussed, an understanding of strategic trade policy helps us make sense of international trade agreements that disallow export subsidies.

**Limitations and extensions**

There are significant difficulties in implementing strategic trade policy. A main problem is that strategic trade policy incentives depend very much on the nature of the underlying oligopolistic interaction. In particular, the strategic argument for export subsidies requires that outputs be strategic substitutes, which typically holds for a Cournot duopoly. However, as shown by Eaton and Grossman (1986), outputs are typically strategic complements under Bertrand competition ($\pi(x) > 0$ and $\pi(y) > 0$), giving rise to an incentive to tax rather than to subsidize exports. Other conditions, such as a greater number of domestic relative to foreign firms, can also change optimal policy from a subsidy to a tax.

These findings imply that governments need to know a lot about a particular industry in order to correctly identify whether to target exports with a subsidy or a tax. As a practical matter, there is also the political economy argument that governments might choose to target unprofitable ‘sunset industries’ rather than profitable industries (see Spencer, 1986, for consideration of what should be targeted). In addition, the argument for subsidies is weakened once we recognize that the marginal cost of raising revenue to pay for a subsidy is increased by the distortionary effects of taxation. However, strategic trade policies that use taxes or tariffs are made more attractive by recognizing the full value of government revenue.

Notwithstanding the various limitations of strategic trade policy, the basic insight that governments may have a unilateral incentive to influence the outcome of strategic interactions in international oligopoly remains. Also, strategic trade policy has been analysed in a wide range of contexts and is robust to a range of generalizations. These extensions include consideration of the effects of unionization of the industry, dynamic effects on investment and R&D, vertical integration and trade in intermediate and final goods, and extension to general equilibrium.

strategic voting

Timothy Feddersen
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Strategic voting in elections occurs when a voter submits a ballot in an election with the intention of maximizing the likelihood of a good election outcome given his expectation of how others are voting. Strategic voting is typically contrasted with sincere voting. When election rules permit ballots that amount to a rank ordering of alternatives, a voter is said to vote sincerely if his ballot ranks more preferred alternatives above less preferred ones. There is evidence of strategic voting in real elections, and an extensive theoretical literature demonstrates incentives for strategic voting under almost all election rules.

Keywords

approval voting; Arrow's theorem; binary agenda voting; collective choice; mechanism design; plurality voting; sincere voting; social choice; strategic voting

Article

A voter in an election is said to vote strategically (or tactically) if he casts a ballot that maximizes his expected payoff from voting in the election. Strategic voting is typically contrasted with sincere voting. When election rules permit ballots that amount to a rank ordering of all the alternatives, a voter is said to vote sincerely if his ballot ranks his more preferred alternatives above less preferred ones. Readers interested in an early definition and discussion of strategic voting should see Farquharson (1969). The term ‘tactical voting’ is also used to describe voting behaviour in real world mass elections (see Niemi, Whitten and Franklin, 1992.)

For many voting methods sincere voting can be difficult to define. Approval voting (see Weber 1977; 1995, and also Brams and Fishburn, 1978), for example, specifies that voters must cast a ballot in which they may vote for as many candidates or alternatives as they wish. Thus, if three or more candidates were on the ballot a voter might cast one vote for 0, 1, 2 or even all of the candidates. There is no unique
strategic voting: The New Palgrave Dictionary of Economics

map from a voter's strict preferences over the candidates into a ballot that necessarily gives some candidates the same number of votes. Moreover, even when sincere voting is clearly defined strategic and sincere voting models often predict equivalent behaviour.

Interest in strategic voting increased as a consequence of central results in social choice theory. Social choice theory explores the relationship between individual preferences and collective choice rules including common methods of voting. Interested readers may consult Austen-Smith and Banks (1999) for a comprehensive survey of the social choice theory literature. Arrow's (1963) General Possibility Theorem demonstrated that collective choices among three or more alternatives using choice rules that are minimally responsive to citizen's preferences cannot be guaranteed to satisfy minimal rationality conditions unless the method of choice is dictatorial (Arrow, 1963). Gibbard (1973) and Satterthwaite (1975) independently exploit Arrow's theorem to show that all non-dictatorial voting methods are manipulable, that is, preference profiles can arise in which, given all other citizens truthfully report their preferences, at least one citizen will have an incentive to misrepresent his preferences.

The Gibbard and Satterthwaite theorems show that almost all voting methods over three or more alternatives create incentives for strategic voting. Riker (1982) illustrates the broad range of voting methods in which three or more citizens may have incentives to vote strategically. In a legislative assembly in which three legislators vote over a set of alternatives \{x, y, z\} using a binary agenda method, let us suppose that the legislature first votes between x and y with the alternative receiving the most votes in the first round facing \(z\) in a second round of voting. If legislators have cyclic preferences, that is, a majority prefers \(x\) to \(y\), \(y\) to \(z\) and \(z\) to \(x\), then at least one legislator will have an incentive to vote strategically between \(x\) and \(y\) in the first round. The reason is that if \(x\) wins in the initial round then in the final round \(z\) beats \(x\), while if \(y\) wins in the initial round then it also wins in the final round against \(z\). Strategic voters will anticipate the result in the final round and realize that a vote for \(x\) in the first round is really a vote for \(z\) to be the final outcome. If voters behave strategically a majority will vote for \(y\) over \(x\) in the first round even though a majority actually prefers \(x\) to \(y\). Banks (1985) provides results for a model of strategic voting over binary agendas.

There are also incentives for strategic voting in simultaneous elections with three or more alternatives. Consider an election in which voters must choose between three alternatives (A, B and C) using the plurality rule – the alternative receiving the most votes wins the election. Under plurality rule a voter may cast a vote for at most one of the alternatives. Suppose a voter prefers alternative A to B and B to C. Under the standard interpretation of sincere voting this voter should vote for A. However, if the voter is strategic then he will determine how to vote by comparing the relative likelihood of his vote being pivotal and able to change the outcome of the election: from B to A, from C to A; and from C to B (since the voter likes candidate C the least, he or she will never vote for C). Suppose this voter expects that his vote is relatively unlikely to be pivotal between A and either of the other alternatives, compared with the probability his vote may be pivotal between B and C. In that case the voter has an incentive to strategically vote for B. Myerson and Weber (1993) highlight the importance of comparing the relative likelihood of pivot events in determining incentives for strategic voting. Myerson (2002) provides formulae for calculating the relative likelihood of pivot events under various voting rules.

Incentives for strategic voting exist even in two alternative elections when voters have identical preferences and private information (see Austen-Smith and Banks, 1996, and Feddersen and Wolfgang, 1996; 1998, for a discussion of strategic voting incentives in two alternative elections with private
strategic voting: The New Palgrave Dictionary of Economics

Consider an election in which a jury of three or more people must decide whether to acquit or convict a defendant. In order to convict the defendant the jury must vote unanimously for conviction, otherwise the defendant is acquitted. Assume that each juror has a private signal known only to himself (guilty or innocent) and that all jurors prefer to convict the defendant if and only if a majority of the private signals are guilty. In this case a sincere voter who observes the guilty signal would vote to convict while one who observes an innocent signal would vote to acquit. A strategic juror who expects that others are voting sincerely properly reasons that the only event in which his vote could be pivotal would be when all the other voters are voting guilty. In this case, he knows that a majority of the private signals are guilty, and therefore he prefers to vote guilty even though he has observed the innocent signal.

The demonstration of the ubiquity of settings in which citizens have incentives to vote strategically has led formal political theorists to increasingly focus on analysing collective choice situations as games and to consider the design of political institutions as a mechanism design problem. Readers may consult Austen-Smith and Banks, 2005, for survey of the literature on strategic models of politics. Chapter 3, in particular, has a careful discussion of the implications of the Gibbard and Satterthwaite theorems for voting models.

Whether or not voters or legislators vote strategically or sincerely in real elections is a difficult question to resolve empirically because preferences are not directly observable. Riker (1982; 1986) provides cases of legislative voting that are consistent with the strategic voting hypothesis. Cox (1997) examines cross-national data on voting patterns as a function of different electoral systems and finds evidence of strategic voting behaviour in mass elections. Degan and Merlo (2006) discuss the empirical difficulties associated with testing the strategic voting hypothesis in mass elections and find evidence that suggests ‘virtually all’ voter behaviour in US elections can be explained by the sincere voting hypothesis. Guarnaschelli, McKelvey and Palfrey (2000) provide evidence from laboratory experiments that is consistent with the predictions of strategic voting models in two-candidate elections with private information.

strategy-proof allocation mechanisms

Mark A. Satterthwaite
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

An allocation mechanism is a function mapping agents' preferences into allocations. Each agent's preferences, however, are private to himself, so in reporting them he can misrepresent them if that achieves a more preferable allocation. A strategy-proof allocation mechanism eliminates incentives to misrepresent: each agent, no matter what his preferences are and no matter what preferences other agents report, maximizes by reporting his preferences truthfully. While the Gibbard–Satterthwaite theorem establishes that no useful strategy-proof allocation mechanisms exist in general, useful ones do exist for a number of specific, economically important classes of allocation problems.

Article

An allocation mechanism is a function mapping agents' preferences into final allocations. For example, the competitive allocation mechanism calculates market-clearing prices to select a feasible, Pareto optimal, final allocation that varies with agents' preferences. This simple view, however, of the mechanism as a map from preferences to final allocations is inadequate because it ignores agents' propensity to maximize. The problem is that each agent can misrepresent his preferences in reporting them to the mechanism because they are private to him and not verifiable. Therefore, he will tend to misrepresent whenever he realizes that misreporting his true preferences will result in a more preferable allocation than a truthful report. If, as is the case with the competitive mechanism, agents do have
incentives to misrepresent their preferences, then the resulting allocation is optimal only with respect to their reported preferences, not to their true preferences.

Strategy-proof allocation mechanisms neutralize the complications that strategic misrepresentation creates. Informally, an allocation mechanism is strategy-proof if each agent's maximizing choice of what preference ordering to report depends only on his own preferences and not on the preferences that other agents report. If the mechanism is strategy-proof, then each agent's incentives are to disregard his expectations concerning other agents' reports and truthfully report his own preference ordering because, no matter what, it secures the allocation that is maximal among those that his choice of reported preferences could secure. That is, truth telling is every agent's dominant strategy if the mechanism is strategy-proof. Strategy-proofness makes understanding the strategic choices of agents trivial: they always play their dominant strategy of reporting their true preferences. Whenever a mechanism fails strategy-proofness, game theoretic methods with all their complications become essential to understand its true optimality properties.

Gibbard–Satterthwaite theorem

Strategy-proof mechanisms are desirable, but do they exist? That most voting procedures and the competitive mechanism fail strategy-proofness suggests the conjecture that many, if not all, attractive allocation mechanisms also fail strategy-proofness. This conjecture, which Dummett and Farquharson (1961, p. 34) first made, turns out to be true. Gibbard (1973) and Satterthwaite (1975) independently proved that for general environments no strategy-proof allocation mechanisms exist that satisfy minimal requirements for responsiveness to agents' preferences.

Precise statement of this fundamental result requires some notation. Let $J = \{1, 2, ..., n\}, n \geq 2$, be a fixed set of agents who must select a single alternative from a set $X = \{x, y, z, ...\}$ of $|X|$ distinct, final allocations. Each agent $i \in J$ has transitive preferences $P_i$ over the allocations $X$. Let $P_i$ represent strict preference and $I_i$ represent indifference. Thus for each $x, y \in X$ and each $i \in J$, only three possibilities exist: $xP_iy$ (agent $i$ strictly prefers $x$ over $y$), $yP_ix$ (agent $i$ strictly prefers $y$ over $x$), or $xI_iy$ (agent $i$ is indifferent between $x$ and $y$). Not every transitive ordering $X$ is necessarily admissible as a preference ordering $P_i$. For example, for a particular $x, y \in X$, $xP_iy$ might be the only admissible ordering because allocation $x$ dominates allocation $y$ in terms of the usual non-satiation axiom of consumer demand theory. Therefore, let $\Sigma$ represent all possible transitive preference orderings over $X$ and let $\Omega_i \subset \Sigma$ represent the set of all transitive preference orderings over $X$ that are admissible. Thus $P_i$ is an admissible ordering for agent $i$ only if $P_i \in \Omega_i$. Let $\Omega = \Omega_1 \times \Omega_2 \times ... \times \Omega_n$ be the product of all agents' sets of admissible preference orderings. If every transitive ordering is admissible, then preferences are said to be unrestricted and $\Omega = \Sigma^N$. Call the triple $\{J, X, \Omega\}$ the environment.

An $n$-tuple $P = (P_1, ..., P_n) \in \Omega$ is called a preference profile. An allocation mechanism is a function $f: \Omega \rightarrow X$ that maps each admissible preference profile into a final allocation. Agent $i$ can manipulate allocation function $f$ at profile $P \in \Omega$ if an admissible ordering $P'_i \in \Omega_i$ exists such that:
strategy-proof allocation mechanisms. The New Palgrave Dictionary of Economics

\[ f \left( P_1, \ldots, P_{i-1}, P'_i, P_{i+1}, \ldots, P_n \right) P_i f (P). \]  
(1)

The interpretation of (1) is this. Preference ordering \( P_i \) is agent \( i \)'s true preferences. The other agents report preference orderings \( P_{-i} = (P_1, \ldots, P_{i-1}, P_{i+1}, \ldots, P_n) \). If agent \( i \) reports his preferences truthfully, then the outcome is \( f (P_i, P_{-i}) = f (P) \). If he misrepresents his preferences to be \( P'_i \), then the outcome is \( f (P'_i, P_{-i}) = f (P_1, \ldots, P_{i-1}, P'_i, P_{i+1}, \ldots, P_n) \). Relation (1) states that agent \( i \) prefers \( f (P'_i, P_{-i}) \) to \( f (P_i, P_{-i}) \). Therefore agent \( i \) has an incentive to manipulate \( f \) at profile \( P \) by misrepresenting his preferences to be \( P'_i \) rather than \( P_i \).

An allocation mechanism \( f \) is strategy-proof if no admissible profile \( P \in \Omega \) exists at which \( f \) is manipulable. This means that even if, for instance, agent \( i \) has perfect foresight about the preferences the other \( n-1 \) agents will report, agent \( i \) can never do better than to report his true preferences \( P_i \). Truth is always every agent’s dominant strategy. Presumably this is sufficient to induce every agent always to report his preferences truthfully. Gibbard (1973) and Satterthwaite (1975) show that strategy-proof allocation mechanisms generally do not exist.

**Theorem:** If admissible preferences are unrestricted \( (\Omega = \Sigma^n) \) and at least three possible allocations exist \( (|X| \geq 3) \), then no strategy-proof allocation mechanism \( f \) exists that is non-dictatorial and Pareto optimal.

An allocation mechanism is dictatorial if, for and all profiles \( P \in \Omega^n \), an agent \( i \) exists such that \( f (P) \in \max x P_i \) where

\[
\max x P_i = \{ x : x \in X \text{ and, for all } y \in X, \text{ not } y P_i x \}.
\]

That is, a dictatorial mechanism always gives the dictator one of the allocations that he most prefers. A non-dictatorial mechanism is a mechanism that is not dictatorial. A mechanism satisfies Pareto optimality if and only if, for any profile \( P \in \Omega^n \) and any \( x, y \in X \), \( x P_i y \) for all \( i \in I \) implies \( f (P) \neq y \). Pareto optimality implies that, if unanimity exists among the agents that an allocation \( x \) is the most preferred feasible allocation, then the mechanism picks \( x \).

The theorem can be proved either through appeal to Arrow's impossibility theorem (1951) for social-welfare functions or through a direct argument. Reny (2001) constructs parallel direct proofs for both the Arrow and the Gibbard–Satterthwaite theorems that make transparent their identical foundations.

The theorem is an impossibility theorem because mechanisms that violate either non-dictatorship or Pareto optimality are unattractive. If, however, the environment \( \langle J, X, \Sigma \rangle \) contains only two allocations \( (|X| = 2) \), then impossibility no longer obtains: majority rule is an attractive, non-dictatorial, Pareto
optimal, and strategy-proof mechanism. Normally, however, for economic environments $|X| > 2$. Therefore the theorem implies that existence can be obtained (if at all) only for environments $\langle J, X, \Omega \rangle$ where admissible preferences $\Omega$ are restricted to a strict subset of $\Sigma^n$.

Environments with restricted admissible preferences

In classical economic environments, whether for private goods or for public goods, admissible preferences are naturally constrained so that for all agents admissible preference orderings $\Omega_i$ are a strict subset of $\Sigma$. Consequently the Gibbard–Satterthwaite theorem does not rule out strategy-proof, non-dictatorial, and Pareto optimal mechanisms. Nevertheless, with one significant exception, classical economic environments do not admit useful strategy-proof mechanisms.

Consider an exchange economy with private goods first. It involves an enormous restriction in $\Omega$ relative to $\Sigma^n$: each agent cares only about his private allocation from the economy's endowment and, over his possible private allocations, has smooth preferences that generate classical indifference surfaces. Despite this, building on a long series of papers that includes Hurwicz and Walker (1990), Serizawa and Weymark (2003) show that no strategy-proof allocation mechanism exists that always prescribes allocations that are Pareto optimal and, additionally, provide every agent with a consumption bundle that exceeds some positive, minimum level. Thus strategy-proofness and optimality is incompatible with an acceptable distribution of real income.

Turn next to the canonical spatial model of public goods. Let there be $m \geq 2$ public goods so that allocations lie in the non-negative orthant of $\mathbb{R}^m_+$. Each agent's admissible preferences $\Omega_i$ includes preference orderings characterized by a most preferred allocation $x \in \mathbb{R}^m_+$ surrounded by convex indifference surfaces of less preferred allocations. Zhou (1991) shows that every strategy-proof mechanism in this environment is dictatorial provided that its range within $\mathbb{R}^m_+$ has dimension at least two. This, as Zhou points out, is precisely analogous to the Gibbard–Satterthwaite theorem since Zhou's requirement that the range have dimension two parallels Gibbard and Satterthwaite's twin requirements that $f$ is Pareto optimal and $X$ includes at least three allocations.

If, however, in this set-up there is only one public good ($m=1$) so that all feasible allocations lie on the non-negative half line $\mathbb{R}^1_+$, then the set of admissible preference profiles reduces to profiles of ‘single-peaked preferences’ and impossibility switches to possibility. A preference ordering $\mathcal{P}_i \in \Omega_i$ is single-peaked if it is characterized by a most preferred allocation $x \in \mathbb{R}^1_+$ with the desirability of other allocations $y$ strictly decreasing as the distance $|x - y|$ increases. Given that for all agents $\Omega_i$ contains only single-peaked preferences, strategy-proof and Pareto optimal mechanisms exist. Ching (1997) describes the full set of these mechanisms. The simplest of these rules is the generalization of majority rule that picks the median of the agents’ most preferred allocations. Other, more complicated rules in this set are augmented median voter rules that make use of ‘phantom voters’.

Even though useful strategy-proof mechanisms do not exist in general for classical economic environments, they do exist in some cases for the particular environment of a small-scale allocation problem. Two important examples are briefly discussed here. The first concerns a committee $J$ whose $n$
strategy-proof allocation mechanisms. The New Palgrave Dictionary of Economics

members are considering a set \( K = \{ a_1, \ldots, a_m \} \) of \( m \geq 2 \) proposals and must decide which one of its subsets \( B \subset K \) should be approved and implemented. Each member has preferences \( P_i \) over the \( 2^m \) subsets of \( K \); thus if \( A, B \subset K \) and \( A \succ_i B \), this means that member \( i \) prefers that the set \( A \) of proposals be approved and implemented rather than the set \( B \) of proposals. For each \( P_i \in \Omega_i \), let \( G(P_i) = \{ a \in K | \{ a \} \cap P_i \neq \emptyset \} \). Denote member \( i \)'s ‘good’ proposals. These are just the proposals \( a \) that \( i \) would vote to approve if the committee were restricted to choosing between approving the single proposal \( \{ a \} \) and no proposals at all. A member \( i \)'s preferences are separable if, for each ordering \( P_i \in \Omega_i \) and each subset \( A \subset K \),

\[
A \cup \{ a \} \cap P_i \neq \emptyset \iff a \in G(P_i).
\]

In words, adding proposal \( a \) to the set \( A \) of approved proposals improves the outcome in \( i \)'s eyes if and only if \( a \) is one of the proposals he deems good.

Barbera, Sonnenschein and Zhou (1991) fully characterize all useful strategy-proof voting rules when preferences are restricted to be separable. The simplest member of this class of strategy-proof rules is ‘voting by quota’. Under that rule, which is defined by a positive integer \( Q \), each committee member casts a ballot listing the proposals that he judges to be good. Any proposal that is listed on at least \( Q \) of the ballots is declared approved. For instance, for election to a club that currently has 100 members, each proposed member might need to be named on the ballots of at least 60 current members in order to be allowed to join.

The second example concerns the Vickrey–Clarke–Groves combinatorial auction in which a seller has a set \( K = \{ a_1, \ldots, a_m \} \) of \( m \geq 2 \) of unique objects that he is selling to a set \( J \) of \( n \geq 2 \) buyers. An allocation is a vector \( x = \{ x_1, x_2, \ldots, x_m \} \) where the value of \( x_j \in \{ 0, 1, 2, \ldots, n \} \) indicates to which buyer \( i \) object \( j \) is assigned (with the convention that the seller is labelled as buyer 0). Thus if \( x_3 = 2 \), then the third object is assigned to the second buyer.

Buyer \( i \) has quasi-linear utility if his utility (in dollars) for an allocation \( x \) and monetary transfer \( t_i \) to the seller takes the form \( v_i(x) = u_i(x) - t_i \) where \( t_i \) is the payment buyer \( i \) makes to the seller and \( u_i(x) \) is the value that he places on allocation \( x \). Let \( \Omega_i \) consist of all possible quasi-linear utility functions. The efficient allocation \( x^* \) assigns the objects to those buyers who most highly them:

\[
x^* \in \arg \max_{x \in X} \sum_{k \in I} u_k(x)
\]

where \( X \) is the set of all possible allocations. If buyer \( i \) declines to participate and only the other the other \( n - 1 \) buyers bid, then \( x^*_\neg i \in \arg \max_{x \in X} \sum_{k \in J \setminus i} u_i(x) \) is the efficient allocation for the remaining buyers.

The value of the \( m \) objects if they are optimally allocated to all \( n \) buyers is \( V^* = \sum_{k \in I} u_k(x^*) \) and their value if they are optimally allocated to the \( n - 1 \) buyers excluding \( i \) is \( V_{-i}^* = \sum_{k \in I \setminus i} u_k(x_{-i}^*) \).

With this notation in place, the Vickrey–Clarke–Groves auction consists of three steps. First, each buyer \( i \in I \) sends the seller a list of bids for each possible allocation: \( u_i(x) \) for all \( x \in X \). Second, the seller computes and implements the optimal allocation \( y^* \). Third, the seller collects the Vickrey–Clarke–Groves payments from each buyer for that bundle of goods the buyer is allocated under \( y^* \). Buyer \( i \)'s payment is \( V_{-i}^* - (V^* - u_i(x^*)) \): the total value the other buyers accrue if \( i \) does not participate less their total value if \( i \) does participate. This is the opportunity cost of the bundle agent \( i \) receives in the optimal allocation. Given that \( \Omega_i \) contains only quasi-linear utility functions, this auction is strategy-proof: each buyer's dominant strategy is to report truthfully his \( u_i(\cdot) \) to the seller. The reason it is strategy-proof is that (a) truthful reporting guarantees that he receives a bundle of goods if and only if the value he places on it exceeds its opportunity cost and (b) his bundle's opportunity cost is independent of his report. Groves and Loeb (1975) derive the efficiency and incentive properties of this mechanism, Green and Laffont (1979) develop its full theory, and de Vries and Vohra (2003) review its application to combinatorial auctions.

stratification

Stephen L. Morgan
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

‘Stratification’ refers to a structure of inequality where individuals occupy differentiated positions that are ranked hierarchically according to broadly recognized standards. Prominent in 20th-century sociology, the term was used by Parsons and his students to explain why individuals in the most functionally important positions in society receive the greatest rewards for their services. In sociology, the most important legacy of stratification research is the cross-national study of intergenerational mobility between occupational categories. Recently, economists have joined sociologists in studying the relationship between increasing inequalities within the labour markets of industrialized countries and rates of intergenerational mobility.

Article

‘Stratification’ is a term used to characterize a structure of inequality where (a) individuals occupy differentiated structural positions and (b) the positions are situated in layers (or strata) that are ranked hierarchically according to broadly recognized standards. The implied reference to sedimentary layers from geology reflects the relative permanence of the posited structure and the long history that is assumed to have generated it. Stratification researchers focus primarily on the empirical study of (a) the sources of the rankings that generate the hierarchy of strata, (b) the mobility of individuals between strata, and (c) the mechanisms of integration that allow societies to cope with the existence of persistent inequalities between strata.

The structural orientation of stratification scholarship can be contrasted with distributional approaches to the study of inequality that have dominated economics. Modelling the distribution of valued resources across individuals makes possible explanations of change in response to short-run interventions and shocks from unforeseen exogenous events. For stratification researchers, short-run variation in
inequality is considered to be noise that dissipates as social inequalities are reproduced.

The development of the concept of stratification

Although the sociologist Pitirim Sorokin is often credited with first developing and then using the concept of stratification in empirical work, the clearest lineage emerges in the work of Talcott Parsons and that of his students. In his essay ‘An analytical approach to the theory of social stratification’, Parsons (1940, p. 841) wrote: ‘Social stratification is regarded here as the differential ranking of the human individuals who compose a given social system and their treatment as superior and inferior relative to one another in certain socially important respects.’ Parsons (1940, p. 849) then wrote that the ‘status of any given individual in the system of stratification in a society may be regarded as a resultant of the common valuations underlying the attribution of status to him’ in dimensions such as achievements, possessions, authority, and power.

In 1945 Parsons’s students, Kingsley Davis and Wilbert Moore, wrote ‘Some principles of stratification’ in which they specified a clear (but ultimately controversial) conception of the sources and inevitably of stratification. Adopting the functionalist framework championed by Parsons, Davis and Moore maintained that society is a functioning social system, directly analogous to a living organism, which survives because it determines necessary social positions, recruits appropriate individuals to fill each position, and induces individuals to perform their assigned duties. To foster efficiency, the social system attaches differential rewards to alternative positions, where the sizes of the rewards are based on (a) the functional importance of the position to the society as a whole and (b) the counterfactual scarcity of individuals willing to take the position in the absence of appropriate rewards. Davis and Moore (1945, p. 243) claimed that ‘Social inequality is thus an unconsciously evolved device by which societies insure that the most important positions are conscientiously filled by the most qualified persons.’ (As discussed later, this view of the sources, functional necessity, and inevitably of stratification was challenged almost immediately by scholars wishing to focus on the mutability of the structure of inequality as well as the power dynamics that pervade it.)

Thirteen years after his initial essay on the topic, and eight years after the seminal Davis and Moore piece, Parsons (1953, p. 92) began ‘A revised analytical approach to the theory of social stratification’ with the bold assertion: ‘It has come to be rather widely recognized in the sociological field that social stratification is a generalized aspect of the structure of all social systems, and that the system of stratification is intimately linked to the level and type of integration of the system as a system.’ Parsons then discussed how societies cope with the functional necessity of stratification by developing norms and value standards that, by and large, attribute differences in attainment to differences in achievement. Parsons and his colleagues assumed that moderately high levels of intergenerational mobility are essential for the efficiency and integration of society. Functionally important positions must be staffed by the most qualified individuals and hence based on past achievements rather than social origins. And, to ensure integration and social order, reward for achievement rather than reward for social origins must be reasonably expected and then observed. In later work, Parsons (1959) specified the social processes that develop and then transmit these norms of achievement in his essay ‘The school class as a social system’. He argued that schools serve two primary functions in society – socialization and allocation – which they fulfil in a simultaneous four-part process: (a) emancipation of children from exclusive
attachment to their parents, (b) inculcation of values and norms that cannot be taught by parents, (c) differentiation of the school class on actual achievement and on differential valuation of achievement, and finally (d) an allocation of individuals to positions in the adult role system. Parsons (1959, p. 145) wrote: ‘Differentiation of the class along the achievement axis is inevitably a source of strain, because it confers higher rewards and privileges on one contingent than on another within the same system. … [The] common valuation [of achievement] helps make possible the acceptance of the crucial differentiation, especially by the loser in the competition.’

As a result of this scholarship, the term ‘stratification’ gained popularity in sociology, becoming the name for the entire sub-field of inquiry concerned with the causes and consequences of inequality. Thereafter, the term diffused throughout the social sciences and was drawn upon by historians and anthropologists to frame comparative studies of inequality. Within economics, the term has been used less frequently and with no consistent definition. For early studies of racial–ethnic inequality, one can find the term used in the dissimilar work of Closson (1896) and Myrdal (1944). More recently, the term has been used to refer to the determinants of labour market earnings that arise from family background rather than one’s own skills (see Heckman and Hotz, 1986). For Durlauf (1994) and Benabou (1996), the term is used to refer to persistent neighbourhood differences in average levels of family income and well-being.

Complexity and contention

The foregoing presentation of the Parsonian perspective on stratification is sanitized in two important respects. First, it ignores alternative perspectives which rejected the Parsonian vision at the time it was being proposed and which later grew into the neo-Marxist scholarship of the 1960s onward. This scholarship led Pierre Bourdieu (1984, p. 245) to look back at the stratification literature of the 1950s and 1960s and declare that ‘the opposition between theories which describe the social world in the language of stratification and those which speak the language of class struggle corresponds to two ways of seeing the social world.’

Second, the presentation overly formalizes what for some was an informal term, often used as shorthand for the simple notion of a systematic pattern of inequality. In fact, many of the scholars who worked within the stratification tradition used a mixture of class-based and stratification-based terminology in the course of the empirical analysis that was their main interest. For example, Sorokin (1927, p. 11) wrote: ‘Social stratification means the differentiation of a given population into hierarchically superposed classes.’ Edward Shils (1962, p. 249) wrote: ‘The class system, or the system of stratification of a society, is the system of classes in their internal and external relationships.’ And Melvin Kohn (1969, p. 11) wrote: ‘we use a multidimensional index of class, based on the two dimensions of stratification that appear to be the most important in contemporary American society – occupational position and education.’

Empirical mobility research in sociology and economics

The most important legacy of stratification research is the empirical study of mobility between strata, however defined. Mobility researchers have comprehensively modelled rates and patterns of
intergenerational and intragenerational movement between strata (see Morgan, Grusky and Fields, 2006, for a review and examples from both sociology and economics). Two approaches to mobility have dominated sociology. In the first, mobility is modelled by accounting for movement between aggregated occupations, sometimes labelled social classes. Accordingly, intergenerational mobility is analysed via inspection of cross-classifications of parents’ and children’s occupations. In the early literature, levels of mobility were summarized by alternative indices, often derived in the course of analysis of cross-classifications drawn from different societies. The later literature dispensed with mobility indices, focusing instead on the fine structure of patterns of mobility using new log-linear modelling techniques. With the publication of Blau and Duncan’s *American Occupational Structure* in 1967, a second approach to the study of mobility reached maturity in sociology, later labelled status attainment research. In this tradition, sociologists focus on the causes and consequences of differences in socio-economic status (often defined in terms of scores attached to occupational titles, based on the average educational attainment and earnings of incumbents). Levels of social mobility are measured by intergenerational correlations of socio-economic status, and these correlations are then decomposed with the use of intervening variables in structural equations models.

An important concern of this literature has been the impact of structural change over time on mobility outcomes and hence the extent to which such change has altered the stratification order. In particular, the degree to which shifts in occupational distributions generate upward mobility has been studied extensively. Such outcomes were welcomed in the middle of the 20th century, and elaborated in scholarship where it was argued that the growth of higher-status occupations is an inevitable outcome of the process of industrialization (and also, by implication, that Marxist claims of the inevitability of class polarization under capitalism had been exaggerated). Perhaps reflecting the growing pessimism and radicalism of sociology in the 1960s and 1970s, such structurally induced upward mobility was deemed less theoretically meaningful than levels of mobility purged of these effects. The study of what came to be known as pure exchange mobility then became possible with the development of log-linear modelling techniques that could be used to ascertain margin-free measures of mobility. This work is best represented by the cross-national research of Erikson and Goldthorpe (1992), which supported the claim that industrialized societies can be characterized by broadly similar patterns of intergenerational occupational mobility (in spite of national mythologies that claim that some societies are more open and meritocratic than others).

In economics, mobility has been a topic of theoretical and empirical work as well, even though it is not connected directly with any tradition of stratification research in sociology. Rather, the early work arose out of labour economics, based on the ‘unified approach to intergenerational mobility and inequality’ (Becker and Tomes, 1979, p. 1154), which brought together human capital theory with dynastic investment models for family behaviour. As with the status attainment tradition in sociology, economists working in this area often seek single-number expressions for levels of mobility, generally intergenerational correlations of income (although estimated as elasticities from regressions of log earnings across generations; see Solon, 1999). In contrast to the sociological literature, economists have argued recently that there are substantial cross-country differences in mobility, with greater intergenerational mobility of earnings in mainland Europe than in either the United States or the United Kingdom (see Solon, 2002). In addition to the large economics literature on earnings mobility, a well-developed literature on the intergenerational dynamics of wealth inequality now exists (see Mulligan,
Economists have begun to focus, like sociologists, on categorical representations of the structure of inequality, examining placement within the distribution of earnings and wealth (using either fixed categories across generations or relative ranks within distributions). When analysed as cross-classifications of quantiles, these methods are similar in spirit and method to the between-social-class mobility studies of sociology. In fact, Björklund and Jäntti (1997) refer to income groups as income classes, and reference the log-linear tradition of mobility research in sociology.

Economists have also become interested in the extent to which increasing inequalities within the labour markets of industrialized countries between the 1970s and the 1990s can be seen as less consequential to the extent that they have been accompanied by increasing chances of intergenerational mobility (see Welch, 1999). Relatedly, some economists have sought to determine the extent to which increasing chances of upward mobility sustained support for the market reforms in eastern Europe and the former Soviet Union that increased inequality (see Birdsall and Graham, 2000). This work is reminiscent of the concern with societal integration that is most closely associated with Parsons in sociology, and it may represent a shared territory which both sociologists and economists will further cultivate.

stratified and cluster sampling

Jeffrey M. Wooldridge

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The random sampling paradigm, typically introduced in basic statistics courses, ensures that a sample of data is, loosely speaking, ‘representative’ of the underlying population. When the population parameters are identified, many common estimation techniques, including least squares, maximum likelihood, and instrumental variables, have desirable statistical properties under random sampling. Unfortunately, while random sampling is convenient, it can be, and often intentionally is, violated when cross-sectional data and panel data are collected. Two important deviations from random sampling are stratified sampling and cluster sampling, or perhaps a combination.

Keywords

cluster correlation; cluster sampling; exogenous sampling; heteroskedasticity; multinomial sampling; probability sampling; sampling; stratified sampling; survey sampling; two-stage sampling; unbiased estimators; variable probability sampling; variance; weighted least squares

Article

With stratified sampling, some segments of the population are over- or under-represented by the sampling scheme. For example, a survey of income and demographic characteristics may oversample those with below-median incomes. Intuitively, it is clear that using descriptive statistics from such a sample will not necessarily produce satisfying estimates of population moments. Fortunately, if we know enough information about the stratification scheme, we can often modify standard econometric methods and consistently estimate population parameters.

There are two common types of stratified sampling, namely, standard stratified (SS) sampling and variable probability (VP) sampling. A third type of sampling, typically called multinomial sampling, is practically indistinguishable from SS sampling, but it generates a random sample from a modified population (thereby simplifying certain theoretical analyses). See Coslett (1993), Imbens and Lancaster (1996), and Wooldridge (1999) for further discussion. We focus on SS and VP sampling here.

SS sampling begins by partitioning the sample space (set of possible outcomes), say $Z$, into $G$ non-
Stratified and cluster sampling: The New Palgrave Dictionary of Economics

Overlapping, exhaustive groups, \( \{ Z_g: g = 1, \ldots, G \} \). Then a random sample is taken from each group \( g \), say \( \{ Z_{gi}: i = 1, \ldots, N_g \} \), where \( N_g \) is the number of observations drawn from stratum \( g \) and 
\[ N = N_1 + N_2 + \ldots + N_G \]
the total number of observations. If \( Z \) is a random vector representing the population, and taking values in \( Z \), each random draw from stratum \( g \) has the same distribution as \( Z \) conditional on \( Z \) belonging to \( Z_g \). Therefore, the resulting sample consists of independent but not identically distributed observations. But, unless we are told, we have no way of knowing that our data came from SS sampling.

What if we want to estimate the mean or expected value of \( Z \) from an SS sample? It turns out we cannot get an unbiased or consistent estimator of \( E(Z) \) unless we have some additional information. Typically, the information comes in the form of population frequencies for each of the strata. Specifically, let 
\[ Q_g = P(Z \in Z_g) \]
be the probability that \( Z \) falls into stratum \( g \); the \( Q_g \) are often called the ‘aggregate shares’.

For example, if \( Z \) represents the distribution of wealth in a country, \( Q_g \) is simply the fraction of people in the population whose wealth falls into stratum \( g \) (probably defined as intervals in this case). Sometimes very precise estimates of the population frequencies \( Q_g \) can be obtained from very large surveys or censuses, in which case they can be treated as known. In some cases, small random samples (sometimes called a ‘supplementary sample’) are collected and these can be used to estimate the \( Q_g \).

If we know the \( Q_g \) (or can consistently estimate them), then \( E(Z) \) is identified by a weighted average of the expected values for the strata:

\[
\mu_Z = E(Z) = Q_1 E(Z|Z \in Z_1) + \ldots + Q_G E(Z|Z \in Z_G)
\]

Because we can estimate each of the conditional means using the random sample from the appropriate stratum, an unbiased estimator of \( \mu_Z \) is simply

\[
\hat{\mu}_Z = Q_1 \bar{Z}_1 + Q_2 \bar{Z}_2 + \ldots + Q_G \bar{Z}_G
\]

where \( \bar{Z}_g \) is the sample average for stratum \( g \). Using an asymptotic analysis where the number of observations in each stratum gets large, \( \hat{\mu}_Z \) is also a consistent estimator of \( \mu_Z \). The variance of \( \hat{\mu}_Z \) is easily estimated, too, because

\[
\text{Var}(\hat{\mu}_Z) = Q_1^2 \text{Var}(\bar{Z}_1) + \ldots + Q_G^2 \text{Var}(\bar{Z}_G)
\]
and the variance of each sample average can be estimated by the usual unbiased variance estimator within each stratum.

SS sampling is convenient when the members from each stratum are easily identified before sampling. Variable probability sampling is more convenient for telephone or email surveys, where little, if anything, is known ahead of time about those being contacted. With VP sampling, each stratum \( g \) is assigned a nonzero sampling probability, \( p_g \). A random draw \( Z_i \) is kept with probability \( p_g \) if \( Z_i \) falls into stratum \( g \). With VP sampling, the population is sampled \( N_o \) times. Typically, \( N_o \) is not reported along with VP samples. Instead, we know how many data points were kept, and we call this \( N \). Because of the randomness in whether an observation is kept, \( N \) is properly viewed as a random variable. As discussed in Wooldridge (1999), it is handy for deriving properties of estimates to define a selection indicator, \( S_i \), which is equal to unity if observation \( i \) is kept, and zero otherwise. When \( S_i=1 \), we observe the stratum for the observation (or at least its associated sampling probability).

A key formula underlying estimation of the mean from a population under VP sample is

\[
E(Z) = N_o^{-1} \sum_{i=1}^{N_o} E[(S_i / p_g)Z_i].
\]

(4)

Because observations within each stratum \( g \) are kept with the same probability \( p_g \), it can be shown that \( E[(S_i / p_g)Z_i] = E(Z_i) = \mu Z \); see, for example, Wooldridge (1999). In other words, weighting an observation by the inverse of its probability of being kept in the sample restores its unbiasedness for the population mean. Equation (4) cannot be used directly in estimation because \( N_o \) is typically unknown. A consistent estimator is

\[
\hat{\mu}_Z = \frac{1}{N} \sum_{i=1}^{N} W_i Z_i
\]

(5)

where \( W_i = 1 / p_g i \) is the inverse probability weight for the kept observations (\( N \) of them): \( \hat{\mu}_Z \) is simply a weighted average using the observed data points. Observations with \( p_g i = 1 \) are always kept and are therefore fully represented in the sample. If, say, \( p_g i = 1 / 3 \), the observation needs to be given three times the weight so that its frequency in the sample reflects its population frequency. Wooldridge (1999) uses the selection indicator setup to show that this estimator (and many others that use inverse probability weighting, or IPW) is consistent under VP sampling.
In the context of SS sampling, (5) is also consistent if the weights are chosen appropriately. Letting \( H_g = N_g / N \) be the fraction of observations falling into stratum \( g \), the appropriate weight is \( w_i = Q_g / H_g \). This shows explicitly that observations underrepresented in the sample relative to the population (\( Q_g > H_g \)) receive a weight greater than one.

Virtually all standard estimation methods, including least squares, instrumental variables, quantile estimation, maximum likelihood and quasi-ML, can be appropriately modified for SS and VP samples. For example, if we partition \( Z_i \) as \( Z_i = (X_i, Y_i) \) where \( Y_i \) is a scalar and \( X_i \) is a row vector, then a linear least squares problem is

\[
\min_{\beta} \sum_{i=1}^{N} w_i \cdot (Y_i - X_i \beta)^2.
\]

As has been demonstrated by many authors, including Jewell (1985) and Wooldridge (2001), the solution to (6), \( \hat{\beta} \), sometimes called a ‘weighted least squares’ estimator, is consistent for \( \beta_0 = [E(X'X)]^{-1}E(X'Y) \), the vector in the linear least squares projection of \( Y \) on \( X \). Nonlinear regression functions can replace linear regression functions, as demonstrated by Wooldridge (2001). The squared residual in (6) can be replaced with a log-likelihood function, as in Manski and Lerman (1977).

It is important to understand that the weighting in (6) is not used to correct for heteroskedasticity in the underlying population; therefore, one must use care when estimating the asymptotic variance of \( \hat{\beta} \). The usual ‘sandwich’ form of the asymptotic variance estimator, of the type appearing in White (1982), \( \hat{\Sigma}^{-1} \hat{B} \hat{\Sigma}^{-1} \), turns out to be consistent in many cases. (Here, \( \hat{\Sigma} \) is an estimate of the expected Hessian of the objective function and \( \hat{\Sigma} \) is outer product of the weighted score.) In particular, the sandwich estimator is consistent under VP sampling with known sampling probabilities; see Wooldridge (1999) for a general treatment that applies to a wide variety of estimation methods. (The sandwich form is also consistent under exogenous sampling of any type, a case we consider in the next section.)

Interestingly, in cases where the usual sandwich estimator is inconsistent, it is always conservative. These include VP sampling with known population frequencies, \( Q_g \), and SS sampling (see, for example, Cosslett, 1993; Imbens and Lancaster, 1996; Wooldridge, 1999; 2001). If the sandwich standard errors are suitably small, one might be satisfied with conservative standard errors. But the adjustment to the usual sandwich estimator is straightforward, provided stratum membership is known for each observation. In constructing \( \hat{\Sigma} \), one should subtract off the mean of the score within each stratum, which reduces the total variation in the outer product of the score (see Wooldridge, 1999; 2001, for further discussion). Fortunately, statistical software that supports survey sampling commands computes the correct variance matrix estimator provided the strata identifiers are indicated for each observation.

Using modern software, it is easy to analyse data sets that involve both SS and VP sampling. Often, strata are first assigned and then within strata a VP sampling scheme is adopted. The sampling weights reflect both the initial stratification and the variable probability sampling.
**Exogenous sampling**

When we partition the random vector $Z = (X, Y)$, and we are interested in modelling some feature of the conditional distribution $D(\gamma|X)$, such as a conditional mean or even the full conditional density, then it makes sense to define the notion of ‘exogenous’ sampling. For most purposes, it is sufficient to equate exogenous sampling with strata defined in terms of the conditioning variables $X$ only.

Exogenous sampling has three important implications. First, one need not apply weighting to consistently estimate the population parameters. Second, if one does employ weighting, the usual sandwich-type asymptotic variance matrix estimators are consistent. The adjustments used under endogenous sampling described above simply introduce estimation error. Third, there is typically a set of assumptions under which weighting is less efficient than not weighting. For correctly specified maximum likelihood, it is always inefficient to use sampling weights under exogenous sampling. The same is true for nonlinear regression with a correctly specified conditional mean and homoskedasticity. See Wooldridge (2002) for references and further discussion.

Is there a reason to use sampling weights if we know that the sampling is a function of exogenous variables? The answer is ‘yes’, for two reasons. First, if, say, there is heteroskedasticity in a regression model, it may be more efficient to use sample weights than not, although the most efficient method is to weight based on the form of heteroskedasticity, ignoring the sampling weights. Second, weighting always consistently estimates the parameters of a population optimization problem even in the presence of misspecification. So, if we use linear regression but the conditional mean is not linear, using sample weights nevertheless consistently estimates the parameters in the population linear projection; the unweighted estimator does not.

**Cluster sampling**

Cluster samples are obtained from one of two basic sampling schemes. One type arises when disaggregated units present themselves naturally as relatively small clusters in the population, and then those clusters are sampled. For example, to study the effects of school inputs on a national fourth-grade mathematics test, we might randomly sample public schools and obtain test results for all students in each school, or for a random sample of students within each school. Under this sampling scheme it makes sense to think of each fourth grader as belonging to his or her cluster (school). While there is randomness in outcomes within a school, typically we think that the outcomes for students within a school will be correlated, due to both observed and unobserved school characteristics. When we apply econometric methods to cluster samples we generally need to account for within-cluster correlation, as was recognized by Scott and Holt (1982) for ordinary least squares. These days, so-called ‘cluster-robust’ standard errors are routinely computed by many statistical packages.

A cluster sample presents itself in much the same way as a stratified sample: a cluster or group identifier is included for each observation. But, because clusters are sampled, valid inference requires accounting for within-cluster correlation (except in the rare case where it is not present). Typically, this correlation is dealt with through ‘cluster-robust’ estimation of the matrix $B$ in the middle of the sandwich formula (although, in some cases, generalized least squares-type methods are used). Theoretically, the cluster-robust variance matrix estimators are valid when the number of clusters is ‘large’ and the cluster sizes are relatively small, although these estimators are employed sometimes for small group sizes. Wooldridge (2003) contains a survey.
Sometimes clustering arises in the context of survey sampling, which also involves some kind of probability sampling. Two-stage sampling is the simplest example. In the first stage, one chooses ‘primary sampling units’ (PSUs), which might be local labour markets, cities, or census block groups, for example. The PSUs are typically not exhaustive because they are selected from a large group of potential PSUs. In the second stage, observations within each PSU are obtained by VP sampling. (If the PSUs are based on a stratification of the initial population, the sampling probabilities reflect that, too.) An observation comes with its PSU identifier and a sampling weight. When sampling is endogenous, weighting is needed to obtain consistent estimators of the population parameters. Additionally, one must account for the within-cluster correlation. For example, we can apply OLS pooled across all observations but with inverse probability weighting. For each $g$, let $M_g$ denote the number of observations for PSU $g$. Then, the $M_g \times 1$ vector $y_g$ is the data on the response variable for PSU $g$ and the $M_g \times K$ matrix $X_g$ is the collection of data on the covariates. If $\hat{\beta}$ is the IPW least squares estimator, then its asymptotic variance is estimated by the sandwich form

$$
\hat{\text{Var}}(\hat{\beta}) = \left( \sum_{g=1}^{G} \sum_{i=1}^{M_g} X_g' g_i / p_{gi} \right)^{-1} \left( \sum_{g=1}^{G} \sum_{i=1}^{M_g} \sum_{h=1}^{M_g} \hat{y}_g i \hat{y}_g h X_g' g_i g_h / (p_{gi} p_{gh}) \right) \times \left( \sum_{g=1}^{G} \sum_{i=1}^{M_g} X_g' g_i / p_{gi} \right)^{-1}
$$

(7)

where we need to explicitly index observations by PSU ($g$) and unit within PSU ($i$), and the sampling probabilities can differ within PSU. This rather daunting formula is simply a general sandwich form, where the inner term properly accounts for the weighting and within-cluster correlation. Without the probability weights, (7) properly accounts for clustering. If in the middle term we drop the summands with $i \neq h$, and assume constant sampling probabilities within each PSU, then (7) is the proper formula to account for VP sampling without cluster correlation.

strikes

John Kennan
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

An economic strike is a suspension of production while workers and their employer argue about how to divide the surplus from their relationship. Modern economic theories of strikes assume that at least one side has private information about the surplus, viewing the lost production as a cost of extracting information. Empirically, strikes are quite rare. There is evidence that strike incidence is high at the peak of the business cycle, but strike duration seems to fall when the economy is strong. Strike activity is evidently influenced by the legislative environment, and particularly by legislation restricting the use of replacement workers.

Keywords

Attrition; bargaining; collective bargaining; employment surplus; Hicks paradox; opportunity cost; private information; replacement workers; screening; signalling; strikes

Article

The value of an employee's labour is generally greater than the wage paid by the employer: that is after all the point of the employment relationship. This gives rise to a surplus to be divided between the worker and the employer. A strike is a suspension of production while the two sides argue about how this surplus is to be divided.

Under ideal competitive conditions, the employment surplus is negligible: each employer competes with many other employers, who bid up the wage until it matches the value of the employee's labour, and each worker competes with many other workers who bid down the wage until it matches the value of the worker's alternative use of time. An employee who strikes for a higher wage is replaced by an equivalent worker who is willing to accept the competitive wage, and an employer who attempts to cut the wage is replaced by another employer who pays the competitive wage. Thus strikes occur only in non-competitive labour markets, where there is a surplus worth fighting about. Even then, it is not easy to explain why strikes happen. Indeed, if one could explain both the
strikes: The New Palgrave Dictionary of Economics

occurrence of strikes and the terms of settlement, then strikes would be quite pointless, since the settlement could be reached without the waste associated with strikes. This is sometimes called the Hicks paradox, since the theoretical difficulty of a complete theory of strikes was first articulated by Hicks (1932). As Hicks observed (1932, pp. 146–7), ‘Any means which enables either side to appreciate better the position of the other will make settlement easier; adequate knowledge will always make a settlement possible.’

Building on Hicks’s observation, modern economic theories of strikes assume that at least one side has private information about the size of the surplus to be divided. The apparent waste associated with a strike is then seen as a cost of obtaining information.

The main idea can be illustrated by using a simple example. Consider a union negotiating a one-year labour contract with an employer who has private information about the market value of the product being produced. The union is not strong enough to maintain a strike indefinitely, but it can strike for a period of length $s$ (measured in years). Moreover, the union has the power to make offers that the employer must accept or reject. In the most favourable case, $v_H$ is the employer’s demand price for labour (that is, the highest wage that the employer would pay), and in the worst case the demand price is $v_L$, where both are measured relative to the workers’ supply price (which is thus normalized to zero). If these are in fact the only two possibilities, then it is easy to see that the union should demand either a low wage or a high wage, leaving either the low or high employer type indifferent between acceptance and rejection. A strike occurs when the low employer type rejects the high wage demand.

Thus strikes arise when the union is relatively confident that the employer can afford to pay a high wage, but this confidence is in fact misplaced. If $p$ is the probability that the employer is in the high state, the union chooses between $v_L$ for sure, or a higher wage $W$ with probability $p$. This higher wage leaves the high-state employer indifferent between acceptance, with profit $v_H−W$, or rejection, with profit $(1−s)(v_H−v_L)$, since rejection entails a strike of length $s$, followed by agreement at the low wage. Thus $W=v_L+s(v_H−v_L)$, and the union threatens a strike if $pW+(1−p)(1−s)v_L>v_L$, that is if

$$p > \frac{v_L}{v_H}.$$ 

Thus the union’s decision as to whether to use the strike threat is influenced by two factors: (a) the probability $p$ that the more favourable state is realized, and (b) the importance of private information, represented by the ratio $v_L/v_H$, or equivalently by the spread $v_H−v_L$ as a proportion of the opportunity cost $v_L$. Strengthening either of these factors can tip the balance in favour of the strike threat. Whether a strike actually happens depends on the realized state of demand. Thus an increase in $p$ at some point triggers the use of the strike threat, but further increases in $p$ reduce the probability that a strike will actually occur. The strength of the union, represented by its ability to commit to a strike of length $s$, has no influence on whether a strike occurs, although it obviously affects the duration of a strike if it does occur, and the terms of settlement if there is no strike.

This simple model is analysed in more detail in Kennan (1986). A much more extensive analysis,
allowing for private information on both sides, is presented in Kennan and Wilson (1993), with applications to legal conflicts as well as labour negotiations. A general treatment of games with private information, with many bargaining examples, can be found in Myerson (1991).

Three main categories of private information bargaining models can be used to interpret data on labour market negotiations. First, the simple model discussed above is an example of a screening model, in which an uninformed bargainer makes offers that are acceptable only if the informed bargainer knows that the realized surplus is relatively large. More general versions of the screening model assume that once an offer has been rejected, another offer will be made after some specified length of time, since take-it-or-leave-it offers are generally not credible. This leads naturally to a theory of strike durations in which the union makes a declining sequence of wage demands such that in more favourable demand states the employer finds it more profitable to accept an early offer rather than suffer a long strike, and conversely for an employer in a less favourable demand state. In signalling models (the second category), offers are made by bargainers who have private information; this leads to complications arising from a desire to remain ‘inscrutable’, rather than making an offer that reveals valuable information. In attrition models (the third category), the parties fight ‘to the death’ until one side concedes everything; no compromise is allowed.

In a series of papers, Cramton and Tracy (1992; 2003) have presented detailed analyses of collective bargaining negotiations in North America, using a model that includes both screening and signalling components. They emphasize that unions can (and very often do) apply pressure by refusing to sign a new contract after the old contract expires, while continuing to work under the terms of the old contract rather than launching a strike. It is assumed that the employer has private information about the size of the surplus, and that the union makes the first offer. If this offer is refused, the union either continues to work under the old contract, or calls a strike, depending on how optimistic the union is about the size of the surplus relative to the opportunity cost of a strike, as represented by the wage under the old contract. An employer who refuses the initial offer waits some time before making a counter-offer, and the wage settlement then gives each side half or the actual surplus (where the employer's delay is just enough to signal that the surplus is no bigger than it actually is).

**Empirical analysis of strike activity**

There are many well-known examples of long and hard-fought strikes involving large numbers of workers. But strikes are in fact quite rare, by any measure. Many workers are not covered by collective bargaining agreements; relatively few wage negotiations involve strikes, and most strikes are fairly short. In Britain in 1926 (the year of the General Strike) about nine workdays per worker were lost due to strikes. In 1979, the loss due to strikes was a little more than one day per worker. These are the exceptional cases. In the 79 years following 1926, the number of workdays lost in Britain was fewer than two hours per year per worker. In the United States, idleness due to strikes never exceeded 0.5 per cent of total working days in any year during the period 1948–2005; the average loss was 0.1 per cent per year. Similarly, in Canada over the period 1980–2005, the annual number of work days lost due to strikes never exceeded one day per worker; on average over this period work time lost due to strikes was about one-third of a day per worker. Although the data are not readily available for a broad sample of developed countries, the pattern described above seems quite general: days lost due to strikes amount to

only a fraction of a day per worker per annum, on average, exceeding one day only in a few exceptional years.

In recent years, the number of workdays lost due to strikes has fallen far below even these low levels. For example, in the United States since 1990, the average loss was about 0.016 per cent, which is about 20 minutes per worker per annum. According to International Labour Organization (ILO) data, similar declines have occurred quite generally in developed countries; even in Spain, which historically has had high rates of strike activity, the average loss since 1990 was about one-fifth of a day per worker per annum. If strikes are caused by private information about rents, as has been argued in the recent theoretical work described above, then a fall in the costs of acquiring information must lead to a decrease in strike activity. It is undeniable that information costs have fallen sharply as computers have improved, and it is tempting to conclude that this is the reason for the decline in strike activity.

**Cyclical fluctuations**

The relationship between strike activity and business cycle fluctuations is analysed extensively in the literature. The main conclusion from early work in this area is that strikes are more frequent when general economic conditions are good. Although this conclusion is supported by a considerable body of evidence, it is of limited interest because it lumps together strikes of all sorts, including many minor disputes that occur during the term of ongoing labour contracts. More recent work has attempted to determine whether economic conditions affect the incidence of contract strikes. This work largely relies on North American data, because unions in the United States and Canada generally negotiate contracts covering clearly defined periods of a few years, so that one can count the number of negotiations that might lead to a strike, and use this to measure strike incidence.

The empirical results on strike incidence are well summarized by Card (1990); some more recent findings are reviewed by Cramton and Tracy (2003). Surprisingly, the evidence indicates that strike incidence and duration move in opposite directions over the business cycle. Strike incidence is generally found to be pro-cyclical, although the relationship between strikes and general economic conditions is not strong enough to dominate other sources of variation, so that a long time series is needed to establish the result. Although less work has been done on cyclical movements in strike duration, there is solid evidence that duration moves counter-cyclically. Some attempts have also been made to distinguish between the effects of cyclical fluctuations in product markets and in labour markets. There is no clear pattern in these results, and the theoretical significance of the distinction is also unclear. Indeed, if the probability distribution governing the private information about the size of the surplus changes, changes in the incidence and duration of strikes are to be expected, but it should not matter whether the source of this change in the distribution is the product market or the labour market.

**Effects of collective bargaining legislation**

Strike activity is clearly affected to a large extent by laws governing the tactics available to workers and employers as they negotiate over the division of the employment surplus. This is a large subject in itself, which cannot be dealt with here; Cramton and Tracy (2003) give an overview of some of the main issues with respect to North American legislation. One topic worth considering briefly is the use of
replacement workers. The availability of replacement workers directly affects the employment surplus. For example, in the simple screening model described above, suppose that the existing workforce can be permanently replaced, at a cost $C$ (including legal costs, and costs of providing security for the replacement workers). If $\rho < 1$ is the productivity of the replacements, relative to the incumbents, the condition governing the union's strike decision becomes

$$p > 1 - \frac{\nu_H - \nu_L}{\nu_H + \frac{C}{1-\rho}}.$$

If the incumbent workers can be replaced without cost, the effect of $\rho$ is merely to scale down the surplus, with no effect on strike incidence. But when $C$ is positive, strike incidence falls. The reason for this is that as the cost of replacements increases, the surplus increases by the same amount in both states of demand, so the opportunity cost of a strike rises while the potential gain is unchanged. Thus if the use of permanent replacement workers is banned (or made more difficult), strike incidence falls.

In the case of temporary replacement workers (who are employed only while a strike is going on) the effects on strike incidence may be quite different: a ban on temporary replacements means that the union can obtain a larger share of the surplus in the favourable demand state, so the union makes a more aggressive demand, and strike incidence rises. Cramton and Tracy (2003) review the theoretical implications of banning temporary replacements, and also review the empirical relationship between differences in strike incidence and differences in labour laws. Much remains to be done in this area.

Robert Strotz's highly original work in economic theory foreshadowed the contemporary field of behavioural economics and introduced the formal analysis of adjustment costs.

He trained at the University of Chicago, receiving his Ph.D. in 1951. Appointment in 1947 as an instructor at nearby Northwestern University, where he would spend his entire academic career, kept him physically as well as intellectually close to researchers at the Cowles Commission (then in Chicago), from whom he drew inspiration. In 1955 he succeeded Ragnar Frisch as managing editor of *Econometrica*, a post he held until 1968, nurturing the journal in both size and quality to its current pre-eminence.

Strotz's most widely recognized contribution appeared in a commissioned review of investment literature. To analyse effects of interest rates on investment timing, he formulated a model in which interest costs are an increasing function of investment, and applied the calculus of variations to solve for the optimal time path of investment. The paper popularized a new approach to dynamic optimization and clarified links between the short and long runs.

Strotz was the first to analyse the apparent irrationality of consumers who make optimal future plans, then violate them when the future arrives, even though their expectations of future conditions are realized. To stick to plans, they must pre-commit to carrying them out, a common form of behaviour that economists had heretofore been unable to explain. This novel paper was slow to gain recognition but is now viewed as a seminal work in behavioural economics.

Strotz also made contributions to consumer decision theory, distributional ethics, and concepts of causality. His writing was always replete with memorable examples to elucidate difficult points; and a playful wit was often in evidence, for example, when he introduced a paradoxical theorem in distributional ethics with the warning, 'I wish to indicate … that the views expressed are not necessarily my own’. Had he not largely withdrawn from economics to become dean at Northwestern in 1966 and

In his time as president in 1970, his influence and fame as a scholar would no doubt be even greater.

structural change, econometrics of

Pierre Perron

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article is concerned with methodological issues related to estimation, testing and computation in the context of structural changes in linear models. The topics covered are: methods related to estimation and inference about break dates for single equations with or without restrictions, with extensions to multi-equations systems where allowance is also made for changes in the variability of the shocks; tests for structural changes including tests for single or multiple changes and tests valid with unit root or trending regressors, and tests for changes in the trend function of a series that can be integrated or trend-stationary.

Keywords

break dates; cointegration; computation; convergence; estimation; heteroskedasticity; hypothesis testing; Lagrange multiplier tests; likelihood ratio; linear models; long-run variance; quasi-maximum likelihood; serial correlation; spurious regression; structural change, econometrics of; temporal dependence; testing; trending variables; unit roots; variance; vector autoregressions; Wald test; Wiener process

Article

This article covers methodological issues related to estimation, testing and computation for models involving structural changes. The amount of work on this subject since the 1950s is truly voluminous in both the statistics and econometrics literature. Accordingly, any survey is bound to focus on specific aspects. Our aim is to review developments as they relate to econometric applications based on linear models. Recently, substantial advances have been made to cover models at a level of generality that allows a host of interesting practical applications. These include models with general stationary regressors and errors that can exhibit temporal dependence and heteroskedasticity, models with trending variables and possible unit roots and cointegrated models, among others. Advances have been made pertaining to computational aspects of constructing estimates, their limit distributions, tests for structural
structural change, econometrics of: The New Palgrave Dictionary of Economics

changes, and methods to determine the number of changes present. For a more extensive review the reader is referred to Perron (2006).

We consider the following multiple linear regression with \( m \) breaks (or \( m+1 \) regimes):

\[
y_t = x_t' \beta + z_t' \delta_j + u_t, \ t = T_{j-1} + 1, ..., T_j,
\]

for \( j = 1, ..., m+1 \). In this model, \( y_t \) is the observed dependent variable; both \( x_t \) (\( p \times 1 \)) and \( z_t \) (\( q \times 1 \)) are vectors of covariates and \( \beta \) and \( \delta_j \) (\( j = 1, ..., m+1 \)) are the corresponding vectors of coefficients; \( u_t \) is the disturbance. The break dates \( (T_1, ..., T_m) \) are explicitly treated as unknown (the convention that \( T_0 = 0 \) and \( T_{m+1} = T \) is used). The purpose is to estimate the unknown regression coefficients together with the break points when \( T \) observations on \( (y_t, x_t, z_t) \) are available. This is a partial structural change model since the parameter vector \( \beta \) is not subject to shifts. When \( p = 0 \), we obtain a pure structural change model where all coefficients are subject to change. Note that using a partial structural change model can be beneficial in terms of obtaining more precise estimates and having more powerful tests.

The estimates are obtained by minimizing the overall sum of squared residuals

\[
\sum_{i=1}^{m+1} \sum_{t=T_{i-1}+1}^{T_i} [y_t - x_t' \beta - z_t' \delta_j]^2.
\]

Let \( \hat{\beta}(\{T_j\}) \) and \( \hat{\delta}(\{T_j\}) \) denote the estimates based on the given \( m \)-partition \( (T_1, ..., T_m) \) denoted \( \{T_j\} \). Substituting these in the objective function and denoting the resulting sum of squared residuals as \( S_T(\{T_1, ..., T_m\}) \), the estimated break points \( (\hat{T}_1, ..., \hat{T}_m) \) are such that

\[
(\hat{T}_1, ..., \hat{T}_m) = \arg\min_{(T_1, ..., T_m)} S_T(\{T_1, ..., T_m\}),
\]

with the minimization taken over a set of admissible partitions (see below). The parameter estimates are those associated with the partition \( \{\hat{T}_j\} \), that is

\[
\hat{\beta}(\{\hat{T}_j\}) \quad \text{and} \quad \hat{\delta}(\{\hat{T}_j\}).
\]
\[ \hat{\beta} = \hat{\beta}(\{\hat{T}_j\}), \quad \hat{\delta} = \hat{\delta}(\{\hat{T}_j\}). \]

This framework includes many contributions as special cases depending on the assumptions imposed; for example, single change, changes in the mean of a stationary process, and so on. However, since estimation is based on the least-squares principle, even if changes in the variance of \( u_t \) are allowed at the same dates as the breaks in the parameters of the regression they are not exploited to increase the precision of the break date estimators unless a quasi-likelihood framework is adopted (see below).

**The assumptions and their relevance**

To obtain theoretical results about the consistency and limit distribution of estimates of the break dates, some conditions need to be imposed on the regressors, the errors, the set of admissible partitions and the break dates. To our knowledge, the most general set of assumptions in the case of weakly stationary regressors are those in Perron and Qu (2006). Some are simply technical (for example, invertibility requirements), while others restrict the potential applicability of the results.

The assumptions on the regressors specifies that for \( \mathbf{w}_t = (x'_t, z'_t)' \), \( \sum_{t=T^0}^{T^0 + [\nu T]} \frac{1}{(T^0 + [\nu T])} \mathbf{w}_t \mathbf{w}_t' \to p Q_i(\nu) \) a non-random positive definite matrix uniformly in \( \nu \in [0,1] \). It allows their distribution to vary across regimes. It, however, requires the data to be weakly stationary stochastic processes. This can be relaxed on a case-by-case basis though the proofs then depend on the nature of the relaxation. For instance the scaling used forbids trending regressors, unless they are of the form \( \{1, (t/T), \ldots, ((t/T)^p)\} \), say, for a polynomial trend of order \( p \). Casting trend functions in this form can deliver useful results in many cases. However, there are instances where specifying trends in unscaled form, that is, \( \{1, t, \ldots, t^p\} \), can deliver much better results, especially if level and trend slope changes occur jointly. Results using unscaled trends with \( p=1 \) are presented in Perron and Zhu (2005). A comparison of their results with other trend specifications is presented in Deng and Perron (2006).

Another important restriction is implied by the requirement that the limit be a fixed, as opposed to stochastic, matrix. This, along with the scaling, precludes integrated processes as regressors (that is, unit roots). In the single break case, this has been relaxed by Bai, Lumsdaine and Stock (1998) who considered structural changes in cointegrated relationships in system of equations. Kejiwal and Perron (2006a) provide general results for multiple structural changes in a single cointegrating vector. Consistency still applies but the rate of convergence and limit distributions of the estimates are different. The assumptions on \( u_t \) and \( \{w_t u_t\} \) impose mild restrictions on the vector \( w_t u_t \) and permits a wide class of potential correlation and heterogeneity (including conditional heteroskedasticity) and lagged dependent variables. It rules out errors that have unit roots. However, unit root errors can be of interest, for example when testing for a change in the deterministic component of the trend function for an integrated series, in which case the estimates are consistent (see Perron and Zhu, 2005). The set of conditions is not the weakest possible. For example, Lavielle and Moulines (2000) allow the errors to be strongly
dependent (long memory processes) but consider only the case of multiple changes in the mean. It is also assumed that the minimization problem defined by (2) is taken over all partitions such that \( T - T_{i-1} \geq \varepsilon T \) for some \( \varepsilon > 0 \). This is not restrictive in practice since \( \varepsilon \) can be small. Another assumption specifies that the break dates are asymptotically distinct, that is, we have \( T_i^0 = \{ T \lambda_i^0 \} \), where \( 0 < \lambda_1^0 < \ldots < \lambda_m^0 < 1 \). It dictates the asymptotic framework adopted, whereby all segments increase in length in the same proportions as \( T \) increases.

Under these conditions, the break fractions \( \lambda_i^0 \) are consistently estimated, that is, \( \hat{\lambda}_i \equiv (\hat{T}_i / T) \rightarrow p \lambda_i^0 \) and that the rate of convergence is \( T \). Note that the estimates of the break dates are not consistent themselves, but the differences between the estimates and the true values are bounded by some constant, in probability. Also, this implies that the estimates of the other parameters have the same distribution as would prevail if the break dates were known. Kejriwal and Perron (2006a) obtain similar results with \( I(1) \) regressors for a cointegrated model subject to multiple changes, using the static regression or a dynamic regression augmented with leads and lags of the first differences of the \( I(1) \) regressors.

**Allowing for restrictions on the parameters**

Perron and Qu (2006) consider the issues in a broader framework whereby arbitrary linear restrictions on the parameters of the conditional mean can be imposed in the estimation. The class of models considered is

\[
y_t = z_t' \delta_j + u_t, \quad t = T_{j-1} + 1, \ldots, T_j,
\]

where \( R \delta = r \), with \( R \) a \( k \times q \) matrix with rank \( k \) and \( r \), a \( k \) dimensional vector of constants. The assumptions are the same as discussed above. There is no need for a distinction between variables whose coefficients are allowed to change and those whose coefficients are not allowed to change. A partial structural change model is obtained specifying restrictions that impose some coefficients to be identical across all regimes. This is a useful generalization since it permits a wider class of models of practical interests – for example, a model with a specific number of states less than the number of regimes, or one where a subset of coefficients may be allowed to change over only a limited number of regimes. Perron and Qu (2006) show that the same consistency and rate of convergence results hold. Moreover, the limit distribution of the estimates of the break dates are unaffected by the imposition of valid restrictions, but improvements can be obtained in finite samples. The main advantages of imposing restrictions are that more powerful tests and more precise estimates are obtained.

**Method to compute global minimizers**

To estimate the model, we need global minimizers of the objective function (2). A standard grid search
requires least squares operations of order $O(T^{m})$ and becomes prohibitive when the number of breaks is greater than two. Bai and Perron (2003a) discuss a method based on a dynamic programming algorithm that is very efficient (see also Hawkins, 1976). Indeed, the additional computing time needed to estimate more than two break dates is marginal compared with the time needed to estimate a two break model.

Consider the case of a pure structural change model. The basic idea is that the total number of possible segments is at most $T(T+1)/2$ and is therefore of order $O(T^2)$. One then needs a method to select which combination of segments yields a minimal value of the objective function. This is achieved efficiently using a dynamic programming algorithm. For models with restrictions (including the partial structural change model), an iterative procedure is available, which in most cases requires very few iterations (see also Perron and Qu, 2006). Hence, even with large samples, the computing cost is small.

The limit distribution of the estimates of the break dates

With the assumptions on the regressors, the errors and given the asymptotic framework adopted, the limit distributions of the estimates of the break dates are independent of each other. Hence, for each break date, the analysis is the same as that of a single break. This holds because the distance between each break increases at rate $T$, and the mixing conditions on the regressors and errors impose a short memory property so that events that occur a long time apart are independent. This independence property does not hold with integrated data (see below).

The limit distribution of the estimates of the break dates depends on: (a) the magnitude of the change in coefficients (with larger changes leading to higher precision); (b) the (limit) sample moment matrices of the regressors for the segments pre and post break (allowed to be different); (c) the so-called ‘long-run’ variance of $\{w_t\mu_t\}$, which accounts for serial correlation in the errors (also allowed to be different pre and post break); (d) whether the regressors are trending or not. In all cases, the nuisance parameters can be consistently estimated and appropriate confidence intervals constructed, which need not be symmetric given that the data and errors can have different properties before and after the break.

A feature of the limit distribution is that, for given fixed magnitude of change, it depends on the finite sample distribution of the errors. To get rid of this dependence, the asymptotic framework is modified with the change in parameters getting smaller as $T$ increases, but slowly enough for the estimated break fraction to remain consistent. The limit distribution obtained in Bai (1997a) and Bai and Perron (1998) applies to the case with no trending regressors. With trending regressors, a similar result is still possible (on the assumption of trends of the form $(t/T)$) and the reader is referred to Bai (1997a) for the case where $z_t$ is a polynomial time trend. For an unscaled linear trend, see Perron and Zhu (2005).

The simulations in Bai and Perron (2006) show that the shrinking shifts asymptotic framework provides useful approximations to the finite sample distributions. The coverage rates are adequate, in general, unless the shifts are quite small, in which case the confidence interval is too narrow. But in such cases, the breaks are unlikely to be detected by test procedures. On the other hand, Deng and Perron (2006) show that the shrinking shift asymptotic framework leads to a poor approximation in the context of a change in a linear trend and that the limit distribution based on a fixed magnitude of shift is preferable. In a cointegrating regression with I(1) variables, Kejriwal and Perron (2006a) show that, if the coefficients of the integrated regressors are allowed to change, the estimated break fractions are
asymptotically dependent so that confidence intervals need to be constructed jointly. Methods to construct such confidence intervals are discussed. If, however, only the intercept and/or the coefficients of the stationary regressors are allowed to change, the estimates of the break dates are asymptotically independent.

**Estimating breaks one at a time**

Bai (1997b) and Bai and Perron (1998) showed that it is possible to consistently estimate all break fractions sequentially, that is, one at a time. When estimating a single break model in the presence of multiple breaks, the estimate of the break fraction will converge to one of the true break fractions, the one that is dominant in the sense that taking it into account allows the greatest reduction in the sum of squared residuals. Then, allowing for a break at the estimated value, a one-break model can be applied to each segment which will consistently estimate the second dominating break, and so on. Bai (1997b) considers the limit distribution of the estimates and shows that they are not the same as those obtained when estimating all break dates simultaneously. Except for the last estimated break date, the limit distributions depend on the parameters in all segments of the sample. To remedy this problem, he suggested a repartition procedure, which re-estimates each break date conditional on the adjacent break dates. The limit distribution is then the same as when the break dates are estimated simultaneously.

**Estimation in a system of regressions**

Estimating structural changes in a system of regressions is relatively recent. Bai, Lumsdaine and Stock (1998) consider estimating a single break date in multivariate time series allowing stationary or integrated regressors as well as trends. They show that the width of the confidence interval decreases when series having a common break are treated as a group and estimation is carried using quasi-maximum likelihood (QML). Bai (2000) considers a segmented stationary vector autoregression (VAR) model when the breaks can occur in the parameters of the conditional mean, the covariance matrix of the error term, or both. The most general framework is that of Qu and Perron (2007), who consider models of the form

\[
y_t = (I \otimes z_t') S \beta_j + u_t
\]

for \( T_{j-1} + 1 \leq t \leq T_j \) \(( j = 1, \ldots, m + 1)\), where \( y_t \) is an \( n \)-vector of dependent variables and \( z_t \) is a \( q \)-vector that includes the regressors from all equations, and \( u_t \sim (0, \Sigma_j) \). The matrix \( S \) is of dimension \( nq \) by \( p \) with full column rank (usually a selection matrix that specifies which regressors appear in each equation). The set of basic parameters in regime \( j \) consists of the \( p \) vector \( \beta_j \) and of \( \Sigma_j \). Qu and Perron (2007) also allow for the imposition of a set of \( r \) restrictions of the form \( g(\beta, \text{vec}(\Sigma)) = 0 \), where
structural change, econometrics of

$\beta = (\beta_1, \ldots, \beta_{m+1})', \Sigma = (\Sigma_1, \ldots, \Sigma_{m+1})$ and $g(\cdot)$ is an $r$ dimensional vector. Both within- and cross-equation restrictions are allowed, and in each case within or across regimes. The assumptions on the regressors $z_t$ and the errors $u_t$ are similar to those discussed above. Hence, the framework permits a wide class of models including VAR, SUR, linear panel data, change in means of a vector of stationary processes, and so on. Models with integrated regressors (that is, models with cointegration) are not permitted.

Allowing for general restrictions on the parameters $\beta_j$ and $\Sigma_j$ permits a very wide range of special cases that are of practical interest: (a) partial structural change models, (b) block partial structural change models where only a subset of the equations is subject to change; (c) changes in only some elements of the covariance matrix $\Sigma_j$; (d) changes in only the covariance matrix $\Sigma_j$, while $\beta_j$ is the same for all segments; (e) models where the breaks occur in a particular order across subsets of equations; and so on.

The method of estimation is again QML (based on normal errors) subject to the restrictions. Qu and Perron (2007) derive the consistency, rate of convergence and limit distribution of the estimated break dates. They obtain a general result stating that, in large samples, the restricted likelihood function can be separated in two parts: one involving only the break dates and the true values of the coefficients, so that the estimates of the break dates are not affected by the restrictions; the other involving the parameters of the model, the true values of the break dates and the restrictions, showing that the limiting distributions of these estimates are influenced by the restrictions but not by the estimation of the break dates. The limit distributions for the estimates of the break dates are qualitatively similar to those discussed above.

Though only root-$T$ consistent estimates of $(\beta, \Sigma)$ are needed to construct asymptotically valid confidence intervals, it is likely that more precise estimates of these parameters will lead to better finite sample coverage rates. Hence, it is recommended to use the estimates obtained imposing the restrictions even though imposing restrictions does not have a first-order effect on the limiting distributions of the estimates of the break dates. To make estimation possible in practice, Qu and Perron (2007) present an algorithm which extends the one discussed in Bai and Perron (2003a) using, in particular, an iterative generalized least squares (GLS) procedure to construct the likelihood function for all possible segments. The theoretical analysis shows that substantial efficiency gains can be obtained by casting the analysis in a system of regressions.

Qu and Perron (2007) also consider a novel aspect to the problem of multiple structural changes labelled ‘locally ordered breaks’. This applies when the breaks across two equations are ‘ordered’ in the sense that we have the prior knowledge that the break in one equation occurs after the break in the other. The breaks are ‘local’ in the sense that the time span between their occurrence is expected to be short. Hence, the breaks cannot be viewed as occurring simultaneously, nor can the break fractions be viewed as asymptotically distinct. An algorithm to estimate such models is presented. Also, a framework to analyse the limit distribution of the estimates is introduced. Unlike the case with asymptotically distinct breaks, the distributions of the estimates of the break dates need to be considered jointly.

Tests that allow for a single break

To test for a structural change at an unknown date, Quandt (1960) suggested the likelihood ratio test
structural change, econometrics of: The New Palgrave Dictionary of Economics

evaluated at the break date that maximizes it. This is a non-standard problem since one parameter is only identified under the alternative hypothesis. This problem was treated under various degrees of specificity that culminated in the general treatment by Andrews (1993). The basic method is to use the maximum of the likelihood ratio test over all possible values of the parameter in some pre-specified set. In the case of a single change, this translates into the statistic \( \sup_{\lambda_1 \in \Lambda_\varepsilon} LR_T(\lambda_1) \), where \( LR_T(\lambda_1) \) denotes the likelihood ratio evaluated at some \( T_1 = [T \lambda_1] \) and the maximization is restricted over break fractions that are in the set \( \Lambda_\varepsilon = [\varepsilon_1, 1 - \varepsilon_2] \). The limit distribution is given by

\[
\sup_{\lambda_1 \in \Lambda_\varepsilon} LR_T(\lambda_1) \Rightarrow \sup_{\lambda_1 \in \Lambda_\varepsilon} \frac{[\lambda_1 W_q(1) - W_q(\lambda_1)]'}{[\lambda_1 W_q(1) - W_q(\lambda_1)]} \frac{\lambda_1(1 - \lambda_1)}{\lambda_1 W_q(1) - W_q(\lambda_1)}
\]

with \( W_q(\lambda) \) a vector of independent Wiener processes of dimension \( q \), the number of coefficients that are allowed to change (this result holds with non-trending data). The limit distribution depends on \( \Lambda_\varepsilon \). If \( \varepsilon_1 = \varepsilon_2 = 0 \), the test diverges under the null hypothesis, and critical values grow and the power of the test decreases as \( \varepsilon_1 \) and \( \varepsilon_2 \) get smaller. Hence, the range over which we search for a maximum must be small enough for the critical values not to be too large and for the test to retain decent power, yet large enough to include break dates that are potential candidates. In the single break case, a popular choice is \( \varepsilon_1 = \varepsilon_2 = .15 \).

Andrews (1993) also considered tests based on the maximal value of the Wald and Lagrange multiplier (LM) tests and shows that they are asymptotically equivalent, that is, they have the same limit distribution under the null hypothesis and under a sequence of local alternatives. All tests are also consistent and have non-trivial local asymptotic power against a wide range of alternatives, namely, for which the parameters of interest are not constant over the interval specified by \( \Lambda_\varepsilon \). This does not mean, however, that they all have the same behaviour in finite samples. Indeed, the simulations of Vogelsang (1999) for the special case of a change in mean with serially correlated errors, showed the sup \( LM_T \) test to be seriously affected by the problem of non-monotonic power, in the sense that, for a fixed sample size, the power of the test can rapidly decrease to zero as the change in mean increases.

For Model (1) with i.i.d. errors, the LR and Wald tests have similar properties, so we shall discuss the Wald test. For a single change, it is defined by (up to a scaling by \( q \)):

\[
\sup_{\lambda_1 \in \Lambda_\varepsilon} W_T(\lambda_1; q) = \sup_{\lambda_1 \in \Lambda_\varepsilon} \frac{\delta' H'(H(\bar{z}' M \bar{z})^{-1} H')^{-1} \delta}{\text{SSR}_K / (T - 2q - p)}
\]

(4)
where $\bar{Z} = \text{diag}(Z_1, \ldots, Z_m, 1)$ with $Z_j = (z_{T_i-1+1}, \ldots, z_{T_i})'$. $H$ is the conventional matrix such that

$$(\mathcal{H} \hat{\delta})' = (\hat{\delta}_1 - \hat{\delta}_2)'$$

and $M_X = I - X(X'X)^{-1}X'$. Here $SSR_k$ is the sum of squared residuals under the alternative hypothesis. Note that break point that maximizes the Wald test is the same as the estimate obtained by minimizing the sum of squared residuals provided the minimization problem (2) is restricted to the set $\Lambda_{\epsilon}$, that is, $\sup_{\lambda_1 \in \Lambda_{\epsilon}} W_T(\lambda_1; q) = W_T(\hat{\lambda}_1; q)$. When serial correlation and/or heteroskedasticity in the errors is permitted, the Wald test must be adjusted to account for this. In this case, it is defined by

$$W_T^*(\lambda_1; q) = (T - 2q - p) \hat{\delta}' \mathcal{H}^{-1} \hat{\delta},$$

where $\hat{\delta}$ is an estimate of the variance covariance matrix of $\delta$ that is robust to serial correlation and heteroskedasticity; that is, a consistent estimate of

$$\hat{V}(\hat{\delta}) = \lim_{T \to \infty} T \mathcal{Z}' M_X \mathcal{Z}^{-1} \mathcal{Z}' M_X \Omega M_X \mathcal{Z}^{-1}$$

where $\Omega$ is the covariance matrix of the errors. Note that it can be constructed allowing identical or different distributions for the regressors and the errors across segments. This is important because if a variance shift occurs at the same time and is not taken into account, inference can be distorted (Pitarakis, 2004).

The computation of the robust version of the Wald test (5) can be involved. Since the estimate of $\lambda_1$ is $T$-consistent even with correlated errors, an asymptotically equivalent version is to first take the supremum of the original Wald test, as in (4), to obtain the break point, that is imposing $\Omega = \sigma^2 I$. The robust version is obtained by evaluating (5) and (6) at this estimated break date, that is, using $W_T^*(\hat{\lambda}_1; q)$ instead of $\sup_{\lambda_1 \in \Lambda_{\epsilon}} W_T(\lambda_1; q)$, where $\hat{\lambda}_1$ is obtained by minimizing the sum of squared residuals over the set $\Lambda_{\epsilon}$. This is especially convenient when testing for multiple structural changes.

**Optimal tests**

Andrews and Ploberger (1994) consider a class of tests that are optimal, in the sense that they maximize
a weighted average of the local asymptotic power function. They are weighted functions of the standard Wald, LM or LR statistics for all permissible fixed break dates. Using either of the three basic statistics leads to tests that are asymptotically equivalent. Here, we shall proceed with the version based on the Wald test. On the assumption that equal weights are given to all break fractions in some trimmed interval $[\varepsilon_1, 1 - \varepsilon_2]$, the optimal test for distant alternatives is the following so-called Exp-type test

$$\text{Exp} - W_T = \log \left( T^{-1} \sum_{T_1 = [T\varepsilon_1] + 1}^{T-[T\varepsilon_2]} \exp \left( \frac{1}{2} W_T(T_1 / T) \right) \right).$$

For alternatives close to the null value of no change the optimal test is the Mean-$W_T$ test

$$\text{Mean} - W_T = T^{-1} \sum_{T_1 = [T\varepsilon_1] + 1}^{T-[T\varepsilon_2]} W_T(T_1 / T).$$

Andrews and Ploberger (1994) provide critical values for both tests for a range of values for symmetric trimmings $\varepsilon_1 = \varepsilon_2$ (which can be used for some non-symmetric trimmings as well). The Mean-$W_T$ has highest power for small shifts and the Exp-$W_T$ performs better for moderate to large shifts. None of them uniformly dominates the Sup-$W_T$ test and Andrews and Ploberger (1994) recommend the Exp-$W_T$ test. The Sup-$W_T$ test is not a member of the class of tests that maximize some weighted version of the local asymptotic power function, though it is admissible.

Kim and Perron (2006) approach the optimality issue from a different perspective using the approximate Bahadur measure of efficiency. They show that tests based on the Mean functional are inferior to those based on the Sup and Exp (which are as efficient) when using the same base statistic. When considering tests that incorporate a correction for potential serial correlation in the errors: (a) for a given functional, using the LM statistic leads to tests with zero asymptotic relative efficiency compared with using the Wald statistic; (b) for a given statistic the Mean-type tests have zero relative efficiency compared to using the Sup and Exp versions, which are as efficient. These results are in contrast to those of Andrews and Ploberger (1994) and the practical implication is that the preferred tests should be the Sup or Exp–Wald tests. Any test based on the LM statistic should be avoided.

**Non-monotonicity in power**

The Sup–Wald and Exp–Wald tests have monotonic power when only one break occurs under the alternative. As shown in Vogelsang (1999), the Mean–Wald test can exhibit a non-monotonic power
function, though the problem has not been shown to be severe. All of these, however, suffer from some important power problems when the alternative is one that involves two breaks (for example, Vogelsang, 1997). This suggests that a test will exhibit a non-monotonic power function if the number of breaks present under the alternative hypothesis is greater than the number of breaks explicitly accounted for in the construction of the tests. Hence, though a single break test is consistent against multiple breaks, substantial power gains can result from using tests for multiple structural changes.

Tests for multiple structural changes

The literature on tests for multiple structural changes is relatively scarce. Here, the problem with the Mean-\(WT\) and Exp-\(WT\) tests is practical implementation as they require the computation of the Wald test over all permissible partitions of the sample, a number of order \(O(T^m)\), which is prohibitively large when \(m>2\). Consider instead the Sup-Wald test. With i.i.d. errors, maximizing the Wald statistic is equivalent to minimizing the sum of squared residuals when the search is restricted to the same possible partitions of the sample. As discussed above, this problem can be solved with a very efficient algorithm. This is the approach taken by Bai and Perron (1998). In the context of model (1) with i.i.d. errors, the Wald test for testing the null hypothesis of no change versus the alternative hypothesis of \(k\) changes is given by

\[
W_T(\lambda_1, \ldots, \lambda_k; q) = \left( \frac{T - (k + 1)q - p}{k} \right) \hat{\delta}' H'(H(Z'M'Z)^{-1}H')^{-1} H \hat{\delta}
\]

where \(H\) now is the matrix such that \((H\hat{\delta})' = (\hat{\delta}_1' - \hat{\delta}_2', \ldots, \hat{\delta}_k' - \hat{\delta}_{k+1})\). The Sup–Wald test is defined by

\[
\text{sup}_{(\lambda_1, \ldots, \lambda_k) \in \Lambda_k, \epsilon} W_T(\lambda_1, \ldots, \lambda_k; q) = W_T(\hat{\lambda}_1, \ldots, \hat{\lambda}_k; q),
\]

where

\[
\Lambda_k, \epsilon = \{(\lambda_1, \ldots, \lambda_k) ; |\lambda_{i+1} - \lambda_i| \geq \epsilon, \lambda_1 \geq \epsilon, \lambda_k \leq 1 - \epsilon\}
\]

and \((\hat{\lambda}_1, \ldots, \hat{\lambda}_k) = (\hat{T}_1 / T, \ldots, \hat{T}_k / T)\), with \((\hat{T}_1, \ldots, \hat{T}_k)\) the estimates of the break dates obtained by minimizing the sum of squared residuals by searching over partitions defined by the set \(\Lambda_{k, \epsilon}\). When
serial correlation and/or heteroskedasticity in the residuals is allowed, the test is

\[ W_T^* (\lambda_1, \ldots, \lambda_k; q) = \left( \frac{T - (k + 1)q - p}{k} \right) \hat{\delta}' H' (H\hat{\delta}H')^{-1} H\hat{\delta}, \]

with \( \hat{\delta} \) as defined by (6). Again, the asymptotically equivalent version with the Wald test evaluated at the estimates \( (\hat{\lambda}_1, \ldots, \hat{\lambda}_k) \) is used to make the problem tractable. The limit distribution of the tests under the null hypothesis is the same in both cases, again on the assumption of non-trending data. Critical values are presented in Bai and Perron (1998; 2003b). The importance of the choice of \( \varepsilon \) for the size and power of the test is discussed in Bai and Perron (2003a; 2006). They also discuss variations in the construction of the test that allow imposing various restrictions on the nature of the errors and regressors, which can help improve power.

**Double maximum tests**

Often, one may not wish to pre-specify a particular number of breaks. Then a test of the null hypothesis of no structural break against an unknown number of breaks given some upper bound \( M \) can be used. These are called ‘double maximum tests’. The first is an equal-weight version defined by

\[ UD \max W_T (M, q) = \max_{1 \leq m \leq M} W_T (\hat{\lambda}_1, \ldots, \hat{\lambda}_m; q). \]

The second test applies weights to the individual tests such that the marginal p-values are equal across values of \( m \) and is denoted \( WD \max F_T (M, q) \) (see Bai and Perron, 1998, for details). The choice \( M=5 \) should be sufficient for most applications. In any event, the critical values vary little as \( M \) is increased beyond 5.

The double maximum tests are arguably the most useful to apply when trying to determine if structural changes are present. First, there are types of multiple structural changes that are difficult to detect with a single break test (for example, two breaks with the first and third regimes the same). Second, as discussed above, is the potential non-monotonic power problem when the number of changes is greater than specified. Third, the power of the double maximum tests is almost as high as the best power that can be achieved using the test that accounts for the correct number of breaks (for example, Bai and Perron, 2006).

**Sequential tests**

Bai and Perron (1998) also discuss a test of \( \bullet \) versus \( \bullet + 1 \) breaks, which can be used to estimate the number of breaks using a sequential testing procedure. For the model with \( \bullet \) breaks, the estimated break points denoted by \( (\hat{T}_1, \ldots, \hat{T}_q) \) are obtained by a global minimization of the sum of squared residuals. The strategy proceeds by testing for the presence of an additional break in each of the (\( \bullet + 1 \)) segments obtained using the partition \( \hat{T}_1, \ldots, \hat{T}_q \). We reject in favour of a model with (\( \bullet + 1 \)) breaks if the minimal
value of the sum of squared residuals over all segments where an additional break is included is sufficiently smaller than that from the breaks model. The break date selected is the one associated with this overall minimum. The limit distribution of the test is related to that of a test for a single change. Bai (1999) considers the same problem allowing the breaks to be global minimizers of the sum of squared residuals under both the null and alternative hypotheses. The limit distribution of the test is different. A method to compute the asymptotic critical values is discussed and the results extended to the case of trending regressors.

These tests can form the basis of a sequential testing procedure by applying them successively starting from $\bullet=0$, until a non-rejection occurs. The estimate of the number of breaks thus selected will be consistent provided the significance level used decreases at an appropriate rate. The simulation results of Bai and Perron (2006) show that such estimate of the number of breaks is better than those obtained using information criteria as suggested by, for example, Liu, Wu and Zidek (1997) (see also Perron, 1997). But this sequential procedure should not be applied mechanically. In several cases, it stops too early. The recommendation is to first use a double maximum test to ascertain if any break is at all present. The sequential tests can then be used starting at some value greater than 0 to determine the number of breaks.

**Tests for restricted structural changes**

Consider testing the null hypothesis of 0 break versus an alternative with $k$ breaks in a model which imposes the restrictions $R\delta = r$. In this case, the limit distribution of the Sup–Wald test depends on the nature of the restrictions so that it is not possible to tabulate critical values valid in general. Perron and Qu (2006) discuss a simulation algorithm to compute the relevant critical values given some restrictions. Imposing valid restrictions results in tests with much improved power.

**Tests for structural changes in multivariate systems**

Bai, Lumsdaine and Stock (1998) considered a Sup–Wald test for a single change in a multivariate system. Qu and Perron (2007) extend the analysis to the context of multiple structural changes. They consider the case where only a subset of the coefficients is allowed to change, whether it be the parameters of the conditional mean, the covariance matrix of the errors, or both. The tests are based on the maximized value of the likelihood ratio over permissible partitions assuming i.i.d. errors. The tests can be corrected for serial correlation and heteroskedasticity when testing for changes in the parameters of the conditional mean assuming no change in the covariance matrix of the errors. However, when the tests involve potential changes in the covariance matrix of the errors, the limit distributions are only valid assuming a Normal distribution for these errors.

An important advantage of the general framework analysed by Qu and Perron (2007) is that it allows studying changes in the variance of the errors in the presence of simultaneous changes in the parameters of the conditional mean, thereby avoiding inference problems when changes in variance are studied in isolation. Also, it allows for the two types of changes to occur at different dates, thereby avoiding problems related to tests for changes in the parameters when a change in variance occurs at some other
These tests are especially important in light of Hansen’s (2000) analysis. First note that the limit distribution of the tests in a single equation system has the stated limit distribution under the assumption that the regressors and the variance of the errors have distributions that are stable across the sample. Hansen shows that when the regressors are not stationary the limit distribution changes and the tests can be distorted, especially when a change in variance occurs. He proposes a fixed regressor bootstrap method to construct valid tests. But both problems of changes in the distribution of the regressors and the variance of the errors can be handled using the framework of Qu and Perron (2007). If a change in the variance of the residuals is a concern, one can perform a test for no change in some parameters of the conditional model allowing for a change in variance since the tests are based on a likelihood ratio approach. If changes in the marginal distribution of some regressors are a concern, one can use a multi-equations system with equations for these regressors.

Tests valid with \(I(1)\) regressors

With \(I(1)\) regressors, a case of interest is a system of cointegrated variables. For testing, Hansen (1992) considered the null hypothesis of no change in both coefficients. The tests considered are the Sup and Mean–LM tests directed against an alternative of a one time change in the coefficients. Hansen also considers a version of the LM test directed against the alternative that the coefficients are random walk processes. Kejriwal and Perron (2006b) provide a comprehensive treatment of issues related to testing for multiple structural changes at unknown dates in cointegrated regression models using the Sup–Wald test. They allow both \(I(0)\) and \(I(1)\) variables and derive the limiting distribution of the Sup–Wald test under the null hypothesis of no structural change against the alternative hypothesis of a given number of cointegrating regimes. They also consider the double maximum tests and provide critical values for a wide variety of models that are expected to be relevant in practice. The asymptotic results have important implications for inference. It is shown that, in models involving both \(I(1)\) and \(I(0)\) variables, inference is possible as long as the intercept is allowed to change across regimes. Otherwise, the limiting distributions of the tests depend on nuisance parameters. Simulation experiments show that with serially correlated errors the commonly used Sup, Mean and Exp–LM tests suffer from the problem of non-monotonic power in finite samples both with a single and multiple breaks. Kejriwal and Perron (2006b) propose a modified Sup–Wald test that has good size and power properties.

Note, however, that the Sup and Mean–Wald test will also reject when no structural change is present and the system is not cointegrated. Hence, the application of such tests should be interpreted with caution. No test are available for the null hypothesis of no change in the coefficients allowing the errors to be \(I(0)\) or \(I(1)\). This is because when the errors are \(I(1)\), we have a spurious regression and the parameters are not identified. To be able to properly interpret the tests, they should be used in conjunction with tests for the presence or absence of cointegration allowing shifts in the coefficients (see the discussion and references in Perron, 2006). A partial solution to this problem is the following. If a spurious regression is present, the number of breaks selected will always (in large samples) be the maximum number of breaks allowed. Thus, selecting the maximum allowable number of breaks can be indicative of the presence of \(I(1)\) errors (using a Sup–Wald test uncorrected for serial correlation in the errors). The same is true when information criteria are used to select the number of breaks.
Tests valid whether the errors are $I(1)$ or $I(0)$

The issue of testing for structural changes in a linear model with errors that are either $I(0)$ or $I(1)$ is of interest when the regression is a polynomial time trend (for example, testing for a change in the slope of a linear trend). The problem here is to devise a procedure that has the same limit distribution in both the $I(0)$ and $I(1)$ cases. The first to provide such a solution is Vogelsang (2001). He also accounts for correlation with an autoregressive approximation so that the Wald test has a non-degenerate limit distribution in both the $I(0)$ and $I(1)$ cases. The novelty is that he weights the statistic by a unit root test scaled by some parameter. For any given significance level, a value of this scaling parameter can be chosen so that the asymptotic critical values will be the same. Vogelsang's simulations show, however, the test to have little power in the $I(1)$ case so that he resorts to advocating the joint use of that test and a normalized Wald test that has good properties in the $I(1)$ case but has otherwise very little power in the $I(0)$ case.

Perron and Yabu (2007b) builds on the work of Perron and Yabu (2007a) who analysed the problem of hypothesis testing on the slope coefficient of a linear trend model. The method is based on a feasible quasi generalized least squares approach that uses a super-efficient estimate of the sum of the autoregressive parameters $\alpha$ when $\alpha = 1$. The estimate of $\alpha$ is the OLS estimate from an autoregression applied to detrended data and is truncated to take a value 1 whenever it is in a $T^{-\delta}$ neighbourhood of 1. This makes the estimate 'super-efficient' when $\alpha = 1$ and implies that inference can be performed using the standard Normal or Chi-square distribution for all $|\alpha| \leq 1$. Theoretical arguments and simulation evidence show that $\delta = 1/2$ is the appropriate choice. Perron and Yabu (2007b) analyse the case of testing for changes in level or slope of the trend function of a univariate time series. When the break dates are known, things are similar. When the break dates are unknown, the limit distributions of the Exp, Mean and Sup functionals of the Wald test across all permissible breaks dates is no longer the same in the $I(0)$ and $I(1)$ cases. However, the limit distribution is nearly the same using the Exp functional. Hence, it is possible to have tests with nearly the same size in both cases. To improve the finite sample properties of the test, use is made of a bias-corrected version of the OLS estimate. This makes possible a testing procedure that has good size and power properties in finite samples.

Summary

There has been tremendous progress since the early 1990s in developing methods to analyse structural changes for a variety of cases that are of practical interest. Still, much remains to be done, in particular in providing tools to analyse changes in the variance of the errors without the need to assume a Normal distribution.

Structural change

Kiminori Matsuyama

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Structural change is a complex, intertwined phenomenon, not only because economic growth brings about complementary changes in various aspects of the economy, such as the sector compositions of output and employment and the organization of industry, but also because these changes in turn affect the growth process. Using a simple two-sector model, we highlight some driving forces behind structural change, attempt to convey the complexity of the phenomenon and identify some key issues discussed in the literature.

Keywords

agricultural productivity growth; development failure; economic growth; Engel's Law; exogenous productivity growth; product diversity; resource curse; Rostow, W.; rural–urban migration; specialization; stages theory of growth; staple trap; structural change; total factor productivity

Article

Structural change can occur as a consequence of significant shocks, such as plagues, wars, revolutions, the discovery of a continent, and major technological advances. Here, however, we confine ourselves to the structural change experienced by an economy over the course of its development. It is a complex, intertwined phenomenon, not only because economic growth brings about complementary changes in various aspects of the economy, such as the sector compositions of output and employment, the organization of industry, the financial system, income and wealth distribution, demography, political institutions, and even the society's value system, but also because these changes can in turn affect the growth processes.

Earlier work on the subject attempted to establish some stylized facts, that is, the patterns of development followed by most countries. Among the best known are Fisher (1939), Clark (1940), Kuznets (1966) and Chenery and Syrquin (1975), who postulated that, as the economy grows, the production shifts from the primary (agriculture, fishing, forestry, mining) to the secondary (manufacturing and construction) to the tertiary sector (services). Also notable is Rostow (1960), who argued that the economy passes through various stages of development, from the traditional stage to the take-off stage to the mass consumption stage. This literature is mostly descriptive, trying to provide a sweeping overview of the development process, with the emphasis on the multifaceted nature of structural change.

In contrast, recent work tends to be more analytical, using formal models designed to focus on a few specific aspects of structural change. There is also an increasing awareness that the two-way causality between economic growth and structural change can provide possible explanations for development failures.

From the rural agricultural society to the urban industrial society

Structural change caused by exogenous productivity growth

To illustrate some of the driving forces behind structural change, consider a simple two-sector model, adopted from Matsuyama (1992a). The \( j \)-th sector \((j=1,2)\) produces its output
with $j = A_j F_j(n_j)$, where $A_j$ is its total factor productivity (TFP), and $F_j(n_j)$ is an increasing, concave production function, and $n_j$ is the employment share, with $n_1 + n_2 = 1$.

Consumers have Stone–Geary preferences, $U(C_1, C_2) = \beta \log(C_1 - \gamma) + \log(C_2)$ with $\gamma > 0$. In competitive equilibrium, the marginal values of labour in the two sectors are equalized;

$$A_1 F'_1(n) = \beta A_2 F'_2 (1 - n),$$  

where $p$ is the relative price of good 2 and $n = n_1 = 1 - n_2$ is the first sector's employment share. Since the consumer demand satisfies $C_1 = \gamma + (\beta p) C_2$, the goods market equilibrium (in the closed economy) is given by $A_1 F'_1(n) = \gamma + A_2 F_2 (1 - n) (\beta p)$. Combining the two conditions yields

$$F_1(n) - \beta F_2 (1 - n) F'_1(n) / F'_2 (1 - n) = \gamma / A_1,$$

which implicitly defines $n$ as a decreasing function of $A_1$, $n = N(A_1)$. By interpreting the first sector as agriculture and the second as industry, this offers one explanation for the transformation from the decline of agriculture and the rise in industry: Engel's Law. Because the demand for agricultural goods has lower income elasticity than the demand for manufacturing goods, agricultural productivity growth helps to release labour for industry. This mechanism plays an important role in, for example, Murphy, Shleifer and Vishny (1989), Matsuyama (1992a, s. 2), Laitner (2000), Caselli and Coleman (2001), and Gollin, Parente and Rogerson (2002).

The above argument suggests that productivity gains in agriculture push the workers out of agriculture. There is an entirely opposite view that productivity gains in industry pull the workers out of agriculture. To capture this view, let us change the consumer's preferences to $U(C_1, C_2) = C_1 / \beta p C_2$, with $p$ now given exogenously. One interpretation is that the economy has the two different techniques to produce a single consumption good. The first is traditional, land-based, craft production, and the second is modern, capitalistic, manufacturing. In this case, eq. (1) alone determines the equilibrium allocation, which means that $n$ increases with $A_1/A_2$. Thus, faster productivity growth in the modern sector (or relative stagnation in the traditional sector) induces more workers to abandon the traditional sector. This captures in essence the structural change mechanism envisioned by Lewis (1954) and many others (see Hansen and Prescott, 2002, for a neoclassical treatment). Alternatively, this case can be interpreted as the case of a small open economy, where the two sectors, agriculture and industry, produce different goods, but the relative price $p$ is determined exogenously in the world market. Then, a higher $A_1/A_2$ increases $n$, by shifting the country’s comparative advantage towards agriculture, contrary to what Engel's Law suggests.

**Productivity growth caused by structural change**

Let us introduce some dynamics into the above model by making the total factor productivity (TFP) of the second sector endogenous. More specifically, let $A_2(t) = A_2(Q_t)$, where $A(\cdot)$ is an increasing function, and $Q_t$ is the stock of the experience accumulated in the second sector through learning-by-doing, and follows the law of motion, $dQ_t / dt = H(1 - n_e)$, where $H(\cdot)$ is an increasing function with $H(1 - n_c) = 0$. This captures the idea that, with higher employment, the firms in the second sector can learn faster; but without a critical mass of employment, $1 - n_c$, productivity declines. Let us also assume that learning-by-doing is external, so that the firms take $A_2(t)$ as given when choosing their level of employment. For simplicity, $A_1$ is assumed to be exogenous and constant.

Then, the equilibrium condition in the closed economy is given by eq. (2) at any $t$, so that $n_t = N(A_1)$ and $dQ_t / dt = H(1 - N(A_1))$, which is increasing in $A_1$. In other words, a higher $A_1$, by releasing labour from the first sector, leads to faster productivity growth in the second sector. This captures a version of ‘the staple theory of growth’ (Watkins, 1963), which argues that a productive primary sector triggers the growth of the industry. In a small open economy, however, the equilibrium condition is $A_1 F'_1(n_t) = \gamma A(Q_t) F'_2 (1 - n_t)$.
which suggests that a higher $A_1$ implies a higher $n_t$ for any level of $Q_t$. For $A_1 < \frac{\partial A(Q_t) F_2'(1 - n_t)}{F_1'(n_t)}$, $n_t < n_c$ and hence $H(1 - n_t) > 0$, which leads to productivity growth in industry and a steady decline in $n_t$. For $A_1 > \frac{\partial A(Q_t) F_2'(1 - n_t)}{F_1'(n_t)}$, $n_t > n_c$ and hence $H(1 - n_t) < 0$, which leads to a productivity decline in industry and a steady increase in $n_t$. This suggests the so-called staple trap or resource curse, the situation where the abundance of natural resources prevents the country from growing. Indeed, even a temporary boom in the resource sector could lead to a permanent decline in industry, the so-called Dutch Disease (see Matsuyama, 1992a, s. 3, for more detailed analysis).

Impediments to structural change

The above analysis assumes perfect labour mobility across sectors, equating the marginal value of labour instantly. Many studies have modelled various impediments that slow down the reallocation of labour. In the Lewis (1954) model, the workers earn the average (not marginal) value of labour in the traditional sector, which causes its overemployment. In the Harris and Todaro (1970) model, moving to the urban area is necessary but not sufficient to find a high-wage job in the modern sector, which leads to the urban–rural wage gap, offset by the risk of unemployment in the urban area. In Matsuyama (1991, 1992b), only the young can migrate to the urban sector. In Banerjee and Newman (1998), credit constraints prevent some workers from moving. In Caselli and Coleman (2001) and Lucas (2004), the frictions come from the need to acquire skill or accumulate human capital. These models have implications that a reduction in such frictions accelerates structural change.

The circular causality between productivity growth and structural change

Even without any frictions, structural change and development may fail to materialize due to the circular causality. As pointed out above, productivity growth can cause structural change, which in turn leads to further growth in productivity. The circular causality, however, is a double-edged sword, as lack of productivity growth and lack of structural change can reinforce each other, creating a vicious circle of poverty. To illustrate this point, let us go back to a version of the above model, where the economy has traditional and modern sectors, both producing perfectly substitutable goods, so that the equilibrium is given solely by eq. (1). Now, modify it by assuming that the modern sector is subject to economies of scale, so that its TFP increases with its employment share, as $A_2 = A(1 - n)$. For simplicity, let us assume that higher productivity is entirely due to external economies so that the firms take $A_2$ as given when choosing their level of employment. Then, the equilibrium is given by $A_1 F_1'(n) = \frac{\partial A(1 - n)}{F_2'(1 - n) F_1'(n)}$. This could generate multiple equilibria, each corresponding to a different level of development, as shown in Figure 1. One of them, $E$, may be viewed as the state of underdevelopment, where the modern sector cannot attract much workers due to low productivity, and hence cannot take advantage of the scale economies, implying low productivity. Yet there is another equilibrium, $E'$, characterized by high productivity and a high employment share of the modern sector. A move from $E$ to $E'$ implies both productivity growth and a change in sectoral composition, generating the same observations as models of structural change with exogenous productivity growth; but, in this model, the causality goes in both directions.

Figure 1

Development failures due to two-way causality between productivity growth and structural change

The notion of underdevelopment as a low-level equilibrium generates many conceptual and methodological issues which are poorly understood. These issues are discussed at length in Matsuyama (1991; 1995; 1997). There are also significant misunderstandings regarding its policy implications; see Matsuyama (1996a).

Other aspects of structural change

The transformation from rural agricultural society to urban industrial society is just one of many aspects of structural change discussed in the literature. Due to space constraints, we mention just two.

From old to new industries

The compositions of output and employment change also within the manufacturing sector. Economic growth requires a continuous shift from one industry to another, as existing
industries become older and new industries are born. Several authors have studied how the economy may succeed or fail in such structural change. The key issue is whether productivity gains in one industry help or hinder growth in the next industry. See, for example, Stokey (1988), Lucas (1993), Matsuyama (2002), and Foellmi and Zweimüller (2002).

Increasing product diversity and specialization

Productivity growth is often associated with a greater indirectness of production, as many advanced technologies require a wide variety of highly specialized inputs and services. In poor countries, the lack of local support industries forces the use of relatively simple production methods in downstream industries, which in turn implies a small market size for specialized inputs, which prevents a network of support industries from springing up in the economy. In contrast, rich countries are characterized by a network of highly specialized firms producing a wide range of products. This aspect of structural change, discussed by Young (1928), has been formalized by Romer (1987), Ciccone and Matsuyama (1996), Fafchamps and Helms (1996), and Rodriguez-Clare (1996), among others. For surveys, see Matsuyama (1995; 1997). See also Saint-Paul (1992) and Acemoglu and Zilibotti (1997), who use similar arguments to model the interaction between the development of financial markets and economic growth, thereby capturing some of the issues discussed by Gurley and Shaw (1955).

Concluding comments

Most existing studies of structural change, whether descriptive or theoretical, examine the experience of a country in isolation, and fail to take into account the interactions between countries. This can be misleading. (Recall that, in the above model, productivity gains in agriculture can have opposite implications on sector compositions in the closed and small open-economy cases.) Of course, some notable exceptions exist; for example, Brezis, Krugman, and Tsiddon (1993), Krugman and Venables (1995), Matsuyama (1992a; 1996b; 1998), Puga and Venables (1996), and Fafchamps (1997). However, more research will be needed in this area. The central question is whether structural change in one country will slow down or speed up structural change in other countries.

active labour market policies; aggregate demand; cyclical unemployment; frictional unemployment; Kondratieff cycles; Okun curve; principle of substitution; segmented labour markets; structural unemployment; technical change; technological unemployment; unemployment; uneven development; wage flexibility; wage rigidity

Article

Economists have generally distinguished between various types of unemployment, in terms of both their characteristic features and their underlying causal mechanisms. Some of these distinctions are non-controversial and relatively straightforward both in their definition and in their measurement. Thus, for example, there is not too much disagreement about the scale and nature of ‘seasonal unemployment’ or about the need for ‘seasonal adjustments’ to the regular monthly series of unemployment statistics published in all industrial countries.

However, when it comes to such categories as ‘structural’ unemployment and ‘cyclical’ unemployment, and even more in the case of ‘voluntary’ unemployment, ‘natural’ unemployment or ‘technological’ unemployment, there is intense disagreement not only with respect to their importance but even with respect to their very existence. In the case of structural unemployment, there is agreement that such a phenomenon does indeed exist, but there is a wide area of disagreement about its extent and even more about its causes.

The distinction between ‘frictional’ and ‘structural’ unemployment has never been a precise and unambiguous one. Nevertheless, there is general agreement that whereas frictional unemployment is a transitory and very short-lived form of unemployment based on minor imperfections in the labour market, structural unemployment is a more intractable and persistent phenomenon. Some frictional unemployment is generally regarded as an inevitable accompaniment of a dynamic economy, since there will probably always be imperfections in the available information about job opportunities, in the speed of response and in mobility. However, such frictional unemployment can be reduced to a very low level (that is, less than half of one per cent) of the aggregate labour force, as the experience of many countries...
showed in the high boom period after the Second World War.

Structural unemployment could in principle be caused by a variety of forms of ‘mismatch’ in the labour market with more persistent characteristics. The ‘mismatch’ might, for example, be caused by regional disparities in the availability of new employment opportunities, and in the decline of older industries. The persistence of high unemployment levels in southern Italy over prolonged periods, when there were labour shortages in northern and in central Italy, is one instance of this type of structural disequilibrium in regional development, which exists to a greater or lesser degree in most industrialized countries.

Another form of ‘mismatch’ relates to the skill profile of the labour force. Whereas the concept of ‘frictional’ unemployment presupposes a rapid process of retraining or learning-by-doing (or none at all), in practice the skill requirements for new job opportunities may differ very substantially from the skills of those in search of work. The degree of mismatch may be so great and so deeply rooted in educational and cultural aspects of society, that it is necessary to analyse ‘segmented’ labour markets, each with its own specific characteristics. If mobility between ‘segments’ is very low, then it is possible to explain the persistence of, for example, very high levels of unemployment among young, black, unskilled workers in the big cities of the United States, side by side with labour shortages in other segments of the market associated with high professional and skill requirements, and lower levels of general unemployment (Doeringer and Piore, 1971; Edwards, Reich and Gordon, 1975).

Whereas almost all economists would agree that such problems as change in skill requirements and the uneven development of different regions of a country may give rise to problems of structural adjustments, they have differed greatly in their views about the severity of such problems, about their underlying causes and about the appropriate policy prescriptions. They have differed in particular about the feasibility of substitution between labour and capital and the time lags involved.

Ricardo provoked an intense and continuing debate amongst economists with his famous remark that ‘The opinion entertained by the labouring class that the employment of machinery is frequently detrimental to their interests, is not founded on prejudice or error, but is conformable to the correct principles of political economy’ (Ricardo, 1821, p. 387).

Although controversy still continues about the interpretation of his remarks and he himself revised some of his earlier formulations because they were misunderstood, it is nevertheless clear that Ricardo was drawing attention to the fact that rapid technical change in the form of mechanization of existing processes of production could in principle give rise to serious unemployment problems for the labour force, at least in specific industries and regions. Although he certainly acknowledged that what would now be called ‘compensation mechanisms’ could ultimately lead to the growth of new employment, both in the machine-building industries and elsewhere in the system, he was pointing out that there could be substantial time lags in the adjustment of the capital stock and the mobility of the labour force. In today's terminology he was emphasizing that rapid process innovation could lead to structural unemployment. This conclusion has never been a comfortable one for neoclassical economics, which has generally sought to minimize the severity and complexity of these problems, and to put the emphasis almost exclusively on wage flexibility. One of the reasons for this was the neoclassical ‘principle of substitution’ between capital and labour which, provided wages and interest rates are flexible, should in theory assure that there cannot be more than short-term disequilibrium in the labour market. Since entrepreneurs are assumed to be free to make a rational choice between a wide spectrum of alternative combinations of labour and capital, they will substitute labour for capital in the event of a surplus of labour and an appropriate fall in wage rates and vice versa in the case of a shortage of labour.
structural unemployment: The New Palgrave Dictionary of Economics

means that a self-regulating mechanism will always tend to clear the labour market.

Indeed, in the period before the First World War, when neoclassical theories were first established, it was often assumed that structural unemployment could not and would not be a serious problem, and that the problem of ‘technological unemployment’ simply did not exist (Gourvich, 1940). The remaining problems of imperfect information, imperfect mobility and retraining could be handled through such institutional innovations as ‘labour exchanges’ (Beveridge, 1909).

The relative neglect of the issue of unemployment by most mainstream neoclassical theory led Keynes (1936) to complain when he came to write his General Theory of Employment, Interest and Money that he could not find any adequate statement of a theory of employment in the classical tradition. The somewhat myopic way in which Say's Law was invoked to rule out the possibility of persistent high levels of unemployment was one reason for the severity of Keynes's onslaught on the classical tradition. The rather complacent mainstream view was shattered by the deep depression of the 1930s, and even before that by high levels of unemployment in many countries already in the 1920s. Although traditional theorists continued to emphasize the issue of wage flexibility, most professional economists in the 1930s and 1940s ultimately followed Keynes in recognizing that there were other fundamental problems in maintaining a high level of employment. The Keynesian school can probably best be distinguished from the neoclassical school by its rejection of the notion that equilibrium necessarily implies full employment. Keynes (1936) denied both to wages and to interest rates the self-regulating equilibrating functions which neoclassical theory had assumed. Thus, within a Keynesian framework of analysis there is far more scope for positive structural adjustments policies designed to deal with the problems of regional disequilibrium, skill mismatch and technical change. The problem of structural unemployment is by no means assumed out of existence, but is tackled within an overall framework, emphasizing the cardinal importance of aggregate demand. Beveridge (1944) suggested that, given a strong commitment to ‘full employment’ policies on the part of central government, structural unemployment could be reduced to a relatively low figure, perhaps one per cent of the labour force.

An alternative critique of the neoclassical general equilibrium theory of employment came from Schumpeter (1939) and from other economists, who, for want of a better description, might be designated as ‘structuralists’. In his theory of economic development, Schumpeter stressed in particular the role of major technical innovations as a disequilibrating phenomenon. Such revolutionary new technologies could give rise to ‘creative gales of destruction’ in which old industries, technologies, crafts and employment were decimated by the rise of investment in new products and processes and the opening up of new market.

Schumpeter (1939) regarded the process of technical change as inherently uneven and disequilibrating, giving rise to cyclical behaviour in the system:

Economists have a habit of distinguishing between, and contrasting cyclical and technological unemployment. But it follows from our model that, basically, cyclical unemployment is technological unemployment … We have seen, in fact, in our historical survey, that periods of prolonged supernormal unemployment, coincide with the periods in which the results of inventions are spreading over the system … (vol. 2, p. 515)

Schumpeter (1952) criticized the Keynesian model for its neglect of technical change and for its
In Schumpeter's view the most important problems were associated with long-term processes or Kondratiev cycles. Thus, in his analysis, periods of ‘supernormal unemployment’ occurred approximately every half century or so, that is, in the 1820s, in the 1880s and in the 1930s, when problems of structural adjustment to technical change were particularly severe. Lederer (1931) had already pointed out that severe structural unemployment could arise from the problems of adjustment in the capital stock. The shift of capital investment from ‘static’ branches to the innovative sectors would be hampered by the inertia and rigidity of the existing pattern of investment; ‘capital shortage’ unemployment could be a serious problem side by side with surplus capacity in declining branches of the economy. Thus capital mismatch may give rise to structural unemployment as well as skill mismatch, since the ‘principle of substitution’ does not in fact operate in the simple and instantaneous manner postulated in neoclassical models.

In the prolonged boom after the Second World War Keynesian ideas predominated both in academic economics and in the policy advice offered to governments. Unemployment fell to historically low levels in most industrial OECD countries; female participation rates rose to much higher levels, and in many countries there was substantial net immigration. In these circumstances there was again some tendency to assume that the problems of structural unemployment had been largely resolved, this time through a combination of aggregate demand management policies and active labour market and regional policies. In such countries as Sweden, the German Federal Republic and Austria in particular, active labour market policies were followed which laid great stress on the training and retraining of the labour force to cope with changing skill requirements, and these did indeed help to minimize structural unemployment problems. In the 1970s and 1980s, however, there came renewed recognition that the problem had still not completely disappeared and with general unemployment rates in the OECD area often two or three times as high as in the 1960s, and a rising proportion of long-term unemployed within the total, structural problems of adjustment once more moved to the centre of the stage.

The increasing seriousness of structural mismatch unemployment within the OECD area was shown by ‘Okun curve’ analysis in papers presented to the OECD conference on employment and structural change (Soete and Freeman, 1985) and in the OECD's own publications (OECD, 1985). This evidence showed that the problem was no longer just a cyclical one since the level of unemployment associated with any particular degree of capacity utilization had tended upwards in the 1970s and 1980s, most notably in Europe, but also in the USA and even in Japan. The Secretary-General of the OECD, M. Paye, used the results of this analysis to emphasize the magnitude of the problems of structural adjustment confronting all the OECD countries, and to point to major problems of ‘mismatch’ both in relation to the skill composition of the work force and in relation to the capital stock.

This marked some degree of consensus within the economics profession that the wave of new
technology associated with computerization and microelectronics did indeed raise important problems of structural adjustment. The mismatch of skill requirements was very widely recognized and almost all countries initiated special training and retraining programmes to cope with this problem. It was also increasingly recognized that mismatch in the capital stock could give rise to problems of capital shortage unemployment, particularly in countries which had experienced structural rigidity in adapting to new technology. The severe international disequilibria arising from differential rates of technical change once again aroused anxiety over those problems of international structural adjustment which had so much concerned both Ricardo and Keynes.

However, opinions continue to diverge about the relative significance of wage flexibility, incomes policies, interest rates, national and international monetary and demand policies, industry and technology policies in overcoming the structural unemployment problems. Both neoclassical economists and Keynesians continued to insist on the crucial importance on the one hand of wage rigidity and on the other hand of aggregate demand in explaining the persistence of high unemployment and indicating the appropriate remedies (Layard and Nickell, 1985).

structural vector autoregressions

Jesús Fernández-Villaverde and Juan F. Rubio-Ramírez
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Structural vector autoregressions (SVARs) are a multivariate, linear representation of a vector of observables on its own lags. SVARs are used by economists to recover economic shocks from observables by imposing a minimum of assumptions compatible with a large class of models. This article reviews the relation of SVARs to dynamic stochastic general equilibrium models, discusses the normalization, identification, and estimation of SVARs, and concludes with an assessment of the advantages and drawbacks of SVARs.

Keywords

bootstrap; dynamic stochastic general equilibrium models; estimation; identification; Markov chain Monte Carlo methods; neoclassical growth theory; normalization; reduced-form representation; Sims, C. A.; structural vector autoregressions; vector autoregressions

Article

Structural vector autoregressions (SVARs) are a multivariate, linear representation of a vector of observables on its own lags and (possibly) other variables as a trend or a constant. SVARs make explicit identifying assumptions to isolate estimates of policy and/or private agents’ behaviour and its effects on the economy while keeping the model free of the many additional restrictive assumptions needed to give every parameter a behavioural interpretation. Introduced by Sims (1980), SVARs have been used to document the effects of money on output (Sims and Zha, 2006a), the relative importance of supply and demand shocks on business cycles (Blanchard and Quah, 1989), the effects of fiscal policy (Blanchard and Perotti, 2002), or the relation between technology shocks and worked hours (Galí, 1999), among many other applications.

Economic theory and the SVAR representation
Dynamic economic models can be viewed as restrictions on stochastic processes. From this perspective, an economic theory is a mapping between a vector of $k$ economic shocks $w_t$ and a vector of $n$ observables $y_t$ of the form $y_t = D(w^t)$, where $w^t$ represents the whole history of shocks $w_t$ up to period $t$. The economic shocks are those shocks to the fundamental elements of the theory: preferences, technology, informational sets, government policy, measurement errors, and so on. The observables are all variables that the researcher has access to. Often, $y_t$ includes a constant to capture the mean of the process. The mapping $D(\cdot)$ is the product of the equilibrium behaviour of the agents in the model, implied by their optimal decision rules and consistency conditions like resource constraints and market clearing. The construction of the mapping $D(\cdot)$ is the sense in which economic theory tightly relates shocks and observables. Also, the mapping $D(\cdot)$ can be interpreted as the impulse response of the model to an economic shock.

Often, we restrict our attention to linear mappings of the form $y_t = D(L)w_t$, where $L$ is the lag operator. For simplicity of exposition, $w_t$ will be i.i.d. random variables and normally distributed, $w_t \sim N(0, \Sigma)$. More involved structures – for example, allowing for autocorrelation between the shocks – can be accommodated with additional notation.

We pick the neoclassical growth model, the workhorse of dynamic macroeconomics, to illustrate the previous paragraphs. In its basic version, the model maps productivity shocks, the $w_t$ of the theory, into observables, $y_t$, like output or investment. The mapping comes from the optimal investment and labour supply decisions of the households, the resource constraint of the economy, and the law of motion for productivity. If the productivity shocks are normally distributed and we solve the model by linearizing its equilibrium conditions, we obtain a mapping of the form $y_t = D(L)w_t$ described above.

If $k=n$, that is, we have as many economic shocks as observables, and $|D(L)|$ has all its roots outside the unit circle, we can invert the mapping $D(L)$ (see Fernández-Villaverde, Rubio-Ramírez and Sargent, 2005) and obtain

$$A(L)y_t = w_t$$

where $A(L) = A_0 - \sum_{k=1}^{\infty} A_k L^{-k}$ is a one-sided matrix lag polynomial that embodies all the (usually nonlinear) cross-equation restrictions derived by the equilibrium solution of the model. In general, $A(L)$ is of infinite order. This representation is known as the SVAR representation. The name comes from realizing that $A(L)y_t = w_t$ is a vector autoregression (VAR) generated by an economic model (a ‘structure’).

**Reduced form representation, normalization, and identification**

Consider now the case where a researcher does not have access to the SVAR representation. Instead, she
structural vector autoregressions: The New Palgrave Dictionary of Economics

has access to the VAR representation of $y_t$:

$$y_t = b_1 y_{t-1} + b_2 y_{t-2} + \ldots + \epsilon_t,$$

where $E y_{t-j} \epsilon_t = 0$ for all $j$ and $E \epsilon_t \epsilon'_t = \Omega$. This representation is known as the reduced-form representation. Can the researcher recover the SVAR representation using the reduced-form representation? Fernández-Villaverde, Rubio-Ramírez, and Sargent (2005) show that, given a strictly invertible economic model, that is, $|D(L)|$ has all its roots strictly outside the unit circle, there is one and only one identification scheme to recover the SVAR from the reduced form. In addition, they show that the mapping between $\epsilon_t$ and $w_t$ is $\epsilon_t = A_0^{-1} w_t$. Hence, if the researcher knew $A_0^{-1}$, she could recover the SVAR representation from the reduced form, noting that $A_j = A_0 B_j$ for all $j$ and $w_t = A_0 \epsilon_t$.

Hence, the recovery of $w_t$ from $y_t$ requires the knowledge of the dynamic economic model. Can we avoid this step? Unfortunately, the answer is, in general, ‘no’, because knowledge of the reduced-form matrices $B_i$ and $\Omega$ does not imply, by itself, knowledge of the $A_i$ and $\Sigma$, for two reasons. The first is normalization. Reversing the signs of two rows or columns of the $A_i$ does not matter for the $B_i$. Thus, without the correct normalization restrictions, statistical inference about the $A_i$’s is essentially meaningless. Waggoner and Zha (2003) provide a general normalization rule that maintains coherent economic interpretations.

The second is identification. If we knew $A_0$, each equation $B_i = A_0^{-1} A_i$ would determine $A_i$ given some $B_i$. But the only restrictions that the reduced-form representation imposes on the matrix $A_0$ comes from $\Omega = A_0 \Sigma A'_0$. In this relationship, we have $n(3n+1)/2$ unknowns (the $n^2$ distinct elements of $A_0$ and the $n(n+1)/2$ distinct elements of $\Sigma$) for $n^2$ knowns (the $n(n+1)/2$ distinct elements of $\Omega$). Thus, we require $n^2$ identification restrictions. Since we can set the diagonal elements of $A_0$ equal to 1 by scaling, we are left with the need of $n(n-1)$ additional identification restrictions (alternatively, we could scale the shocks such that the diagonal of $\Sigma$ is composed of ones and leave the diagonal of $A_0$ unrestricted). These identification restrictions are dictated by the economic theory being studied.

The literature, however, has often preferred to impose identification restrictions that are motivated by the desire to be compatible with a large class of models, instead of just one concrete model and its whole set of cross-equations restrictions. The hope is that, thanks to this generality, the inferences drawn from SVAR can be more robust and can compensate for the lack of efficiency derived from not implementing a full information method.

The most common identification restriction has been to assume that $\Sigma$ is diagonal. This assumption relies on the view that economic shocks are inherently different sources of uncertainty that interact only through their effect on the decisions of the model's agents. Since this assumption imposes $n(n-1)/2$ restrictions, we still require $n(n-1)/2$ additional restrictions. To find these additional restrictions, economists have followed two main approaches: short-run
restrictions and long-run restrictions. Sims (1980) pioneered the first approach when he proposed to impose zeros on $A_0$. The motivation for such a scheme comes from the idea that there is a natural timing in the effect of economic shocks. For example, to place a zero on $A_0$, we can use the intuition that monetary policy cannot respond contemporaneously to a shock in the price level because of informational delays. Similarly, institutional constraints, like the timing of tax collections, can be exploited for identification (Blanchard and Perotti, 2002). Sims (1980) ordered variables in such a way that $A_0$ is lower triangular. Sims and Zha (2006a) present a non-triangular identification scheme on an eight-variable SVAR.

The long-run restrictions were popularized by Blanchard and Quah (1989). These restrictions are imposed on $A(1) = A_0 - \sum_{k=1}^{\infty} A_k$. Since $A^{-1}(1)=D(1)$, long-run restrictions are justified as restrictions on the long-run effects of economic shocks, usually on the first difference of an observable. For example, Blanchard and Quah (1989) assume that there are two shocks (‘demand’ and ‘supply’) affecting unemployment and output. The demand shock has no long-run effect on unemployment or output. The supply shock has no long-run effect on unemployment but may have a long-run effect on output. These differences in their long-run impacts allow Blanchard and Quah to identify the shocks and trace their impulse response function.

New identification schemes have been proposed to overcome the difficulties of the existing approaches. See, for instance, Uhlig (2005) for an identification scheme of monetary policy shocks based on sign restrictions that hold across a large class of models.

**Estimation**

Why is the previous discussion of the relation between the reduced and structural form of a VAR relevant? Because the reduced form can be easily estimated. An empirically implementable version of the reduced-form representation truncates the number of lags at the $p$th order:

$$y_t = \bar{b}_1 y_{t-1} + \cdots + \bar{b}_p y_{t-p} + \bar{a}_t$$

where $\bar{E} \bar{a}_t \bar{a}_t' = \bar{\Omega}$. We use hats in the matrices and the error $\bar{a}_t$ to indicate that they do not correspond exactly to the reduced form of the model but to the truncated version. The effects of the truncation on the accuracy of inference delivered by SVARs are unclear (see Chari, Kehoe and McGrattan, 2005, and Christiano, Eichenbaum and Vigfusson, 2007, for two opposite assessments). The resulting truncated VAR can be taken to the data using standard methods: GMM, maximum likelihood, or Bayesian. The Bayesian approach is especially attractive. SVARs are proliferatively parametrized. The number of parameters in $B(L)$ grows with the square of the number of variables and the number of lags. Consequently, given the short period of data typically available to macroeconomists, classical methods become unreliable. A careful use of prior information alleviates the problem of overparametrization and
improves the quality of the inference. The advent of modern simulation techniques, especially Markov chain Monte Carlo methods, has made the implementation of the Bayesian paradigm straightforward, even for sophisticated priors.

The point estimates \( \hat{B}_i \) for \( i=1,\ldots,p \) and \( \hat{\Omega} \) can be used to find estimates of \( \hat{A}_i \) and \( \hat{\Sigma} \) by solving
\[
\hat{B}_i = \hat{A}_0^{-1} \hat{A}_i \quad \text{for} \quad i=1,\ldots,p, \quad \text{and} \quad \hat{\Omega} = \hat{A}_0 \hat{\Sigma} \hat{A}_0'.
\]
With an estimate of \( \hat{A}_0 \) and the \( \alpha_t \), we can get \( \hat{w}_t = \hat{A}_0 \hat{\alpha}_t \).

Thus, the reduced form plus the identifying restrictions deliver both an estimate of the economic shocks and the impulse response of the variables in the economy to those shocks. Confidence intervals for point estimates and error bands for impulse response functions can be estimated by resorting to Markov chain Monte Carlo techniques or the bootstrap.

In an important contribution, Sims and Zha (2006b) have extended the estimation of SVARs to allow for changes in equation coefficients and variances. This article opens the door for the analysis of richer dynamic models with parameter instability, arguably a more realistic description of observed aggregate variables.

Assessment of SVARs

SVARs offer an attractive approach to estimation. They promise to coax interesting patterns from the data that will prevail across a set of incompletely specified dynamic economic models with a minimum of identifying assumptions. Moreover, SVARs can be easily estimated, even with commercial software and freely available routines from the Internet. In the hands of skilful researchers, SVARs have contributed to the understanding of aggregate fluctuations, have clarified the importance of different economic shocks, and have generated fruitful debates among macroeconomists.

However, SVARs have also been criticized. We mention only three criticisms. First, it has been argued that the economic shocks recovered from an SVAR do not resemble the shocks measured by other mechanisms, such as market expectations embodied in future prices. Second, the shocks recovered from an SVAR may reflect variables omitted from the model. If these omitted variables correlate with the included variables, the estimated economic shocks will be biased. Third, the results of many SVAR exercises, even simple ones, are sensitive to the identification restrictions. Related to this criticism is the view that many of the identification schemes are the product of a specification search in which researchers look for ‘reasonable’ answers. If an identification scheme matches the conventional wisdom, it is called successful; if it does not, it is called a puzzle or, even worse, a failure (Uhlig, 2005).

Consequently, there is a danger that economists will get stuck in an a priori view of the data under the cloak of formal statistical inference.

structural vector autoregressions: The New Palgrave Dictionary of Economics

doi:10.1057/9780230226203.1642
Abstract

Structuralist analysis advocates a focus on a system in its totality and on the interrelations between its elements rather than on individual elements in isolation: for instance, understanding the world economy as a system within which the centre and periphery are intrinsically linked, with many economic problems of the periphery deriving from that interaction. Structuralist development economics, as associated with, for example, Raúl Prebisch and Celso Furtado, essentially turns on two phenomena considered inherent to development in countries of the periphery that export almost exclusively commodities: foreign-exchange constrained growth and the tendency towards deterioration in the terms of trade.

Article

Structuralism is essentially a theoretical approach that challenges the methods of empiricism and positivism. Structuralism features in several disciplines across the humanities and the social sciences, but not as a cohesive school of thought. In so far as there are common elements, the conception of an integrated system of distinguishable yet mutually constitutive elements could be said to be the most important feature. These elements derive their meaning in relation to one another – such as, for instance in economics, the understanding of development and underdevelopment as related, mutually constitutive
processes within an integrated world economic system. This is as distinct from the analysis of the elements as relatively independent units.

The emergence of structuralism is typically traced to the linguistic work of De Saussure, who analysed language as a system whose elements can be defined only through their relations of equivalence or opposition to one another, with these relations forming the structure. The term ‘structuralism’ was apparently coined by Jakobson, a member of the Prague School of linguistics, in 1929. Structuralism is also strongly associated with the work of Lévi-Strauss in anthropology, notably in his analysis of the structures within cultures through which meanings are produced and reproduced. Other writers often associated with structuralism include Althusser, Barthes, Derrida, Godelier, and Lacan (although not all identified themselves as structuralist nor would be universally regarded as such).

Structuralism can be considered as having methodological, epistemological, and ontological dimensions. However, in different disciplines and for different writers variously identified as ‘structuralist’, not all these dimensions necessarily feature.

As a methodology, structuralist analysis advocates a focus on a system in its totality and on the interrelations between its elements, rather than on individual elements in isolation. For instance, in terms of economic analysis, this might point towards an emphasis on understanding the world economy as a unified system, with the economic dynamics of its constituent parts – centre and periphery – being defined in terms of their interrelationship. Such a methodological approach relates closely to the seminal focus in structuralist linguistics on synchronic rather than diachronic analysis (that is, an emphasis on a comprehensive analysis of a linguistic structure at a given conjuncture, even at the expense of historical or comparative approaches). Structuralism can be distinguished in this respect from historicist analysis. It would also tend to offer non-narrative explanations (in terms of an emphasis on analysis of the underlying dynamics rather than on descriptive explanations).

In terms of epistemology, structuralism requires the penetration of appearance in order to grasp the deep underlying structure. In this sense, structuralism is anti-phenomenological and may also be considered anti-empiricist. From this perspective, structuralist approaches in economics hold that there is a set of economic and social structures that are themselves unobservable, yet generate observable social and economic phenomena. The latter could not be properly understood unless the analysis focuses on the unobservable underlying structures.

In terms of ontology, structuralism tends to favour explanations as to how structures cause or at least condition or asymmetrically constitute aspects such as agency. This ontological approach is particularly relevant to structuralist political theory and structuralist Marxism (notably in Althusser), and stands in opposition to humanist and historicist interpretations of Marxism. There are two dimensions here: structure and agency. Notwithstanding important differences between structuralist approaches, a shared characteristic is the ontological primacy accorded to structure over an event or a phenomenon. Agents are regarded as often unaware of the economic structure, or the totality of the social relations of production, so that there is a gap between their discourse and the collective social practice that constitutes the objective economic structure. This is expressed in Althusser's theory of social practice as a process of transformation without a subject: by transforming the social and natural environment through work, people determine the economic structure, but not as subjects, through their agency, but through internalized social organization and practice. Hence, structuralism seeks to explain social phenomena by reference to the underlying structure of the mode of production and the social organization – or practice – that determines it. This approach can be distinguished from humanist
approaches that privilege agency, stressing the role of human consciousness and action in social change.

In modern economics, structuralism is mostly associated with the United Nations Economic Commission for Latin America and the Caribbean (ECLAC), whose work merged into a coherent school of thought in the late 1950s. However, at least some of the core elements of ECLAC thought can be traced to earlier Continental European contributions, in particular to the ‘structuralist’ economic school in France. The earliest use of the modern concept of economic structure – after Marx – can be found in the work of Wagemann, who introduced the notion of structure in his business cycle studies. For Wagemann, certain types of business cycles correspond to specific underlying economic structures. A system is determined by all the particularities of a country and its people, or by the totality of the data. In a similar vain, Åckerman developed a ‘structuralist’ view of the economy in relation to the study of business cycles. From a dynamic point of view, Åckerman defines economic structures as those structures that are invariable in the short term.

Wagemann's and Åckerman's work was well known to Perroux, who is probably the best-known representative of French economic structuralism (and who was the main intellectual influence in Furtado's early work, including his doctoral dissertation at the Sorbonne; see Furtado, 1995). Perroux (1939) defined structural economics as the science of the relations characteristic of an economic system (ensemble) situated in time and space. Central to Perroux's approach was the view that, over and above the 'givens' of neoclassical theory (preferences, resources and technology), the analysis of institutions and structures over time had to be at the heart of economic analysis. An important innovative contribution by Perroux concerns his theory of domination that is central to ECLAC's conception of economic systems: rather than being constituted by relationships between equal agents, the economic world is conceptualized in terms of hidden or explicit relationships of 'force', 'power' and 'constraints' between dominant and dominated entities. Perroux applies the theory of domination to different levels of analysis, first, to markets (such as the effects of the level of unemployment on relations of dominance in the labour market), next to the theory of firms, especially regarding imperfect competition, and finally to the international economy, in terms of the relationship between 'dominant' and 'dominated' economies, particularly concerning trade and finance.

French economic ‘structuralism’ clearly anticipates important aspects of ECLAC thought. This is not surprising, given the close personal links between the main protagonists on both sides. In addition to the Perroux–Furtado relationship, Wagemann immigrated to Chile where he worked with leading ECLAC economists and promoted the ideas of Sombart who, apart from Perroux, was also an important influence on Prebisch and Furtado.

ECLAC first explicitly termed its own analysis ‘structuralist’ in the mid-1950s in its controversies with the monetarist view of inflation (see Noyola, 1957; Pinto, 1963; and Sunkel et al., 1963; see also Kaldor, 1957). In brief, the ECLAC argument was that money was endogenous in Latin America's persistent inflation, which was seen as a cost-push phenomenon that mainly originated in the supply rigidities of the agricultural sector (an idea initially advanced by Austin Robinson in his early works on India). ‘Anglo-American’ development economics of the 1950s and early 1960s – associated with the work of Lewis, Rosenstein-Rodan, Nurkse, Chenery and Syrquin, among others – also centred around the analysis of structural change.

From the very beginning ECLAC's analysis was structuralist in the sense that it was associated with both a view of the world economy as a system within which the centre and the periphery are intrinsically related to one another, and that most economic problems of the periphery (such as inflation, stop/go
ECLAC's analysis was also structuralist in the sense that it tried to focus on underlying structures and relationships, as opposed to epiphenomena. More specifically, the hub on which the whole of ECLAC's analysis of underdevelopment turned was the idea that the structure of production in the centre and in the periphery differed substantially. That of the centre was seen as homogeneous and diversified, that of the periphery as heterogeneous and specialized – heterogeneous because economic activities with remarkably different productivity–growth dynamics existed side by side, with two extremes of a modern export sector and subsistence agriculture; specialized because the production of commodities for exports had very limited backward and forward linkages with the rest of the economy (see ECLAC, 1969).

It was this structural difference between the two types of economy that underpinned the different function of each pole in the international division of labour. These structural differences could not be defined or understood in static terms, as the transformation of either pole would be conditioned by the interaction between them. Centre and periphery formed a single system, dynamic by its very nature. This approach differs from the traditional Marxist view of the time, which still saw the periphery simply as a ‘backward’ region that had not yet succeeded in revolutionizing relations of production and the class structure in ways similar to the transformation achieved by more advanced capitalist countries (see dependency).

The nucleus of ECLAC analysis was the critique of the (‘non-product specific’) Solow-type growth models, and of the (‘static resource endowment specific’) comparative advantages approach found in the Heckscher–Ohlin–Samuelson-type models of international trade (see Palma, 2005). It aimed to show that growth was both a ‘product specific’ phenomenon, and that comparative advantages can also be acquired. The key issue here is that, according to ECLAC, in terms of both growth and welfare the international division of labour which conventional trade theory claimed to be ‘naturally’ produced by (static) comparative advantages was of much greater benefit to the centre (where manufacturing production is concentrated) than to the commodity-exporting periphery. The greatest asymmetries could be found in short-term welfare gains from trade, and in the effectiveness of exports as a long-term engine of growth.

From this perspective, ECLAC's structuralism did not question the basic postulate of mainstream economics – that free interaction of rational and selfish agents in the market leads to ‘equilibrium’. What it argued was both that this equilibrium was not optimal for long-term growth and welfare in the periphery, and – following the post-war Keynesian tradition – that there was something that the periphery could do to improve upon this suboptimal equilibrium.

The ECLAC analysis essentially turns on two basic phenomena which are considered inherent to the development of countries in the periphery that export almost exclusively commodities: foreign exchange-constrained growth, and the tendency toward deterioration of the terms of trade. In terms of foreign exchange-constrained growth, as long as domestic production of tradables continues to be concentrated in primary commodities, the periphery is bound to experience external disequilibrium leading to foreign exchange-constrained growth. Successful commodity exporters will tend to have a weak manufacturing sector not just because they can afford deficits in their trade balance in manufacturing, but also due to ‘Dutch Disease’ effects (see Palma, 2005, and de-industrialization, ‘premature’ de-industrialization and the Dutch Disease). Given that income elasticity for imported manufactures in the periphery is much
greater than that for commodities in the centre, growth in commodity-exporting countries is likely to be foreign exchange-constrained (see McCombie and Thirlwall, 1994). The need for a long-term trade balance between centre and periphery would imply that, for a given rate of growth of real income in the centre, the disparity between the income elasticities of imports at each pole will impose a limit upon the rate of growth of real income in the periphery. This growth will tend to be less than that of the centre in proportion to the degree of disparity between the respective income elasticities of demand for imports. If the periphery attempts to surpass this limit, subsequent trade deficits would force it to decelerate. Although in the short term the periphery can borrow its way out of trouble, the only long-term alternative to this trend towards growth divergence is for the periphery to try to reduce this disparity in income elasticity for imports. That is, to make a significant effort to satisfy the highly income-elastic demand for manufactures through import substitution, and/or to diversify its export trade towards more income-elastic products. While Latin America tried to overcome its foreign-exchange constrained growth almost exclusively through a process of import-substituting industrialization, East Asia more ambitiously attempted both routes (while also curbing domestic demand for luxury consumer goods). Thus, given ECLAC’s assumptions, only a process of industrialization can enable the periphery to enjoy a rate of growth of real income higher than that determined by the growth rate in the centre and by the disparity between income elasticities of demand for imports in both poles. Therefore, for ECLAC growth ends up being ‘product-specific’ in a double sense. From a demand point of view, only a process of industrialization can lift the foreign-exchange constraint on growth. From a supply point of view, only manufacturing is a good engine of growth (in a Kaldorian sense) due to its potential for sustained high productivity growth. This is because ‘learning by doing’, dynamic economies of scale, increasing returns, externalities and spillover effects are more prevalent in manufacturing than elsewhere in the economy.

In terms of the second major problem that ECLAC considered inherent in the development of the commodity-exporting periphery – the tendency toward deterioration of its terms of trade (and the asymmetries which this brings with it in terms of the welfare gains from trade between centre and periphery) – in ECLAC thought this is also a logical analytical deduction from the phenomena of specialization and heterogeneity. That is, contrary to common perception, the terms of trade issue is not the starting point of ECLAC thought, but, given its assumptions and hypotheses, a logical analytical deduction.

There are demand and supply forces behind this tendency to deterioration in the terms of trade of the periphery. The fundamental problem is the specific effect that economic growth has on the terms of trade (see Prebisch, Raúl for a detailed analysis of this point; see also Singer, 1949; and Kindleberger, 1956).

In sum, according to ECLAC, it is possible for the commodity-rich periphery to escape from the negative growth and welfare effects of passive integration into the world economy, through the transformation of its economic structure. The central element in this structural transformation is to accelerate industrialization in the periphery. Thus Prebisch often summarized ECLAC’s task as having been that of showing that rapid industrialization was an unavoidable prerequisite for development; in fact, he appears at times to use the concepts ‘industrialization’ and ‘development’ as synonyms (see Prebisch, Raúl).

If industrialization were perceived as a necessary (and sometimes in the work of some structuralist writers apparently even sufficient) condition for a rapid and sustainable rate of economic growth, this
process could not be expected to occur spontaneously. It would be inhibited by the international division of labour which the centre would attempt to impose, and by various structural obstacles internal to the peripheral economies. Consequently, a series of measures was proposed to promote deliberate, ‘forced’, or ‘state-led’ (import-substituting) industrialization. These included state intervention in the economy, both through trade and industrial policies and as a direct productive agent. Among the economic policies suggested in order to create incentives (rents) to direct resources towards domestic manufacturing and associated activities were those of ‘healthy’ protectionism, exchange-rate management, the attraction of foreign capital, and the stimulation and orientation of domestic investment. State intervention in directly productive activities was recommended in areas where large amounts of slow-maturing investment were needed, and particularly where this need coincided with the production of essential inputs and services for manufacturing, and of ‘complementary capital’ (such as infrastructure and utilities).

The various elements of ECLAC thought are brought together by its internal unity and its structuralist nature. The two most important problems of the development of the economy in the periphery (that is, foreign exchange-constrained growth and the tendency to deterioration in the terms of trade) derive directly from the characteristics of its structure of production and of its interaction with the centre. The possibility of tackling them is thus seen in terms of an ideal pattern of transformation, indicating the conditions of structural proportionality which must hold if these problems are to be avoided. This leads to the formulation, tacitly or explicitly, of the law of proportionality in the transformation. This would avoid heterogeneity and specialization and thus allow the escape from external disequilibria (and stop/go growth), eventually also counteracting the tendency towards deterioration of the terms of trade. It would also assist the periphery in achieving full productive utilization of its labour force, a more equal distribution of income, and lower inflation.

Nevertheless, it is also in this very structuralist nature that the limitations of ECLAC thought lie. At this level of analysis no consideration is given to the social relations of production which developed with import-substituting industrialization, nor to the problems arising from the broader social transformation that inevitably followed. Furthermore (and mainly as a result of its own intellectual ‘structural rigidities’, arising from the fact that ECLAC is a UN organization), structuralist thinkers never properly addressed the issue that it is one thing to use trade and industrial policies to create rents to divert resources towards more ‘dynamic’ activities, but quite another for the state to have the institutional capabilities necessary to ensure that the capitalist elite uses those rents effectively.

ECLAC proposes an ideal model of sectoral growth – and hence of overall growth – designed to avoid the reproduction of the tendencies peculiar to economic development in the commodity-rich periphery. From this model are derived the necessary conditions of domestic accumulation that ensure a balanced (proportional) transformation of the different production sectors. Nevertheless, even when pushed to the limits of its potential internal coherence, the structural approach is inadequate for the analysis of the long-term evolution of the economic system as a whole, as this clearly involves more than the transformation of the structure of production alone (see Hirschman, 1971 and Rodríguez, 2006). ECLAC theories describe and examine certain aspects of the development of the forces of production (to the extent that the theories deal with the productivity of labour and the degree of diversification and homogeneity of the structures of production). However, they do not touch on relations of production, nor, as a result, on the manner in which the two interact. In fact, initial attempts to introduce into the traditional ECLAC analysis various ‘social’ and ‘political’ aspects (for example, Prebisch, 1963), far from strengthening the analysis, revealed its fragility (see Palma, 1978).
Furthermore, the analysis of the asymmetries of development cannot be undertaken solely in terms of the patterns of accumulation necessary to avoid the creation of certain disproportionalities between the different sectors of production, as their feasibility depends more upon the general conditions in which accumulation occurs globally than upon the possibility of accumulation and structural change in the periphery. If the intention is to analyse the asymmetries of the centre–periphery system, it is inadequate just to consider the inequality of the development of the forces of production. It is just as necessary to bear in mind that those forces of production develop in the broader context of the generation, appropriation and utilization of the economic surplus. This process, and the relations of exploitation upon which it is based, are not reproduced purely within each pole, but also between the two poles of the world economy (see Rodríguez, 2006).

It is not surprising that ECLAC immediately attracted considerable criticism, particularly as it went beyond theoretical pronouncements to offer packages of policy recommendations. It was criticized from sectors of the Left for failing to sufficiently denounce the mechanisms of exploitation within the capitalist system, and for criticizing the conventional theory of international trade only from ‘within’ (see for example Frank, 1967). On the other hand, from the other end of the political spectrum the reaction was immediate: ECLAC’s policy recommendations were totally heretical from the perspective of conventional economic theory, and threatened the political interests of significant sectors of both the traditional capitalist elite, and of foreign capital and finance. A leading critic in academic circles was Haberler (1961), who accused ECLAC of failing to take due account of economic cycles, and argued that single factorial terms of trade would be a better indicator than the simple relationship between the prices of exports and imports.

On the political front, the right accused ECLAC of being the ‘Trojan horse of Marxism’, on the grounds of the degree of coincidence between parts of both analyses. In both cases the principal economic obstacle was located externally (international division of labour imposed by the centre), and both shared the conviction that without a strenuous effort to remove the obstacles to development (the traditional sectors that benefited from the status quo, and their external allies) the process of industrialization would be significantly impeded. Furthermore, the coincidence between crucial elements in the analysis of the two respective lines of thought is made more evident by the fact that both schools underwent simultaneous exercises in the revision of established lines of thought (see dependency). Moreover, both reformulations had one extremely important element in common: a growing pessimism regarding the possibility of capitalist development in the periphery.

Aspects of the ECLAC analysis re-emerged in the 1980s in some North American academic circles (the most imaginative contribution is that of Taylor, 1983), but rather than revitalizing structuralism as a new method of enquiry into economic analysis these only succeeded in integrating some of the key assumptions and hypotheses of the traditional ECLAC analysis into mainstream economic thinking. In the South there was also a (relatively short-lived) attempt to develop a ‘neo-structuralist’ school by reformulating classical ECLAC thought using modern economic analysis and techniques (see Fajnzylber, 1983; and Sunkel, 1991; see also Rodríguez, 2006). The main aim was to build a coherent set of economic ideas as an alternative to the then rapidly emerging neoliberalism. Very few ‘neo-structuralists’ stayed the course for long (except mainly for José Antonio Ocampo and Lance Taylor).

The concept of ‘stylized facts’ is usually attributed to Nicholas Kaldor, who discussed this concept in a well-known 1958 Corfu conference paper (1961) on capital accumulation and economic growth. While the term ‘stylized facts’ is widely used today in many varied contexts, Kaldor had a specific use in mind. Kaldor (1961, p. 177) noted that everyone agrees ‘that the basic requirement of any model is that it should be capable of explaining the characteristic features of the economic process as we find them in reality’. But how are we to explain results of a theoretical model which are contrary to what we observe in reality? Too often, Kaldor complains, the contrary results are explained away by simply noting that the assumptions of the model did not account for changes in such things as knowledge or merely assumed away uncertainty and technological progress. For Kaldor, such a method of explaining away discrepancies between the results of the theoretical model and the facts of the world we see outside of our window is of very little ‘interpretive value’.

The problem that Kaldor is concerned with is not the simplistic view that recognizes that assumptions of models and theories ‘must necessarily be based on abstractions’. Rather, it is the more difficult one of being careful to choose a type of abstraction that is ‘appropriate to the characteristic features of the economic process as recorded by experience’. In Kaldor's view, when choosing between competing theoretical approaches the proponents of the two competing approaches ‘ought to start off with a summary of the facts’ which both regard as relevant to the task at hand.

Since Kaldor wished to focus our attention on the difficult problem of choosing an appropriate type of abstraction for the economic world we hope to explain, he wanted to avoid unproductive debate over details of historical accuracy. He said that we should be free to start off with a ‘stylized’ view of the facts to be explained. Specifically, we should be free to concentrate on broad tendencies, ignoring individual detail, and proceed with what he calls the ‘as if’ method. His use of an ‘as if’ method is
different from the common neoclassical use of an ‘as if’ method. Unlike neoclassical economists who employ simplistic assumptions ‘as if’ they were true, Kaldor would have us explain ‘stylized’ facts as if they truly represented the reality we want to explain. As long as proponents of competing explanations can come to an agreement regarding the ‘stylized’ facts that both wish to explain, the comparative appropriateness of competing explanatory abstractions can be brought into clear and decisive focus. In Kaldor's day, the issue was the construction of a theoretical model of economic growth and capital accumulation. The competitor to his Keynesian–classical model was anyone promoting a neoclassical model. To focus the debate, Kaldor suggested six ‘stylized’ facts as a starting point. These included such things as a steady rate of growth of production and productivity of labour, a growing capital–labour ratio, a steady rate of profit on capital, steady capital–output ratios over long periods, high correlation between the share of profits in income and the share of investment in output, with allowance for the fact that there are differences between societies in the rates of growth of labour productivity and of total output. With this in mind, Kaldor went on to claim that none of his suggested ‘stylized facts’ can be plausibly ‘explained’ by the assumptions of neoclassical models, while the alternative model of income distribution and capital accumulation which he presents is capable of explaining some if not all of his ‘stylized facts’.

Economists today who claim to explain ‘stylized facts’ usually are not fully aware that Kaldor used the term only in the context of a theoretical comparison between two competing approaches. For a while in the 1970s and 1980s most neoclassical model-builders claimed to be explaining stylized facts merely as a convenient simplification of the model-building process. There was rarely a mention of a competing approach. If these model-builders thought they were following Kaldor's lead, they were clearly mistaken. Today, stylized facts are used mainly in macroeconomics (for example, D. Romer, 1996, p. 15) and is consistent with the primary methodological reason Kaldor gave for using stylized facts: ‘facts, as recorded by statisticians, are always subject to snags and qualifications, and for that reason are incapable of being accurately summarized.’ The difference is that today, when one claims to be using stylized facts, one is claiming that there exists a ‘scientific consensus’ that those facts are an acceptable characterization of the data one is trying to explain. So, the issue is never about a debate between competing models or approaches but merely a laying out of a commonly accepted task for the model-builder. A successful model is expected to at least explain those ‘stylized facts’. Interestingly, when the theoretical domain at issue is an economy's economic growth, Kaldor's stylized facts are still part of the picture that any growth model would have to explain (see for example P. Romer, 1989, pp. 53–4). Even if we were to leave aside Kaldor's methodological purpose for using ‘stylized facts’ and instead see them as an indication of the commonly accepted characterization of what we wish to explain, the model is still open to dispute as to whether the claimed stylized facts do in fact represent an acceptable characterization. To this extent things have not changed in the last four or five decades. Discussing Kaldor's stylized facts, Robert Solow (1970, p. 2) said that there ‘was no doubt that they are stylized, though it is possible to question whether they are facts’. Nevertheless, Kaldor is to be admired for insisting that we identify our facts to be explained before engaging in a critical comparison of competing explanatory models.

In ancient economies where slave labour was the predominant form of labour, and for a long time after, when the material conditions of the labourer were not much better, the earnings of labour were viewed as not very different from the feed of horses. There were no ‘theories’ of wages but it was automatically supposed that they receive subsistence, certain fixed quantities of the necessaries of life. As working horses need to be maintained in adequate supply, the worker or the slave would be so provisioned as to be enabled to work and reproduce.

During the second half of the 17th and early 18th century with the rapid rise of commercial capitalism, intensification of competition among trading nations seeking new markets and sources of supply in Europe, discussions arose on management of labour and of wages – in particular, the advantages of maintaining cheap labour. In pursuance of mercantilist ideas, cheap labour was considered a favourable factor in competition. ‘National Wealth’, wrote Mandeville ‘consists not in money’ but in a ‘multitude of laborious poor’. It was also believed that hard work could be compelled out of the poor only by extreme need and want. ‘Men have nothing to stir them up to be serviceable but their wants which it is Prudence to relieve but Folly to cure’ (Mandeville, 1714, p. 194). It was believed that low wages not only spur productivity but also yield commercial advantage since cheap labour meant cheap produce. Thus the mercantilist policy sought to encourage population and selective migration to keep prices of necessaries high through taxes, if necessary, and set wages at a low subsistence level. ‘An increase of people in the country to such a degree as may make things necessary to life dear and thereby force general industry from each member of the family’ seemed a statesman's maxim (William Temple, 1673, p. 116). Discussions on wages were, at this stage, an issue of labour policy and the idea of fixed
subsistence and subsistence wages: The New Palgrave Dictionary of Economics

subsistence rested on the extant conditions, as observed. No attempt either to explain the level or the mechanisms stabilizing or restoring that level were discussed. However, it was already recognized, as a practical premise, that taxes on necessaries of subsistence were likely to be accompanied by a rise in money wages (cf. among others, Thomas Mun, 1664, and John Locke, 1692).

It is in William Petty, rightly considered by Marx as among the founders of political economy, that a theoretical role was assigned to the norm of subsistence and the difference between the labourer's subsistence and his produce brought to the fore. Petty was also concerned with quantitative relations within production and with evolving a measure of value.

The most important consideration in Political Oeconomics [is], viz how to make a Par and Equation between lands and labour, so as to express the value of anything by either alone•

…•wherefore the days food of an adult man•…•and not the days labour, is the common
measure of value•…•(Petty, 1691, p. 181)

Thus subsistence became a constant measure of value. Defining the value of a commodity in terms of the quantity of food necessary for the day's payment for an adult, he extended the same measure for valuation of different types of labourers. The unit of food was thus a standard of commodity wage. Already by Petty's time the legislative fixation of wages and actual compliance to it were being violated. Attention was gradually drawn to the observed stable level of subsistence, not as an axiom or as a statutory fixation but as an economic condition. The mechanisms that tend to keep wages down were thus explored. John Locke (1692) attempted to explain its existence in terms of psychological inertia among the poor induced by the lowness of wage itself. While active struggle occurred between the land owners and merchants,

the labourer's share, being seldom more than a bare subsistence, never allows that body of men time or opportunity to raise their thoughts above that unless when some common and great distress, uniting them in one universal ferment, makes them forget respect and emboldens them to carve to their wants with armed force; and then sometimes they break it upon the rich, and sweep all like a deluge. (Locke, 1692, p. 57)

The phenomenon of wages gained importance with the gradual breakdown of guilds, spread of commercial capital and ‘labour’ becoming a commodity. The role played by migration of labour to level wages down to a subsistence level appeared prominently in the writings of Josiah Child who highlighted the effects of national and international migration and brought to the fore also the possibility that higher wage levels may go along with national riches. In contrast to the English emphasis on migration, in France, Boisguilbert and Cantillon took up the question of variations in wages and their effect on accumulation. They, too, while not explaining the level of the wage, took it as a datum to draw out the implications of an increase in wage on agricultural surplus and accumulation. The hypothesis of wage as a necessary part of productive consumption led them to consider the net product and the circular process of reproduction. Boisguilbert argued that a higher wage, cutting into the revenues of the landlord, would inhibit further expansion of agriculture and, in turn, diminish the demand for labour, thus putting a downward pressure on wages to revert to their subsistence level. Agriculture was, for him, the branch of
the economy which conditioned the national economy – a position that continued with the Physiocrats – and wage rises in agriculture and its adverse effects on accumulation would spread to other spheres of the national economy. However Boisguilbert did not discuss the possibility of wages getting depressed below subsistence or analyse its implications. Cantillon (1755) who also developed the important role of the agricultural surpluses in forming and shaping the effective demand for products and, in turn, demand for various categories of labour, emphasized the mechanism by which the numbers of farmers, artisans and labourers adjust their supplies of labour to match the level and pattern of demands. He emphasized the role of territorial migration, intra-occupational mobility and also the population mechanism through which supplies of labour adjusted themselves to needs. This however did not explain the level of the wage norm but only the tendencies towards uniformity. While accepting as given the limitation of wages of the unskilled labourer to the amounts necessary for subsistence, he discussed the wage differentials among various occupations arising from ‘varying conditions and circumstances’ – such as

the number of tradesmen in a given branch of industry, the period of time necessary for learning the trade, the skill and the quality of the labour, the risks and dangers connected with it and finally, the degree of responsibility required of the person entrusted with the performance of a given task. (1755, pp. 25–7)

(An echo of these, we find in Adam Smith's discussion of the natural differences in wages of different labourers.) Unlike his predecessors, Cantillon did give some thought to the content of the subsistence wage and, on certain assumptions (that half the children born die before 17, one-third under one year, and that the labour of the wife, on account of her necessary attendance on the children, is no more than sufficient to provide for herself), he worked out that a worker, to maintain himself and the family, must have double what he requires for his own subsistence, which may be ‘somewhat exceeding that of a slave’.

With the Physiocrats, the assumption of the given necessary wage, constituting part of ‘productive consumption’, being ‘advanced’, played an important role in the theory of production and accumulation. Quesnay argued that a tax on necessaries would inevitably be shifted to entrepreneurs. Further, a ‘high price of bread’ was advantageous, not only to the agriculturists but also to the workers (whose money wages would rise sympathetically). ‘It would’, he argued, ‘encourage agriculture, increase the revenue of the nation, increase the wages of the worker and insure a life of comfort, plenty and convenience which would attract people to the land and keep them where they partake all the advantages’. Contrary effects would follow with constraints on exports or a fall in the price of bread. Quesnay, unlike Boisguilbert, did not stress forces preventing the rise of wages above subsistence. He was concerned, it would seem, more with establishing the harmony of interests among the workers and the agriculturists.

It was, however, Turgot who offered a more complete theoretical treatment of subsistence wages:

The exchange value of food products, profits, the level of wages, and the population are phenomena which are mutually inter-connected and interdependent. The balance among them is established in accordance with a peculiar natural proportion and the proportion is constantly maintained if trade and competition are completely free. (1844, pp. 437–8)
The interaction was visualized as follows. A higher wage (above the natural) increases costs of production, reduces net product, decreases profits. On the other hand, a reduction below the proper level reduces efficiency of labour and also reduces consumption demand, leading eventually to a fall in prices of the produce. A high wage may encourage growth of population or lead to immigration and then, competition among the labourers would tend to lower wages again. Thus for the continued and harmonious economic reproduction, wages and profits must bear a ‘natural proportion’. Thus Turgot attempted to combine, in a complementary fashion, the analysis of Boisguilbert (effect of wage changes on the price of the product, prosperity of entrepreneurs and their demand for labour) and that of Sir Josiah Child (effects of wage changes on migration of labour and its effect on competition).

Somewhat as a reaction to the Physiocratic notion of the ‘natural order’ the writing of Jacques Necker (1775) reflected the political unease of the impending revolution in France. He attributed the tendency of wages to fall to the subsistence minimum to ‘social forces’, particularly to the highly inequitable relationship of power and need that bound the owners ‘who force others to serve them and the propertyless who serve the owners’. The price of labour could adjust to the price of bread only after a time, worsening the state of the worker in the meanwhile. He thus foresaw a ‘dark struggle’ between the owners and the workers. The numerousness of the propertyless, their consequent immediate need and acute competition rendered their bargaining power hopelessly weak, while the growing concentration of property, accentuated further by technical innovations, enhancing productivity of labour but not wages, widened the gap relentlessly. He also pointed out that the accumulation of luxuries at the cost of means of production was leading to a decline in demand for labour. Many of Necker's ideas were to find an echo in Adam Smith.

Steuart (1767) whose approach to wages was more from the point of view of establishing a norm of subsistence for a suitable wage policy beneficial to the development of industry, offered many interesting observations on the process of ‘primitive accumulation’. An interesting contribution on the discussion of subsistence was his distinction between the needs, ‘physically necessary’ and ‘politically necessary’; the former, being ‘ample subsistence where no superfluity is implied’ and the latter, ‘proceeding from the affections of his mind, are formed by habit and education, and when once regularly established create another kind of necessity’ (Steuart, 1767, p. 312). Already the subsistence as strict physiological necessity was being modified with ‘custom’, ‘habit’, ‘rank-based conventions’ playing an important part.

With Adam Smith, Ricardo and Marx, a more integrated view of distribution emerged, along with a distinction between natural wage and market wage. While the forces that tend to put down wages were recognized, the assumption of a fixed wage was replaced by a ‘given’ wage, determined by a complex of historical and economic factors.

The Physiocratic notion of capital as ‘wages advanced’ and the idea that the demand for labour was limited by the provision of subsistence, developed in later classical theory into the concept of wage fund and to an explanation of wage determined by the ‘proportion of capital to labour’. In an entirely different theoretical framework, Böhm-Bawerk used also the notion of subsistence fund to represent given endowments of ‘capital’. In both, the explanation of wage was different from that of the ‘natural wage’.

Economists have found it surprisingly hard to nail down the obvious intuition that in some rough unspecified way tea and coffee are substitutes, and bacon and eggs complements. Not that they can’t do it. Quite the opposite, they have all too many ways of doing it, so much so that even if their less attractive inventions are discarded still an abundance is left, each with its own usefulness and charm. Yet because complementarity and income effects are the two chief impediments to sharp results in microeconomic theory, this question of appropriate definition cannot be shrugged off. Neither does it help that what ‘appropriate’ means tends to vary from problem to problem.

Two important examples exhibit briefly and in turn the fair face of substitutability and the ugly mug of complementarity. In the theory of Walrasian adjustment processes for multiple markets, a famous result traceable in its origins to Metzler (1945) is that if all commodities are (gross) market substitutes then equilibrium is reached from any initial position, i.e. the system is globally stable (see Negishi, 1962). Secondly, in capital theory Hatta (1976) has shown that in order for the output/labour ratio to fall as the interest rate falls, i.e. in order for capital perversities to appear, it is necessary that at least one input pair be (net) complements, which in turn implies that there must be at least three inputs in total.

Despite these examples and purely for reasons of space, this essay will concentrate entirely on substitution and complementarity in the theory of consumer’s demand, to the neglect of production. In doing this it differs only in degree rather than kind from the literature of the subject, of which surveys may be found in Schultz (1938, pp. 22–4, and chs 18 and 19, written with the help of Milton Friedman), Stigler (1950, section VI; reprinted in 1965), Georgescu-Roegen (1952) and Samuelson (1974).

Two further disclaimers are in order. Neither the important role in the Austrian theory of value played by what Menger called complementary goods (e.g. 1950, ch. I.3), nor the question of the relations between complementarity and changes in tastes or endowments (begun by Lange, 1940, and analysed by Hicks, 1956, pp. 161–8) is discussed here.

I The Auspitz–Lieben Definitions

Passing recognition that certain pairs of goods can be called substitutes and other pairs complements
must have occurred ever since economics became a serious subject. However, that is far from developing formal definitions and results. A clear though crude attempt to derive explicit comparative static propositions for substitutes and ‘co-elements’ may be found in chapter IX of Donisthorpe (1876) but a more adequate theory had to await formulation of utility functions in general form, i.e. \( u(x, y, \ldots) \), rather than in the additively separable form \( u^1(x) + u^2(y) + \ldots \) employed for example by Jevons.

So it is not unexpected that the first hint of a definition is to be found in *Mathematical Psychics* (1881, p. 34). Edgeworth was concerned to prove that his newly-minted indifference curves between ‘sacrifice objectively measured’ \( x \), and ‘objectively measured remuneration’ \( y \), were convex. Writing \( u_x, u_{xx}, \ldots \) for \( \frac{\partial u}{\partial x}, \frac{\partial^2 u}{\partial x^2}, \text{etc.} \), Edgeworth’s five assumptions may be expressed:

\[ u_x < 0, \quad u_y > 0, \quad u_{xx}, \quad u_{yy}, \quad \text{and} \quad u_{xy} \text{ all ‘continually negative. (Attention is solicited to the interpretation of the third condition.)’} \]

Maddeningly, he stopped right there. Here, the invited attention will be delayed for two paragraphs.

At various times Fisher (1892, Part II), Edgeworth (1897, p. 21; 1925, Vol. I, p. 117 n.1), and Pareto (e. g. 1927, pp. 268–9, 575–6) have each been said to have introduced the first formal definitions of substitutes and complements. However, Stigler (1950; 1965, p. 131) pointed out that in fact the credit belongs to Auspitz and Lieben (1889, p. 482; 1914, Texte, pp. 318–19), for whom two commodities \( x \) and \( y \) were complements, independent, or competitive according as

\[ u_{xy} > 0; \quad u_{xy} = 0; \quad u_{xy} < 0; \]

These A–L definitions (as they will be called here) have three important virtues and one fatal flaw. First, they are intuitively appealing. It seems commonsensical to say that \( y \) is a complement of \( x \) if an increase in the latter raises the marginal utility of the former, and so on. Secondly, for sufficiently smooth utility functions Young’s Theorem implies that always \( u_{xy} = u_{yx} \), so that the A–L definitions are symmetrical; if (and only if) \( x \) is a substitute for \( y \) then \( y \) is a substitute for \( x \). Finally, the relations between any pair of commodities involve only that pair alone and the individual agent. In particular, they do not ‘depend upon the incidents of a comparatively advanced regime, such as the distribution of money among different purchases’ (Edgeworth, 1925, Vol. II, p. 465), i.e. they do not depend upon market phenomena. For positivistically inclined economists like Slutsky ([1915] 1951, pp. 52–56) this last property appeared more vice than virtue.

However, the flaw truly is (as Bertrand would say) ‘une objection peremptoire’. Suppose that \( u \) is transformed to \( v = F(u) \), where \( F' > 0 \). Then \( u_x \) is transformed to \( v_x = F' u_x \) and \( u_{xx} \) to

\[ v_{xx} = F' u_{xx} + F'' u_x^2 \]

and similarly for \( u_y \) and \( u_{yy} \), respectively; in particular, \( u_{xy} \) is changed to

\[ v_{xy} = F' u_{xy} + F'' u_x u_y \].

So by cunning choice of \( F \) the sign of \( u_{xy} \) can be changed. For example, \( F \) can be taken to be very convex by making \( F'' \) positive and large, in this way changing a negative \( u_{xy} \) into a positive \( v_{xy} \). Substitutes can be made complements, or complements substitutes, all without any change.
Substitutes and complements: The New Palgrave Dictionary of Economics

occurring in the agent's tastes. The A–L definitions are therefore meaningless in any theory of demand that abandons cardinal utility.

Now to interpret Edgeworth's assumption \( u_{xy} < 0 \). According to the A–L definitions, \( u_{xy} < 0 \) means that sacrifice \( x \) is a substitute for remuneration \( y \); increasing the amount of labour supplied, for example, lowers the marginal utility of the commodity received, so that leisure (non-labour) is then a complement for \( y \) (c.f. Stigler, 1965, p. 99, fn 84). While the argument of the last paragraph would seem to imply that this A–L interpretation is obviously meaningless, as so often with Edgeworth matters are actually rather more subtle. His sufficient condition \( C \) for strict convexity of indifference curves, given in (1881, pp. 35–6), is indeed the same as the modern strong quasiconcavity condition on the bordered Hessian of \( u \), as given by Hicks (1939, p. 306). Hence \( C \) is invariant under strictly monotonic transformations \( F \), and so one cannot pick \( F \) merely to change from \( u_{xy} < 0 \) to \( v_{xy} > 0 \). The \( F \) chosen to do this trick must also simultaneously transform \( u_x, u_y, u_{xx}, \) and \( u_{yy} \) in such a way as to preserve \( C \) as well.

II Johnson and after

Pareto himself, so vehement against cardinal utility, seems never to have seen the inconsistency between that epistemological position and his continued use of the A–L definitions, and in this he was followed by Zawadzki (1914, pp. 171–4). But not by Slutsky, who was quite explicit that the A–L definitions were meaningless in his radically new theory of demand ([1915] 1951, pp. 54–5). However, unlike Hicks and Allen (1934) he did not see the possibilities, opened up by the new theory, of defining substitutes and complements in a way free of dependence on cardinally measurable utility.

One reason for this omission may have been Slutsky's apparent unawareness of the work of the logician W.E. Johnson (1913; 1968) who, from the partial-equilibrium isolation of Cambridge and without specific reference to anybody else, had already offered definitions not dependent on a particular utility index. Let \( V = u_x / u_y \) and \( W = V^{-1} \), so that in Hicks–Allen language \( V \) is the marginal rate of substitution of \( y \) for \( x \). Then Johnson (1968, 108) defined \( x \) and \( y \) to be complementary if both \( \partial V / \partial x \) and \( \partial W / \partial y \) are negative, while they are competitive if either \( \partial V / \partial x \) or (disjunctively) \( \partial W / \partial y \) is positive. He shows later (p. 114) that, at least in the case of two goods, \( x \) and \( y \) are complementary if and only if (iff) each of them is normal (i.e. has a positive income elasticity), whereas \( \partial V / \partial x > 0 (\partial W / \partial y > 0) \) holds iff \( x \) is normal (inferior) and \( y \) inferior (normal).

These definitions are clearly invariant to permissible transforms of \( u \), and equally obviously symmetrical; moreover, they are at least formally independent of market phenomena. The main difficulties in accepting them are their lack of intuitive appeal (which Johnson did nothing to mitigate) and their excessively stringent implications. An ex post facto rationalization of the definition of complements can however be given, using arguments couched in the language of cardinally measurable utility (a similar account can be given of his substitutes). Thus an increase in \( x \) has two effects: (a) If \( y \) is a complement of \( x \) in the rough everyday sense, then as in the A–L case we would expect \( u_y \) to rise, and hence the rate of compensation for the loss of \( x \) by this now more highly valued \( y \) to fall; and (b) By the law of diminishing marginal utility \( u_x \) is lowered, and so again this reduces the necessary rate of compensation by \( y \) for the loss of \( x \).

The implication that if both goods are normal they must be Johnsonian complements seems
unacceptably restrictive, though perhaps little more so than the conclusion that if there are only two goods they must be Hicks–Allen substitutes. The latter result has of course been familiar and broadly accepted for over half a century, though not without serious criticism (see e.g. Pearce, 1958, pp. 136ff). The textbook definitions of substitutes and complements used today first appeared in Hicks and Allen (1934), although recent versions are much simpler and more transparent than the original. Given that their work was in large part a response to the lack of invariance of the A–L definitions (Hicks, 1981, p. 27, fn42), it is not surprising that substitution and complementarity played so prominent (to modern eyes, too prominent) a role in both parts of their paper. Moreover, Hicks’ ‘literary’ expositions of this topic, not only in (1934) but also in (1939, ch. 3) and (1956, ch. 16), seem overly complex and unrelated to his mathematical expositions, to such a degree that Samuelson (1947, pp. 183–9) was led to allege actual inconsistencies between them, a criticism that he later formally withdrew (1950, p. 379, fnl; 1974, p. 1286).

One reason why it is hard to understand Hicks's analysis is that he works always with a numéraire commodity (‘money’), which itself enters into the agent's preferences. Thus in considering Hicks–Allen substitutability between a pair of goods \( x \) and \( y \), for example, he has to consider the effect of a change in the ‘money’ price of \( x \) on the compensated demand for \( y \), which necessarily involves three goods, \( x, y \) and ‘money’, not two. It is simpler and clearer to treat all goods symmetrically, by normalizing their prices not by use of a numéraire but by income or total expenditure, assumed always to be positive. Such a normalization will be used throughout the next section, even though that prevents any direct comparison of its analysis with much of the earlier literature on the subject, especially that influenced by Hicks.

### III Some modern definitions

Assume that the representative agent (trader, consumer) has preferences \( \succeq \) defined over the commodity space \( \mathbb{R}^n \), and focus attention on his (or her) “target” bundle \( z^t=(x^t, y^t, \ldots) \), assumed for present purposes to be given exogenously. Then his “better set” \( B^t \) is \( \{z: z \in \mathbb{R}^n, z \succ z^t\} \), which will be assumed always to be convex, closed and such that if \( z \) is in it then so is \( \lambda z \) for all \( \lambda \geq 1 \). If preferences are incomplete a utility function will not exist, but in any case those preferences can be represented by an \( s \)-gauge function for \( B^t \), defined as follows (see the entry on GAUGE FUNCTIONS):

\[
 j\left( z \mid z^t \right) = \sup \{ \mu > 0: z \in \mu B^t \} \text{ if } z \neq \emptyset = 0 \text{ if } z = \emptyset
\]

(1)

where \( O \) denotes the origin. This function \( j( \cdot \mid z^t) \) is a generalization of the so-called distance function, discussed for example in Deaton (1979) and Deaton and Muellbauer (1980, pp. 53–7). It is easy to show that it is concave and positively homogeneous of degree 1 (phd1) in \( z \). Next, assume that the agent faces
a vector of prices \( p=(p_x, p_y, \ldots) \) determined on competitive markets, and give him the following problem of cost-minimization for the target \( z' \):

Find \( z \in \mathbb{R}^n \) that achieves \( \inf(z, p) \) subject to \( z \in B^t \) where \( \langle \ldots \rangle \) denotes the inner product of \( z \) and \( p \). The value of any solution to this problem is functionally dependent on its parameters \( p \) and \( z' \), a fact summarized by writing down the expenditure function \( e(p+z') \). Assume now and always that \( e(p+z') \) is positive and divide each market price by this amount, thus arriving at a vector of normalized (indeed personalized) prices \( w=(w_x, w_y, \ldots) \). Following this normalization, the function \( e(\cdot \mid z') \) becomes the cost function \( \ell(\cdot \mid z') \), where \( \ell(w|z')=1 \), a pure number. This function is concave and \( \phi \delta \lambda \) in \( w \), and is actually the (concave) support function of \( B^t \).

So defined, the \( s \)-gauge and cost functions are dual to each other, in the sense that under general conditions \( \ell(\cdot \mid z') \) is the \( s \)-gauge function of the set \( B^{t*} \) in the (normalized) price space that is polar to \( B^t \); and dually, under similar conditions \( \gamma(\cdot \mid z') \) is the concave support function of \( B^{t*} \).

We can now expeditiously set out various modern definitions of substitutes and complements. For this purpose I will assume where necessary and without blushing that each function concerned is as differentiable as desired.

A Hicks-Allen

By the well-known Shephard's Lemma, the compensated or Hicksian demand function \( h_i \) for the \( i \)th commodity is given by

\[
\forall i h_i(\mathbf{w} z^t) = \partial \ell(\mathbf{w} + z^t) / \partial w_i
\]

(2)

Then good \( x \) is a substitute (net or Hicks-Allen substitute) for good \( y \) if

\[
\partial h_x(\mathbf{w} z^t) / \partial w_y > 0
\]

(3)

i.e. increasing the price of \( y \) leads the agent to buy more \( x \), all the time keeping to the better set \( B^t \) and minimizing the cost of doing so (as Marshall would say, obeying the Law of Substitution). Similarly, \( x \) is a complement (net or Hicks–Allen complement) if the inequality in (3) is reversed; otherwise, \( x \) is independent of \( y \).
It follows from (2) and (3) that it is equivalent to say that \( x \) is a substitute for \( y \) if

\[
\partial^2 \varepsilon(\mathbf{w}z^t) / \partial w_y \partial w_x > 0
\]  
(4)

For sufficiently smooth \( \varepsilon(\cdot | z^t) \), the left-hand-side (LHS) of (4) is the same as \( \partial^2 \varepsilon(\mathbf{w}z^t) / \partial w_x \partial w_y \), from which it follows that if \( x \) is a substitute (complement, independent) of \( y \), then \( y \) is a substitute (complement, independent) of \( x \). The Hicks-Allen definitions are symmetrical.

Since \( \varepsilon(\cdot | z^t) \) is phd1 it follows from (2) that \( h_i(\cdot | z^t) \) is phd0, and thence from Euler’s Theorem that

\[
\forall i \left[ w_i \nabla h_i(\mathbf{w}z^t) \right] = 0
\]  
(5)

Because \( \varepsilon(\cdot | z^t) \) is concave, \( \partial^2 \varepsilon(\mathbf{w}z^t) \partial w_i^2 \geq 0 \) for every \( i \). So it follows from this and (5) that, taking the summation over all \( j=1, 2, \ldots, n-1 \) for \( j \neq i \),

\[
\forall i \sum w_j \partial h_i(\mathbf{w}z^t) / \partial w_j \geq 0
\]  
(6)

Hence, while all goods can be substitutes for each other, it cannot happen that all goods are complements, for that would imply the negation of the inequality in (6). It is in this sense that, in a Hicks-Allen world, substitution predominates. Moreover, in the two good \((x, y)\) case (6) implies that \( \partial h_x(w + z^t) / \partial w_y \geq 0 \), so that \( x \) and \( y \) cannot ever be complements. An extension of this reasoning shows that in the three good case, at most one pair of goods can be complements; and so on.

B Hicks–Deaton

By design, the \( s \)-gauge function \( j(\cdot | z^t) \) has just the same mathematical properties as its polar transform \( \varepsilon(\cdot | z^t) \). So the following result is polar to Shephard’s Lemma and is obtained in precisely the same way
substitutes and complements: The New Palgrave Dictionary of Economics (cf Deaton, 1979, 394):

\[ \forall i \omega_i = \partial j \left( z_i z^t \right) / \partial z_i \]

(7)

The interpretation of (7) is that it yields the compensated or Hicksian inverse demand functions. Roughly speaking, these show how the “marginal valuation” of (or the “marginal-willingness-to-pay” for) good \( i \) varies, as one moves around the lower boundary of \( B^t \) (see Hicks, 1956, ch. 16, which uses a numéraire, and Deaton, 1979, which does not). Note the similarities to and contrasts with the definitions of Johnson, which did not involve movements around this lower boundary but, instead, movements away from it.

Denote these inverse Hicksian functions by \( H_i \), so that from (7)

\[ \forall i H_i \left( z_i z^t \right) = \partial j \left( z_i z^t \right) / \partial z_i \]

(8)

If \( x \) and \( y \) are complements in the rough everyday sense, one would expect that as one has more \( y \) one would be willing to pay more for a marginal unit of \( x \), while if they are substitutes one would be willing to pay less. This is the intuitive basis for the following Hicks–Deaton definitions. A good \( x \) is a \( q \)-substitute for \( y \) if \( \partial H_x (z_i z^t) / \partial y < 0 \), and a \( q \)-complement if this inequality is reversed; otherwise, \( x \) and \( y \) are \( q \)-independent (the language, though not the precise definitions, is due to Hicks, 1956, ch. 16).

From (7) and (8) these definitions are symmetrical.

Since \( j( \cdot | z^t) \) is phd1 each \( H_i( \cdot | z^t) \) is phd0. From this and the fact that \( j( \cdot | z^t) \) is concave, analogues to (5) and (6) are readily derived and imply, for example, that in the Hicks–Deaton world \( q \)-complements predominate, and that in a two-good world there cannot be \( q \)-substitutes. It obviously follows that it is not true in general that if \( x \) and \( y \) are Hicks–Allen substitutes then they are \( q \)-substitutes, and similarly for the two definitions of complements.

Note that the gradient mappings \( \nabla j( \cdot | z^t) \) and \( \nabla \epsilon( \cdot | z^t) \) are inverse to each other, a property which persists even when compensated demand functions (direct and inverse) are generalized to compensated demand correspondences (see Theorem 9 in the entry on GAUGE FUNCTIONS).

**C Samuelson's money-metric definitions**

Samuelson (1974, pp. 1272–3) proposed the following ‘local measure of money-metric
Substitutes and complements: The New Palgrave Dictionary of Economics

The good $x$ is a substitute for, independent of, or a complement of $y$, according as $\partial^2 \mathcal{E}(\mathbf{w}^*) / \partial x \partial y$ is negative, zero, or positive, i.e. the test criterion is the behaviour of (minimized) cost as the target bundle $z'$ is varied. The original paper should be consulted for Samuelson's rationale of this measure, which does not appear to have become popular.

IV Gross substitutes and complements

Stigler (1950; 1965, pp. 134–5) argued that once the intuitively appealing A–L definitions have succumbed to the ordinalist critique, there is no point in stopping at such halfway non-intuitive houses as the Johnson or the Hicks–Allen definitions. Instead, one should go the whole way to ‘simple criteria such as the cross-elasticity of demand’, moving completely from psychological to market data.

For individual ordinary (Marshallian) demand functions $z_i = f_i(p, \omega)$, $i=1, 2, \ldots, n$, where $w$ is the individual's wealth and prices are normalized by a numeraire, these criteria in essence reduce to the following definitions, given originally by Mosak (1944, p. 45): A good $x$ is a \textit{gross substitute} for $y$ if $\partial f_x(p, \omega) / \partial p y$ is positive, a \textit{gross complement} if it is negative, and \textit{independent} of $y$ otherwise.

Actually, in Mosak's original definitions these three situations corresponded not to $x$ being a gross substitute for $y$, etc., but to $y$ being a gross substitute for $x$, etc. Subsequent literature has continued this ambiguity, which is by no means trivial, for the chief problem with these ‘simple criteria’ is that they are not symmetrical. Hence $x$ can be a gross complement for $y$, and $y$ simultaneously a gross substitute for $x$, a highly non-intuitive state of affairs.

The proof of such possible non-symmetry is standard textbook fare and so is only quickly sketched here. The standard Hicks decomposition of the effect on the (ordinary) demand for a good $x$ of a simple price change in a good $y$, utility level $\tau^*$ and chosen bundle $z^* = (x^*, y^*, \ldots)$ is,

$$\partial f_x(p, \omega) / \partial p y = \partial h_x\left(p, \tau^*\right) / \partial p y - \gamma^* \partial f_x(p, \omega) / \partial \omega$$

Suppose $x$ is a gross substitute for $y$, so that the LHS of (9) is positive. Suppose also that $x$ is a Hicks–Allen substitute for $y$, so that the first term on the RHS is also positive ($h_x$ being the compensated demand function for $x$). Consider now the similar Hicks decomposition for good $y$. By the symmetry of Hicks–Allen substitutes the first term on its RHS will be the same as the corresponding term of (9), and so positive. But if $y$ is a normal good and $x^*$ sufficiently large, then the whole RHS might be negative, and so $y$ a gross complement for $x$. If on the other hand $x$ is a Hicks–Allen complement for $y$ the first term on the RHS of the decomposition for $y$ will be negative, and so if it is a normal good, again it will be a gross complement for $x$.

Given a fixed distribution of endowments the individual ordinary demand functions for each good may be aggregated to a market demand function (or an excess demand function) for that good, and gross substitutes and complements then defined in terms of these market functions, as done for example by
Metzler (1945). Mosak (1944, pp. 46–7) inverted such market functions and defined ‘gross complementarity [and substitutability] in the inverse sense’, which differs from ordinary gross complementarity in very roughly the same way that q-complements differ from Hicks–Allen complements.

The sugar industry is the set of firms involved in processing sugar from sugar cane or sugar beets and distributing it to consumers. The industry is both ancient and modern. Sugar production has occurred for thousands of years. But the developments since 1880 have received the most attention from economists. Over subsequent decades, the industry experienced several structural changes and legal regimes. The industry’s evolution provides a window into central questions such as the sources of market power, and the theory of the firm. Much of this research has focused on the United States, although it was a global industry.

A firm or a group of firms is able to exercise market power when they are able to charge prices above marginal cost and earn supra-competitive profits over a prolonged period of time. One possible source of market power is through mergers with competitors. In the United States, the trust movement and the merger wave at the turn of the 20th century were early and dramatic attempts. In 1887, the Sugar Trust was formed, later reorganized as the American Sugar Refining Company (ASRC). Eichner’s exhaustive study (1969) details the rise of ASRC, its attempts to maintain its market power as a dominant firm, its decline in market share in part due to an antitrust action, and its subsequent position as an oligopoly leader.

For a firm to retain market power, it must prevent entry from eroding its profits. After 1887, two major entry episodes sparked price wars. Zerbe (1969) interprets this as a return to competition. In contrast, Genesove and Mullin (2006) agree with Eichner (1969) that ASRC's actions were predatory. Genesove and Mullin (2006) show that price fell below direct measures of marginal cost, and below counterfactual competitive prices. Predation forced the prey to sell out on favourable terms, and may have
Sugar industry: The New Palgrave Dictionary of Economics

deterred future entry. Predation worked by strengthening ASRC's reputation.

An important empirical issue is how to measure or infer market power when a researcher is unable to
observe marginal cost, and therefore the price–cost margin. A large literature uses static oligopoly
models to estimate market conduct and unobserved cost components. Genesove and Mullin (1998)
evaluate this approach by comparing the estimated measures to direct measures. The approach is largely
validated, although partial cost information can still be useful.

Besides attempts by a single firm to achieve market dominance, market power may also be created by a

group of firms acting collusively, or attempting to soften competition between themselves. That was the
primary aim of the Sugar Institute, a trade association of cane sugar refiners that operated from 1928 to
1936. During that time, price fixing was illegal, but non-price agreements and non-price discussions
were permitted. Genesove and Mullin (2001) explore the theory of collusion by a detailed examination of the Institute's
workings as revealed by the internal business memoranda prepared by one of its participants. The
analysis reveals how firms may alter their environment to enhance the probability of detecting price-
cutting through both specific rules and institutional structure. In particular, the Institute served as a
forum for communication. In practice, these communications provided advance notification of changes
in business practices, a method of coordinating behaviour, and determination of guilt when a firm was
accused of violating the industry's Code of Ethics.

The Institute also facilitated the exchange of firm-level information. The Institute collected production
and delivery data from the individual firms and returned them in aggregated form. But attempts to
exchange sales data were stymied by the larger firms, and so firm heterogeneity was an important
impediment to more successful information sharing (Genesove and Mullin, 1999).

The sugar industry had important international dimensions.
The early 20th century saw intense and visible debate in the United States on trade policy. Ellison and
Mullin (1995) examine the factors, such as location of corporate headquarters, constituent employment
in the sugar industry, and constituent shareholding in sugar firms, that affected legislators’ votes on
sugar tariff legislation. They find that political efficacy lay in large, unconcentrated interest groups, such
as sugar cane and beet farmers. Ironically, the latter groups would not have existed absent prior
protective tariff legislation (Krueger, 1990).

Sugar cane was best grown and processed into raw sugar in the tropics. Dye (1998) shows that much of
the development of the Cuban sugar industry can be explained by modern theories of the firm. For
example, the adoption of new technologies by mills was strongly influenced by asset-specificity
concerns as predicted by transaction cost economics.

sunspot equilibrium

Karl Shell
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

‘Sunspots’ is short for an extrinsic random variable, that is, one that does not affect economic fundamentals but can affect economic outcomes. Sunspots are said to matter when the allocation of resources depends in a non-trivial way on the realization of the sunspot random variable. Sunspot equilibria are instances of ‘excess volatility’. They arise even when expectations are fully rational. Separate sources of sunspot equilibria include unbounded time horizons, incomplete markets, restricted market participation, imperfect competition, non-convexities, externalities, asymmetric information and financial indeterminacy. Sunspot equilibria are typically not mere randomizations over certainty equilibria.

Article

The volatility of market outcomes such as the price level, stock market prices, unemployment rates, interest rates, and exchange rates and what to do about this are important subjects in macroeconomics. Some of the observed randomness in market outcomes is the result of shocks to the fundamentals (preferences, technologies, and endowments) that are transmitted through the economy. Uncertainty about the economic fundamentals is intrinsic uncertainty. The general-equilibrium model extended by Arrow (1953; 1964) to include uncertainty provides an explanation of how volatility in the fundamentals is transmitted through the economy, resulting in volatile prices and quantities. This is not the only possible source of the volatility in economic outcomes. The market economy is a social system. In attempting to optimize her own actions, each agent must attempt to predict the actions of the other agents. A, in forecasting the market strategy of B, must forecast B’s forecasts of the forecasts of others including those of A herself. An entrepreneur is uncertain about the moves of his customers and his rivals, and they of his moves. It is not surprising that this process may generate uncertainty in outcomes even in the extreme case in which the fundamentals are non-stochastic. The uncertainty generated by the economy is market uncertainty. It is either created by the economy or adopted from outside the economy as a means of coordinating the plans of individual agents. Market uncertainty is not transmitted through the fundamentals. It can be driven by extrinsic uncertainty.

Extrinsic uncertainty

‘Sunspots’ is shorthand for ‘the extrinsic random variable’ (or ‘extrinsic randomizing device’) upon which agents coordinate their decisions. In a proper sunspot equilibrium, the allocation of resources depends in a non-trivial way on sunspots. In this case, we say that sunspots matter; otherwise, sunspots do not matter. Sunspot equilibrium was introduced by
Cass and Shell (see Shell, 1977; Cass and Shell, 1982, 1983). Sunspot models are complete general-equilibrium models that offer an explanation of excess volatility. It was by no means a new idea that economies can and do generate excess volatility, but the sunspots model is the first general-equilibrium model to exhibit excess volatility even when agents are fully rational. The sunspots model also allows for non-rational agents, but the excess volatility from this source – while possibly empirically substantial – is less novel. ‘Sunspots’ is an unfair spoof on Jevons (1884), who in serious empirical work attempted to explain the business cycle by relating it to the observed (through telescopes) cycle of actual sunspot activity. To the extent that actual sunspot activity does affect economic fundamentals (such as crop yields and cancer risk), this is an instance of intrinsic uncertainty, but the effects of actual sunspots on fundamentals are probably very small. If actual sunspots have only a minor effect on the fundamentals, but they do have a substantial effect on the economy, they must serve a role in the economy beyond their effects on the fundamentals. Manuelli and Peck (1992) show that a sunspot equilibrium can be interpreted as the limit of traditional rational-expectations equilibria as the uncertainty in the fundamentals vanishes (see Spear, Srivastava and Woodford, 1990). Roughly speaking, ‘Jevons equilibrium’ becomes ‘Cass–Shell equilibrium’ as the effects of actual solar activity on the fundamentals disappear. Cass–Shell sunspot equilibria are easy to interpret because in the basic sunspots models the only uncertainty is extrinsic uncertainty; hence any volatility in outcomes is excess volatility. Engineers compute ‘gain’ in noise as the volatility of the output signal divided by the volatility of the input signal. In a sunspot equilibrium, the gain is $+\infty$.

**Overlapping generations sunspots**

The first sunspots model, Shell (1977), is of an overlapping-generations exchange economy with taxes and transfers denominated in fiat money. This OG model is based on the very simple (degenerate) example used in Shell (1971) to show that restrictions on market participation are inessential in the Samuelson perfect-foresight (non-stochastic) OG model. The only stochastic element in the 1977 paper is sunspot-driven extrinsic uncertainty about the price level. Shell used the fact that there is a continuum of equilibria (parameterized by the initial price level) in the non-sunspots version to construct the sunspot equilibrium allocation by a bootstrap method. This particular sunspot equilibrium, while bootstrapped from multiple certainty equilibria, is not a mere randomization over certainty equilibria, contrary to what some popularizers of sunspot equilibrium have claimed. Sunspot equilibria can be randomizations over certainty equilibria, but typically they are not. In unpublished work in about 1975, Cass and Shell generalized the OG sunspots analysis from the degenerate linear model to the concave-utility-function OG model of Gale (1973). Peck (1988) showed that, for the ‘Samuelson’ and related cases in the OG economy, sunspots can be active in every period for economies with even non-stationary environments.

Azariadis (1981) translated the pure-exchange OG model into a macro-oriented Lucas-style OG model with capital investment and endogenous labour supply. Azariadis showed instances – based on a backward-bending offer curve – of economies that exhibit long-run stationary sunspot cycles. Azariadis and Guesnerie (1986) employed the backward-bending offer curve to exhibit economies with long-run deterministic cycles. They thus established a link between sunspot cycles and deterministic cycles. Roughly speaking, if there is room to condition expectations on sunspots, there is also room to condition them on calendar time and vice versa (see Cass and Shell, 1980).

**Sunspot immunity**

To better understand how sunspot equilibria arise, consider two simple, related examples. In the first, the economy is immune from sunspots. In the second, all competitive equilibria are sunspot equilibria. Consider the two-consumer, one-good, two-states-of-nature, competitive exchange economy. Draw the Edgeworth box. Measure consumption $x$ in state $\alpha$ (‘sunspots’) on the horizontal and consumption in state $\beta$ (‘no sunspots’) on the vertical. Endowments $\omega$ lie on the minor diagonal, because endowments are by definition independent of the state of nature. For the same reason, the Edgeworth box is a square. Assume that consumers possess smooth, strictly concave von Neumann–Morgensten utility functions. Competitive equilibrium exists. There are two cases: (1) Consumers share the same probability beliefs $\pi$ about the occurrence of sunspots. Indifference curve tangency and hence competitive equilibrium occurs only on the minor diagonal with contingent claims prices $p$ proportional to the probabilities $\pi$. Sunspots do not matter. This is an instance of the **Cass–Shell sunspot immunity theorem** (1983, Proposition 3). It holds when the box is square, that is, whenever there is no aggregate uncertainty (Figure 1).

**Figure 1**

Sunspots do not matter

![Diagram](http://www.dictionaryofeconomics.com/library/lemoyne.edu/article?id=pde2008_S000325&goto=S&result_number=1679)
The slope of the line is given by: 
\[
\text{slope} = - \frac{\pi(\alpha)}{\pi(\beta)}
\]
(2) Consumers differ in their beliefs. Indifference curves will be tangent to each other but always off the minor diagonal. Sunspots matter (Figure 2).

Figure 2
Sunspots matter

\[
\pi_h(\alpha) = \pi(\alpha) \text{ and } \omega_h(\alpha) = \omega_h(\beta) \text{ for } h = 1, 2
\]
Heterogeneity of (probability) beliefs is a source of sunspot equilibria, but it is hardly the only source. The sunspots immunity theorem is based on a finite model with strictly convex preferences and convex production and a full range of perfectly competitive markets. Any departure from these assumptions could be a possible source of sunspots that matter. (See Shell, 1987, p. 550, for the so-called Philadelphia Pholk ‘Theorem’ on how to find sunspots that matter.) For example, the usual overlapping-generations models (including the one in Shell, 1977) fail to fit the assumptions of the immunity theorem in three ways.

1. **There are restrictions on participation in the securities markets.** If a random variable is realized before your birth, you cannot buy securities dependent on its realization; see Cass and Shell (1983) for analysis of sunspot equilibria caused solely by restricted market participation. Balasko, Cass and Shell (1995) also focus on restrictions on market participation. If there are no (or sufficiently few) restricted agents, then sunspots do not matter in convex, finite economies. If all individuals are restricted, then sunspot equilibria are randomizations over non-sunspot equilibria. Otherwise, the typical sunspot equilibrium is not a mere lottery over non-sunspot equilibria.

2. **The securities market is incomplete.** There is only one money. Completeness of the market would require instead state-contingent Arrow securities for each state of nature at each date. General equilibrium with incomplete markets, sometimes studied under the acronym GEI, is an important area in financial economics that was spawned by the sunspot-equilibrium model. Cass (1989; 1992), Balasko and Cass (1989), and others have played central roles in developing the GEI model and placing it in the sunspots-equilibrium literature. It is worth noting, however, that incomplete markets do not necessarily lead to sunspot equilibria; see, for example, Antinolfi and Keister (1998), who show that with only a few options (puts and calls) with the right strike prices the economy can be immune from sunspots even when there are many sunspot states of nature.

3. **The OG model is not a finite model.** There are a countable number of individuals and a countable number of dated commodities. There can be sunspot equilibria in the OG economy even if we assume that markets are completed with Arrow securities for every state and every date, and that, contrary to actual biology and demography, agents are not restricted in the trades of these securities. In this thought experiment, they can even buy securities to hedge against events that occur before their natural lifetimes (see Cass and Shell, 1989). The unbounded horizon permits bubbles in the form of public debt that need not be retired. If a bubble is possible in an infinite-horizon economy, then it is likely that there can also be a stochastic (or sunspot) bubble. The infinite horizon is in itself a source of sunspot equilibria. Sunspots can be an imperfect substitute for fiat money in the ‘Samuelson’ case of the OG model (see Cass and Shell, 1989).
Each of these three departures from the finite, perfect-market competitive equilibrium economy is in itself a separate source of sunspot equilibrium allocations. So the OG model is a natural and – it turns out – a relatively easy place to find sunspots that matter. It is also natural to expect that non-convexities create a role for sunspot equilibria. Random allocations would seem to offer the possibility of at least partially ‘convexifying’ the certainty economy. This turns out to be the case. Shell and Wright (1993) analyse sunspot equilibria in competitive, exchange economies with an indivisible good. They show that the Rogerson (1988) indivisible-labour lottery equilibrium can be decentralized as a sunspot equilibrium even in finite economies (as well as in continuum-of-agents economies). Unlike the situation in the finite, convex economy, (1) sunspot equilibrium allocations in these non-convex economies are Pareto optimal among stochastic allocations and often strictly dominate the best allocations available in the related economy that does not have access to randomization; (2) the certainty allocations do not necessarily reappear in the sunspots model as non-sunspot equilibrium allocations. Goenka and Shell (1997b) extend the Shell–Wright analysis to non-convex production (see also Goenka and Shell, 1997a). An earlier paper on sunspots in non-convex economies is Guesnerie and Laffont (1991). Indivisible labour and sunspots are central to a recent contribution to the theory of money and search (see Rocheteau et al., 2007). Previous monetary search models have required for tractability the apparently restrictive assumption that agents possess quasi-linear utility functions. If one assumes that labour is indivisible and is allocated to work or leisure by a sunspot process, then von Neumann–Morgenstern agents act as if their utilities are quasi-linear.

Lotteries and sunspots

What is the relationship between the sunspot-equilibrium concept and the lottery-equilibrium concept introduced by Prescott and Townsend (1984a; 1984b)? The original motivations for the two concepts were very different. The first sunspot papers focused on stochastic allocations that are Pareto non-optimal, cases where sunspots lead to inefficient allocations because of restrictions on market participation, incomplete markets, the infinite horizon, or imperfect competition. The first Prescott–Townsend lottery equilibrium papers focused on random allocations that partially remedy the effects of ‘non-convexities’ in the certainty economy due to moral hazard constraints. Because sunspots form the basis for coordination of individual plans, the sunspot equilibrium notion is directly applicable in economies with few agents, many agents, or even a continuum of agents. The original lottery equilibrium notion was applicable only to economies with a continuum of agents, in which detailed coordination is not necessary because of the law of large numbers. An important formal difference between these two stochastic equilibrium concepts is based on how commodities are defined. In the sunspots model, the commodity might be chocolate delivered in state α. In the lottery model, the commodity might be chocolate delivered with probability ρ. If the sunspot random variable used in each case is continuous (that is, has a non-atomic density function), then lottery equilibrium allocations are always sunspot equilibrium allocations (see Garratt et al., 2002). For lottery equilibria to make sense in finite economies (without the law of large numbers), the lottery equilibrium notion must be suitably adjusted as in Garratt (1995) to ensure that in equilibrium materials balance for every realization of the randomizing device. After making the Garratt adjustment, it is shown by Garratt et al. (2002) that for economies with a finite number of agents or a continuum of agents, and a continuous randomizing device, the set of sunspot equilibrium allocations is identical to the set of lottery equilibrium allocations. Garratt, Keister and Shell (2004) show that this equivalence does not always hold when the randomizing device is finite. Keohoe, Levine and Prescott (2002) establish the equivalence of sunspot equilibrium allocations and lottery equilibrium allocations in economies with a continuum of agents facing ‘non-convexities’ caused by moral hazard constraints. Prescott and Shell (2002) provide a review of the sunspot and lottery literatures and attempt to highlight the relatively strong similarities and the non-trivial differences between the two concepts.

Imperfect competition, correlated equilibria and sunspot equilibria

While the notion of sunspot equilibrium was not immediately accepted by macroeconomists, game theorists were not at all shocked by the idea of stochastic outcomes in non-stochastic environments. Think mixed strategy and – more generally – correlated equilibrium. Peck and Shell (1991) analyse in market games the relationship of sunspot equilibria to correlated equilibria defined by Aumann (1974; 1987). Peck and Shell show that every correlated equilibrium allocation can be decentralized as a sunspot equilibrium allocation, but the converse is not true. Correlated equilibria are self-enforcing while sunspot equilibria allow for transfer of incomes across states of nature. The market game is the leading general-equilibrium model of imperfect competition. It is shown by Peck and Shell that unless endowments are Pareto optimal, there is always a proper sunspot equilibrium due to imperfect competition. Imperfect and monopolistic competition are highly prone to sunspot effects. Imperfect competition is one of the very useful building blocks for calibrating applied sunspot models to business cycle data. Peck and Shell (1991) also incorporate asymmetric information into the sunspots model. Earlier examples of sunspot equilibria in which the randomizing device provides asymmetric (but correlated) information to agents are Azariadis and Guesnerie (1982) and Maskin and Tirole (1987).

Detailed market structure matters in imperfectly competitive economies. Peck and Shell (1989) construct two different securities games from the same certainty market game. In one, there is a full spectrum of Arrow financial securities. In the other, there is a full spectrum of real contingent commodities. A sunspot Nash equilibrium allocation in the Arrow securities game which is not a mere lottery over certainty Nash equilibrium allocations is never a Nash equilibrium allocation to the contingent-commodities game. The two games differ because the market power of individual agents depends on the way markets are organized.
Symmetry breaking

Yves Balasko (1983) provides a general definition of extrinsic uncertainty. Modelling how extrinsic uncertainty affects technologies and endowments is straightforward: endowments and input–output pairs are independent of the realization of the randomizing device. Modelling ex ante preferences is more subtle. Sunspots affect preferences only through allocations. Otherwise uncertainty would be intrinsic; the randomness would not be sunspot randomness. In particular, if the states of nature are renamed, say: \( \alpha \) becomes \( \beta \), the allocation in \( \alpha \) becomes the allocation in \( \beta \), and the probability \( \pi(\alpha) \) becomes \( \pi(\beta) \), then ex ante utility is unaffected. This generalizes von Neumann–Morgenstern utility. Balasko (1990) shows how sunspot equilibrium is an instance of symmetry-breaking in economics. The non-sunspot equilibrium is the symmetric solution to symmetric equations. The sunspot equilibrium breaks the symmetry of endowments, technologies and preferences. It is an asymmetric solution to the symmetric equations.

Sunspots and empirical business cycle research

Benhabib and Farmer (1994), Farmer and Guo (1994), and Galí (1994) launched the field of applied sunspot business cycle analysis (see also Benhabib and Farmer, 1996; Benhabib and Nishimura, 1998; Benhabib and Wen, 2004). They made only simple adjustments to the standard real business cycle (RBC) model of Kydland and Prescott (1982) in their set-ups. For example, Benhabib and Farmer (1994) – following the lead of Spear (1991) – introduced an externality in production, leading to aggregate increasing returns to scale. Without this adjustment, sunspots would not matter because the standard RBC model (based on a single infinite-lived individual) is equivalent to a planning model, so when preferences and technology are convex, sunspots cannot matter. With this adjustment, there can be a multiplicity of certainty equilibrium paths, which leads to the existence of equilibrium fluctuations driven by sunspots. Farmer and Guo (1994) calibrated a discrete-time version of the Benhabib–Farmer model to match business cycle facts while employing only sunspot uncertainty. Yi Wen (1998) replaced the Benhabib–Farmer externality with capacity utilization, reducing the size of the externality to a more reasonable level, while still matching business cycle facts without positing any intrinsic uncertainty. Calibration of sunspot-driven business cycles is a major and growing area. There is barely room in this review to scratch the surface. The applied sunspots business cycle calibrators were wise in deviating only in relatively small steps from the well-established RBC model for their experiments; otherwise they would have been less likely to get the attention of the calibration community. On the other hand, one guesses that sunspot allocations will be easier to find and easier to match to data in the overlapping-generations economy.

Sunspots, bank runs and economic fragility

Some sharp economic downturns have been attributed to ‘panics’ or ‘bursting bubbles’ in financial markets. People ‘run’ on a bank or other financial institution when they expect others to run. In their classic bank-run model, Diamond and Dybvig (1983) highlight the fragile nature of financial intermediaries. Banks attempt to smooth consumption between depositors who turn out to be patient (and can afford to wait) and those who turn out to be impatient (and need to withdraw early). The problem is that the ‘patient’ people might panic, attempting to withdraw early and causing a run on the bank. In the standard bank contract, there are two equilibria to the post-deposit game: (1) the (good) no-run equilibrium and (2) the (bad) run equilibrium. However, the run equilibrium is not an equilibrium for the pre-deposit game: if individuals know in advance that there will be a run on the bank, they will not make a deposit. Hence, in the formal model bank runs are not possible. Diamond and Dybvig suggest that sunspots will play a role in panic-based runs. Peck and Shell (2003; 2005) validate their intuition. It is shown that panic-based bank runs can part of a sunspot equilibrium for the pre-deposit game even when partial suspension of convertibility is allowed. Sunspot-driven bank runs are possible, but they are typically not mere randomizations over certainty equilibria. If the probability of the run is small, the optimal banking contract tolerates runs. If the probability of the run is large, then the optimal banking contract is run-proof. Ennis and Keister (2003) exploit these ideas to investigate the implications of the possibility of bank runs on economic growth. Gu (2006) considers an asymmetric-information, extrinsic randomizing device in the banking set-up. If the sunspots signals are highly correlated, there exists a proper correlated equilibrium for some banking contracts. In the equilibrium, depending upon the realization of the signals, either a full bank run, a partial bank run, or no bank run will occur.

What policies should be taken to stabilize or even immunize the economy from sunspot fluctuations? Complete immunization might not be feasible and when feasible it might not be desirable. For example, we know that while avoiding bank runs can be feasible, the optimal banking contract tolerates runs at small probabilities. See Ennis and Keister (2005) for some other examples. Grandmont (1985; 1986) designs government policies that immunize the economy from sunspot effects. Grandmont's policies set taxes according to feedback rules that render the current price level as predetermined and thus immunizing it from sunspots. Smith (1994) considers the policy of inflation-rate targeting in an overlapping-generations economy. If the government maintains a target price-level path by standing ready to exchange money for interest-bearing assets, this immunizes the economy from sunspots but at the cost of substantial inefficiency. Other policies that target a given price level lead to smaller inefficiencies even though they do not immunize the economy from
sunspot equilibrium. Woodford (1994) considers a cash-in-advance economy in which the government either fixes the constant money growth rate or fixes a constant nominal interest rate. Woodford finds that there is a unique equilibrium under the interest rate rule, but the corresponding constant money growth economy is susceptible to sunspot shocks. Woodford (1994) differs from Smith (1994), because Woodford uses a transversality condition not appropriate in Smith's OG environment. For Woodford, under the interest rate rule all price histories but one result in too rapid accumulation of government debt. Keister (1998) studies a model with segmented asset markets in which the amount of sunspot-driven volatility in consumption depends on the government's tax-transfer policy. A policymaker concerned about inequality may choose to accept sunspot volatility in order to achieve some redistribution. It has been proposed that narrow banks, banks that are restricted to holding only liquid assets, are more stable than wide banks, banks that are unrestricted in asset holding. Peck and Shell (2005) show that narrow banks are subject to sunspot-based panic runs while wide banks are immune from these. On the other hand, wide banks are subject to running out of funds in the face of intrinsic shocks, while the narrow banks are immune from these shocks because of their over-investment in the liquid asset. Goenka (1994a) shows that restrictions on government institutions intended to increase bureaucratic accountability can also increase the fragility of the economy in the face of sunspot shocks. For example, forcing government agencies to finance their separate budgets through agency-specific taxes can introduce sunspot instability and inefficiency.

Stability of sunspot equilibria

Can sunspot equilibria be dismissed as less ‘stable’ or more ‘fragile’ than non-sunspot equilibria? The current answer to the question seems to be ‘no’, meaning sunspot equilibria cannot in general be dismissed. For example: (1) Woodford (1990) shows that under some plausible assumptions, the economy will learn to believe in sunspots. (2) Balasko, Cass and Shell (1995) show that if the parameters of the sunspot economy are slightly perturbed then sunspot equilibrium allocations will typically move to nearby sunspot equilibrium allocations. Of course, these stability results are only for specific models. It has been possible to sketch only a few of the many excellent contributions to the very rich and extensive literature on sunspot equilibrium. Sunspots now play important roles in both descriptive and normative economics. They naturally arise in dynamic economies in which expectations play a central role. They matter when markets are incomplete or participation in them is restricted. They matter when the horizon is infinite. They matter when preferences and/or technologies are non-convex. … Sunspots matter.

supermodularity and supermodular games

Xavier Vives

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The mathematical concept of supermodularity formalizes the idea of complementarity and opens the way for a rigorous treatment of monotone comparative statics and games with strategic complementarities. The approach is based on lattice methods and provides conditions under which optimal solutions to optimization problems change in a monotone way with a parameter. The theory of supermodular games exploits order properties to ensure that the best response of a player to the actions of rivals is increasing in their level. It yields strong results that apply to a wide range of games including dynamic games and games of incomplete information.

Article

The concept of complementarity is well established in economics at least since Edgeworth (1881). The basic idea of complementarity is that the marginal value of an action increases with the level of other actions available. The mathematical concept of supermodularity formalizes the idea of complementarity. The theory of monotone comparative statics and supermodular games provides the toolbox to deal with complementarities. This theory, developed by Topkis (1978; 1979), Vives (1985; 1990) and Milgrom and Roberts (1990a), in contrast to classical convex analysis, is based on order and monotonicity properties on lattices (see Topkis, 1998; Vives, 1999; and Vives, 2005, for detailed accounts of the theory and applications). Monotone comparative statics analysis provides conditions under which optimal solutions to optimization problems change monotonically with a parameter. The theory of supermodular games exploits order properties to ensure that the best response of a player to the actions of rivals increases with their level. Indeed, this is the characteristic of games of strategic complementarities (the term was coined in Bulow, Geanakoplos and Klemperer, 1983). The power of the approach is that it clarifies the drivers of comparative statics results and the need of regularity conditions; it allows very general strategy spaces, including indivisibilities and functional spaces such as those arising in dynamic or Bayesian games; it establishes the existence of equilibrium in pure strategies (without requiring quasi-concavity of payoffs, smoothness assumptions, or interior solutions); it allows a global analysis of the equilibrium set when there are multiple equilibria, which has an order structure with largest and smallest elements; and, finally, it finds that those extremal equilibria have strong stability properties and there is an algorithm to compute them. We will provide an introduction to the approach and some definitions, move on to the basic monotone comparative statics results, and provide the basic results for supermodular games.

Preliminaries and definitions

A binary relation $\geq$ on a nonempty set $X$ is a partial order if $\geq$ is reflexive, transitive, and antisymmetric (a binary relation is antisymmetric if $x \geq y$ and $y \geq x$ implies that $x = y$). A partially ordered set $(S, \geq)$ is completely ordered if for $x$ and $y$ in $S$ either $x \geq y$ or $y \geq x$. An upper bound on a subset $A \subseteq X$ is $z \in X$ such that $z \geq x$ for all $x \in A$. A greatest element of $A$ is an element of $A$ that is also an upper bound on $A$. Lower bounds and least elements are defined analogously. The greatest and least elements of $A$, when they exist, are denoted max $A$ and min $A$, respectively. A supremum (resp., infimum) of $A$ is a least upper bound (resp., greatest lower bound); it is denoted sup $A$ (resp., inf $A$). A lattice is a partially ordered set $(X, \geq)$ in which any
two elements have a *supremum* and an *infimum*. Any interval of the real line with the usual order is a lattice since any two points have a *supremum* and an *infimum* in the interval. However, the set in \( \mathbb{R}^2 \) \{ (1,0), (0,1) \} is not a lattice with the vector ordering (the usual component-wise ordering), since (1,0) and (0,1) have no joint upper bound in the set. However, if we add the points (0,0) and (1,1) the set becomes a lattice with the vector ordering (see Figure 1 and let \( x=(0,1) \) and \( y=(1,0) \)). A lattice \( (X, \geq) \) is *complete* if every non-empty subset has a *supremum* and an *infimum*. Any compact interval of the real line with the usual order, or product of compact intervals with the vector order, is a complete lattice. Open intervals are lattices but they are not complete (for example, the *supremum* of the interval \( (a, b) \) does not belong to \( (a, b) \)). A subset \( L \) of the lattice \( X \) is a *sublattice* of \( X \) if the *supremum* and *infimum* of any two elements of \( L \) belong also to \( L \). A lattice is always a sublattice of itself, but a lattice need not be a sublattice of a larger lattice. Let \( (X, \geq) \) and \( (T, \geq) \) be partially ordered sets. A function \( f:X \rightarrow T \) is *increasing* if, for \( x, y \) in \( X \), \( x \geq y \) implies that \( f(x) \geq f(y) \).

Figure 1
Supermodular functions

A function \( g: X \to \mathbb{R} \) on a lattice \( X \) is supermodular if, for all \( x, y \) in \( X \), \( g(\text{min}(x, y)) + g(\text{max}(x, y)) = g(x) + g(y) \). It is strictly supermodular if the inequality is strict for all pairs \( x, y \) in \( X \) that neither \( x \geq y \) nor \( y \geq x \) holds. A function \( f \) is (strictly) submodular if \(-f\) is (strictly) supermodular; a function \( f \) is (strictly) log-supermodular if \( \log f \) is (strictly) supermodular. Let \( X \) be a lattice and \( T \) a partially ordered set. The function \( g: X \times T \to \mathbb{R} \) has (strictly) increasing differences in \( (x, t) \) if \( g(x', t) - g(x, t) \) is (strictly) increasing in \( t \) for \( x' > x \) or, equivalently, if \( g(x, t') - g(x, t) \) is (strictly) increasing in \( x \) for \( t' > t \). Decreasing differences are defined analogously.

Supermodularity is a stronger property than increasing differences: if \( T \) is also a lattice and if \( g \) is (strictly) supermodular on \( X \times T \), then \( g \) has (strictly) increasing differences in \( (x, t) \).

However, the two concepts coincide on the product of completely ordered sets: in such case a function is supermodular if and only if it has increasing differences in any pair of variables.

Both concepts formalize the idea of complementarity: increasing one variable raises the return to increase another variable. For example, the Leontief utility function

\[
U(x) = \min \{ a_1 x_1, \ldots, a_n x_n \} \quad \text{with} \quad a_i \neq 0 \quad \text{for all} \quad i
\]

is supermodular on \( \mathbb{R}^n \). The complementarity idea can be made transparent by thinking of the rectangle in \( \mathbb{R}^n \) with vertices \( \{ \text{min}(x, y), y, \text{max}(x, y), x \} \) and rewriting the definition of supermodularity as \( g(\text{max}(x, y)) - g(x) \geq g(y) - g(\text{min}(x, y)) \). Consider, for example, points in \( \mathbb{R}^2 \) \( x=(x_1, x_2) \) and \( y=(y_1, y_2) \) with the usual order. Then going from \( \text{min}(x,y) = (x_1, y_2) \) to \( y \), for given \( y_2 \), increases the payoff less than going from \( x \) to \( \text{max}(x,y) = (y_1, x_2) \), for given \( x_2 \geq y_2 \) (see Figure 1).

If \( X \) is a convex subset of \( \mathbb{R}^n \) and if \( g: X \to \mathbb{R} \) is twice-continuously differentiable, then \( g \) has increasing differences in \( (x_i, x_j) \) if and only if

\[
\frac{\partial^2 g(x)}{\partial x_i \partial x_j} \geq 0 \quad \text{for all} \quad x \in X \quad \text{and} \quad i \neq j.
\]

For decreasing differences (or submodularity) we would have

\[
\frac{\partial^2 g(x)}{\partial x_i \partial x_j} \leq 0.
\]

This characterization has a direct counterpart with the concept of (weak) cost complementarities if \( g \) is a cost function and \( x \geq 0 \) the production vector. If \( \frac{\partial^2 g(x)}{\partial x_i \partial x_j} > 0 \) for all \( x \) and \( i \neq j \), then \( g \) is strictly supermodular. The differential characterization of supermodularity can be motivated by the figure as before. As an example consider assortative matching when types \( x \) and \( y \) in \([0,1]\) produce \( f(x,y) \) when matched and nothing otherwise. If \( \frac{\partial^2 f}{\partial x \partial y} > 0 \) then in a core allocation matching is positively assortative, that is, matched partners are identical (Becker, 1973; see Shimer and Smith, 2000, for a dynamic model with search where it is required also that \( \frac{\partial^2 f}{\partial x \partial y} > 0 \) and \( \frac{\partial^2 f}{\partial x \partial y} > 0 \) are supermodular).

Positive linear combinations and pointwise limits preserve the complementarity properties (supermodularity/increasing differences) of a family of functions \( g_n: X \times T \to \mathbb{R} \). Supermodularity is also preserved under integration. This has important consequences for comparative statics under uncertainty and games of incomplete information (see Vives, 1990; and Athey, 2001).

Supermodularity is also preserved under the maximization operation. Supermodularity is unrelated to convexity, concavity or returns to scale. Indeed, any real-valued function on a completely ordered set (say the reals) is both supermodular and submodular. This fact also makes clear that supermodularity in Euclidean spaces, in contrast to concavity or convexity, has no connection with continuity or differentiability properties. Note also that if \( g \) is a twice-continuously differentiable function, supermodularity only puts restrictions on the cross partials of \( g \) while the other concepts impose restrictions also on the diagonal of the matrix of second derivatives.

Monotone comparative statics

http://www.dictionaryofeconomics.com/library/lemoyne.edu/article?id=pde2008_50004865&goto=S&result_number=6880&format=html
Let $X$ be a compact rectangle in Euclidean space and let $T$ be a partially ordered set. Let $g: X \times T \to \mathbb{R}$ be a function that (a) is supermodular and continuous on $X$ for each $t \in T$ and (b) has increasing differences in $(x, t)$. Let $\Phi(t) = \arg\max_{x \in X} g(x, t)$. Then (Topkis, 1978):

1. $\Phi(t)$ is a non-empty compact sublattice for all $t$;
2. $\Phi$ is increasing in the sense that, for $t' > t$ and for $x' \in \Phi(t')$ and $x \in \Phi(t)$, we have $\sup(x', x) \in \Phi(t')$ and $\inf(x', x) \in \Phi(t)$; and
3. $\sup \Phi(t)$ and $\inf \Phi(t)$ are increasing selections of $\Phi$.

Several remarks are in order: (i) The continuity requirement of $g$ can be relaxed. In more general spaces the requirement is for $X$ to be a complete lattice and for $g$ to fulfill an appropriate order continuity property. (ii) If $g$ has strictly increasing differences in $(x, t)$, then all selections of $\Phi$ are increasing. (iii) If solutions are interior, and $\partial g / \partial x$ is strictly increasing in $t$ for some $i$, then all selections of $\Phi$ are strictly increasing (Edlin and Shannon, 1998). (iv) Milgrom and Shannon (1994) relax the complementarity conditions to ordinal complementarity conditions (supermodularity and supermodular games) and develop necessary and sufficient conditions for monotone comparative statics.

Let us illustrate the result when $T \subset \mathbb{R}$ and $g$ is twice-continuously differentiable on $X \times T$. Suppose first that $X \subset \mathbb{R}$, $g$ is strictly quasi-concave in $x$ (with $\partial^2 g / \partial x^2 < 0$), and that the solution to the maximization problem $\Phi(t)$ is interior. Then, using the implicit function theorem on the interior solution, for which $\partial g(\Phi(t), t) / \partial x = 0$, we obtain that $\Phi$ is continuously differentiable and

$$\Phi' = -\frac{\partial^2 g}{\partial x \partial t} \frac{\partial^2 g}{\partial x^2} \bigg(\frac{\partial^2 g}{\partial x \partial t} \bigg)^{-1}.\quad \text{Obviously, sign } \Phi' = \text{sign } \frac{\partial^2 g}{\partial x \partial t}.\quad \text{The solution is increasing (decreasing) in } t \text{ if there are increasing, decreasing, nonnegative differences. The monotone comparative statics result asserts that the solution } \Phi(t) \text{ will be monotone increasing in } t \text{ even if } g \text{ is not strictly quasi-concave in } x, \text{ in which case } \Phi(t) \text{ need not be a singleton or convex-valued, provided that } \frac{\partial^2 g}{\partial x \partial t} \text{ does not change sign. For example, if we consider a single-product monopolist with revenue function } R(x) \text{ and cost function } C(x, t), \text{ where } x \text{ is the output of the firm and } t \text{ a cost efficiency parameter, we have } g(x, t) = R(x) - C(x, t). \text{ If } C(\cdot) \text{ is smooth and } \frac{\partial^2 C}{\partial x^2} < 0, \text{ an increase in } t \text{ reduces marginal costs. Then if } R(\cdot) \text{ is continuous the comparative static result applies, and the largest } \Phi(t) \text{ and the smallest } \Phi(t) \text{ monopoly outputs are increasing in } t. \text{ If } \frac{\partial^2 C}{\partial x^2} < 0, \text{ then all selections of the set of monopoly outputs are increasing in } t. \text{ It is worth noting that the comparative statics result is obtained with no concavity assumption on the profit of the firm.}

Suppose now that $X \subset \mathbb{R}^k$. If $g$ is strictly concave in $x$ (with the Jacobian of $g$ with respect to $x$, $H_x$, negative definite) and the solution to the optimization problem $\Phi(t) = (\Phi_1(t), \ldots, \Phi_k(t))$ is interior, then $\Phi(t)$ is continuously differentiable, and $\frac{\partial \Phi_1}{\partial t}, \ldots, \frac{\partial \Phi_k}{\partial t}$ is the Jacobian of $g$ with respect to $x$.

The off-diagonal elements of $H_x$ are nonnegative for all $i$ (the statement also holds with strict inequalities). As before, even if $H_x$ is not negative definite, the assumptions that $\frac{\partial^2 g}{\partial x \partial x^2} \geq 0, j \neq i$, and that $\frac{\partial^2 g}{\partial x_i \partial x_j} \geq 0$ imply that the solution set $\Phi(t)$ has the monotonicity properties stated in the monotone comparative statics result. Note that when $X$ is multidimensional, the restriction that $g$ be supermodular on $X$, ensuring that for any components $i$ and $j$ an increase in the variable $x_i$ raises the marginal return of variable $x_j$ when coupled with increasing differences on $X \times T$ is needed to guarantee the monotonicity of the solution. For example, let us consider a multiproduct monopolist. If the revenue function $R(\cdot)$ is continuous and supermodular on $X$, the cost function $C(\cdot)$ continuous and submodular on $X$, and $C(\cdot)$ displays decreasing differences in $(x, t)$, the comparative static result follows. That is, the largest $\Phi(t)$ and the smallest $\Phi(t)$ monopoly output vectors are increasing in $t$. In the differentiable case, $\frac{\partial^2 g}{\partial x_i \partial x_j} \geq 0$ and $\frac{\partial^2 C}{\partial x_i \partial x_j} \leq 0$, for all $i \neq j$, and $\frac{\partial^2 C}{\partial x_i^2} \geq 0$ for all $i$. The result hinges on revenue and cost complementarities among outputs, and the impact of the efficiency parameter on marginal costs, and not concavity of profits.

Now let us consider a team problem. Suppose that $n$ persons share a common objective $g(x_1, \ldots, x_n, t)$ where the action of player $i$, $x_i$, is in the rectangle $X_i \subset [R]^{k_i}$ for each $i$ and $t$ is a payoff relevant parameter. If $g$ is supermodular on $X = \prod_{i=1}^n X_i$ and has strictly increasing differences in $(x, t)$, then any optimal solution is increasing in the level of the parameter. For example, the optimal production $g(x, t)$ of the firm (seen as a team problem) is increasing in the level of information technology $t$ (which raises the marginal productivity of any worker of the firm).
Consider the game \((A_i, \pi_j ; i \in N)\) where for each \(i=1, \ldots, n\) in the set of players \(N, A_i\) is the strategy set, a subset of Euclidean space, and \(\pi_j\) the payoff of the player (defined on the cross product of the strategy spaces of the players \(A\)). Let \(a_i \in A_i\) and \(a_{-i} \in \prod_{j \neq i} A_j\) (that is, denote by \(a_{-i}\) the strategy profile \((a_1, \ldots, a_n)\) except the \(i\)th element). The strategy profiles are endowed with the usual component-wise order. We will say that the game \((A_i, \pi_j ; i \in N)\) is (strictly) supermodular if for each \(i, A_i\) is a compact rectangle of Euclidean space, \(\pi_j\) is continuous and (i) supermodular in \(a_i\) for fixed \(a_{-i}\) and (ii) displays (strictly) increasing differences in \((a_i, a_{-i})\). We will say that the game \((A_i, \pi_j ; i \in N)\) is smooth (strictly) supermodular if furthermore \(\pi_j(F)\) is twice continuously differentiable with (i) \(\partial^2 \pi_j / \partial a_{ij} \partial a_{ik} \geq 0\) for all \(k \neq h\), and (ii) \(\partial^2 \pi_j / \partial a_{ij} \partial a_{ik} \geq (>) 0\) for all \(j \neq i\) and for all \(h, k, j\) and \(k\), where \(a_{ij}\) denotes the \(i\)th component of the strategy \(a_i\) of player \(i\). Condition (i) is the strategic complementarity property in own strategies \(a_i\). Condition (ii) is the strategic complementarity property in rivals’ strategies \(a_{-i}\).

In a more general formulation strategy spaces need only be complete lattices and this includes functional spaces such as those arising in dynamic or incomplete information games. The complementarity conditions can be weakened to define an ‘ordinal supermodular’ game (see Milgrom and Shannon, 1994). Furthermore, the application of the theory can be extended by considering increasing transformations of the payoff (which do not change the equilibrium set of the game). For example, we will say that the game is log-supermodular if \(\pi_j\) is nonnegative and log \(\pi_j\) fulfills conditions (i) and (ii). This is the case of a Bertrand oligopoly with differentiated substitutable products, where each firm produces a different variety and marginal costs are constant, whenever the own-price elasticity of demand for firm \(i\) is decreasing in the prices of rivals, as with constant elasticity, logit, or constant expenditure demand systems.

In the duopoly case \((n=2)\) the case of strategic substitutability can also be covered. Indeed, suppose that there is strategic complementarity or supermodularity, in own strategies \((\partial^2 \pi_j / \partial a_{ij} \partial a_{ik} \geq 0, \partial^2 \pi_j / \partial a_{ij} \partial a_{ik} \leq 0)\) and strategic substitutability in rivals’ strategies or decreasing differences in \((\partial^2 \pi_j / \partial a_{ij} \partial a_{ik} \geq (>) 0)\). Then the game obtained by reversing the order in the strategy space of one of the players, say player 2, is supermodular (Vives, 1990). Cournot competition with substitutable strategies displays typically strategic substitutability in the strategy profiles of the players.

In a supermodular game best responses are monotone increasing even when \(\pi_j\) is not quasi-concave in \(a_i\). Indeed, in a supermodular game each player has a largest, \(\pi_j(a_{-i})=\sup \pi_j(a_{-i})\), and a smallest, \(\pi_j(a_{-i})=\inf \pi_j(a_{-i})\), best reply, and they are increasing in the strategies of the other players. Let \(\bar{\pi} = (\bar{\pi}_1, \ldots, \bar{\pi}_n)\) and \(\underline{\pi} = (\underline{\pi}_1, \ldots, \underline{\pi}_n)\) denote the extremal best reply maps.

**Result 1:** In a supermodular game there always exist a largest \(\bar{\pi} = \sup \{a \in A : \bar{\pi}(a) \geq a\}\) and a smallest \(\underline{\pi} = \inf \{a \in A : \pi(a) \leq a\}\) equilibrium (Topkis, 1979).

The result is shown applying Tarski’s fixed point theorem to the extremal selections of the best-reply maps, \(\bar{\pi}\) and \(\underline{\pi}\), which are monotone because of the strategic complementarity assumptions. Tarski’s theorem (1955) states that if \(A\) is a complete lattice (for example, a compact rectangle in Euclidean space) and \(f : A \rightarrow A\) an increasing function then \(f\) has a largest \(\sup \{a \in A : f(a) \geq a\}\) and a smallest \(\inf \{a \in A : a \geq f(a)\}\) fixed point.

**Result 2:** In a symmetric supermodular game (that is, a game with payoffs and strategy sets exchangeable against permutations of the players) the extremal equilibria \(\bar{\pi}\) and \(\underline{\pi}\) are symmetric and, if strategy spaces are completely ordered and the game is strictly supermodular, then only symmetric equilibria exist (see Vives, 1999).

The result is useful to show uniqueness since if there is a unique symmetric equilibrium then the equilibrium is unique. For example, in a symmetric version of the Bertrand oligopoly model with constant elasticity of demand and constant marginal costs, it is easy to check that there exists an unique symmetric equilibrium. Since the game is (strictly) log-supermodular, we can conclude that the equilibrium is unique. The existence result of symmetric equilibria is related to the classical results of McManus (1962; 1964) and Roberts and Sonnenschein (1976).

**Result 3:** In a supermodular game if there are positive spillovers (that is, the payoff to a player is increasing in the strategies of the other players) then the largest (smallest) equilibrium point is the Pareto best (worst) equilibrium (Milgrom and Roberts, 1990a; Vives, 1990).

Indeed, in many games with strategic complementarities equilibria can be Pareto ranked. In the Bertrand oligopoly example the equilibrium with higher prices is Pareto dominant for the firms. This has proved particularly useful in applications in macroeconomics (for example, Cooper and John, 1988) and finance (for example, Diamond and Dybvig, 1983).

**Result 4:** In a supermodular game:

1. (a) Best-reply dynamics approach the interval \([\bar{\pi}, \underline{\pi}]\) defined by the smallest and the largest equilibrium points of the game. Therefore, if the equilibrium is unique it is globally stable. Starting at any point \(A^k(A^-)\) in the intersection of the upper (lower) contour sets of the largest (smallest) best replies of the players, best-reply dynamics lead monotonically downwards (upwards) to an equilibrium (Vives, 1990; 1999). This provides an iterative procedure to find the largest (smallest) equilibrium (Topkis, 1979) starting at \(\sup A\) (\(\inf A\)) (see Figure 2).

Figure 2
Supermodularity and supermodular games: The New Palgrave Dictionary of Economics

Best-reply dynamics in a supermodular game (with best-reply functions \( r_1(\cdot), r_2(\cdot) \)). Source: Vives (1999, p. 54).
2. (b) The extremal equilibria correspond to the largest and smallest serially undominated strategies (Milgrom and Roberts, 1990a). Therefore, if the equilibrium is unique, the game is dominance solvable. Rationalizable (Bernheim, 1984; Pearce, 1984) or mixed strategy outcomes must lie in the interval $[\underline{a}, \overline{a}]$.

In the Bertrand oligopoly example with linear, constant elasticity, or logit demands, the equilibrium is unique and therefore it is globally stable, and the game is dominance solvable. In the team example it is clear that an optimal solution will be a Nash equilibrium of the game among team members. If the equilibrium is unique, then best-reply dynamics among team members will converge to the optimal solution. This need not be the case if there are multiple equilibria (see Milgrom and Roberts, 1990b, for an application to the theory of the firm).

**Result 5:** Let us consider a supermodular game with parameterized payoffs $\pi_i(a_i, a_{-i}, t)$ with $t$ in a partially ordered set $T$. If $\pi_i(a_i, a_{-i}, t)$ has increasing differences in $(a_i, t)$ (in the smooth version $\partial^2 \pi_i / \partial a_i \partial t \geq 0$ for all $h$ and $i$), then the largest and smallest equilibrium points increase with an increase in $t$, and starting from any equilibrium, best reply dynamics lead to a (weakly) larger equilibrium following the parameter change. The latter result can be extended to adaptive dynamics, which include fictitious play and gradient dynamics (see Lippman, Mamer and McCardle, 1987; and Sobel, 1988, for early results; and Milgrom and Roberts, 1990a; Milgrom and Shannon, 1994; and Vives, 1999, for extensions). It is worth noting that continuous equilibrium selections that do not increase monotonically with $t$ predict unstable equilibria (Echenique, 2002). The result yields immediately that an increase in an excise tax in a (log-)supermodular Bertrand oligopoly raises prices at an extremal equilibrium.

The basic intuition for the comparative statics result is that an increase in the parameter increases the actions for one player, for given actions or rivals, and this reinforces the desire of all other players to increase their actions because of strategic complementarity. This initiates a mutually reinforcing process that leads to larger equilibrium actions. This is a typical positive feedback in games of strategic complementarities. In this class of games, unambiguous monotone comparative statics obtain if we concentrate on stable equilibria. We can understand this as a multidimensional version of Samuelson's (1947) correspondence principle, which was obtained with standard calculus methods applied to interior and stable one-dimensional models.

**A patent race**

Let us consider $n$ firms engaged in a memory-less patent race that have access to the same R&D technology. The winner of the patent obtains the prize $V$ and losers obtain nothing. The (instantaneous) probability of innovating is given by $h(x)$ if a firm spends $x$ continuously, where $h$ is a smooth function with $h(0)=0$, $h'(x) > 0$, $\lim_{x \to \infty} h'(x) = 0$, and $h'(0) = \infty$. It is assumed also that $h$ is concave but a region of increasing returns for small $x$ may be allowed. If no patent is obtained the (normalized) profit of a firm is zero. The expected discounted profits (at rate $r$) of firm $i$ investing $x_i$ if rival $j \neq i$ invests $x_j$ is given by

$$\Pi_i = \frac{h(x_i) V - x_i}{h(x_i) + \sum_{j \neq i} h(x_j) + r}.$$  

Lee and Wilde (1980) restrict attention to symmetric Nash equilibria of the game and show that, under a uniqueness and stability condition at a symmetric equilibrium $x^*$ expenditure intensity increases with $n$. The classical approach requires assumptions to ensure a unique and stable symmetric equilibrium and cannot rule out the existence of asymmetric equilibria. Suppose that there are potentially multiple symmetric equilibria and that going from $n$ to $n+1$ new equilibria appear. What comparative static result can we infer then? Using the lattice approach we obtain a more general comparative statics result that allows for the presence of multiple symmetric equilibria (Vives, 1999, Exercise 2.20; and 2005, Section 5.2). Let $h(0)=0$ with $h$ strictly increasing in $[0, \infty)$, with $h(x) V - x < 0$ for $x \geq 0$ and $h'(0) = \infty$. Under the assumptions the game is strictly log-supermodular and from Result 2 only symmetric equilibria exist. Let $x_i = x$ and $x_j = y$ for $j \neq i$. Then $\log \Pi_i$ has (strictly) increasing differences in $(x, n)$ for all $y > 0$ and, according to Result 5, the expenditure intensity $x^*$ at extremal equilibria is increasing in $n$. 

http://www.dictionaryofeconomics.com/views/article?id=pde2008_50004665&goto=5&result_number=0680
Furthermore, starting at any equilibrium, an increase in $n$ will raise research expenditure with out-of-equilibrium adjustment according to best-reply dynamics. This will be so even if new equilibria appear, or some disappear, as a result of increasing $n$. Finally, if $h$ is smooth with $h' > 0$ and $h''(O) = \infty$, then $\partial \log \eta_i / \partial x_i$ is strictly increasing in $n$ and (at extremal equilibria) $x^*$ is strictly increasing in $n$. This follows because, under our assumptions, equilibria are interior and must fulfill the first-order conditions.

The results can be applied to dynamic and incomplete information games, which have complex strategy spaces. For example, in an incomplete information game, if for given types of players the ex post game is supermodular, then the Bayesian game is also supermodular and therefore there exist Bayesian equilibria in pure strategies (Vives, 1990). If, furthermore, payoffs to any player have increasing differences between the actions of the player and types, and higher types believe that other players are also of a higher type (according to first-order stochastic dominance), then extremal equilibria of the Bayesian game are monotone increasing in types (Van Zandt and Vives, 2007). This defines a class of monotone supermodular games. An example is provided by global games, introduced by Carlsson and Van Damme (1993) and developed by Morris and Shin (2002) and others with the aim of equilibrium selection. Global games are games of incomplete information with type space determined by each player observing a noisy private signal of the underlying state. The result is obtained applying iterated elimination of strictly dominated strategies. From the perspective of monotone supermodular games we know that extremal equilibria are the outcome of iterated elimination of strictly dominated strategies, that they are monotone in type (and therefore in binary action games there is no loss of generality in restricting attention to threshold strategies), and the conditions put to pin down a unique equilibrium in the global game amount to a lessening of the strength of strategic complementarities (see Vives, 2005, Section 7.2).

superneutrality

Jean-Pierre Danthine
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Money is said to be superneutral – or long-run neutral – if changes in the steady-state rate of growth of the money supply do not affect the value of real economic variables. Superneutrality depends on the hypothesis that the marginal productivity of capital is not affected by the level or the growth rate of money balances. It may hold true in steady state equilibria where the marginal utility of consumption is constant over time. Qualitatively, superneutrality is a fragile, knife-edged result that fails in a variety of contexts. Empirically, however, it is not clear that deviations from superneutrality are quantitatively significant.

Article

Money is said to be neutral when a change in the quantity of money affects only the level of prices, and not the level of output or of other real variables. By extension, money is said to be superneutral – or long-run neutral – if changes in the steady-state rate of growth of the money supply do not affect the value of real economic variables (with the exception of money balances, whose steady-state real value usually decreases as the rate of inflation, and thus the cost of holding money balances, increases).

Tobin (1965) may be viewed as having sparked the modern discussion of this issue. In a growth model with a constant savings ratio, he showed that an increased inflation rate, by lowering the return to money, encourages portfolio holders to increase their demand for real assets at the expense of money holdings, and thereby displaces the equilibrium time path of the economy to one of higher per capita
Casting the same question in the context of an optimal growth model, Sidrauski (1967) showed that when the savings rate becomes endogenous the superneutrality result obtains: the steady-state values of per capita capital stock and output are unaffected by the growth rate of the money supply. Sidrausky's model is one in which the representative, infinitely lived agent maximizes the discounted sum of future utilities arising from consumption and real money balances. She may hold two assets, money balances depreciating at the inflation rate \( \pi \) and real capital \( k \) depreciating at a rate \( \delta \). At any date \( t \), the first-order condition determining the level of investment is of the type

\[
MU_t = \beta MU_{t+1} \left( MP_{t+1} + (1 - \delta) \right),
\]

where \( MU_t \) refers to the marginal utility of consumption at time \( t \), \( \beta \) is the discount factor and \( MP_{t+1} \) is the marginal productivity of capital. The LHS of eq. (1) is the utility value of sacrificing one unit of consumption in any period \( t \), while the RHS is the gain in utility from transforming that unit of commodity into capital and producing \( MP_{t+1} \) units of the good with a depreciation rate \( \delta \). In an economy with identical agents, this first-order condition for the representative individual's problem also defines the equilibrium values of the corresponding aggregates, consumption, real balances (entering the \( MU \)), capital stock and possibly other variables (entering the \( MP \)). Since, by definition, \( MU \) is constant in the steady state, it drops out from both sides of the equation and the steady-state capital stock level \( k^* \) must satisfy

\[
\beta [MP(k^*, \cdot ) + (1 - \delta)] = 1.
\]

If, as in Sidrauski's model, the marginal product of capital depends only on the capital stock, eq. (2) uniquely determines the steady-state level of capital \textit{independently of monetary considerations}: hence the superneutrality results. It is then easy to show that real money balances are inversely related with the rate of money creation in the steady state.

It is clear from eq. (2) that Sidrauski's superneutrality result is relatively fragile to changes in the hypotheses or structure of the model. We give a few illustrations below for models which are close in spirit to Sidrauski's original model. Further departures from the neoclassical growth framework, for instance in the directions illustrated by the New Keynesian literature, are bound to yield the same conclusion.

First of all, superneutrality depends on the hypothesis that the MP of capital is not affected by the level or the growth rate of money balances. Suppose instead that money enters a production function with
superneutrality, The New Palgrave Dictionary of Economics

standard properties (money balances acting as firms’ working capital), then higher inflation, by penalizing money holding and thus decreasing steady-state money balances, diminishes the productivity (or the return) to the complementary input, capital. Money is not superneutral but the effect of a higher rate of money creation is opposite to the one suggested in the portfolio view of Tobin, in which money and capital are substitutable assets.

In the same vein, the real business cycle literature has introduced labour-leisure choices as an important additional element of the neoclassical growth model. In a model where money holding is motivated by a cash-in-advance constraint, Cooley and Hansen (1989) show that an increase in steady-state inflation leads individuals to shift away from activities that require cash, such as consumption, for activities that do not require cash, such as leisure. Labour supply thus shifts leftward at higher inflation rates and output falls. Thus, superneutrality fails to hold in this context as well with the opposite of the Tobin effect obtaining.

The derivation of eq. (2), and hence superneutrality, also hinges on the fact that the MU has to be constant in the steady state of a model with infinitely lived agents. The ‘Tobin effect’ reappears if one breaks away from this property, as shown by Fisher (1979), who looks at the effect of money growth on capital accumulation in the transition to a new state, by Weiss (1980) who casts the problem in an overlapping generations framework, and by Danthine, Donaldson and Smith (1987) who introduce uncertainty, and thus a richer definition of the steady state, into Sidrauski’s model. Using numerical techniques, however, the last named authors are able to quantify such an effect of money on growth and reveal that this effect appears to be quantitatively small. In particular, it is dwarfed by the impact of a change in money growth on real balances and prices. They conclude that, while in a strict sense superneutrality is violated in their setting, it holds as a reasonable approximation.

The New Keynesian literature – for example, Goodfriend and King (1997) – is the latest development relevant for the superneutrality issue. New Keynesian models differ from the optimal growth model discussed above on two grounds: they move away from perfect competition, introducing market power by monopolistically competitive producers; they additionally feature nominal rigidities such as ‘menu costs’ preventing prices from adjusting instantaneously to nominal changes. Such rigidities imply the possibility of a trade-off between inflation, and real variables and quite naturally superneutrality fails to hold in this context. The basic result is that the distortions arising from menu costs are minimized if prices are stable, that is, at a zero rate of inflation. Positive inflation rates entail output (and welfare) losses as relative prices are distorted by the inability of a fraction of producers to adjust their prices at the time of the inflationary shock. There is a countervailing effect, however: the mark-up set by monopolistic producers is affected by the presence of inflation. Early Keynesian analyses had recognized that inflation would erode the market power of firms, and indeed imperfect competition includes a bias in favour of inflation. Goodfriend and King, however, show this bias to be quantitatively very small so that the output maximizing rate of inflation is very close to zero.

Further away from a Walrasian perspective on labour markets, the superneutrality issue is related to the question of the slope of the long-run Phillips curve. Thus Phelps’s natural rate of unemployment hypothesis (1967) can be developed into an argument in favour of superneutrality. And, at the empirical level, recent attempts at rediscovering a long run trade-off between inflation and unemployment can be reinterpreted in the same vein. Notable is King and Watson (1994), who use VAR methodology with various identification hypotheses on United States data to conclude that there is evidence of a long-run
negative trade-off between unemployment and inflation, although the slope of the trade-off has declined since 1972. The authors perform causality tests suggesting that changes in unemployment are causing changes in inflation, a result that hints at a reality where lower unemployment places workers in a position to extract higher wages. Modelling such a reality requires a richer perspective on the labour market than the one adopted in the literature reviewed so far.

The very large empirical literature concentrating on the inflation and growth nexus is also relevant here. One of the long-run monetary facts of McCandless and Weber (1995) is that the rate of inflation and the growth rate of output are essentially uncorrelated. This is somewhat different from much of what is reported elsewhere in the literature, where typically a small negative correlation between the inflation rate and the growth rate of output is uncovered. Barro (1996), however, stresses that ‘the clear evidence for adverse effects of inflation comes from the experience of high inflation’. McCandless and Weber argue that one high-inflation outlier is responsible for the standard result.

More directly focusing on superneutrality, Bullard and Keating (1995) use a structural VAR on long-run data from 16 countries. Their general conclusion is that ‘superneutrality describes well most of the postwar economies we study’.

Gigantic incomes and rare talents attract attention and elicit a search for an explanation. Sherwin Rosen has provided us with an elegant neoclassical model whose market equilibrium is characterized by a superstar. Given a fixed cost of consumption, customers flock to talented sellers. If there are no costs of production, the most talented seller becomes a superstar. Discrete gaps in the talent distribution allow less talented sellers to survive but they must charge lower prices. A competitive market equilibrium thus exhibits a skewed distribution of earnings and outputs.

Marshall, A.; motion pictures, economics of; Rosen, Sherwin; Simon, H.; superstars, economics of; Yule distribution

Article
The settings in which superstars are found share two common elements. ‘First, a close connection between personal reward and the size of one's own market, and second a strong tendency for market size and reward to be skewed toward the most talented people in the activity’ (Rosen, 1981, p. 845). The modern world seems to be characterized by an increasing number of activities dominated by superstars. What is the defining characteristic of a superstar? Why do we have more of them today? In this article, I first review the original Rosen model. I next turn to the Yule distribution which yields the skewness in returns. The final section relaxes the assumption of a fixed distribution of talents among potential sellers that is costlessly known to all agents.

Skewness in equilibrium
An individual derives utility from a composite good $x$ and a flow of services $y$ which is a function of the
quantity $N$ and the quality $z$ of each unit.

$$U = U(x, y), \quad y = g(z, N).$$  \hspace{1cm} (1)

*Gone with the Wind* was an A movie, while *Getting Gertie's Garter* was a B movie. I can get a larger service flow $y$ by seeing better movies or going to more movies. Consumption of $y$ takes time. There is a fixed cost of consumption per unit irrespective of quality. The cost of the service flow depends on quantity $N$ times the full cost per unit.

$$C = [p + s]N.$$  \hspace{1cm} (2)

Suppose that quantity and quality multiplicatively determine the service flow, $y = Nz$. If $x$ is the numeraire, the budget constraint is given by,

$$x + y = l, \quad \nu = \frac{[p(z) + s]}{z}.$$  \hspace{1cm} (3)

A consumer will substitute quality for quantity and demand a higher-quality good if $p(z)$ rises at a modest rate as $z$ is increased.

On the supply side, the quality of a unit of output is a function of the talent of a seller $q$ and her market output $m$.

$$z = h(q, m), \quad h_q > 0, \quad h_m < 0.$$  \hspace{1cm} (4)

A seller's output is a function of her talent, $m = m(q)$ which is chosen to maximize profits.

$$R(q) = p(q, m)^* m - c(m).$$  \hspace{1cm} (5)
where \( c(m) \) is the total cost of producing \( m \) units of output, and \( p(q,m) \) is the price that consumers will pay for a unit of output supplied by a type \( q \) seller. A seller's net revenue is a convex function of her talent. She will supply a service flow \( y \) if \( R(q) \geq k \) where \( k \) is the return in some alternative activity. Turn first to the market equilibrium when production is characterized by what Rosen called a public goods technology. There are no costs of production, \( c(m) = 0 \). The price of a unit of output must satisfy the equilibrium condition,

\[
p = vq - s.
\]

(6)

where \( v \) is the implicit price for a unit of the service flow. Since one seller can costlessly supply the entire market, the implicit price for \( y \) and the price \( p \) for a unit of output yielding \( Q = z \) units of the service flow are bid down to the zero profit level. The superstar located at the right extreme of the distribution of talents \( \phi(q) \) is the only supplier, but she cannot raise the price above \( p_0 = (vq_0 - s) \) because the second most talented seller is nearly a perfect substitute. If, however, there is a discrete gap in the talent distribution so that \( q_0 = q_1 + \varepsilon \). The superstar can charge a price, \( p_0 = (vq_0 - s) \), while the second best has to settle for a lower price, \( p_1 = (vq_1 - s) \). The superstar can realize a total rent of \( \forall \in N \) where \( N \) is the market demand.

If there are diseconomies of scale, several sellers producing differentiated services can survive. Each firm equates marginal cost to marginal revenue. More talented sellers charge higher prices and supply larger outputs. The quantity–talent gradient is steeper than the price–talent gradient. A highly talented seller is less contaminated by the presence of competitors. A high-\( q \) seller can and does handle larger crowds who are drawn to her in order to spread the fixed cost of consumption. One unit of a high-quality product yields a larger service flow. Technological advances in communication, transportation and packaging enabled the most talented sellers to increase their share of the total market. Alfred Marshall (1920, p. 686) observed, ‘But so long as the number of persons who can be reached by a human voice is strictly limited, it is not very likely that any singer will make an advance on the ten thousand pounds said to have been earned in a season by Mrs. Billington at the beginning of the last century’. The skew distribution of earnings in the Rosen model is the outcome of a competitive market equilibrium. ‘(a) All sellers maximize profits and cannot earn larger amounts in other activities, and (b) all buyers maximize utility and cannot improve themselves by purchasing from another seller’ (Rosen, 1981, p. 846).

A stochastic model

A skew distribution is not limited to certain economic activities. Herbert A. Simon (1955, p. 426) noted five other examples: distribution of \( (a) \) words in a book, \( (b) \) scientists by number of papers published, \( (c) \)
Superstars are found in certain kinds of economic activities where there is a concentration of output among a few individuals, marked skewness in the distribution of income. Do we identify these activities by measures of concentration and inequality of incomes? The individuals at the top not only supply a higher-quality product but they also enjoy massive scale economies. Borghans and Groot (1998) contend

\[
f(i) = \psi B(i, \rho + 1).
\]

where \(\psi\) and \(\rho\) are constants, and \(B(i, \rho + 1)\) is the Beta function. Chung and Cox (1994) describe a process that can generate the Yule distribution. Each consumer sequentially buys one record. After the last consumer has made her purchase, the process repeats itself and so on, where (record \(s \neq s_{\text{record}}\)) with \(s, t = 1, 2, \ldots n\). It is assumed that \(a\) the probability that consumer \(k + 1\) chooses a record that was already chosen by \(i\) of the previous \(k\) consumers is proportional to \(i\), and \(b\) there is a constant probability \(\delta\) that \(k + 1\) chooses a record that was not yet chosen by the previous \(k\) consumers. Chung and Cox report that in the 1958–89 period 1,377 recording artists had at least one gold record. The list was headed by the Beatles with 46 gold records, followed by Elvis Presley with 45. Setting \(\rho = 1\), the Yule distribution predicts that half of the sample should report having exactly \(i = 1\) gold record; the actual fraction was \(f(1) = .485\). A chi-square test confirms the goodness of fit of the data to the Yule distribution.

M. Adler (1985) motivates this process by arguing that consumption requires knowledge. One has to talk to others to learn about an artist's work. Consumers minimize the cost of searching for knowledgeable discussants by choosing the most popular artist. It can be supposed that consumers initially believe that all artists are equally likely to become stars. Each consumer lives for \(n\) periods and revise their prior distributions after each period. If a slight majority of consumers choose an artist as their first choice, that artist will snowball into a star because her majority will steadily increase. Notice that there need be no dispersion in the talents of potential superstars. One performer attains a slight majority of consumers who spread the word to other consumers. The model is vague about how long it takes to establish a stable skewed Yule distribution. Elvis Presley skyrocketed into stardom quickly. Nat King Cole was struggling on Avalon Boulevard in Los Angeles in 1938. It took him nearly two decades to become a star. The speed with which information spreads ought to influence the time to reach stardom. Notice that nothing had to be assumed about the fixed cost of consumption or about the technology of production to obtain the J-shaped Yule distribution.

Talent and superstars

Superstars are found in certain kinds of economic activities where there is a concentration of output among a few individuals, marked skewness in the distribution of income. Do we identify these activities by measures of concentration and inequality of incomes? The individuals at the top not only supply a higher-quality product but they also enjoy massive scale economies. Borghans and Groot (1998) contend
that these activities are mainly media events in show business, arts and letters, and sports. These industries are characterized by competition for the number one position. Those at or near the top acquire endogenous property rights which yield additional income. ‘The extra reward is not due to the way in which the superstar performs but the fact that people are not satisfied to see other players once the superstar has been identified’ (Borghans and Groot, 1998, p. 555.). Their model also shows that income increases with the extent of the market, and market size is more important than the superiority of the superstar. Small differences in talent can be associated with large differences in income when output can be almost costlessly replicated.

Rosen assumed that there was a fixed distribution of talent among potential sellers. Borghans and Groot argue that a superstar acquires an endogenous property right which entitles her to a super-normal return. Talent-like ability is an attribute that defies easy quantification. Alan Krueger (2005) approximates talent \( q \) by the length of a performer's biography in the *Rolling Stones Encyclopedia of Rock & Roll.* Campbell McConnell is the author of the economics principles text which is allegedly the best-seller and hence is at the top of the talent distribution (McConnell and Brue, 2005). Defining and measuring talent in sports ought to be simpler. There are lots of statistics to identify the best shortstop. What is amazing is the sharp rise in salaries. A major league ballplayer received an average salary of $29,303 in 1970, which was 4.23 times the annual earnings in manufacturing. The ratio rose to 6.93 in 1977. The average salary of all major league ballplayers exceeded one million dollars in 1992 (The Baseball Archive). (The average salary in 1997 was 1.38 million dollars, which was 48.1 times the annual earnings in manufacturing.) The averages conceal the wide dispersion among individual players. Free agency and cable television apparently account for rising incomes for these superstars. The extent of the market again seems to be more important than the superiority of the talent.

In the Chung and Cox model, all sellers are equally talented. Consumer choices are proportional to the previous frequency of purchases which generated the J-shaped Yule distribution of record sales. Performers differ in Adler's world. Individuals search for information about performers through discussions with friends and experts. Performers could lobby the experts, bribe the disc jockeys, or invest in training resulting in a different distribution of ‘talents’. Will the search for information and actions by potential sellers generate a stable distribution of talents?

Gigantic incomes and rare talents attract attention, elicit conjectures, and encourage the search for an explanation. The phenomenon of superstars calling for an explanation is the shape of the income distribution with its long right tail. It is not the talent of the superstar or the determinants of the star's income. Sherwin Rosen has provided us with an elegant neoclassical model. Consumers patronize the most talented sellers to spread the fixed cost of consumption. Talented sellers have access to a low marginal cost technology enabling them to dominate their nearby competitors. Market size and rewards are skewed towards these talented superstars. Rosen's is a neat competitive market equilibrium explanation for all kinds of superstars.

‘supply and demand’

Peter Groenewegen
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Article

Although the notion of supply and demand in the context of market price determination potentially goes back to the economic writings of the Greek philosophers, the terminology itself is of more recent origin. It was not given any prominence in a chapter title or table of contents until well into the second decade of the 19th century (see Groenewegen, 1973), though during the previous two decades the phrase was used in the literature with increasing frequency. Its first use in English writings appears to have occurred in 1767 (see Thweatt, 1983). The discussion here is confined to English usage: French, Italian and German developments are omitted. This unfortunately means ignoring the interesting distinction made in German by Marx between ‘Zufuhr und Nachfrage’ (supply and demand) and ‘Angebot und Nachfrage’ (offer and demand) with its analytical connotations for more modern developments in economics (see Schefold, 1981).

It is certain that by the end of the 17th century the expression ‘supply and demand’ was not in use by English economic writers. For example, Locke (1691, pp. 45–6, 59, 61), despite the importance of the concept for his general argument, followed the contemporary practice and expressed the notion either in terms of the ‘proportion of the number of Buyers and Sellers’ or, more novel, the ‘quantity in proportion to [the] vent’. This terminology was explicitly criticized by John Law (1705, p. 5) who stated, ‘The Prices of Goods are not according to the quantity in proportion to the Vent, but in proportion to the Demand.’ By the end of the 1730s the demand part of the phrase was being used by prominent authorities like Erasmus Philips, Jacob Vanderlint and Bishop Berkeley and during the 1730s and 1740s was partially transformed by Francis Hutcheson (1755, II, pp. 53–4) into the argument that ‘prices of goods depend on these two jointly, the Demand … and the Difficulty of acquiring …’.

Another Scottish writer, Sir James Steuart, has the distinction of combining supply and demand together
on a number of occasions in the context of price determination and competitive analysis and thereby originating the first major use of the phrase. For example, in his chapter ‘Of Demand’, Steuart (1767, p. 153) argues, ‘The nature of demand is to encourage industry; and when it is regularly made, the effect of it is, that the supply for the most part is found to be in proportion to it, and then the demand is simple.’ Steuart (for example, 1767, p. 184) used the phrase on a number of other occasions and presumably it is from this source that it spread to authors like Adam Smith, Malthus, Thornton, James Mill, Horner, Brougham, Lauderdale and others, whose practice in this respect has been documented by Thweatt (1983). Some other aspects of the adoption in economics of the phrase ‘supply and demand’ may be mentioned. By the middle of the second decade of the 19th century usage of the phrase was still relatively rare. Only a few examples of more than 20 uses in a single work have been identified, no more than a dozen works use it more than ten times and most of the works Thweatt (1983) examined used the phrase only sparingly. Secondly, Scottish use of the new terminology was decisive with Steuart as the pioneer, Smith as a considerable influence and the *Edinburgh Review* circle as most important disseminator of the new terminology. This is not to say that English sources were unimportant. Malthus, for example, used it no less than 20 times in his influential second edition of the *Essay on Population* (1803); Torrens used it 29 times in his *The Economists Refuted* (1808) and over 70 times in his *Essay on Money and Paper Currency* (1812). However, the phrase ‘supply and demand’ did not really gain prominence until 1817 when Ricardo (1817, p. 382) used it in a chapter heading, while in the previous year, Mrs Marcet (1816, p. 296) had used it in the summary table of contents at the start of her *Conversation XV on value and price*.

Three further observations can be made on the etymology of the phrase ‘supply and demand’. First, the very slow adoption of the word ‘supply’ in conjunction with the much earlier use of ‘demand’ may be explained by the distinct usages associated with that word in expressions like ‘granting supply’ used in the language of public finance and its associated military connotations of supply troops. Secondly, the predominance of Scottish usage of the new terminology combined with their undisputed role in originating its usage in English economic discourse suggests the adaptation of the word from the French *supplier*, a verb with a less restricted meaning than English usage of the verb ‘to supply’. Thirdly, and most importantly, up to the 1830s either term was rarely used in its modern sense, that is, as a function of price. English pioneers in this modern usage appear to have included West (1826), Whewell (1930) and Longfield (1833) but systematic exposition of the practice had to await the work of Cournot (1838) and to a lesser extent that of John Stuart Mill (1848), and was of course especially developed by Marshall.

Groenewegen, Peter. "'supply and demand'." *The New Palgrave Dictionary of Economics*. Second
supply chains

Martin A. Lariviere
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

A supply chain encompasses all the resources and processes required to fulfill the demand for a product. A properly functioning supply chain is critical for a firm to be able to equate supply and demand at a reasonable cost. We first review common measures of supply chain performance and inventory related costs. We next discuss how facility choices, transportation modes, inventory policies and information structures interact to determine the profitability and responsiveness of a supply chain. We conclude with common criteria for categorizing supply chains.

Keywords

bullwhip effect; excess demand; flow time; information technology; inventory and holding costs; inventory investment; inventory policy; inventory theory; supply chains; supply-chain profitability

Article

Supply chains are all the resource and processes required to fulfill the demand for products. A supply chain encompasses physical assets such as factories, warehouses, and trucks as well as non-physical assets such as product design organizations, forecasting processes, and inventory tracking systems. As such, the supply chain affects nearly everything a firm does. A smoothly operating supply chain is essential for satisfying customers and consequently necessary for supporting marketing campaigns. Similarly, funding facilities and inventories is among the biggest capital needs of the firm and hence central to finance decisions.

Evaluating supply chains

Two important metrics of supply-chain performance are flow time and profitability. Flow time is the average amount of time a unit of material spends in the supply chain. Flow time directly affects the
amount of inventory in a supply chain. For a fixed rate of material flow, inventory increases in proportion with the flow time. Flow time also affects the firm's ability to react to shifts in market demand and its exposure to product obsolescence.

Supply-chain profitability is a function of revenues and costs. Revenues depend on the supply chain's ability to manage the flow of material, avoiding market downs while still satisfying demand. On the cost side, production and transportation costs will be driven by the product's design and the firm's choice of facilities. Additionally, there are costs associated with managing inventory, notably fixed costs of acquiring inventory and holding costs. The latter include out-of-pocket costs such as insurance and the opportunity cost of tying up capital in inventory. There may also be goodwill costs for missing sales (on the assumption that excess demand is lost) or forcing customers to wait (on the assumption that excess demand is back-ordered).

Additional measures reflect service quality. The fill rate is the fraction of product demand filled from inventory. The service level is the probability that all demand in a selling season is satisfied. It is straightforward to define these for a single product, but customers often order multiple items, and a high line-item fill rate may not result in a high order fill rate.

Determinants of supply-chain performance

Assuming supply equals demand is a staple of economic analysis, but equating the two in practice is challenging. Managing a supply chain requires a variety of decisions that vary in the costs and timing involved. Following Chopra and Meindl (2004), we group these decisions around four drivers of supply-chain performance: facilities, transportation, inventory, and information.

The facilities of a supply chain can broadly be classified as either processing material or storing material. Processing should be understood as adding value to the product; this may involve complex manufacturing or simply packaging. Storing material may involve more than keeping products safe. Distribution centres often ‘break bulk’, taking in large quantities (for example, truckloads) but sending out small quantities (for example, cases).

Investing in facilities is both time-consuming and costly. Consequently, the design of a facility network is a long-term, strategic choice that must balance current and future needs. Primary decisions are the number and locations of facilities. Centralized processing facilities usually result in lower average cost per unit produced. Centralizing storage facilities decreases the amount of inventory required to provide a given service level (Eppen, 1979). For either type of facility, centralization savings must be balanced with increased travel times and costs. Location also affects the available workforce, the supply of raw materials, tariffs and many other factors.

Supply-chain design must also consider the capacity of facilities and their operating characteristics. Capacity affects both cost and responsiveness. More capacity implies a greater investment, but this does not mean that a firm should build the minimum capacity necessary to cover expected demand. Markets are dynamic and uncertain, and a supply chain must be able to react to surges in demand. Having capacity above expected demand allows the firm to respond without imposing excessive delays on customers. The importance of additional capacity typically increases with the level of uncertainty in demand. An example of a relevant operating characteristic of a facility is its flexibility in handling different product mixes. Mix flexibility depends on both capital choices and workforce training. Much like carrying extra capacity, it adds cost but enables greater responsiveness.
Once facilities are specified, there is the question of how to move material through the network. Transportation modes represent trade-offs in speed and cost. Airfreight is faster than rail but also more expensive. Transportation decisions are intimately tied to inventory and facility choices. Because shorter transportation times allow for lower inventory, paying for premium service may be warranted. Facility decisions dictate the viable transportation decisions; a factory, for example, must be near a railhead in order to utilize trains. While firms often have one primary mode of transportation, it is not unusual for multiple transportation methods to be used. Transportation decisions thus include the rules governing which shipments are sent by which methods. In addition, a firm must decide the extent to which it will aggregate shipments over time. When a shipment method has a fixed capacity (for example, a truckload), combining today’s shipments with tomorrow’s may result in a higher utilization of capacity and a lower average cost at the expense of delay.

Inventory is what most people associate with supply chains. The primary reasons for carrying inventory are economies of scale and the time to execute supply processes. Economies of scale arise when there is a fixed cost for initiating production or transporting goods that is independent of the quantity involved. Producing or shipping in a batch then results in lower average cost but creates inventory in excess of the firm's immediate needs. When demand is relatively stable, such ‘cycle stocks’ are simply a cost of doing business. When demand shifts rapidly, fixed costs can greatly hinder a firm’s ability to adapt to the market. Supply-chain improvement initiatives consequently concentrate on reducing fixed costs. Beyond simply lowering costs, reduced fixed costs allow for smaller inventories and shorter flow times.

When fulfilling demand is time-consuming, ‘pipeline’ inventory of material in production or in transit is inevitable even with perfectly stable demand. When demand is uncertain, the firm must hold additional inventory. ‘Safety stocks’ buffer customers from production and distribution processes so demand can be filled without delay. Safety stocks increase both cost and flow time. Reducing safety stocks while maintaining service levels requires more accurate forecasts and shorter lead times.

Inventory decisions take place at different levels. At a low level, there are the basic questions of when and how much to order. Inventory policies depend on the costs of the system and desired service performance. For example, an order size may be found from the classical economic order-quantity model which trades off holding costs with fixed ordering costs. A reorder point, which dictates when to place an order, can be found from the service level the firm needs to offer the market.

At a higher level, there is also the question of what form of inventory to hold. Should the firm hold finished goods, sub-assemblies or merely components? In a multi-product environment, delaying product differentiation (much like centralizing inventory) allows the firm to provide a given level of service with less inventory. In some settings (for example, laundry detergent), customers demand quick service, and holding finished goods is inevitable. In others (for example, paint), the final processing steps are sufficiently quick and customer tastes sufficiently heterogeneous that a postponement strategy is viable. Because customers will tolerate a delay to get exactly what they want, the firm may postpone differentiation and save on inventory costs. The appropriate form of inventory depends on both customer needs and available technology. Supply-chain management thus reaches back to product and process design.

The final supply-chain performance driver is information. Managing inventory requires an estimate of the distribution of demand and how it varies over time, not just a forecast of mean demand. One must also know the firm’s pricing and promotional plans and estimate how these will affect demand. The better the estimate of demand, the less safety stock is required. The difficulty of forecasting demand
interacts with other decisions the firm has made. If the firm exploits postponement and holds only sub-assemblies, it may forecast demand at the sub-assembly level rather than at the end-product level. Also, not all levels of a supply chain will necessarily have the same information available to them. Demand information often becomes distorted and more variable as one moves up a supply chain away from the market, a phenomenon termed the ‘bullwhip effect’ (Lee, Padmanabhan and Whang, 1997).

Beyond knowing demand, a supply chain also needs to know supply. Tracking the amount of inventory on hand seems a simple matter of comparing what has come in with what has gone out. In practice, maintaining accurate inventory records is a complicated process. A supermarket carries tens of thousands of distinct products, and there is no way to maintain correct records without information technology that integrates receiving databases with point-of-sales scanners. Even these systems are not perfectly accurate because they do not account for misplaced or stolen items. Further, this deals with only one location. Optimal decisions may depend on the available inventory at multiple locations as well the status of goods in production or transit.

Modern information systems have greatly affected supply chains, both at individual locations and between locations. They have had an additional benefit in reducing the effort and cost of placing orders. Electronic data interchange systems reduce the fixed costs of placing orders and hence result in lower cycle stocks.

Classifying supply chains

Supply chains can be classified by their physical structure, their strategic focus and their economic organization. The physical structure reflects how material moves through a supply chain. The simplest supply chains have a serial structure. Each echelon (or level) consists of a single node and all material moves from the highest to the lowest echelon. Alternatively, one can have an assembly system in which multiple nodes at a higher level all supply a single node at a lower level. Thus, not all material follows the same path through the supply chain. Distribution systems are essentially the reverse of assembly systems. A single point at an upper echelon supplies multiple points at a lower echelon. These structures can be combined. Looking upstream from an auto assembly plant, one sees an assembly structure with parts arriving from many facilities. Looking downstream, one sees a distribution system as completed cars are sent to multiple dealers.

The physical structure dictates the decisions that must be made. The analysis of serial systems focuses on what the inventory policy should be at each echelon. Assembly systems with one end product are similar, but if there are multiple products one must also determine how orders are to be filled as a function of available inventory. In a distribution system, one needs to consider how to ration stock among the multiple end points when the central higher node has limited inventory.

Following Fisher (1997), the strategic focus of supply chains can be either efficient or responsive. Efficient supply chains are designed to produce and deliver goods as cheaply as possible even though such a design may greatly increase flow times. Responsive supply chains sacrifice low cost for speed. This classification is useful because there is no one best supply-chain design. Firms must make trade-offs to align their supply chains with the markets they serve. Efficient supply chains are appropriate for ‘functional’ products such as consumer staples with long life cycles and low variety. ‘Innovative’ products, such as fashion clothing and consumer electronics with short life cycles and high variety, require greater responsiveness.
Finally, one may classify supply chains based on their economic organization, the degree to which they are centralized or decentralized. We have assumed a completely centralized supply chain and used the terms ‘firm’ and ‘supply chain’ interchangeably. However, essentially no supply chain today is completely controlled by one party. Rather, most are decentralized with multiple decision makers acting in their own interests. A consumer electronics company may hire one firm to produce an application-specific integrated circuit, contract with a second to assemble the final product, and rely on a third to transport the goods, all while selling through independent retailers.

Designing a supply chain consequently goes beyond determining the supply chain drivers discussed above. One must specify not just where a facility will be located but who will own and operate it. Decentralized supply chains thus raise issues that go beyond traditional supply-chain analysis. For example, who is ultimately responsible for unsold merchandise can make a dramatic difference in the performance of a decentralized supply chain, but it is not an issue in a centralized one (Pasternack, 1985).

surplus

Anthony Brewer
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The surplus produced by an economy, in the sense discussed here, is its output over and above the necessary subsistence of the labour force as well as other costs. This concept has a long history in economics, with the focus sometimes on the uses of the surplus for luxury consumption, state spending, or new investment, and sometimes on income distribution – if workers are paid a subsistence wage then the surplus accrues to non-wage earners.

Article

The key question in defining the surplus is: what should be counted as the cost of maintaining the labour force? If we deduct from output only what is physically necessary to maintain workers at a minimum standard of existence, the resulting surplus measure would represent the amount available for everything else. It could be relevant, for example, to a very poor country or to a situation of total war. In a very crude version of classical economics, wages might be held down to the subsistence minimum by Malthusian population pressures with the surplus over bare subsistence going to others. In modern developed economies wages are well above physical subsistence, so this definition of surplus is of little interest. At the other end of the scale, we could count the actual wage, whatever it might be, as the cost of subsistence of the labour force, so surplus is simply defined as total income less wages, equal by
definition to total non-wage incomes.
Modern proponents of the surplus approach typically claim that (real) wages are determined prior to other variables, at some socially acceptable level (perhaps representing workers’ bargaining power), so wages can be treated as fixed, with profits (plus other non-wage incomes) determined by the remainder, or surplus. With very strong assumptions, the static equilibrium profit rate and prices can then be determined, given the real wage.

Necessities and luxuries: from Petty to Smith

Early writers on economic issues often used a concept of surplus, focusing on the production of necessities (frequently identified with food) and drew conclusions about the relation between sectors, not sources of income. The key idea is that people need a certain amount of food (and other necessities), but no more, since ‘[t]he desire of food is limited in every man by the narrow capacity of the human stomach’ (Smith, 1776, p. 181). The agricultural sector has to feed itself and everyone else. The size of the non-agricultural sector is limited by the agricultural surplus, that is, the output of food less the amount consumed by the agricultural sector itself. Using a somewhat broader definition of necessities, William Petty gave a hypothetical example (with an implausibly high level of productivity for the period): ‘if there be 1000 men in a territory, and if 100 of them can raise necessary food and raiment for the whole 1000’ (Petty, 1899, vol. 1, p. 30). His worry was about employment – only 100 are needed to provide necessities, so what will the rest do? In his example, he suggested a variety of employments (200 produce for export, 400 produce luxuries, and so on) but some might remain unemployed.
David Hume used the idea of an agricultural surplus quite differently. ‘The land may easily maintain a much greater number of men, than those who are immediately employed in its culture, or who furnish the more necessary manufactures to such as are so employed’ (1955, p. 6). The question he asked was: why should farmers work to produce more than they themselves want to eat? They might be forced to do so, in a feudal system, but that was unlikely to generate much of a surplus. If, however, they could buy attractive manufactures, they would have an incentive to produce and market a surplus. ‘When a nation abounds in manufactures and mechanic arts, the proprietors of land, as well as the farmers, study agriculture as a science, and redouble their industry and attention’ (1955, p. 11). For Hume, this was not simply a theoretical point – in his History of England (1778) he described how the introduction of luxuries, initially from abroad, changed the behaviour of successive generations down to his own time.
Adam Smith told a similar story. ‘When by the improvement and cultivation of the land the labour of one family can provide food for two, the labour of half the society becomes sufficient to provide food for the whole’ (1776, p. 180). Although the need for food is limited, ‘the desire of the conveniences and ornaments of building, dress, equipage, and household furniture, seems to have no limit’ (p. 181).
Smith’s account of development in Europe drew on Hume, and stressed that as landlords became more concerned with luxury spending than with maintaining their political power, they switched to forms of tenure which gave better incentives to farmers.

The concept of surplus sketched in the last three paragraphs is a surplus generated in the necessity-producing sector which supports everyone else – soldiers, the upper class and their servants, luxury producers, and so on. There is, however, no presumption that farmers, or workers, are reduced to bare subsistence. Part of the surplus may be extracted as rent, but part accrues to the producers of necessities...
Cantillon and Quesnay

In Richard Cantillon's theory, written before Hume but published later, the land is fundamental and everyone works, directly or indirectly, for the landlords. Whether the owner manages the land himself or lets it out to farmers, the farmers and labourers must ‘have a living’, but the ‘overplus [in the French original, ‘surplus’] of the land’ goes to the owner (1755, p. 6). Wages are set by social convention, at levels which vary between different places. Here, then, the distribution of income between landlords and the rest is determined by the surplus over a socially determined subsistence level. François Quesnay developed Cantillon's model further, using the famous Tableau économique to show the relations between the different sectors of the economy (Meek, 1963). Only agriculture generates a net product (produit net) or surplus of output over costs, since the ‘sterile’ manufacturing sector covers its costs, but no more.

Cantillon treated agricultural productivity as essentially given. Quesnay, by contrast, thought that French agriculture had declined, bringing the whole economy down with it. Investment, he argued, is needed to maintain agricultural productivity. Excessive taxes and restrictions on trade had so reduced agricultural returns that farmers were unable to invest. The net product plays two roles in Quesnay. Reforms which restore returns to a healthy level accrue first to farmers, allowing them to invest, but when leases come up for renewal the owners will be able to capture the increased net product as rent. Whether either Cantillon or Quesnay allowed for any net profit on investment to accrue to tenant farmers in the long run is a matter of debate.

In sum, Quesnay and his followers, the Physiocrats, took a critical step towards classical economics by recognizing the need for investment (financed out of the net product), but did not explicitly recognize the return to investment as a continuing source of income (and a share of the surplus) or make any provision for continued investment beyond the periodic renegotiation of rents. This next step should be credited to Anne Robert Jacques Turgot, who anticipated key elements of Adam Smith's system ten years before the Wealth of Nations.

Classical economics

David Ricardo plays a central role in the surplus interpretation of classical economics (hence the surplus approach is alternatively known as neo-Ricardian economics). He based himself on Smith but concentrated particularly on the distribution of income between wages, profits, and rent, which he thought Smith had not treated adequately. The familiar textbook summary of Ricardian distribution theory makes a good starting point. Land is of varied qualities, and there are diminishing returns to investment on any given piece of land. As cultivation expands (to feed a growing population), marginal returns fall. Marginal land yields no rent so, with a given real wage, profit is the difference between costs (including wages) and returns on marginal land. Better land, of course, yields higher returns, but landowners capture intra-marginal returns as rent. Capital mobility keeps non-agricultural profits in line with returns on marginal land. As the economy grows, the margin moves out and the surplus at the margin falls, bringing the profit rate down. In this reading of Ricardo, then, profit is the surplus over
given wages on marginal land, while rent and profits absorb the surplus for the whole economy. There are two main problems with this reading. First, costs and returns have to be calculated in terms of prices to give profit as a percentage return on investment. Ricardo sought to solve this problem with a labour theory of value – prices proportional to labour inputs. This way, costs and returns could be calculated without reference to the profit rate, which is the unknown in the calculation. Unfortunately, labour values are not compatible with equalization of profit rates across industries. Ricardo had no answer to this problem.

Second, and more relevant here, the surplus reading of Ricardo requires real wages to be treated as independent of profits and prices. It is not clear that this assumption adequately represents Ricardo's wage theory. He defined the natural price of labour, like the natural price of anything else, as the cost of producing it, hence ‘that price which is necessary to enable the labourers … to subsist and perpetuate their race, without either increase or diminution’ (1817, p. 93). But he then admitted that the wage must rise above this level in a growing economy ‘for an indefinite period’ (p. 95). On average, therefore, the actual profit rate must be below the rate calculated using the natural (subsistence) wage throughout the process of growth, until the stationary state is reached. Since growth influences wages and hence profits, and the growth rate of the economy depends (inter alia) on the profit rate and the total size of the surplus, the surplus cannot play the independent causal role that the simple version suggests.

Adam Smith had rejected a subsistence wage theory much more explicitly than Ricardo. He had a notion of agricultural surplus, as noted above, but his (rather confused) theory of profit does not fit the Ricardian surplus pattern at all. If we look at the classical school as a whole, Ricardo's emphasis on factor returns and on surplus as an explanation of non-wage incomes is only a relatively small element in a large body of work devoted to economic growth, to policy issues and incentives, and so on.

Marx

If there is one writer who fits what has been called the surplus approach to income distribution, it is Karl Marx. This is not surprising, because the surplus approach was largely inspired by Marx and by his view of his predecessors.

The substance of Marx's analysis of profit (or surplus value) is very similar to Ricardo's, though Marx's terminology and conclusions are very different. Like Ricardo, Marx adopted a labour theory of value, but where Ricardo saw the labour theory as a theory of price (and one which he knew could not be sustained, as noted above), Marx distinguished between value and price, simply defining value as labour embodied and thus making the labour theory of value true by definition. In the first two volumes of Capital (Marx, 1867–94), he assumed that prices were proportional to values (as defined), without giving any justification.

The value of labour power (the labour value of the real wage) is determined by subsistence needs, including a (rather ill-defined) ‘historical and moral element’. The value produced by each worker depends on the hours worked. Given the assumption that everything (including labour power) sells at a price reflecting its (labour) value, the difference between the value produced and the value of labour power accrues to the capitalist employer as profit.

In the unfinished third volume of Capital, Marx (1867–94) tried to link the analysis of the first two volumes to the determination of what he called ‘prices of production’ (long-run equilibrium prices or Smith's ‘natural prices’). The key idea is that total profit is determined by total surplus value, as
analysed above, but that relative prices adjust to equalize profit rates across industries. His procedure for
doing this is not now regarded as sound. In the third volume he also allowed for some part of surplus
value to be absorbed by incomes other than profit (such as rent).
In sum, Marx explained profit by the surplus of hours worked over the hours needed to produce
subsistence, and hence by output over a socially determined subsistence wage. The main problem of
substance with this theory is that his subsistence wage is a matter of definition, without a satisfactory
account of how wages are determined in the market. When he did provide such an account (in the
splendid account of accumulation in *Capital*, volume I, chapter 25), wages in a growing economy turn
out to be determined simultaneously with profit and accumulation (as in Smith and Ricardo), so the
wage is not determined prior to other variables after all.

The 20th century

By the time Marx's *Capital* was published, the mainstream in economics was moving away from a
subsistence wage theory, and hence away from surplus theories of profit. More generally, late 19th- and
20th-century mainstream (neoclassical) economics had little use for the notion of surplus because
economic variables (including incomes, consumption demand, investment and savings decisions, and so
on) were all to be explained in a common framework, with no distinction between necessities and other
goods or between different types of income.

John Hobson, an avowed heretic, was one of the few to keep the notion of surplus alive. In his account,
one part of output corresponds to the costs of production, including both a subsistence wage (with a
‘moral’ element as well as the bare physical minimum) and a return on investment sufficient to induce
investors to keep their investment unchanged. The remainder is the surplus. In a growing economy,
factor returns have to be higher to induce growth: the part of the surplus absorbed in this way is the
‘productive surplus’ or ‘costs of growth’. The rest is the ‘unproductive surplus’ or ‘unearned
increment’ (1910, ch. 4). In modern society the surplus increases with increased productivity, but much
of it accrues to a small minority who earn so much that they cannot spend it all. The resulting excess
saving causes unemployment, a search for investment opportunities abroad, and hence imperialist
expansion.

Paul Baran's influential *Political Economy of Growth* (1957) has much in common with Hobson. Baran
defined the ‘actual surplus’ as actual output minus actual consumption (of all sorts), making it
effectively equal to new net investment. Up to a certain level, at least, investment determines surplus,
not the other way round, because higher/lower investment will induce higher/lower aggregate demand,
bringing the actual surplus (in Keynesian terms, saving) into line. By contrast, the ‘potential surplus’ is
the difference between maximum potential output and the minimum acceptable level of consumption,
showing the maximum possible investment level. Surplus concepts like these provided a rather loose
framework for radical discussions of growth, unemployment, the role of military spending, and the like
in the mid-late 20th century.

John von Neumann's classic paper on general equilibrium deserves mention, since it embodies a surplus
account of growth, assuming that ‘all income in excess of necessities of life will be reinvested’ (1945, p.
2). It was important in the development of mathematical techniques for handling general equilibrium,
but the surplus aspect was not widely developed.

Piero Sraffa's *Production of Commodities by Means of Commodities* (1960) can be seen as a restatement
of the Ricardo–Marx theory of profit and prices, but avoiding the problems caused by the labour theory of value. Put simply, Sraffa wrote down equations for a many-commodity system showing the conditions for an equal profit rate across all industries, and showed that there remained one degree of freedom, representing the distribution of income between wages and profits (assumed to be the only forms of income). Sraffa did not commit himself on how to close the system, but the majority of his followers have chosen to take the real wage as fixed. When this is done, the profit rate and the set of relative prices are simultaneously determined. Sraffa's system does indeed provide a logically coherent version of the surplus theory of profit free of the labour theory of value. Beyond that, it is not clear why one would want to assume that wages (and the whole pattern of outputs and inputs) are determined independently of and prior to the determination of prices and profits.

Conclusion

Classical economists were acutely aware that wages were not very far above subsistence. An important theme in their work was indeed the generation of a surplus over subsistence and the use of part of the surplus for investment and growth, but an interpretation which insists on treating wages as determined prior to other variables is at best a first approximation, used by some classical writers but only with heavy qualifications. In a modern context, it is hard to see what purpose a concept of surplus serves when wages are far above subsistence.

An important advantage of survey data over, for example, administrative data is the opportunity to directly measure subjective phenomena, such as respondents’ expectations on some future outcomes or their preferences over consumption bundles. The existing literature shows that data on expectations and preferences reported in carefully designed household surveys can greatly enhance the empirical content of models of economic decisions and choices. A particularly promising route is to combine subjective data with data on actual behaviour.

Article
When economists analyse survey data, they must confront characteristics of the data-generating process that may distinguish these data from other types, such as administrative records. Discussions of survey data analysis, such as the text by Chambers and Skinner (2003), typically consider problems caused by response errors, non-response, partially censored responses and complex sampling schemes. These problems are not unique to survey data: administrative records may not perfectly capture the phenomena of interest, may be incomplete, may be ‘masked’ to preserve confidentiality, and may be generated by something very different from simple random sampling or stratified sampling. Detailed discussions of methods for addressing such problems are included elsewhere in this dictionary and in http://www.dictionaryofeconomics.com/library/lemoyne.edu/article?id=pde2008_A000229&goto=S&result_number=1686

http://www.dictionaryofeconomics.com/library/lemoyne.edu/article?id=pde2008_A000229&goto=S&result_number=1686
In this article, we focus on survey data on subjective phenomena. Such data cannot be found among administrative records but are commonly reported in surveys. We discuss methods for interpreting subjective data and utilizing them in econometric analysis of individual behaviour, highlighting recent innovations in the measurement of expectations and preferences. The collection and analysis of subjective data was an important component of mainstream economic research until the mid-20th century, when it fell out of favour. Since then, the standard empirical method for the study of choice behaviour has been one of revealed preference analysis exclusively utilizing data on observed choices and attributes in combination with strong assumptions on expectations and preferences. Yet the empirical basis for rejecting the use of subjective data was very limited (see, for example, Dominitz and Manski, 1997a; 2004). In fact, Tobin (1959, p. 11) concluded his generally negative analysis of expectations and attitudes data with a call to ‘investigate the questions [of] which attitudes are the most important ones to investigate in periodic surveys and what is the best way to use these data in combination with other economic information’. But this call went unheeded by economists, who ‘are taught early in their careers to believe only what people do, not what they say’ (Manski, 1990).

The prevailing scepticism has recently been challenged by researchers who seek to use data on subjective phenomena to weaken assumptions made on individual behaviour and to assess the credibility of maintained assumptions. To be viable, this approach requires careful design and administration of the survey instrument and proper interpretation of survey responses. Of particular concern are loosely worded survey questions that are subject to multiple interpretations by respondents and researchers alike. These concerns apply to the collection and analysis of all forms of survey data but are particularly salient in the context of subjective data. Importantly, even if subjective data suffer more severe response problems than do other forms of data, researchers must confront the limitations of the main alternative to directly measuring expectations and preferences, that is, making strong assumptions on the form of expectations and preferences in order to infer them from realizations data alone.

In this article, we demonstrate that the existing literature provides good reasons to believe that data on expectations and preferences reported in carefully designed household surveys can greatly enhance the empirical content of models of economic decisions and choices. In so doing, we endorse Manski’s (2004) argument in favour of combining subjective data with other data to estimate models of choice behaviour, and we reiterate Tobin’s (1959) call to determine the circumstances under which this combination is most fruitful.

Expectations

Published reports on consumer confidence indices are almost certainly the best-known output from analyses of household survey data on expectations. We begin by summarizing the history of consumer confidence measurement, an important component of the broader history of expectations data collection (see also Dominitz and Manski, 2004). We then discuss recent developments in the analysis of such qualitative expectations data and in methods for eliciting quantitative expectations in the form called for by modern economic theory – that is, subjective probability distributions.

Measures of consumer confidence were developed during the mid-20th century by George Katona and his colleagues at the University of Michigan's Survey Research Center, where much pioneering work in
economic surveys has been conducted. The Index of Consumer Sentiment aggregates responses to
expectations and attitudes questions asked in the monthly Survey of Consumers, with ordered categories
that are coded as positive, neutral, or negative. Responses to the following question, for instance, were
and still are included:

Now looking ahead – do you think that a year from now you (and your family living
there) will be better off financially, or worse off, or just about the same as now?

The Federal Reserve Board formed a committee to assess the value of expectations and attitudes data
soon after initiation of the Michigan surveys, which the Board funded. The committee produced
negative findings on the ability of these and other consumer sentiment data to predict individual savings
and consumption reported in follow-up interviews (Tobin, 1959). Katona (1957) and others argued that
the indices predict aggregate economic outcomes. Over the next half-century, consumer confidence
measures would become widely discussed indicators of the state of the economy and would find some
use in macroeconomic studies of aggregate economic behaviour (Ludvigson, 2004). The qualitative data
on expectations and attitudes that form the basis for these measures, however, were generally not
thought to be of value for use in microeconomic studies of individual behaviour. Recent research has
highlighted limitations that are generic to traditional, qualitative questions eliciting expectations.
The form of these expectations questions necessarily limits the predictive value of individual responses.
Manski (1990) formally modelled respondents who report best predictions (that is, minimize expected
loss) when asked yes/no expectations questions concerning future binary outcomes. These respondents
say ‘yes’ if the subjective probability that the outcome will occur exceeds some threshold. Tobin (1959)
and Juster (1966) had previously posited similar models of survey response. Manski derives sharp
bounds on the correspondence between reported expectations and outcomes in a best-case scenario,
where all respondents form rational expectations and minimize symmetric loss functions. The latter
condition yields a threshold probability of 0.5. Even then, in the absence of an aggregate shock, all we
would expect to find in a follow-up interview is that the outcome will occur for (a) more than half of all
‘yes’ respondents and (b) less than half of all ‘no’ respondents. Das, Dominitz, and van Soest (1999)
extended Manski’s model to ordered-category expectations of the form used in the consumer confidence
questions and conducted a test of rational expectations using income expectations and realizations in a
panel survey. Dominitz and Manski (1997b) emphasize that the vague wording of many expectations questions further
limits the interpersonal comparability and hence the predictive value of responses, as respondents must
determine which possible outcomes would, for instance, constitute being ‘better off financially’, ‘worse
off’, or ‘about the same’. Still, many researchers have formally modelled such qualitative responses,
under strong identifying assumptions, and used the data to learn about expectations formation and the
relationship between expectations and realizations. Pesaran and Weale (2006) review work that analyses
the qualitative and quantitative reports of expectations.
The limitations generic to qualitative survey data on expectations need not apply to quantitative
expectations data. Some surveys use questions of the ‘What do you expect…?’ form to elicit point
expectations of continuous variables. This question format is typical in surveys of professional
forecasters (see Keane and Runkle, 1990), but has also been used in household surveys. Bernheim
survey data, analysis of: The New Palgrave Dictionary of Economics (1989; 1990) studied expectations of retirement age and Social Security benefits reported in the Retirement History Survey, a survey that followed about 11,000 Americans aged 58–63 in 1969 through the 1970s. Lancaster and Chesher (1983) used point expectations of wage offers, in addition to individual reports of the subjective reservation wage, to identify a structural model of job search. These point expectations are typically interpreted as the mean of the subjective distribution, but other models of survey response are certainly plausible. Bernheim (1989), for instance, presents evidence that respondents report the mode of the subjective distribution of retirement age rather than the mean. To clarify the expectations of interest and to obtain information on uncertainty about prospective outcomes, economists designing surveys in the early 1990s began eliciting expectations in the form of subjective probabilities, as previously proposed by Juster (1966). Early examples are found in the Health and Retirement Study (HRS) survey, of which Tom Juster was the Principal Investigator, as well as the Survey of Economics Expectations (SEE), the Bank of Italy's Survey of Household Income and Wealth (SHIW), and the Dutch Center panel.

When the outcome of interest is binary, the probability of its occurrence summarizes the subjective probability distribution. Dominitz and Manski (1997b), for example, use SEE data to study economic insecurity arising from the prospective loss of a job or of health insurance coverage. When the outcome of interest takes on many values, a sequence of probabilities may be elicited to describe the subjective probability distribution. For instance, Hurd and McGarry (2002) use HRS data to study survival probabilities, which they find to be predictive of mortality. Dominitz (2001) demonstrates how SEE income expectations data can be fruitfully combined with income realizations data to estimate income expectations models of the type commonly adopted in research on consumption and savings, but allowing for greater heterogeneity. Guiso, Jappelli and Terlizzese (1992) use SHIW income expectations data to study the relationship between subjective uncertainty and precautionary savings. In each case, the authors impose parametric assumptions on the subjective probability distribution to identify the entire distribution from a handful of subjective probabilities.

Preferences

Standard econometric analysis of behaviour reported in a household survey combines data on household attributes and observed choices to make inferences on preference parameters and to generate predictions of choices not observed in the data. This application of revealed preference (RP) analysis typically requires strong assumptions on the expectations, choice sets, and preferences of households. In some cases, the data on choices and household attributes are sufficiently rich so as to yield credible inferences and predictions under weak assumptions. Many other situations, however, will require strong, untestable, and perhaps untenable assumptions. This may be the case, for instance, if the set of available alternatives varies considerably across households but the survey collects data only on the alternative selected by each household. The restrictiveness of the maintained assumptions may become particularly problematic when choices are made in a life cycle context with uncertainty, where subjective distributions of the future consequences of current choices are important.

The addition of survey questions on subjective phenomena may allow researchers to test and relax the maintained assumptions. First, questions on future expectations can be used, as discussed above. Second, respondents can be asked to make choices in hypothetical situations or to evaluate hypothetical
opportunities, thereby providing *stated preference* (SP) data. Analysis of SP data has been commonplace for quite a long time in marketing research and transportation studies, but considerable scepticism remains in economics. Louviere, Hensher and Swait (2000) review the advantages and drawbacks of using SP data in place of or in combination with data on actual behaviour.

Consider hypothetical choice questions in which respondents are offered a number of alternatives and asked to choose one. Strong assumptions on choice sets required for analysing RP data can be avoided because the alternatives are explicitly given and thus observed by the researcher. This even applies to choices in a life cycle context where the question may specify the distribution of future outcomes associated with each alternative (for example, Barsky et al., 1997); therefore, the researcher may not need to elicit expectations or infer them from realizations data. Moreover, the range of offered alternatives can be manipulated to extract maximal information on preferences and to estimate preference parameters more efficiently than would be possible with RP data.

As with revealed preference analysis of discrete choice behaviour, hypothetical choices may be modelled using a random utility framework in which the utility of each alternative depends upon its specified attributes and an idiosyncratic disturbance term (see McFadden, 1986). For empirical implementation, the multinomial logit model has been the standard (McFadden, 1973), but more general models are available, such as multinomial probit to avoid the assumption of independence of irrelevant alternatives or mixed logit to account for unobserved heterogeneity across respondents (for example, Revelt and Train, 1998).

Still, even with hypothetical choice data some assumptions on choice sets or preference structures will be required, because it is not generally possible to fully specify the characteristics of each alternative. If so, then one may assume that unobserved attributes enter utility additively and are the same for all choice alternatives, so that they do not matter for the choice. Another possibility is to assume that the respondent takes an expectation over the distribution of unobserved attributes, given the information that is provided (Manski, 1999).

Much of the scepticism about SP data seems to arise from the extensive literature on problems with contingent valuation (CV) studies that seek to measure willingness to pay (WTP) for or willingness to accept in exchange for a non-market good, a frequent subject of analysis in environmental economics. In one type of CV survey, respondents get information about the current state (for example, of the environment) and a proposed change (for example, a quality improvement). They are then asked whether they would vote in favour of the change, given that this change would require a certain monetary cost (such as a tax increase). Survey responses are used to estimate the population distribution of the subjective valuation of the good at issue (see Mitchell and Carson, 1989).

Research has shown that CV studies can yield systematically misleading assessments of the value of a good (for example, Diamond and Hausman, 1994). Hanemann (1994) argues that many of the problems with CV arise from the way in which the survey is conducted. He concludes that the existing criticism is often justified but not valid in all circumstances: a well-designed and rigorously conducted CV study can yield reliable estimates of WTP. Note that some criticisms of the collection and analysis of these data actually question the basic assumptions of revealed preference analysis rather than simply the elicitation of preferences (for example, Ariely, Prelec and Loewenstein, 2003).

The problems with CV studies can also apply to SP experiments. For example, they can be sensitive to framing effects because respondents tend to choose the middle category, to anchoring or status quo bias
if one of the alternatives is clearly specified as the benchmark, or to yea-saying if questions have a yes or no format (Schwarz et al., 1985). Recent evidence suggests, however, that serious problems can largely be avoided by a careful and precise wording of the questions (Louviere, Hensher and Swait, 2000).

An obvious way to test and validate SP data is to compare them with RP data (see Louviere, Hensher and Swait, 2000). Among economic studies, Euwals, Melenberg and van Soest (1998) show that stated preferences for changes in working hours are predictive of changes in actual hours, and Kapteyn (1994) compares data on actual expenditures on certain commodities with data on subjective income evaluations, and finds that the two types of data are consistent with a common underlying utility function. The conclusion from studies such as these seems to be that RP and SP data are often consistent with each other, once an appropriate model is used to allow for different sources of idiosyncratic noise. In such a case, SP data can lead to more efficient estimates than RP data, and opportunities for combining the two data sources can be exploited to more accurately estimate parameters of interest.

Louviere, Hensher and Swait (2000) focus on static models of consumer choice, but the potential advantages of SP data also apply to dynamic models of consumer behaviour under uncertainty. Models of intertemporal choice have become increasingly important in many areas of empirical economics as researchers have gained access to rich panel data on households in the Panel Study of Income Dynamics and many subsequent national surveys in the United States and Europe.

Two central parameters of interest describe the agent's time preference and risk aversion. Standard RP analysis would yield inferences on these preference parameters based solely on, for example, observed savings and investment decisions. The rate of time preference indicates how the utility of current consumption is traded off for future consumption (for example, paid for with current savings). Risk aversion parameters indicate how risky alternatives (such as risky assets) are valued relative to less risky ones (such as risk-free assets). A standard identifying assumption in econometric models of intertemporal choice requires that time preferences and risk preferences be invariant across households. In recent years, economists have used SP data to estimate the distribution of time and risk preference parameters in heterogeneous populations. Frederick, Loewenstein and O’Donoghue (2002) summarize empirical measures of rates of time preference (by economists and others) via RP and SP methods and use this to argue that the standard model of intertemporal choice (a single discount rate) is misspecified.

Barsky et al. (1997) use SP data from an experimental module of the HRS. For risk preferences, the survey asks respondents to choose between two jobs, either the current job with the current income or a new job with higher expected income but also with some income risk. For time preferences, the survey asks respondents to make a sequence of choices over alternative consumption profiles across time. Their results show that SP data can be usefully applied to economic choices in a life cycle context, but they also pay attention to the potential pitfalls of using SP data with incompletely specified alternatives, such as the tendency to prefer the current job for reasons other than income.

Similar survey methods have been introduced in the Netherlands. Kapteyn and Teppa (2003) use SP data from the Dutch Center panel to estimate a structural model with habit formation in which preference parameters vary with individual attributes. Donkers, Melenberg and van Soest (2001) use SP data on choices between hypothetical lotteries to identify a structural model that generalizes a standard expected utility model by allowing for reference-dependent utility, loss aversion, and probability weighting.
Conclusion

We have described recent developments in the collection of subjective data on expectations and preferences and the estimation of behavioural models using these data. Combining data on expectations and preferences with each other and with data on actual choice behaviour is an important goal of this endeavour. An ambitious example is Erdem, Keane and Strebel (2005), who estimate a dynamic structural model of information acquisition and purchase decisions by consumers who choose among brands of personal computer. To identify the model, they utilize reports of price change expectations and stated assessments of brand quality in combination with data on actual purchase behaviour.

It is far too early to conclude that the general scepticism among economists about data on subjective phenomena has been overcome. However, we strongly believe that recent innovations in the measurement and analysis of expectations and preferences are enriching the empirical content of economic models and hold great promise for the future.

sustainability

Daniel W. Bromley
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Sustainability concerns the specification of a set of actions to be taken by present persons that will not diminish the prospects of future persons to enjoy levels of consumption, wealth, utility, or welfare comparable to those enjoyed by present persons. Sustainability grows out of a need for intertemporal ethical rules when one generation can determine the endowment of natural and constructed capital that will be passed on to all subsequent generations. Economic models of sustainability seek axiomatic guidance for the selection of rules regarding natural resource use. Ecologists approach sustainability from a related – though not identical – ethical stance.

Keywords

exhaustible resources; Hartwick's rule; Hotelling, H.; intertemporal efficiency; justified commitment; liability rule; natural assets; precautionary principle; pure theory of savings; Ramsey, F.; safe minimum standard; sustainability

Article

The World Commission on Environment and Development (1987) popularized an idea that can be traced to Frank Ramsey's seminal work on the pure theory of savings (1928). Sustainable development meets ‘...the needs of the present without compromising the ability of future generations to meet their own needs’.

Some natural scientists discuss sustainability as it relates to human well-being. For instance, environmental sustainability

seeks to improve human welfare by protecting the sources of raw materials used for human needs and ensuring that the sinks for human wastes are not exceeded, in order to prevent harm to humans. (Goodland, 1995, p. 3)
In a related article, Goodland and Daly (1996, p. 1003) assert that environmental sustainability means ‘maintaining natural capital’. The strict maintenance of natural capital has come to be called ‘strong sustainability’. There are also efforts to connect sustainability with the idea of the earth’s carrying capacity:

Sustainability characterizes any process or condition that can be maintained indefinitely without interruption, weakening, or loss of valued qualities. Sustainability is a necessary and sufficient condition for a population to be at or below carrying capacity … Carrying capacity … always embodies the concept of sustainability. (Daily and Ehrlich, 1996, p. 992).

Notice two key premises here. First, reflecting what Pigou called a ‘faulty telescopic faculty’, the absence of some form of collective action implies that the future is not secure if left to the whims of atomistic agents seeking their best advantage. Second, natural resources are an indispensable asset upon which the future depends. In addition to these two premises, Lele and Norgaard (1996) remind us of the central value judgement inherent in discussions about sustainability, namely, that we ought to care about the future.

Modelling sustainability

Following Ramsey’s early work, Harold Hotelling (1931) developed the general theory of production from non-renewable resources. But economists started to devote consistent attention to the problem of sustainable production from nature only in the mid-1970s, when the Review of Economic Studies published a symposium issue on the subject (Dasgupta and Heal, 1974; Solow, 1974; Stiglitz 1974a; 1974b). An economy produces goods and services in the current period under constant returns to scale, by using previously constructed capital and a pool of labour, and by drawing down some increment of a non-renewable natural resource (such as oil, titanium, copper, magnesium) (Solow, 1986). If population is held constant, and if there is no technical change, Hotelling’s condition asks that the shadow value of the natural resource left in the ground should show instantaneous rates of increase that exactly match the current value of the marginal product of the reproducible capital. If labour and constructed capital are fully employed, if the conditions of intertemporal efficiency are met, and if the economy invests in reproducible capital at each instant the exact amount (value) by which the non-renewable capital stock is being diminished, then society will just be able to maintain a constant stream of consumption into the infinite future. This latter investment policy concerning the augmentation of reproducible capital is known as Hartwick’s rule (Hartwick, 1977; 1978a; 1978b). Martin Weitzman (1976) showed that the maximum welfare along a competitive path from any point into the future is formally identical to what might be obtained from the path of constant consumption.

Unavoidable inconveniences

The formal models of Ramsey, Hotelling, Dasgupta and Heal, Stiglitz, Solow, Hartwick and Weitzman
set out the essential logic of how economists think about sustainability. The models’ austerity is their strength. But, William of Ockham notwithstanding, spare and austere models do not always offer coherent policy guidance. This recognition gave rise to two dominant concepts of sustainability in economics – weak and strong.

The early models deriving optimal trajectories of constant consumption (and utility) provided the conceptual basis for weak sustainability – replace used-up or degraded natural capital with constructed capital in order to assure continued consumption (utility). To the environmental community, weak sustainability is not sustainability at all. Indeed, a better term for this view of sustainability is derived from the realm of medicine, where we encounter organ transplants and replacement therapy. (Technically, replacement therapy is the regular introduction of necessary chemicals into the body that are no longer produced naturally.) To the environmentalist, sustainability as replacement resembles a doctor who says to you, ‘go ahead and drink all you want, and when your liver or kidneys eventually fail we will give you mechanical ones, or we will put you on dialysis’.

Recall that for some aspects of nature it may not matter if we run out of them. That is, for many objects, it is the attributes they bring to us, not the unified bundle that we call ‘coal’ or ‘titanium’, that are the object of our interest. If one worries about the exhaustion of coal, that is simply an expression of concern about where energy will come from when the coal is gone. But the Grand Canyon and Victoria Falls are not coal or titanium. And this brings us to strong sustainability. Strong sustainability concerns specific bundles of attributes that are regarded as valuable in their own right; that is, they are valuable, not because of what they will produce for us, but because of what they mean to us. Their meaning is the cultural imprint we seek to project on to future persons as our legacy to them. The issue of strong sustainability concerns differing perceptions across a population – whether living now or in the future – of the imagined purposes of nature. What, exactly, is nature for? Its meaning to us is what it does for us. When we figure out what nature is for and craft policies accordingly, we are also prefiguring how future persons will come to see the natural assets we have bequeathed to them. We transmit, indeed we impose, our values on to future persons.

For those who worry about nature in terms of its meaning to contemporary and future persons, the idea of replacement sustainability is ethically defective. However, the term ‘strong sustainability’ is also unhelpful. Strong sustainability seems to suggest that all (or most) things must be locked up and preserved indefinitely. Few take it this far, but the terminology suggests as much. The central issue here is a justifiable concern for particular settings and circumstances that ought not to be compromised under any plausibly foreseeable circumstances. In fact, the matter can be put as justified commitments to the protection of specific settings and circumstances that must not to be compromised under any plausibly foreseeable circumstances. The concept of ‘justified commitment’ suggests that the advocates of lasting protection of particular settings and circumstances are under an obligation to offer a plausible and coherent justification to the wider political community. Why, exactly, does this particular setting or object deserve the sort of irrevocable protection you seek for it? Give me good reasons for doing so (Bromley, 2006). Notice that the concept of justified commitments requires the general agreement of a large number of others to whom the reasons advanced are found compelling. Only then can we say that the reasons advanced were sufficient. This is what it means to formulate public policy in a democracy. Several important clarifications and elaborations have entered the literature since the early formal models were advanced (Asheim, 1994; Pezzey and Toman, 2002). A paper by Asheim, Buchholz and Tungodden (2001) derives the properties of a set of economic pathways that are non-decreasing and
efficient. It suggests that, since any such path is sustainable, efficiency and equity can be cited to indict an unsustainable path as ethically flawed. Richard Howarth (1997; 1998) has offered a synthesis of much of the early work, and he writes that ‘optimal’ policies depend on ethical propositions that are impossible to resolve from within economics. We must look outside our models and our analytical apparatus for clear guidance. That is, we must turn to discussions of what is thought to be ‘right’ rather than what is thought to be ‘good’. An intergenerational (intertemporal) golden rule offers some help, but it can be a weak thing indeed. Moral fibre is strongest when not threatened by the sharp blade of self-interest. Like Ulysses, we need to bind ourselves to some mast since we cannot be trusted to do the right thing for the future. The Sirens are too alluring. But which mast will provide sufficient restraint?

Some possible alternatives

One alternative concerns the precautionary principle: (a) safeguard options for future generations by protecting thresholds of resilience in desirable states of nature; and (b) contain the fundamental uncertainties associated with economic activity – either by restricting the level of that activity to preserve a degree of system predictability, or by containing the quantifiable risks associated with innovative activities that test the resilience of the system (Perrings, 2001, p. 196).

A related approach, advanced by S. V. Ciriacy-Wantrup, is the safe minimum standard (Ciriacy-Wantrup, 1968; Bishop, 1978; Woodward and Bishop, 1997). Unique natural assets – particular species, habitats, and situations crucial to ecosystem functions – must be protected unless the costs of doing so are too high. Unfortunately, there are no clear rules to determine whether a level of costs is ‘too high’. But a focus on the safe minimum standard (SMS) of conservation serves to reframe the decision problem along the following lines: ‘are you really sure you want to do that?’ The SMS connects to the earlier idea of justified commitments.

In this vein, Bromley (1989) offers an approach that features the ‘projection of rights’ onto future persons. Specifically, he suggests two possible approaches: (a) an inalienability rule; and (b) a liability rule. Under inalienability, revered natural assets must be justified to a sufficiently large share of the polity as being inviolable. Think of this as civic sanctification. Once recognized, future persons hold inalienable rights, and members of all prior generations, including the present generation, are the reciprocal bearers of a duty towards those future right holders. This approach requires that irrevocable legal steps be taken by those of us now living to make sure that natural assets will be protected in the future. National parks, wilderness areas, and the US Endangered Species Act are of this sort – moral commitments towards future persons that are assured through organized and official legal obligation. Under a liability rule there are two possible options. First, if those of us now living violate our commitment to the future – if we are unable to resist the Sirens – then we owe future persons some form of offsetting compensation. Perhaps we agree to set aside yet larger areas of wilderness, or make special efforts to increase the protection of an expanded list of endangered habitats or valuable species. Second, we atone for our violation of the interests of future persons by establishing an annuity that would pay dividends to future persons in some amount thought commensurate with the harm we have done them. While neither approach adequately accounts for future uncertainty, they both acknowledge our obligation to the future, and both approaches force us to indemnify that obligation. If we are going to become richer by squandering some part of nature that morally belongs in their (future persons) bequest
package, then we need to set aside something to make future persons better off than they would otherwise be.

In a recent paper that builds on Bromley (1989; 1990) and Stern (1997), Gerlagh and Keyser (2001) advocate a ‘trust fund policy’. The trust fund of Gerlagh and Keyser is a long-lived organization – comparable to a central bank – that oversees the entitlement of all members of present and future generations to an equal claim over natural resources. The arrangement would have precise rules of conduct to guarantee that members of future generations receive their claims independently of the preferences of the members of intervening generations.

Svennilson, Ingvar (1908–1972)

Bjorn Hansson

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

investment; planning; Stockholm School; structural transformation; Svennilson, Ingvar; technical change

Article

Svennilson was born and died in Stockholm. With a PhD in economics (1938) at the University of Stockholm, he was co-editor of *Ekonomisk Tidskrift* (1939–56); professor of economics at the University of Stockholm (1947–72) and vice-president of the University of Stockholm (1958–66). His dissertation (1938) tackled the problem of ‘planning in an unplanned world’ and is a theoretical analysis of the investment decisions taken by individual firms under risk and uncertainty. Plans are based on uncertain future events, which implies a choice of strategy in a multiperiod model. The strategy embodies the idea of alternative planning, which means that the firms have plans how to adapt their actions periodically in accordance with the realized events. The ideas and the concepts used in the dissertation are developed from earlier Swedish works on sequence analysis, such as Lindahl’s ‘The rate of interest and the price level’ (1930).

Throughout his career Svennilson published many empirical and theoretical works on the problem of structural transformation and technical change. In Svennilson (1954) structural maladjustment plays the major role in the lagging and unstable growth of the European economy during the interwar period. He always tried to incorporate technical change in the analysis of capital formation, as in Svennilson (1956). In Svennilson (1964) he made an attempt to give a systematic understanding of ‘the residual factor’ in the production function, and the equilibrium is shown to be determined by the growth rate as well as the functional distribution of income.

Svennilson was for 20 years (1947–67) chairman and expert to the Long-Term Planning Commission and he obviously had a significant influence on these documents, which are published almost every fifth year as a Swedish Government Official Report; the reports play an important role in the debates on economic policy. From 1942 to 1952 he was director of the Industrial Institute for Economic and Social Research, which is funded by private industry. This organizational and intellectual background explains why Svennilson always encouraged closer cooperation between government and private research and

Swadeshi movement

Susan Wolcott
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

economics in India; Gandhi, M.; protection; swadeshi movement

Article

The word ‘swadeshi’ is derived from the Bengali, svadesi, or from the Sanskrit, svadesin. Literally, it means from ‘one's own country’ (Leadbetter, 1993, p. 95). It came to mean the use in India of Indian manufactures or services in preference to imported goods or European provided services. Whatever emotional support it may have enjoyed in India, as an economic movement it was effective only in its final phase.

Swadeshi became a rallying cry of Indian nationalists as early as the mid-19th century. In part, it was a response of the decline of the indigenous hand spinning and weaving industries as India became a major importer of British factory produced cotton cloth. Chandra (1966) notes that as early as the 1870s Indian politicians would appear at public meetings dressed in self-spun cloth. He writes, ‘the tide of swadeshi went on rising all over the country during the 15 years from 1880 to 1895’ (Chandra, 1966, p. 126). It was ‘inflamed’ by the removal of the revenue tariff on imported cotton cloth in 1878–82, which was believed to have been done in deference to Lancashire interests. It was further aroused by the imposition of an excise tax on Indian factory production in 1896, which was done to keep Lancashire and India on an even footing when a revenue tariff was reinstated.

But though Chandra may be correct about the degree of hostile feeling these moves engendered, in practice it is difficult to see any real economic effect. Imports of British cloth rose throughout this period. Also, though many indigenous factories started and advertised themselves as swadeshi enterprises, none were successful because they were swadeshi. Consider two examples. The grandson of Dwarkanath Tagore, the very successful Bengali entrepreneur, started a shipping firm to break the exclusive European monopoly of river navigation. The firm was a spectacular failure (Ray, 1984, p. 151). Tata, a Bombay entrepreneur, started the Swadeshi Mill in 1896, which was a successful textile mill. But many Indian cotton textile mills started in this period succeeded, including those owned and
operated by Europeans. Chandra attributes the ineffectualness of the movement in this period to lack of support by prominent Indian cotton textile mill owners, who themselves feared exciting popular opposition to mill-manufactured cloth, and to their fear of arousing the animosity of their British machinery suppliers. He points out that the call for swadeshi did not even get the official endorsement of the Indian National Congress in this early phase (Ray, 1984, p. 141).

The next phase of the swadeshi movement occurred in Bengal between 1905 and 1908. In 1905, Lord Curzon, Viceroy of India, decided that the Bengal presidency was too large to administer, and separated it into two parts. Bengali intellectuals believed that this was at least in part a strategy to divide and conquer. The protest which followed evolved from agitation for the revocation of the partition to agitation ‘to enable the educated Bengalis to break out of the narrow confines of service and professions into the wider fields of commercial and industrial enterprise’ (Ray, 1984, p. 150). Ray argues that this movement was the culmination of several years of rising prices which had put economic pressure on middle class lawyers, administrators and teachers, most of whom were on fixed incomes. The deep resentment of educated Bengalis towards partition provided the issue which finally goaded them to action. A boycott of British goods was officially called on 7 August 1905 at a mass meeting in Calcutta. And, as before, swadeshi enterprises were begun. But this incarnation of swadeshi also remained the purview of the middle classes. Not only were the lower classes largely uninvolved, but the Marwaris, the wealthy caste of merchants, ‘prudently stayed away from these schemes’ (Ray, 1984, p. 164). The movement gradually lost coherence.

Mahatma Gandhi ushered in the final phases of the colonial swadeshi movement. The 1920 Congress at Nagpur for the first time passed a swadeshi resolution. It called on Indians to give up their titles, to shun official ceremonies, to withdraw from government colleges and schools, and to boycott courts, offices and legislative councils. Also, foreign goods should be boycotted, and support given to native enterprises. Finally, there was a call for ‘reviving handspinning in every house and handweaving on the part of millions of weavers who have abandoned their ancient and honourable calling for want of encouragement’ (Leadbetter, 1993, p. 110). This phase is also sometimes called the non-cooperation movement, and lasted from 1920 to 1922. Bose and Jalal (1998, p. 141) write that this boycott of British goods and institutions was much more effective than had been that of 1905. As evidence they point out that the Prince of Wales was greeted in Indian villages by closed shutters on his 1921 visit. Leadbetter (1993) also writes that the boycott of British textile goods was effective, in part because this time it received the support of at least some major mill owners. But none of these authors presents evidence of an economic impact. The one empirical study of the textile industry found no effect. Wolcott (1991) estimated an Indian import demand function for British cotton textile goods covering the years 1890–1914 and 1920–38. She finds no structural break after 1920. Gandhi called another boycott in 1930–32; this is referred to as the ‘civil disobedience movement’. Leadbetter writes that Indian business leaders were even more supportive during this phase, and Wolcott does find a significant, exogenous decline of 28 per cent in sales of British goods after 1930.

Swan, Trevor W. (1914–1989)

Paul A. Johnson
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The first professor of economics at the Australian National University, Trevor W. Swan was an Australian economist known for his foundational contributions to economic growth theory and the theory of economic policy in small open economies. Independently, he and Robert Solow simultaneously formulated what has become known as the Solow–Swan model of economic growth. He devised ‘the Swan diagram’ familiar to generations of students of international economics. A graduate of the University of Sydney, Swan became an Officer of the Order of Australia in 1988 ‘for service to education and to government particularly in the field of economics’.

Keywords

Cobb–Douglas functions; factor substitution; golden rule; Harrod–Domar growth model; international reserves; Klein, L. R.; neoclassical growth theory; open economy macroeconomics; returns to scale; Solow–Swan model; Swan, T. W.; Tinbergen, J.

Article

Trevor W. Swan is perhaps best known for Swan (1956), his foundational contribution to the theory of economic growth. This paper, and that of Solow (1956), relaxes the extant Harrod–Domar assumption of a fixed capital–labour ratio by replacing the fixed-proportions technology with one permitting factor substitution. While the exposition in Swan (1956) differs from that in Solow (1956), the basic economic model in the two papers is the same, and the Solow–Swan model, as it often called, marks the beginning of neoclassical growth theory. The model in Swan (1956) employs a Cobb–Douglas production function. However, the notes on the model, circulated prior to the paper’s publication but after Swan's first public presentation of the model, and later published as Swan (2002), employ a more general constant returns to scale technology. Pitchford (2002) discusses Swan's first public presentation of the model and the relationship between the version in the notes and that in Swan (1956). Dixon (2003) compares the

expositions of Solow (1956) and Swan (1956), and Solow (1997) discusses Swan's contribution to the Solow–Swan model. As is now well known, the model offers two central predictions, namely: (a) a change in the (exogenous) saving rate has a long-run effect on the level of output per worker but not on its growth rate; and, (b) in the absence of continued technological progress, the long-run growth rate of output per worker is zero. After demonstrating this ‘anti-accumulation, pro-technology’ result Swan (1956, p. 338) speculates that ‘… accumulation may give rise to external economies, so that the true social yield of capital is greater than any “plausible” figure based on common private experience’. Such externalities can now be found in models such as Romer (1986) and Lucas (1988). Swan (1964), which was written in 1960, develops the golden rule of economic growth. In this paper Swan also expresses his doubts about the utility of contemporaneous economic growth theory when dealing with applied economic development problems.

Swan also made early contributions to other areas including both macroeconomic model building and the macroeconomics of small open economies. Much of the motivation for his work seems to have been provided by his interest in macroeconomic policy issues. In Swan (1989), which was written in 1945, Swan specifies, calibrates and simulates a Keynesian model of the Australian economy. This was just the second such empirical macroeconomic model ever built – the first being that of Tinbergen and the third that of Klein. The model, sophisticated for its time, specifies consumption, investment and imports as functions of lagged income. Investment is constrained to be non-negative. Imports also include an autonomous component that depends on their domestic currency price. Prices move with marginal cost derived from the aggregate production function which, with a fixed level of technology and a fixed capital stock, also determines the level of employment. The exogenous variables are exports, public investment, and the autonomous part of imports. Simulation of the model shows that it replicates closely the Australian macro-experience of the 1930s. In what may be the first use of such a model for the purpose, Swan uses counterfactual simulations of his model to study policies that would have ‘preserved Australia from the Great Depression’.

In Swan (1960), which was written in 1953, and Swan (1963), which was written in 1955, Swan discusses the problem of simultaneously achieving both internal balance (full employment) and external balance (a current account balance of zero) in a small open economy with a fixed exchange rate. Swan (1963) introduces ‘the Swan diagram’ familiar to generations of students of international economics. This diagram, which still appears in international economics texts (Caves, Frankel and Jones, 1999, p. 323 f, for example), shows the internal and external balance schedules with the real exchange rate on the vertical axis and domestic demand on the horizontal one. The internal balance schedule is negatively sloped because real depreciation (a rise in the real exchange rate), and the consequent increase in net exports, is necessary to maintain internal balance as domestic demand falls. The external balance is positively sloped as real appreciation, and the consequent decrease in net exports is necessary to maintain external balance as domestic demand falls, and hence imports, fall. The curves divide the plane ‘into four zones of economic unhappiness’. An economy in the zone below both curves, for example, suffers from both unemployment and a current account deficit. The intersection of the two curves gives the combination of real exchange rate and domestic demand consistent with both internal and external balance. The correct policy response when away from this intersection depends on the zone in which the economy lies and its location in the zone. For example, in the zone below both curves, if the economy is left of the intersection real depreciation and an increase in domestic demand is appropriate but, right of the intersection, real depreciation and a reduction in domestic demand is called for. After noting that
both targets are likely to be more responsive to changes in demand than to changes in the real exchange rate in the short-run, Swan suggests tying the real exchange rate to a long-run value and using international reserves as a buffer against temporary external imbalances.

Swan was born in Sydney, Australia, and graduated from the University of Sydney in 1940 with a first-class honours degree in economics and a university medal. He held various government positions during and after the Second World War before being appointed as the first professor of economics at the Australian National University in 1950, a position he held until he retired in 1983. In addition to this, and other academic appointments, he was active in Australian economic policymaking until the mid-1980s, serving as an advisor to many post-war Australian governments and on the Board of the Reserve Bank of Australia. In 1988 Swan became an Officer of the Order of Australia ‘for service to education and to government particularly in the field of economics’. Butlin and Gregory (1989) and P. Swan (2006) provide more extensive biographies of Swan, including bibliographies of his published and unpublished works. This article owes much to both.

Sweezy, Paul Marlor (1910–2004)

John Bellamy Foster

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Harvard-trained economist and co-editor of Monthly Review, Paul Sweezy was among the most influential economists and Marxist intellectuals of the 20th century. His contributions extended over six decades from the early 1930s to the early 1990s. He played a role in the development of imperfect-competition analysis and in debates surrounding the Great Depression. His Theory of Capitalist Development (1942) provided the premier exposition of Marxian economics, after Marx. Monopoly Capital (1966, with Paul Baran) was the most influential economic analysis emanating from the US New Left. With Harry Magdoff he extended this analysis into the 1970s, ’80s and early ’90s.

Article

One of the leading figures in Western Marxism in the 20th century and co-editor from 1949 to 2004 of Monthly Review, Sweezy is known both for his leading contributions to economics and his influence on the development of socialist thought.

Born on 10 April 1910 in New York, the son of a vice-president of the First National Bank of New York (part of J.P. Morgan's financial empire), he obtained his early education at Exeter and Harvard

University. At Harvard he was president of the *Harvard Crimson* and studied economics, receiving his BA (*magna cum laude*) in 1932. In 1932 he left Cambridge, Massachusetts, for a year of graduate study at the London School of Economics. Awakened by the Great Depression, and responding to the intellectual ferment in Britain during what was to be a turning point in world history, Sweezy gained sympathy for the Marxist perspective to which he was introduced for the first time. Returning to the United States in 1933 to do graduate studies at Harvard, he found the academic climate much changed, with Marxism becoming a topic of intense interest in some of the larger universities. As he recalled many years later,

It was under these circumstances that I acquired a mission in life, not all at once and self-consciously but gradually and through a practice that had a logic of its own. That mission was to do what I could to make Marxism an integral and respected part of the intellectual life of the country, or, put in other terms, to take part in establishing a serious and authentic North American brand of Marxism. (1981a, p. 13).

In pursuing this goal at Harvard, Sweezy received direct help and indirect inspiration from the great conservative economist Joseph Schumpeter, whose analysis of the origins, development and imminent decline of capitalism revealed a complex, critical appreciation of the Marxian schema. Sweezy's 1943 essay on ‘Professor Schumpeter's Theory of Innovation’, which compared Schumpeter's analysis of entrepreneurial development to Marx's theory of accumulation, was to be one of the path-breaking studies in this area. In the 1930s, while in his twenties, Sweezy published more than 25 major publications – books, articles, government reports, and reviews – on economic topics. He was a member of the founding editorial board of the *Review of Economic Studies*, originally established in 1933 to promote the work of younger economists.

**Imperfect competition, economic stagnation, and war**

Receiving his Ph.D. in 1937, Sweezy assumed a position as instructor at Harvard until 1939, when he rose to the rank of assistant professor. During these years he played a central role in two of the major areas of debate in economics: (a) the theory of imperfect competition, and (b) the issue of secular stagnation. Sweezy's interest in the monopoly question began early in his career, as shown by his first book (winner of the David A. Wells prize), *Monopoly and Competition in the English Coal Trade, 1550–1850* (1938a). His article ‘Demand Under Conditions of Oligopoly’ (1939a), in which he presented the kinked demand curve analysis of oligopolistic pricing, remains one of the classic essays in modern price theory. Along with a small group of Harvard and Tufts economists, Sweezy was one of the authors and signatories of the influential Keynesian tract, *An Economic Program for American Democracy* (1938b), which provided a rationale for a sustained increase in public spending during the final years of the New Deal. While continuing to carry out his teaching responsibilities at Harvard, Sweezy worked for various New Deal agencies (including the National Resources Committee and the Temporary National Economic Committee) investigating the concentration of economic power. His study, ‘Interest Groups in the American Economy’, published as an appendix to the NRC's well-known report, *The Structure of the American Economy* (1939b), was to be an important guide to later research. A famous Harvard debate between Sweezy and Schumpeter (over which Wassily Leontief presided) on the stagnation controversy
of the late 1930s was recounted decades later by Paul Samuelson, who had been in the audience, as one of the great events of his own lifetime (Samuelson, 1969).

From the lecture notes to his Harvard course on the economics of socialism, Sweezy produced his seminal work, *The Theory of Capitalist Development* (1942). Containing a comprehensive review of Marxian economics up until the time of the Second World War, this study also did much to determine the character of later Marxian theory through its advocacy of Laudislaus von Bortkiewitz’s solution to the ‘transformation problem’, its presentation of a logically acceptable ‘underconsumptionist’ model of accumulation and crisis, and its elaboration of Marxian views on monopoly capitalism. Rapidly translated into several languages, *The Theory of Capitalist Development* soon established Sweezy's reputation as the foremost Marxian economist of his generation.

During the Second World War Sweezy served in the Office of Strategic Services (OSS) and was assigned to the monitoring of British plans for post-war economic development. With a number of years still remaining in his Harvard contract when the war ended, he opted to resign his position rather than resume teaching, recognizing that his political and intellectual stance would hinder his receiving tenure. In this period, Sweezy authored numerous articles on the history of political economy and socialism, some of which were reprinted in his book, *The Present as History* (1953), and edited a volume (1949) containing three classic works on the ‘transformation problem’: *Karl Marx and the Close of His System* by Eugene Böhm-Bawerk, *Böhm-Bawerk's Criticism of Marx* by Rudolf Hilferding, and ‘On the Correction of Marx's Fundamental Theoretical Construction in the Third Volume of Capital’ by Ladislaus von Bortkiewicz (which Sweezy translated into English). His 1950 critique (in Sweezy et al., 1976) of Maurice Dobb's *Studies in the Development of Capitalism*, in which Sweezy, following his interpretation of Marx, emphasized the role of the world market in the decline of feudalism, launched the famous debate over the transition from feudalism to capitalism which has played a key role in Marxian historiography ever since. Sweezy's work in this area established him as one of the pioneers of what came to be known as ‘world system theory’.

**McCarthyism and the early Monthly Review years**

With the financial backing of literary critic F.O. Matthiessen, Sweezy and the Marxist historian Leo Huberman founded *Monthly Review* (subtitled ‘An Independent Socialist Magazine’) in 1949 as an intellectual resource for a US left threatened by anti-Communist hysteria. Albert Einstein wrote his article ‘Why Socialism?’ for the first issue. Two years later they began publishing books under the imprint of Monthly Review Press, when it came to their attention that in the repressive climate of the times even such celebrated authors as I.F. Stone and Harvey O'Conner were unable to find publishers for their book manuscripts.

In 1953, at the height of the McCarthyite period in the United States, the state of New Hampshire conferred wide-ranging powers on its Attorney General to investigate ‘subversive activities’. On this basis, Sweezy was summoned to appear before the state Attorney General on two occasions in 1954. Adopting a principled opposition to the proceedings, he refused to answer questions regarding (a) the membership and activities of the Progressive Party, (b) the contents of a guest lecture delivered at the University of New Hampshire, and (c) whether or not he believed in Communism. As a result, he was declared in contempt of court and consigned to the county jail until purged of contempt by the Superior Court of Merimack County, New Hampshire. His case was appealed and worked its way through the
state and federal courts to the US Supreme Court, which ruled in his favour in *Sweezy v. New Hampshire* on 17 June 1957 (US Supreme Court, 1956). *Sweezy v. New Hampshire* is remembered historically as having dealt the death knell to the witch hunt on US campuses.

**Monopoly Capital: an essay on the American economic and social order**

The appearance in 1966 of *Monopoly Capital* by Baran and Sweezy (published two years after Baran's death) represented a turning point in Marxian economics. Although described by the authors as a mere ‘easy-sketch’, it rapidly gained widespread recognition as the most important attempt thus far to bring Marx's *Capital* up to date, as well as providing a formidable critique of prevailing Keynesian orthodoxy. Where Sweezy himself was concerned, *Monopoly Capital* reflected dissatisfaction with the analysis of accumulation and crisis advanced in *The Theory of Capitalist Development*. His earlier study had been written when mainstream economics was undergoing rapid change due to the Keynesian ‘revolution’ and the rise of imperfect competition theory. Thus, he had provided a detailed elaboration of both Marx's theory of realization crisis (or demand-side constraints in the accumulation process), and of work by Marx and later Marxian theorists on the concentration and centralization of capital. As with mainstream theory, however, these two aspects of Sweezy's analysis remained separate. Hence he failed to develop an adequate explanation of the concrete factors conditioning investment demand in an economic regime dominated by the modern large enterprise. It was essentially this critique of Sweezy's early efforts that was provided by Josef Steindl in *Maturity and Stagnation in American Capitalism* (1952, pp. 243–46), who went on to show how a more unified theory could ‘be organically developed out of the underconsumptionist approach of Marx’ based on Michal Kalecki's model of capitalist dynamics, which had connected the phenomenon of realization crisis to the increasing ‘degree of monopoly’ in the economy as a whole.

In fact, it was out of this argument, as outlined by Steindl, that the underlying framework for Baran and Sweezy's own contribution in *Monopoly Capital* was derived. What emerged in their analysis was ‘a Kaleckian version of Marxism, in which monopolist corporations control markets but have problems recovering their surplus because of their underinvestment’ (Toporowski, 2004).

In this analysis Marx's fundamental ‘law of the tendency of the rate of profit to fall’ associated with accumulation in the era of free competition had been replaced, in the more restrictive competitive environment of monopoly capitalism, by a law of the tendency of the surplus to rise (with ‘surplus’ defined as the gap, at any given level of production, between output and socially necessary costs of production). Under these circumstances, the critical economic problem was one of surplus absorption. Capitalist consumption tended to account for a decreasing share of capitalist demand as income grew, while investment was hindered by the fact that it took the form of new productive capacity, which could not be expanded for long periods of time independently of final, wage-based demand. Although there
was always the possibility of new ‘epoch-making innovations’ emerging that would help absorb the potential economic surplus, all such innovations – resembling the steam engine, the railroad and the automobile in their overall effect – were few and far between. Hence, Baran and Sweezy concluded that the monopoly capitalist system had a powerful tendency toward stagnation, rooted in long-term underinvestment, largely compensated for thus far through the promotion of economic waste by means of ‘the sales effort’ (including its penetration into the production process) and military expenditures, and through the expansion of the financial sector. All such ‘countervailing influences’ were, however, of a self-limiting character and would lead to a doubling-over of contradictions in the not-too-distant future. *Monopoly Capital*’s international influence was enormous, making Baran and Sweezy arguably the best known US economists outside the United States. The publication of *Monopoly Capital* coincided with the rise of the New Left, largely in response to the Vietnam War. The work of Baran and Sweezy thus constituted the initial theoretical common ground for a younger generation of radical economists in the United States who formed the Union for Radical Political Economics in 1968. In 1971, Sweezy delivered the Marshall Lecture at Cambridge University. From 1974 to 1976 he served on the executive of the American Economic Association.

The re-emergence of conditions of relative economic stagnation in the 1970s, not long after *Monopoly Capital* was published, confirmed much of Baran and Sweezy’s analysis, pointing to the importance of many of the factors that they had emphasized, including: increasing aggregate concentration; the ascendance of multinational corporations; global surplus capacity; the clustering of technological innovations; continuing high-level military spending; intensification of the sales effort; and the soaring of finance and speculation. Yet, despite the fact that *Monopoly Capital* had both foreseen the advent of stagnation and highlighted many of the key historical factors that increasingly attracted attention as the 1970s and 1980s unfolded, Baran and Sweezy's magnum opus lost much of its lustre among left economists within 20 years of its publication. It seemed to many to be a product of the period of the unquestioned domination of US corporations and undisputed US economic hegemony, rather than the more globalized competitive environment that followed. In the long run, however, the theory continued to gather adherents and was seen as representing a crucial stage in the analysis of the global political economy (see Foster, 2002).

With Harry Magdoff (who replaced Huberman as co-editor of Monthly Review after the latter's death in 1968), Sweezy continued to strengthen the analysis begun in *Monopoly Capital* in the decades following its publication, utilizing the original framework to explain the re-emergence of stagnation and the rise of financial instability, as well as conditions of Third World underdevelopment, in *The Dynamics of US Capitalism* (1970), *The End of Prosperity* (1977), *The Deepening Crisis of US Capitalism* (1979), *Four Lectures on Marxism* (1981a), *Stagnation and the Financial Explosion* (1987), and *The Irreversible Crisis* (1988). In all of these works, the role of financial expansion as a means of utilizing the surplus and countering stagnation, while simultaneously creating growing problems of financial instability, was emphasized – well before this became a central concern in economics as a whole. If there was one criticism to be levelled at *Monopoly Capital*, as Sweezy pointed out again and again, it was that it had not placed enough emphasis on the ballooning of the financial superstructure of the capitalist economy as a response to stagnation – though *Monopoly Capital* had briefly addressed this problem at the end of the chapter on the sales effort. In ‘The Triumph of Financial Capital’ (1994, p. 2) he declared: ‘In earlier times no one ever dreamed that speculative capital, a phenomenon as old as capitalism itself, could grow to dominate a national economy, let alone the whole world. But it has.’

Socialism and ecology

Sweezy's influential analysis of post-revolutionary societies, developed over half a century, maintained a critical distance from these societies, emphasizing their class-exploitative nature. Although the Soviet Union had been brought into being by a revolution under genuine socialist leadership, he argued, it had not continued down the socialist track and had resurrected class relations – giving it an inner logic that was neither capitalist nor socialist. Hence, Sweezy designated it as a political-economic system sui generis, which he labelled Post-Revolutionary Society—the title of a compendium (1981b) of his writings in this area. As early as 1971 in On the Transition to Socialism, which grew out of a lengthy debate with Charles Bettelheim, he wrote:

When the bureaucratically administered economy runs into difficulties (as it certainly must), there are two politically opposite ways in which a solution can be sought. One is to weaken the bureaucracy, politicize the masses, and entrust increasing initiative and responsibility to the workers themselves. This is the road forward to socialist relations of production. The other way is to put increasing reliance on the market (as was the case with the New Economic Policy under Lenin) but as an ostensible step toward a more efficient ‘socialist’ economy. This is in fact to elevate profit-making to the guiding role in the economic process and to tell the workers to mind their own business, which is to work hard so that they can consume more. It is to recreate the conditions in which commodity fetishism flourishes along with its associated false and alienated consciousness. It is, I submit, the road back to class domination and ultimately the restoration of capitalism. (1971, pp. 53–4)

In the concluding paragraph of his Post-Revolutionary Society, written five years before the rise of Gorbachev, Sweezy declared that the Soviet system had ‘entered a period of stagnation, different from the stagnation of the advanced capitalist world but showing no more visible signs of a way out’. Indeed, Sweezy argued beginning in the early 1960s – most notably in Modern Capitalism and Other Essays (1972) – that those interested in the future of socialism should look for leadership not at present to the working class in the advanced capitalist states, nor to the new class societies of the Soviet Union and eastern Europe, but rather to the insurgent populations of the periphery of world capitalism. It was here, in Third World liberation struggles, if anywhere, that the revolutionary proletariat in the Marxist sense (‘the focal point of all inhuman conditions’) continued to struggle in the name of humanity itself. From the 1970s on Sweezy was to turn frequently to the environmental issue, first with his 1973 article on ‘Cars and Cities’ and later notably in articles on ‘Capitalism and the Environment’ (1989a) and ‘Socialism and Ecology’ (1989b). If socialism did not ‘guarantee’ the salvation of the environment, he argued, it was nonetheless a necessary condition for its salvation (1990).

In 1983 Sweezy was granted an honorary doctorate of literature from Jawaharlal Nehru University in India. In 1999 he received the Veblen–Commons Award from the Association for Evolutionary Economics. The results of a survey of its readers by the *Post-Autistic Economics Review* in Issue no. 36 (2006) listed him as one of the 15 ‘greatest twentieth-century economists’. Indeed, as Janek Toporowski had already observed in the *Royal Economic Society Newsletter* in April 2004, ‘If he is to be measured by the impact of his ideas, then he stands among the greatest economists of the twentieth century.’

Dean of St Patrick's Dublin, the austere Rabelais, the party pamphleteer from whom Rousseau learnt to detest politics and society, the high churchman from whom Voltaire and Lessing learnt their religion, the author of *Gulliver's Travels*, Swift is a writer to whose economic views critics are often unjust. *The Humble Petition of the Colliers, Cooks, Cook-maids*, etc., against the use of focused rays by a supposed company instead of fires, represents that this ‘will utterly ruin … your petitioners … and trades on them depending, there being nothing left to them after the said invention but warming of cellars and dressing of suppers in the wintertime’. And ‘whereas the said’ company ‘talk of making use of the moon by night as of the sun by day, they will utterly ruin the numerous body of tallow chandlers’, and so the tallow tax will fail. The fame of Bastiat is chiefly based on his expansion of this parable in the seventh of his *Sophismes Economiques* (1846), of which his admirers still say ‘nothing is more brilliant, nothing more French’.

Swift's *Maxims controuled in Ireland*, suggested perhaps by Sir William Temple (*Works*, 1814 edn, vol. i. p. 177), exposes, after the manner of Bastiat, popular economic fallacies which deceived Temple, Locke, and Child, whom he had studied; e.g. that a large population, high prices for land, dear provisions, and big towns (cf. Barbon) *must* imply wealth, and that low interest *must* be due to much money. For ‘must’, he says, you should write ‘may’, thus, in trading countries like Holland and England, low interest and high capital values for land were effects of the causes alleged, but in Ireland of the absence of trade, and therefore of a demand for loans. He perceived ‘that in the arithmetic of the customs two and two, instead of making four, make sometimes only one’ (Smith, *Wealth of Nations*, book v, ch. ii).

Otherwise Swift belongs to his age. Thus the king of Brobdingnag's belief that ‘whoever could make two ears of corn or two blades of grass to grow … where only one grew before would deserve better of mankind … than the whole race of politicians’, and the echo of this belief at the end of the last of the
Drapier's Letters resembles Molesworth's ideas (1723), and afterwards became a favourite motto with Arthur Young. He thinks with Locke that traces fall mainly upon land, which, like Harrington, he overrates (Works, 1824 edn, vol. iii, p. 518); and his anger against ploughlands being turned into sheep-runs makes him akin to Latimer, Boulter (Letters, 24 February 1727), and, as he himself said, to Ajax. He pillories the trading spirit in his abuse of the Dutch; and wishes a weavers’ corporation to regulate prices and qualities, and to punish offenders by ‘warnings’ (Works, vol. vii, pp. 49, 50, 137). He denounces ‘the restriction’ and urges Irishmen to raise by way of reply what Berkeley called ‘a wall of brass a thousand cubits high’ round Ireland; and thinks that this could be done by a resolution to consume home-made goods instead of ‘unwholesome drugs and unnecessary finery’ imported from India and elsewhere (Proposal for the Universal Use of Irish Manufacture). His sumptuary mercantilism is the same as that of Sir William Temple, Polexfen and Berkeley.

For the rest he advocated national education and beggars’ badges, and adopted Temple's fallacy that high rents caused high prices, Prior's facts and fallacies on absentee, and Molesworth's views on rack-rents; he deplored with Temple the destruction of timber, and opposed Boulter's lowering of the gold coin, and Berkeley's proposal for a bank; and like Prior, Berkeley, James King, Simon, and others, he advocated an Irish mint in his Drapier's Letters (1723–4). In these Swift's economic objection to Wood's copper – if stripped of its figures, which Swift meant to be figures of speech – was that the coin being hammered and not milled was easily forged, was base, excessive, and not convertible by the patentee; further, the patent did not make it legal tender, so that when this was known it would at once lose its mint value unless it should, by an abuse of the royal prerogative, be made full legal tender, in which case it would drive out gold and then depreciate. Swift did not, nor could any writer at that time, analyse the latter process, and he omitted a third possibility, that it might be made limited legal tender. If this omission was uncandid what shall we say of his critics Leslie Stephen (Swift, pp. 153ff.) and Moriarty (Swift, 1893, p. 211), who assume that the coin was legal tender up to \(5\frac{1}{2}d\)? Further, token coins, if redundant and difficult to convert, are open to these objections, so that the omission weakens but does not vitiate the argument. Lastly, facts and dates indicate that there was a likelihood that these coins would be made legal tender either to an unlimited or to a dangerously high extent. Wood boasted, 9 February 1722, that his coins were or would be made legal tender (Coxe, Walpole, ii. 371); and from Lady-day 1722, when his coining rights began, to 16 September 1723, the terms were unknown even in Dublin Castle; had the whole amount, £108,000 been floated in the dark, the hands of ministers must have been forced and most of Swift's fears realized. Again, the crown rent was £100, and Walpole's report valued it at £800; under the Armstrong–Knox patent of 1680 the copper need not be quite so good, and was only limited legal tender, but the rent was only £16. Further, there was virtually no silver in Ireland (Sir John Browne, Scheme, 1729; British Museum, Add. MSS 34358, pp. 74, 79); and every one was either bimetallic or silver-monometallic; and only thirty-three years before James II had substituted full legal tender brass for silver. Further, the customs officers were practically ordered (Coxe, p. 393) to receive these coins without limit, and in the efforts referred to in Coxe (pp. 346–438) and Monck Mason (Appendix, note c) to dissuade ministers from making them legal tender, no limit is mentioned. Lastly, it was clear ever since the first letter that the patent would always be onerous; yet when it was revoked, 14 August 1725, the treasury paid Wood instead of Wood paying the treasury; a compact with Wood to make the coins legal tender would explain this. Ruding cites against these arguments Walpole's Report of the Privy Council, 24 July 1724, which disclaimed any intention to make the coins legal tender; and argues that because danger was averted it was not real. Yes, but Swift's first
Letter was published November (?) 1723, and doubtless caused the report, just as the second letter doubtless caused its publication, and the third letter criticized it. (Faulkner's reprint (1725) misprints ‘four’ for ‘three’ in the third paragraph of the first letter, and so makes the date autumn 1724. A similar sentence occurs in the seventh letter (vol. vii, p. 52) where ‘four’ is correct; the seventh is therefore a year later than the first letter, and its date is the end of October 1724. Lord Midleton probably refers to the first letter as written but not yet published, 1 November 1723 (Coxe, vol. ii, p. 372).) In the next two letters the storm centre shifts from economics to politics; the next is retrospective, the last prospective. Or it will be said ‘how absurd to think that Walpole would do what James II did and in the same way!’ Of course the patent was a mere blunder; if the coin were private it ought to have been, like promissory notes, convertible into legal tender coin by the issuer; if public, it ought to have been legal tender; and it was neither. But blunders often have the same effect as crimes. To conclude, Swift described, with popular but not misleading rhetoric, a grave economic peril which he more than anyone averted.

Reprinted from Palgrave's Dictionary of Political Economy.

With regard to Swift's contributions to economic thought, it might be added that his unmatched gifts for satire tower in general import over his undoubtedly sincere proposals for actual reform. This disparity can be seen, for example, by comparing his ‘Modest Proposal’ with the seventh of the Drapier's Letters, which Swift entitled ‘An Humble Address to Both Houses of Parliament’ (1724). Somewhat less than half of the latter is given over to the larger project of slinging arrows at those who tolerated the Englishman Wood's monopoly in the issue of ‘Hogsheads’ (copper halfpennies). The remainder is taken up with Swift's concrete proposals for the economic restoration of Ireland – proposals which indicate the extent of its economic subjection to England. These proposals include: creation of a national mint, reform of the structure of rent paid to absentee landlords and salaries paid to absentee governmental placeholders, cessation of the forced importation of English goods, and cessation of the devastating practice of deforesting and depopulating the Irish countryside for the creation of pastureland. The last of these reforms was particularly urgent. For, if the ‘Hogshead’ symbolized Ireland's political subjugation and economic dependence on England, Swift was quite aware that the vista of its countryside populated by sheep rather than men signalled something yet more sinister. However, in style, these ‘humbly’ formulated and half-plaintive proposals for reform clearly lack the bite and moral outrage of Swift's direct attacks on Wood. By comparison, the satirical ‘A Modest Proposal for Preventing the Children of Ireland from Being a Burden to their Parents or Country’ (1729) far more effectively ridicules the extent of England's exploitation of Ireland through the image of cannibalism. If England's economic policy towards Ireland is to remain the same, then the ‘modest proposal’ of creating a market for the raising and consumption of Irish children, reveals more starkly both its aims and absurd destructiveness than do the more sober proposals of the Drapier's letters. One may wonder whether in writing this ‘modest proposal’ Swift presumed correctly that the English, like the ministers of Yahoodom, feared far more the sting of having their policies proven foolish than of having them shown to be unjust.

Switching costs arise when transactions, learning, or pecuniary costs are incurred by a user who changes suppliers (including for ‘follow-on’ or ‘aftermarket’ products such as refills and repairs). The *ex post* market power that switching costs give suppliers *need not* create inefficiencies, and early ‘bargain’ prices can compensate consumers for later ‘rip-off’ pricing. More often, however, switching costs make new entry hard, distort firms’ product ranges, raise firms’ profits and lower consumer and social welfare. Similar issues arise in ‘shopping-cost’ markets. Policymakers should scrutinize markets where firms deliberately choose incompatibility.

**Article**

A product exhibits classic switching costs if a buyer will purchase it repeatedly and find it costly to switch from one seller to another. For example, there are high transaction costs in closing an account with a bank and opening another with a competitor; there may be substantial learning costs involved in switching between computer-software packages; and switching costs can also be created by nonlinear pricing as, for example, when an airline enrols passengers in a ‘frequent flyer’ programme that gives them free trips after flying a certain number of miles with that airline.

Switching costs also arise if a buyer will purchase ‘follow-on’, or ‘aftermarket’, products such as service, refills or repairs, and finds it difficult to switch from the supplier of the original product. In
short, switching costs are created whenever the consumer makes an investment specific to his current seller that must be duplicated for any new seller. Large switching costs lock in a buyer once he makes an initial purchase, so unless sellers specify all the future prices and qualities of their products a long-term relationship is governed by short-term contracts. This creates *ex post* market power, for which firms compete *ex ante*; they use strategies such as penetration pricing, price wars, and introductory offers to fight for market share that will generate future profits (see, for example, Klemperer, 1987a; 1989).

The central question in the literature is the extent to which this fierce *ex ante* competition for buyers is an adequate substitute for more standard period-by-period competition without switching costs. In the simplest models, firms’ low ‘bargain’ prices to new customers exactly compensate buyers for the high ‘rip-off’ prices they will pay after lock-in, so buyers’ total ‘life-cycle’ payments are unaffected by their switching costs, and the absence of any price commitments leads to no inefficiencies. But things do not usually work so well.

Most theoretical models confirm the popular intuition that switching costs raise firms’ profits and lower social welfare. Switching costs can segment even an otherwise undifferentiated market as firms concentrate on exploiting their established customers and do not compete aggressively for their rivals’ buyers. Unless new firms will enter the market in the future, an existing firm would usually expect to earn future profits even if it made no current sales (because it could then usually capture a few of its rivals’ lower-switching cost customers, by setting a lower price than its rivals). So rent dissipation is low, allowing oligopolists to extract positive profits overall (as illustrated by Farrell and Shapiro, 1988; Padilla, 1995; Chen, 1997; Taylor, 2003; and others). Furthermore, consumers facing switching costs care about expected future prices as well as about current prices, and are therefore generally less sensitive to current prices than they would be in the absence of switching costs. So firms generally have less incentive to cut prices, and prices and profits are therefore higher, than they would be in the absence of switching costs (see Klemperer, 1987b; Beggs and Klemperer, 1992). Although it is possible to construct models in which switching costs lower profits by making special assumptions about consumers’ expectations and tastes (see von Weizsäcker, 1984), and there is little convincing empirical evidence, the limited laboratory evidence suggests switching costs raise profits (see Cason and Friedman, 2002).

Even when *ex ante* competition fully dissipates *ex post* rents, it may do so in unproductive ways such as through socially inefficient marketing. The ‘lo-hi’ pricing patterns distort buyers’ choices – for example, if a printer is priced below cost but the locked-in ink is expensive, buyers may buy an over-specified printer but then use it too little from the social viewpoint. Such pricing also gives customers wrong signals about whether to switch. If consumers do switch, direct costs are incurred (Klemperer, 1988) and, if consumers avoid those costs by not switching, that obstructs otherwise efficient matching between buyers and sellers. Product variety is less sustainable in the market than if niche products are compatible with mainstream products and so don't require new users to incur switching costs. Switching costs also hamper forms of entry that must persuade customers to pay those costs, in particular, large-scale entry that seeks to attract other firms’ customers (for instance to achieve minimum viable scale, if the market is not growing quickly) (Klemperer, 1987c). The difficulty of new entry may be broadly efficient given switching costs, but is nevertheless a social cost of switching costs. So switching costs often damage competition, and firms may therefore also dissipate further resources.
creating and defending incompatibilities – as, for example, when Gillette famously, and repeatedly, changed the design of its razors to prevent competing manufacturers from selling compatible blades. Likewise, it is alleged that both IBM and Microsoft have deliberately obstructed compatibility between their products and those of their competitors, and Kodak tried to prevent independent repair firms from servicing its photocopiers.

The bargain-then-rip-off pricing structure is clearest when new and locked-in customers are clearly distinguished and can be charged separate prices, as, for example, when prices are individually negotiated, or when locked-in customers buy separate ‘follow-on’ products, such as parts and service, rather than repeatedly buying the same good.

If, instead, each firm has to set a single price to old (locked-in) and new customers (see Beggs and Klemperer, 1992), that price must compromise between a high price to exploit current locked-in buyers and a lower price to attract more buyers to lock in and exploit later. The implications for competition and welfare are similar to those for the bargain-then-rip-off case above, except that here switching costs also create a ‘fat-cat’ effect: firms with large customer bases set higher prices, because they have more to gain from harvesting current customers than winning new ones.

On the one hand, the ‘fat-cat’ effect is a further force for high prices – firms price less aggressively both because they recognize that, if they win fewer customers today, their rivals will be ‘fatter’ and therefore less aggressive tomorrow, and because consumers recognize this too and so are less impressed by lower current prices. On the other hand, it actually facilitates entry that focuses purely on new customers – since an incumbent’s incentive to set a high price against its locked-in buyers creates a price umbrella under which a new entrant can come in.

The fat-cat effect means large shares tend to shrink and small shares to grow; when firms’ shares are similar, they return to stable steady state after any shock. More generally, the trade-off between harvesting old customers and investing in new ones depends on interest rates, the state of the business cycle, expectations about exchange-rates, and so on, with implications for macroeconomics and international trade (Chevalier and Scharfstein, 1996; Froot and Klemperer, 1989; Klemperer, 1995). Some of the same issues as with switching costs arise when shops advertise only some of their prices: customers become ‘locked in’ as they bear the costs of going to a shop, and only afterwards learn its other prices. Just as with dynamic switching costs, this tends to produce bargains on advertised (‘loss leader’) prices and corresponding rip-offs on unadvertised prices (see Lal and Matutes, 1994).

Also closely related are ‘shopping-cost’ markets where consumers face costs of using different suppliers for different goods in a single period but all prices are advertised (though neither time nor commitment problems are central in these markets). Shopping costs encourage firms to offer a full product line – for example, a supermarket stocks a broad range of products to encourage consumers to shop only there – and so help explain multi-product firms. Indeed firms’ product ranges may be too broad from the social viewpoint (Klemperer and Padilla, 1997), but may also be too similar to each other (Klemperer, 1992) so that there is too little variety in the market as a whole. Shopping costs also make single-product entry hard. However, the ‘mix-and-match’ literature, beginning with Matutes and Regibeau (1988), suggests that firms typically prefer to be compatible (no shopping costs) rather than incompatible (infinite shopping costs), at least in symmetric single-period duopolies.

Other literature related to switching costs includes that on network effects (see, for example, Farrell and Klemperer, 2007, and the companion-piece to this article, network goods (theory)), search costs (see, for
switching costs: The New Palgrave Dictionary of Economics

example, Stiglitz, 1989), and ‘experience goods’ (see, for example, Schmalensee, 1982).

The theoretical literature on switching costs described above arguably began with Selten's (1965) model of ‘demand inertia’ (which assumed a firm's current sales depended in part on history, even though it did not explicitly model consumers’ behaviour in the presence of switching costs), and then took off in the 1980s with contributions from von Weizsäcker (1984), Klemperer (1983; 1987a; 1987b; 1987c), Farrell and Shapiro (1988), and others. But, although there is an extensive empirical marketing literature on brand loyalty (or ‘state dependence’) which often reflects, or has equivalent effects to, switching costs (summarized in Seetharaman, Ainslie and Chintagunta, 1999), the empirical economics literature on switching costs is smaller and more recent than the theoretical literature.

Only a few studies attempt to directly measure switching costs. Where microdata on individual consumers’ purchases are available, a discrete choice approach can be used to explore the determinants of a consumer’s probability of purchasing from a particular firm (for example, Greenstein, 1993, on computer systems procurement; Shum, 2004, on breakfast cereal purchases), but, because switching costs are usually both consumer-specific and not directly observable, and microdata on individual consumers’ purchase histories are seldom available, less direct methods of assessing the level of switching costs are often needed (for example, Kim, Kliger and Vale, 2003) estimate a first-order condition and demand and supply equations for Norwegian bank loans, and Shy (2002) uses data on prices and market shares for the Israeli cellular phone market.

One defect of most empirical studies is that few of them model the dynamic effects of switching costs that are the main focus of the theoretical literature; most of them assume consumers myopically maximize current utility without considering the future effects of their choices. Nevertheless, the empirical literature does suggest that switching costs play an important role in many industries, including credit cards, cigarettes, supermarkets, air travel, phone services, electricity suppliers, bookstores, and automobile insurance (see Farrell and Klemperer, 2007, for references, and Klemperer, 1995, for more examples of markets with switching costs); as technology continues to develop, products become more complex, and services become more important, the importance of switching costs seems likely to increase further.

Because switching costs very often make competition, and especially entry, less effective, I (and many others) favour cautiously pro-compatibility public policy. Policymakers should look particularly carefully at markets where incompatibility is strategically chosen rather than inevitable. Because buyers’ early choices are often crucial, and depend on their expectations about firms’ future behaviour, provision of information and consumer protection against deception, and so on, are more important than usual. And competition policy must recognize that the analyses of mergers, monopolization, intellectual property, and predation are all affected by switching costs; it is unsurprising that switching costs have featured importantly in many of the world's best-known and most significant antitrust cases, including the IBM, the Kodak, and the European Microsoft cases.

Farrell and Klemperer (2007) contains a recent and comprehensive survey of switching costs.

Article

Symmetry breaking creates asymmetric outcomes in the symmetric environment. It is the key concept for understanding self-organized (that is, endogenous) pattern formations. For example, cosmologists wonder why matter in the universe is distributed in clusters, leaving much of the universe empty. Earth scientists study the formation of wave patterns, such as jet streams, ocean currents, and continental drifts. Material scientists study phase transitions, how molecules align themselves when they reach the critical temperature. Molecular biologists ask how life began in the primordial soup of amino acids, and developmental biologists attempt to explain how living organisms acquire forms through cell division and morphogenesis (Weyl, 1969; Prigogine, 1980). Similar questions about pattern formations also exist in economics. Why are there rich and poor countries? Why are industries clustered? Why are there booms and recessions? Why are some ethnic groups under-represented in certain jobs or neighbourhoods?

A simple model can illustrate the role of symmetry breaking in self-organized pattern formations. Consider an economy with two inherently identical regions. Each region has an equal amount of an immobile factor, say, land or labour. In addition, there is a single mobile factor, capital, whose allocation is measured along the horizontal axis in Figure 1. Two curves show how the rates of return to capital in the two regions change with the allocation of capital. To the extent that capital has to compete for the use of the immobile factor, the rate of return to capital in one region declines as more capital is allocated to that region. Because the two regions are inherently identical, the two curves are symmetric around the midpoint. When capital is allocated evenly, the rates of return in the two regions are equalized; hence, this is an equilibrium allocation. Furthermore, this allocation is stable: if capital is allocated unevenly, the region with less capital offers a higher rate of return and so attracts capital from the other region, and the resulting capital flow restores the equilibrium allocation. Thus, the ‘centrifugal forces’ of the resource constraint prevent one region from attracting more capital than the other.

Figure 1
Now let us add some agglomeration economies so that the productivity of capital can be enhanced by concentration. If the ‘centripetal forces’ of agglomeration economies dominate the ‘centrifugal forces’ of the resource constraint, the rate of return in one region may increase as more capital is allocated to that region, at least over a certain range (Figure 2). The model now has two stable equilibria and both imply uneven spatial allocations of capital. The even allocation of capital is still an equilibrium, but unstable. If slightly more than half of capital is allocated in one region due to some small historical accidents, the rate of return becomes higher there and so more capital flows from the other region. Once this process gets started, it would feed on itself, and the allocation of capital would be further away from the equal division. One region emerges as the developed core and the other is left behind as the underdeveloped periphery. The model does not say which of the two asymmetric outcomes would emerge, but it does say that the observed outcome has to be asymmetric. Thus, the loss of stability of the symmetric outcome, ‘symmetry breaking’, generates the formation of the core-periphery patterns.

Figure 2
What separates the two situations depicted in Figures 1 and 2 is the relative magnitude of the centripetal to centrifugal forces, which may in turn be determined by a certain parameter of the model, say, \( \lambda \). Figure 3 schematically traces out how stable outcomes might change as \( \lambda \) increases. For \( \lambda < \lambda_c \), there is a unique stable outcome, which is symmetric; no spatial asymmetry appears. As it reaches to a critical value of the parameter, \( \lambda = \lambda_c \), the balance between the two forces is tipped, at which point there will be an abrupt change. For \( \lambda > \lambda_c \), there are two stable asymmetric outcomes (shown by the solid branches of the curve) and the symmetric outcome becomes unstable (as indicated by the dashed line). So, as \( \lambda \) exceeds its critical value, patterns are formed. Figure 3 shows that the rate at which a stable asymmetric outcome responds to a change in \( \lambda \) is arbitrarily large above the critical value. This is a fairly generic feature of models in which two competing forces are at work. At the onset of pattern formation, even a small change in the environment can be amplified to create a large effect.

Figure 3
Symmetry breaking aims to explain the formation of the patterns or the structure. In contrast, most economic analysis treats the structure of the economy as given, which can be a useful short cut for many purposes. For example, if we are interested only in constructing a model consistent with the observed patterns, we could simply assert that the regions are

Some physical analogies may be apt here. If water is heated at atmospheric pressure, nothing drastic happens until it reaches 100°C, when it suddenly starts boiling. If the temperature is lowered, the water suddenly turns to ice at 0°C. Such abrupt changes in the phase of matter are the results of a competition between the attractive intermolecular forces, which tend to order the system, and the individual kinetic energies of the molecules, which have the opposite effect. In a liquid phase, the random motion of water molecules is too violent for intermolecular interaction to hold them in place. Increasing the pressure, which favours the intermolecular forces, or reducing the temperature, which reduces the kinetic energies of the molecules, eventually tips the balance between the two. Once the critical point is crossed, the attractive forces will be strong enough to keep molecules firmly in place and the crystal structure of ice will be developed. Many similar examples exist in nature. At room temperature iron can be magnetized, but when it is heated above the Curie point it loses its ferromagnetic property. Another example would be superconductivity, in which electronic resistance disappears discontinuously at the critical temperature.
symmetry breaking: The New Palgrave Dictionary of Economics

For further discussion on the methodological issues raised by symmetry breaking, circular causation, and multiple equilibria, see Matsuyama (1995a; 1995b; 1997; 2002). (Aoki, 2001). Last but not least, spatial and temporal variations in social behaviour, such as fashion cycles (Matsuyama 1992b), may also be better understood through the lens of symmetry breaking. Due to some institutional complementarities across occupations. Or think of the problem of comparative economic systems. One might be tempted to attribute differences in labour market practices or in financial systems across different categories to the differences in regulations or in national cultures. However, symmetry breaking suggests an alternative view. Due to some institutional complementarities across occupations, or that in some regions the market works more efficiently in some regions than in others, or that people in some regions are more diligent, or that people in other regions lack entrepreneurial spirits, and so on – which would raise yet another question. As long as we try to explain spatial variations in one variable by introducing spatial variations in another variable, there may be no end to this process. The logic of symmetry breaking does not require any exogenous source of variations, because of the circular causation. In the case of Figure 2, not only does better technology attract more capital but more capital leads to better technology, due to agglomeration economies. Such two-way causality can bring about the instability of the symmetric outcome, which leads to the formation of the core-periphery patterns. In other words, symmetry breaking explains such variations purely as an outcome of the internal mechanisms of the system, that is, in a self-organized manner.

This is not to say that some exogenous sources of variations, such as the climate and geography, are unimportant factors in explaining pattern formations. Rather, the central message of symmetry breaking is that such exogenous variations do not have to be large; even small exogenous variations can be amplified to generate large variations. In short, a small cause can create a big effect. Once pointed out, this may seem obvious. Yet some economists may look for a big change in the environment when trying to explain a big movement of a certain economic variable. But the logic of symmetry breaking suggests that their efforts might very well turn out to be futile. When somebody proposes a hypothesis that the difference in $X$ is due to the difference in $Y$, one often hears the criticism that the difference in $X$ is too small to have caused the difference in $Y$. But the logic of symmetry breaking suggests that such a criticism may be unwarranted.

The logic of symmetry breaking has always been central in urban and regional economics (see Fujita, Krugman and Venables, 1999). Symmetry breaking also gives us a fresh perspective on many familiar questions in other areas of economics. In international trade, the patterns of comparative advantage are linked to cross-country differences in productivity, but the sources of the productivity differences are often left unexplained. If productivity improves through accumulation of experience, there will be a two-way causality between trade and technology (Krugman, 1987; Lucas, 1988; Matsuyama, 1992a; see Grossman and Helpman, 1995, for a survey). In the presence of such two-way causality, many of the observed patterns of trade can arise endogenously due to the cumulative effects of small historical accidents.

In the growth and development literature, cross-country differences in per capita income are often attributed to differences in total factor productivity (TFP) or in investment distortions, but these differences themselves are often left unexplained. But lower productivity or greater distortions may not only be a cause of low income, but the low income may also be a cause of lower productivity or greater distortions. With such two-way causality, cross-border movement of goods, as in Krugman and Venables (1995) and Matsuyama (1996; 1999a), or capital, as in Boyd and Smith (1997) and Matsuyama (2004a), amplifies small inherent differences across the countries, which makes balanced development (spatial symmetry) unstable, and the world economy may inevitably evolve into a system of rich and poor, where the countries are divided between a developed core, characterized by high income, high TFP, small investment distortions, and an underdeveloped periphery, characterized by low income, low TFP, and large investment distortions. If so, the problem of an underdeveloped country cannot be looked at in isolation; instead, it has to be examined as a part of the interrelated whole because the rich may be rich in part due to the presence of the poor and the poor may be poor in part due to the presence of the rich.

Likewise, social inequality and a class structure might emerge endogenously, even if people were identical in every conceivable dimension, which suggests the unattainability of a classless society (Freeman, 1996; Matsuyama, 2000; 2006). Francois (1998) and Burdett and Wright (1998) suggest that an outcome in which the two sexes are treated equally may be unstable.

In macroeconomics, booms and recessions are often attributed to fluctuating TFP; yet why TFP fluctuates is often left unexplained. Endogenizing TFP, either through innovation as in Aghion and Howitt (1992) and Matsuyama (1999b), or through distorted allocation of the credit as in Azariadis and Smith (1998) and Matsuyama (2004b; 2005), could cause instability in the stationary path (the temporal symmetry), which generates temporal patterns of booms and recessions, in which it appears that fluctuations are driven by the movements of TFP.

In residential choices, symmetry breaking forces us to ask why an integrated or mixed neighbourhood is difficult to sustain (see Schelling, 1978; Miyao, 1978; Benabou, 1993). And why are certain ethnic groups over-represented or under-represented in certain jobs? The standard model of occupational choice in labour economics would suggest that there are large innate differences in skills across ethnic groups. The logic of symmetry breaking suggests that, if the informational externalities in the process of skill acquisition or job search are greater within the same ethnic group, even small initial differences in skill distributions or some historical accidents may end up sorting different ethnic groups into different occupations. Or think of the problem of comparative economic systems. One might be tempted to attribute differences in labour market practices or in financial systems across countries to the differences in regulations or in national cultures. However, symmetry breaking suggests an alternative view. Due to some institutional complementarities across different practices and across different firms, either most firms in a country would adopt these practices, or else very few firms would adopt them. They may be more prevalent in some countries than in others only because of certain historical accidents. Furthermore, the diversity of national economic systems may be an inevitable feature of an integrated world (Aoki, 2001). Last but not least, spatial and temporal variations in social behaviour, such as fashion cycles (Matsuyama 1992b), may also be better understood through the lens of symmetry breaking.

For further discussion on the methodological issues raised by symmetry breaking, circular causation, and multiple equilibria, see Matsuyama (1995a; 1995b; 1997; 2002).

systems of cities

J. Vernon Henderson
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Research on systems of cities examines five issues. How do cities form and what are the agglomeration benefits driving city formation and sizes? Second, in a hierarchy of cities, what is the role of big versus small cities? Third, how does a system of cities evolve under economic and population growth; and how does urban growth based on localized knowledge spillovers potentially define national economic growth? Fourth, how do governance, institutions, and public policy affect city formation and sizes? Finally where do cities locate and what the effects of history, climate and natural resource location?

Article

Modelling and empirical work on systems of cities focuses on five related sets of questions. First, why do cities form, with so much of economic activity in countries geographically concentrated in cities? The answer has to do with agglomeration benefits, as described below. Second, given there is a hierarchy of cities, with cities of different sizes and types in a country, how do cities interact with each other? What are the potential trade patterns across cities and how do they correspond to the roles of big versus small cities? Third, how does a system of cities evolve under economic and population growth; and how does urban growth intersect with, or even define, national economic growth? In growth theory, endogenous growth is based on knowledge spillovers and sharing, and evidence suggests that much of that interaction must occur at the level of individual cities.
The fourth set of questions asks how governance, institutions, and public policy affect city formation and sizes, which then in turn affect economic efficiency. Cities require enormous public infrastructure investments which affect urban quality of life, in particular health and safety and commuting and congestion costs. Institutions governing land markets, property rights, local government autonomy, and local financing affect the city formation process and city sizes. And national government policies concerning trade, labour policies and national investment in communications and transport infrastructure affect the shape of the urban system. The final set of questions has to do with where cities locate. What are the effects of history, climate and natural resource locations, including rivers and natural harbours, on the location of current urban agglomerations?

To see how economics has tackled, and in some cases avoided, aspects of these questions, we start by describing the economics of a representative city. Then we turn to how to model the urban hierarchy and the role of trade, institutions, geography, and economic growth.

The representative city

In models of a representative city dating back to Mills (1967), as applied to systems of cities in Henderson (1974) and subsequent work, any city is viewed as having an inverted-U relationship between real income or utility per worker and city employment or population. As city sizes increase from low levels, workers benefit from localized agglomeration benefits of increasing scale. This leads to increases in per worker incomes, giving the rising part to the inverted U. These benefits can involve information spillovers in input and output markets from economic agents in close proximity, where information decay over space is very rapid. Thus close spatial clustering of firms is required for efficient information transfer. The benefits can involve search and matching economies in local labour markets. In addition, to draw from the new economic geography literature (Krugman, 1991), they can involve economies of diversity in local intermediate inputs where bigger local markets can support more varieties of local intermediate inputs, which enhances the efficiency of final export good producers in the city. Models of the micro-foundations of these ideas and econometric evidence all yield a monotonic increasing relationship between city employment size and nominal wages per worker. These static agglomeration economies can be augmented with knowledge spillovers, particularly in growth contexts. Local knowledge accumulation as represented by educational attainment enhances productivity, whereby knowledge accumulation either enriches (multiplies) local information spillovers or simply represents improved levels of local technology.

If agglomeration benefits were the end of the story, in each country there would be only one massive city containing the entire urban population. In systems of cities models, the limit on city sizes is modelled as being internal to the city. Cities must house workers, where there are scale diseconomies in city living, including per capita infrastructure costs, pollution, accidents, crime, and commuting costs. Most urban models consider an explicit internal spatial structure of cities, whereby all production occurs at a point in a city, the central business district (CBD). Surrounding the CBD is a residential area from which people must commute to the CBD. People residing nearer the city centre pay higher rents, while those residing further away, who must commute further, pay lower rents as compensation. As city sizes increase, average commuting distances, times and expenditures all rise, as do average housing and land rents paid by residents. The former are resource costs limiting the efficiency of increasing city sizes. The latter – rents – are an income whose distribution is considered below. The rising costs of increasing city
sizes can be modelled also in cities with multiple business districts. Once cities become large enough, at some point the marginal production benefits of increasing city size are surpassed by the marginal costs of rising commuting and other diseconomy costs. At the point of overtake, the inverted-U of real income per worker against city size peaks and then declines with further increases in city size. Although they are not well captured in theoretical models, two other key considerations limit the benefits of increasing city sizes. One is the ‘extent’ of the market for a city's product, represented in Mills (1967) and the new economic geography literature. As cities grow they have to sell their products further and further afield, encountering rising transport costs. The other is spatially dispersed natural resource deposits. Most processing of deposits is weight-reducing. Transport cost considerations result in materials being initially processed in cities at dispersed locations, where natural resources are found, before being shipped to other population and production centers.

City formation

An inverted U tells us that efficient city sizes will be limited. If cities all operate with the same level of technology and market demand for products, national welfare is maximized if all cities operate at the peak to their inverted U's. The critical issue is what institutions and market mechanisms determine how new cities form, and whether cities operate at their peak points. We start with a specific mechanism and discuss how it generalizes, as well as what happens in the absence of any mechanism. Suppose there is an unexhausted supply of identical city sites in the economy, each owned by a different land developer in a nationally perfectly competitive urban land development market (Henderson, 1974, Helsley and Strange, 1990). A developer acts both as a developer and as a ‘private’ local government, where, for an occupied city, she collects local land rents, specifies city population, provides any public services, and offers subsidies, or inducements to firms or people to locate in that city, in competition with other cities. Population is freely mobile. In choosing city attributes, she attempts to maximize profits (land rents less subsidies), but competition in national land markets with other developers for residents drives her profits to zero in equilibrium.

This solution has a variety of properties heralded in the urban literature. First, in simple models, it is a unique equilibrium that is Pareto efficient; it is the only coalition-proof equilibrium; and it is a free mobility equilibrium where the developer-specified populations are self-enforcing, that is, no worker wants to move to another city at the equilibrium configuration. Second, the solution reflects the Henry George Theorem (Flatters, Henderson and Mieszkowski, 1974), under which land rents collected in a city when it is at its efficient size exactly equal the revenues needed to fund all public services and costs of internalizing externalities. In the simple case where there are no public services, the subsidy per worker exactly equals the gap between the social and private marginal product of labour within the city. Thus the subsidy prices scale externalities. A final property of the equilibrium is that, in a large economy with many cities, there are effective constant returns to scale nationally. Increases in national population are accommodated by increased city numbers, where each city is at efficient size (Kanemoto, 1980; Henderson and Ioannides, 1981). If there are not many cities, there is a ‘lumpiness’ or integer problem in solving the model more generally. If there is enough national urban population to support only 3.5 cities of efficient size, an equilibrium is going to have no more than three cities, all a greater size than that where the inverted U peaks.
As shown in Henderson and Becker (2001), the land developer solution arises also under an alternative mechanism where the private government/developer is replaced by a city government that can tax land rents, provide public services, subsidize entrants to the city and potentially exclude residents through zoning regulations (‘no-growth’ restrictions). These autonomous democratic local governments act in a political competition model to maximize the welfare of the representative local voter. In doing so, they also achieve efficient results and the Henry George Theorem applies. Note that critical ingredients are required for either the private government/developer or city government solution to work. Local governments must be able to tax away urban land rents to use as revenues to subsidize entry; otherwise cities will be too small since they can't offer the efficient level of subsidies to induce enough entry and internalize scale externalities. More critically, there must be freely functioning national land markets with autonomous local developers or local governments that are free to set up cities and potentially limit their sizes. That is, either developers must be able to assemble sufficient land to house an entire city or local governments have must have jurisdiction over the same land area. These institutions give a ‘complete’ national land market for city formation.

Absent such institutions and complete markets, cities form only through ‘self-organization’. In simple models with perfect mobility of all resources, the result is potentially enormously oversized cities (Henderson, 1974; Henderson and Becker, 2001). In the inverted-U context, Nash equilibrium city size in terms of atomistic worker migration decisions lies between the efficient size where real income per worker is maximized and a limit size to the far right which is a ‘bifurcation’ point (Krugman, 1991). At that point, city size is so large with such enormous diseconomies that the population is indifferent between being in this oversized city and in a rural settlement of size 1 (the size of a community formed by a defecting migrant). The problem is the familiar one of coordination failure. For example, in a large economy growing in population, we would like population increases to be accommodated by increases in city numbers all of efficient size. But timely formation of the next city to accommodate population growth requires en masse movement of population (drawn in small amounts from each of the many existing cities) into a new city of efficient size. Without coordination in the form of developers or city governments, no such en masse movement is possible, so people wait to migrate from existing cities to a new city until existing cities are all grossly overgrown at their ‘bifurcation point’.

Types of cities: foundations for an urban hierarchy

Henderson (1974) conceives of economies composed of cities specializing in different products. His reasoning is that, in particular for standardized manufactured products, economies of scale are ones of ‘localization’ or are internal to the own industry. So textile producers learn from each other about technology and market conditions by clustering together, but they learn little of interest from any, say, steel producers nearby. But there are costs of collocating steel and textiles in the form of urban diseconomies such as commuting times and congestion. Thus it is efficient (and a unique equilibrium) to have separate steel and textile-type cities. Given differences between the steel and textile industries in the degree of local external scale economies, these city types will have different sizes. With free migration, real incomes per worker in each type of city will be equalized, with both types of cities at the peaks of their particular inverted U's of real income against city size. The numbers of each type of city, along with steel and textile prices, adjust to ensure equalized real incomes across city types;
systems of cities: The New Palgrave Dictionary of Economics

equilibrium the numbers of each type of city yield supplies of steel and textiles equal to national demand for these products.

This idea of urban specialization has two key implications. First, cities trade extensively with each other. Each city has a non-traded goods sector, with housing and retail and personal services, and an export sector where, with urban specialization, widespread inter-city trade is a key aspect of national economic efficiency. Second, while free migration equalizes real incomes across city types, in the bigger types of cities costs of living will be higher. With equalized real incomes, nominal wages must also be higher in bigger cities, reflecting their greater scale economies. Empirical evidence from different countries suggests that, as cities move from a small population (say, 50,000) to very large metro areas, the cost of living and nominal wages both may typically double.

The original system of cities models ignore intercity transport costs; transport costs of goods across cities are zero or infinite, as for housing. The new economic geography literature (Krugman, 1991) appropriately brings transport costs back to the front burner. In simple urban models it is possible to introduce generalized intercity transport, or trade costs without a specific geography, as in Abdel-Rahman (1996). Then, whether cities are all completely specialized depends on the extent of these trade costs. To put cities in ‘real’ geography so as to have endogenous distances and levels of transport costs across cities is very difficult. Fujita, Krugman and Mori (1999) simulate a situation with monopolistic competition in product markets, where cities sell to each other and also to an agriculture population spread along a line. Cities spread out to serve farmers, but the centripetal force limiting the spread is intercity trade costs. In empirical application of urban models, it is helpful to adapt monopolistic competition models to systems of cities models, so each city has a market potential which characterizes the extent of the market for its products. Au and Henderson (2006) do this in the context of estimating the shape to the inverted U curve of real income against city size, for Chinese cities, allowing different types of cities to exist, each with its own inverted U. This is actually the first time the inverted U has been estimated. China has unusual data, such as urban area value-added, and unusual circumstances in the form of migration restrictions that leave some cities undersized and others oversized that allow inverted U's to be traced out.

There are two empirical literatures on the extent to which production patterns differ across space. The first describes the extent of urban specialization. Starting with Bergsman, Greenston and Healy (1972), researchers use cluster analysis to group cities into categories based on similarity of production patterns – correlations (or minimum distances) in the shares of different industries in local employment. Using 1990 data for the USA, Black and Henderson (2003) group 317 metro areas into 55 clusters, ‘defining’ 55 city types based on patterns of specialization for 80 two-digit industries. There are textile, primary metals, machinery, electronics, oil and gas, transport equipment, health services, insurance, entertainment, diversified market centre, and so on, types of cities, where anywhere from five to 33 per cent of local employment is typically found in just one industry. Specialization in manufactured products, especially among smaller cities, tends to be absolute; many cities have absolutely zero employment in industries such as computers, electronic components, aircraft, instruments, and metal-working machinery.

A related but different perspective is the literature on spatial concentration of industry – the extent to which a particular industry is found in a few as opposed to many locations. The key paper is by Ellison and Glaeser (1999), who model the counterfactual to concentration: the spatial patterns that would arise
if location patterns of different industries were determined by random draws across national employment for all industries, where the total number of draws per location is determined by each location's share of national total employment. Ellison and Glaeser develop a specific index measuring the degree of industry concentration relative to this counterfactual, and argue that almost all industries display some degree of spatial concentration. In a related paper, Duranton and Overman (2005) develop a framework to test statistically whether observed industry spatial distributions are statistically significantly different from ‘counterfactual’ distributions if locations were chosen randomly. They examine the distribution of all pairwise distances between plants in an industry, where distributions which have a greater mass of short pairwise distances are more spatially concentrated.

This literature on specialization and concentration of manufacturing activities tends to overlook two key facts about the process. First, simple indices of urban diversity indicate that smaller cities are very specialized and larger cities highly diversified. Second, in modern economies like the USA the ratio of business services to manufacturing tends to rise sharply as we move up the urban hierarchy. Given these facts, what is the role of large metro areas in an economy and their relationship to smaller cities? A recent literature has focused on the role of large metro areas as centres of innovation, headquarters, and business services. In examining one key aspect of this role, Duranton and Puga (2005) model functional specialization. Manufacturing activities require business service activities, summarized as ‘headquarter functions’, for organization of production and final sale of goods. Firms may locate headquarters in large cities, away from production facilities in smaller specialized cities, so as to purchase local intermediate business service inputs such as R&D, marketing, financing, exporting, and so on. Urban agglomeration economies in these metro areas arise essentially from shopping agglomeration benefits – the wide diversity of intermediate business service firms in large metro areas from which headquarters can shop in making their outsourcing decisions. In a related earlier paper, Duranton and Puga (2000) develop another aspect of the role of large metro areas. They are modelled as diversified cities, where new firms may experiment with different technologies until they learn the one that best satisfies their needs; once firms have chosen a standard technology they decentralize to smaller specialized types of cities. This model captures a critical phenomenon. Large diversified metro areas may serve as high-tech, innovative, and R&D incubators where new products are born; and then, following the product cycle model, once production of a product is standardized it moves to small cities or offshore, where land and wage costs are cheaper.

The effect of trade and other policies on urban systems

As noted earlier, at the national level in a large economy with many cities, at the limit there are constant returns to scale, or replicability. If national population doubles, the numbers of cities of each type and national output of each good simply double, with individual city sizes, relative prices and real incomes unchanged. As such, in neoclassical trade models, with two goods and two factors, basic international trade theorems (Rybczynski, factor price equalization, and Stolper–Samuelson) hold (Hochman, 1977). This gives an urban flavour to national policies (Renaud, 1981). For example, trade protection policies favouring the steel industry in relatively large cities over, say, the textile industry in smaller cities will alter national output composition towards steel production and increase the number of large relative to small cities. National urban concentration, or the fraction of the population living in bigger versus
smaller types of cities, will correspondingly rise. Similarly, subsidizing an input such as capital for a high-tech product again, say, produced in a larger type of city will cause the numbers of that type of city to increase, again raising urban concentration. A minimum wage policy which sets a minimum nominal wage for an economy may bind in smaller types of cities which have lower equilibrium nominal wages, but not bind in larger types of cities. This distortion will increase the sizes and costs of products produced in smaller types of cities, reducing their numbers and national output, as production moves to products in cities which face no effective constraint (Henderson, 1988).

**Growth in a system of cities**

In a large system of cities, given replicability, in Henderson and Ioannides (1981) in an exogenous growth model, increases in national population growth are accommodated by increases in numbers of cities, as noted earlier. With exogenous technological change which enhances agglomeration economies or reduces urban commuting costs, efficient city sizes will increase also. Black and Henderson (1999) develop these notions further in an endogenous growth model, where there are two types of cities. Growing dynastic families allocate their members across the two types of cities, which have different technologies and intensities of human capital usage. The only capital in the model is human capital, and as such there is no formal market for it. Families operate as an intra-family capital ‘market’ with members in low capital-intensity cities lending to those in high capital-intensity cities. As such, not only do people in high-intensity human capital cities earn a cost-of-living (positive or negative) premium relative to other types of cities, but their nominal wages must be high enough to pay back the human capital they have borrowed – to earn the returns on their higher required levels of human capital. Under conditions allowing for steady state growth, workers accumulate human capital continuously. Within cities the local stock of human capital generates a knowledge externality, which improves production efficiency – so efficient city sizes continuously increase. These urban knowledge externalities are the source of national economic growth. As economies grow, on the urban side there is parallel growth. Both types of cities grow at the same rate in terms of size; and, with sufficient national population growth, both types of cities also grow in number at the same rate.

For evidence on urban-based growth through knowledge accumulation, Glaeser, Scheinkman, and Shleifer (1995) in a cross-section city growth framework show that cities which had higher median years of schooling in 1960 grew faster from 1960 to 1990 than other cities. Similarly, Black and Henderson (1999) find in a panel context for 1940–90 for the USA that cities with higher fractions of college-educated grow faster over each decade. In terms of parallel growth, papers by Eaton and Eckstein (1997) on France and Japan and by Dobkins and Ioannides (2001) and Black and Henderson (2003) on the USA establish basic facts about the evolution of urban systems. First, there is a wide relative size distribution of cities in large economies that is stable over time. Big and small cities coexist in equal proportions over long periods of time. This fact can be established by direct comparisons of current versus historical relative size distributions. More formally, writers make a division of cities by relative sizes usually into discrete cells, or states. Then, on the assumption of a first-order Markov process, transition matrices and steady-state size distributions can be calculated, where in many cases stationarity of the transition matrix over time can't be rejected. Steady-state distributions tend to be close to beginning- and end-period distributions.
Second, within relative size distributions for a country, individual cities are generally growing in population size over time; and what is considered a big city in absolute terms changes over time. In addition, city numbers are increasing over time with entry of new cities. City sizes in the USA, Japan, and France grew during the 20th century at average annual rates of 1.2–1.5 per cent, depending on the country and exact time interval: rates which involve city sizes increasing 3.3–4.5-fold every century. Worldwide, with an absolute cut-off point of 100,000 to be an urban area, numbers of cities worldwide doubled from 1960 to 2000. And the wide size distribution of cities means that much of the urban action is in smaller cities rather than mega-cities. In 2000, between 70 and 75 per cent of the world’s urban population lived in cities of under 2 million.

Third, within countries as they urbanize and grow in population there is entry of new cities and both rapid growth and decline of cities nearer the bottom of the urban hierarchy. However, at the top of the hierarchy city size rankings are remarkably stable over time. In the transition matrix the probability of a city moving out of the highest state, once there, is remarkably low. In Japan and France, the 39–40 largest cities in 1925 and 1876, respectively, were all in the top 50 in 1985 and 1990 respectively; and, at the top, absolute rankings were unchanged (Eaton and Eckstein, 1997). In the USA, for 1900–90 cities in the top decile of rankings stay in that decile indefinitely, with newer cities joining the decile as the total number of cities expands. Why is this? A common answer is physical infrastructure. Large cities have huge historical capital stocks of streets, buildings, sewers, water mains and parks that are cheaply maintained and almost infinitely lived, which give them a persistent comparative advantage over cities without that built-up stock. A second answer is based on concepts in Arthur (1990): large cities offer persistent accumulations of knowledge, allowing them to outcompete smaller cities for new industries, which also makes large cities more adaptable.

**Zipf's Law**

A heralded empirical ‘fact’ about size distributions of cities within countries is that, at least at the upper tail, they are well approximated by a Pareto distribution, with Zipf's Law applying in many cases (Ioannides and Overman, 2003). If one ranks all cities from smallest to highest (rank 1), Zipf's Law is interpreted as stating that rank times population size across cities in the hierarchy is a constant. Gabaix (1999) argues that if there is a stochastic process whereby individual city growth rates follow Gibrat's Law – the growth rate in any period is unrelated to initial size – then the size distribution that emerges will follow Zipf's Law. One focus of theoretical work has been to try to model why something like Zipf's Law would emerge as cities evolve in an economy. Essential to the modelling is to have shocks to productivity or preferences that follow a random walk; but, to get the result in a model where there is an endogenous number of cities, as opposed to just fixing the number of cities, is difficult and requires very specific assumptions. Rossi-Hansberg and Wright (2004) adapt the Black and Henderson (1999) model, with many types of specialized cities. They group industries and specialized city types into sets. Within each set, industries and city types have the *same* technology, but each individual industry draws its own permanent shock each instant. To have Gibrat's Law lead to Zipf's Law, along with Gabaix (1999) they must impose an arbitrary lower bound on the sizes to which cities can fall. These assumptions lead to Zipf's Law holding for each set of industries, and they show that one can aggregate across sets of industries to get Zipf's Law.
Duranton (2005) tries to model micro-foundations for the stochastic process affecting city sizes and as a result ends up modelling an important, overlooked aspect of city evolution. Duranton has many footloose, mobile products in a quality-ladder model and a limited fixed number of cities. The latest innovation in each product is produced by the monopolist holding the patent, and only this top quality is marketed for any product. Investment raises the probability of a firm making a successful innovation and being the patented next step up in the quality ladder in an industry. But innovation can also lead to the next step up in a different industry – that is, there can be cross-industry innovation. To partake of a winning innovation in a different industry, a footloose industry must locate in the city where the innovator is, so industries move around with cross-industry innovation. Presumably co-location of the inventor and production makes the information needed for the transition to mass production cheaper to exchange. Innovation probabilities depend on R&D expenditures. Industry jumps from city to city according to where the latest innovation is, and city growth also follows a stochastic process. The resulting stochastic process of city growth and decline results in steady-state size distributions that are similar to Zipf's Law. Duranton's formulation has the nice feature that cities have patterns of production specialization which change over time, consistent with the data. Moreover, in this context cities that emerge as big are likely to stay big indefinitely, since they hold so many industries in which an innovation might be realized.

Geography

A variety of studies have examined the role of geography, primarily natural features, in the spatial configuration of production and growth of cities. As noted earlier, in terms of formal modelling of geography we have made little formal progress, given the complexity of the problem (Fujita, Krugman and Mori, 1999). Empirically, Beeson, DeJong and Troeskan (2001) look at US counties from 1840 to 1990. They show that iron deposits, other mineral deposits, river location, ocean location, river confluence, heating degree days, cooling degree days, mountain location, and precipitation all affect the base 1840 county population significantly. However, for 1840–1990 growth in county population, only ocean location, mountain location, precipitation, and river confluence matter, with the 1840 population controlled for. That is, first-nature items strongly affected 1840 and hence indirectly 1990 populations; but growth from 1840 to 1990 is independent of many first-nature influences. Other studies focus on the geography of markets and the role of neighbours in influencing city evolution. Dobkins and Ioannides (2001) show that growth of neighbouring cities influences own-city growth, and cities with neighbours are generally larger than isolated cities. Black and Henderson (2003) show that normalized market potential variables encourage growth, if geography is controlled for. High market potential helps explain why north-east US cities maintain reasonable growth, given that for historical reasons they are in the most densely populated area, despite the hypothesized natural advantages of the West.

The Tableau économique is an important landmark in the history of economics and the earliest attempt to provide a calculable model that can help government in policy making. François Quesnay, who invented the Tableau in 1758, provided several versions of it, both in equilibrium and in disequilibrium, to account for the many cases and policies he discussed in his economic writings.

Article

The Tableau économique is generally considered the first economic model in its own right ever conceived. François Quesnay wrote the first version (or ‘edition’) in December 1758 and sent it to his most prominent disciple, the marquis de Mirabeau, a few days later. Fortunately, the letter and a manuscript copy of this first version have survived (INED, 2005, pp. 391–403). Over the next ten years, Quesnay produced numerous versions of his Tableau économique. Some of these (the second and third versions) he printed privately in Versailles. The others were published in books he co-wrote with Mirabeau, in articles he published in physiocratic periodicals and in Physiocratie, a collection of his own essays edited and published in 1767 by Pierre Samuel Du Pont de Nemours, one of his young disciples. There are also several manuscript versions in Quesnay’s own hand in Mirabeau’s papers at the French National Archives (INED, 2005). However, Quesnay's deep interest in this visual device did not appeal to his contemporaries (Van den Berg, 2002). Even his disciples, who like Mirabeau (1775, pp. 203–4) praised him, calling him a new ‘Socrates’ and the ‘Confucius of Europe’, felt uneasy with the Tableau, and, after Quesnay died in 1774, the Tableau was ignored in the history of economics until Karl Marx
rediscovered it in 1862 (Gherke and Kurz, 1995). It was only with the transformation of economics into a mathematical and diagrammatic science that the Tableau éconómique gained a more important place in economics. At the same time, the Tableau has become an object of controversy for both economists and historians. Of the several problems that have been raised, here we have selected the most significant ones. What is the Tableau éconómique? What are its origins? What was its purpose for Quesnay? And how to interpret it? We will conclude this article by assessing the place of Quesnay's Tableau éconómique in the history of economics.

Our understanding of the nature of the Tableau éconómique and its place in Quesnay's economics has deepened since the rediscovery of the ‘third version (or edition)’ of the Tableau by Marguerite Kuczynski in 1965 and the publication in 2005 of several manuscript versions of the Tableau from Quesnay's own hand (Kuczynski and Meek, 1972; INED, 2005). It is now clear that the Tableau éconómique per se is only the figure and as such ‘just a small part of Quesnay's model’ (Pressman, 1994, p. 5). Hence, the ‘first edition’ consists of three parts: the Tableau itself, Quesnay's marginal commentary explaining its working, and the 22 ‘remarks on the variations in the distribution of the annual revenue of a nation’, an expansion of the 14 maxims from the article ‘Grains’ published in 1757 and which can be best described as a list mixing hypotheses and policy recommendations (see INED, 2005, pp. 198–212). The second and third versions of the Tableau, compiled in 1759, are based on the same structure, despite formal changes. The ‘Remarks’ (23 in the second and 24 in the third version) are presented as an ‘extract of the royal economic memoirs of M. de Sully’. The commentary, still in the margins in the second version, is transformed into an ‘Explanation of the Tableau éconómique’ in the third version. In the version of the Tableau found in the ‘Analyse de la formule arithmétique du Tableau éconómique’ published in Physiocratie (1767), only the Tableau and its explanation (now called ‘analysis’) remained in the same text; the maxims are now expanded to 30, with more numerous and longer notes, and presented in an independent text, ‘General maxims for the economic government of an agricultural kingdom’.

The origins of the Tableau have been seen as a problem since the end of the 19th century, when it was first remarked that there was a likeness between the zigzag diagram of the first three versions and the process of blood circulation. This hypothesis was developed by Foley (1974) and further refined by Christensen (1994). However, other scholars have criticized this theory and pointed out there was no direct evidence in Quesnay's writings to support it (Rieter, 1983; Eltis, 1984, pp. 20–1). Since 1990, several studies have established that the Tableau can be seen as a sort of technological device designed to calculate economic quantities as well as display economic laws. Its features derived from different areas of knowledge, covering, for example, art works, machines and early modern arithmetic, which Quesnay brought together to produce a unique concept (Charles, 2000; 2003; 2004; Rieter, 1990; Wise 1990). Quesnay invented the Tableau éconómique as a visual calculating machine or, as he and Mirabeau put it in the introduction to Philosophie rurale, an ‘arithmetic rule’ and a ‘formula of calculation’ (Mirabeau and Quesnay, 1763, pp. xix, xxiii).

This leads us to the more general problem of the economic interpretation of the Tableau, which has captivated economists since Karl Marx. There have been several articles and books providing interpretations, but no general consensus has emerged and important theoretical aspects of the Tableau have been controversial ever since Marx's rediscovery of the Tableau. One issue that had been discussed at length by commentators is whether the different versions, in particular the zigzag and the late version
from ‘Analyse de la formule arithmétique’, are consistent. The most prominent scholar of physiocracy, R.L. Meek (1962), thought they were, as did several commentators writing under his influence (Barna, 1975; Eagly, 1969; Pressman, 1994). Indeed, the various versions of the *Tableau économique* are based on a single microeconomic unit: a farm made of one plough, four horses and 120 acres of land which is considered as the best technique of production available to agricultural entrepreneurs (Eltis, 1984, pp. 3–13; Herlitz, 1996, p. 17; Cartelier, 1998, p. 249). There are also features common to all versions of the *Tableau*. First, all the *Tableaux* are divided into three columns representing the three classes of citizen relevant to Quesnay's economic representation of society: the productive class (the *classe productive* composed of farmers and professions linked to the primary sector and the marketing of its products), the landowning class (the *classe des propriétaires* which includes landowners, the state and the clergy) and the unproductive class (the *classe stérile*, corresponding roughly to those working in commerce and industry). Second, the *Tableaux* feature a general interdependence between the three classes in the form of rows linking them: these rows signal the mutual expenditures between the classes that take place in the economic system.

However, the two main versions of the *Tableaux* presented significant differences. First, the *Tableau* in zigzag is an open system that functions as a ‘table of expenditure and reproduced produce’, and includes a propagation effect that resembles the Keynesian multiplier and accelerator effect (Herlitz, 1996, p. 13; Hishiyama, 1960, pp. 124–6; Meek, 1962, p. 293). Conversely, the mature version of the *Tableau économique* was designed to provide ‘a consistent account of social reproduction’ as a whole and leave out many details of the process of expenditure and reproduction to concentrate on the general results (Barna, 1975; Herlitz, 1996). These two main versions of the *Tableau* are also based on different economic models (Cartelier, 1982; Herlitz, 1961; 1996). In the zigzag version, emphasis is put on the process of expenditure: it is the spending of the landowning class that comes first in the graphical representation, and is seen to initiate the circulation of wealth in the economy (see the two diagrams in Quesnay, François). In Quesnay's economic model, the prominence of the landowning class is made clear by the fact that the equilibrium of the whole system depended on their expenditure. When landowners spend one-half of their revenue on agricultural products and the other on industrial goods, the *Tableau* (and the model) is in equilibrium and simply reproduces itself without changes. When landowners spend more on industrial goods – indulging in ‘luxe de décoraison’ (excess consumption of luxury goods) – equilibrium is disrupted and the *Tableau* as well as the economy are in decline.

Conversely, when they spend more on agricultural products – indulging in ‘faste de subsistence’ (increased consumption of subsistence goods) – the economy grows and produces a larger economic surplus.

In the latest version of the *Tableau*, emphasis has switched to the expenditure of the productive class in annual advances (invested in production) and in rent payments to the landowners. In this version, the prominent role goes to the farmers and their advances (which do not figure in the zigzag version), which initiate the process of reproduction of wealth. Conversely, the landowners’ expenditure now appears contingent and the landowning class unnecessary for the functioning of the system: the fact that it is the landowners who seize the disposable surplus in the form of rent is arbitrary and linked to the historical context of the society depicted by Quesnay (Ancien Régime France), but has no economic justification (see Cartelier, 1982). The coexistence of two alternative versions of the *Tableau* corresponded to two policy issues underlined by Quesnay in his economic maxims: (a) the necessity of productive advances
and (b) both the moral and the economic imperative of virtuous spending on the part of the landowning class (no excess luxury consumption). At the same time, it signals problems that Quesnay was unable to resolve satisfactorily. As several commentators have noted, in the latest version of the Tableau the landowners’ consumption has no bearing on the economic equilibrium, hence there is no need for the hypothesis that landowners spend half their money on agricultural products and the other half on industrial goods; it is enough that they spend all their revenue and do not hoard (Barna, 1975; Bilingsoy, 1994; Cartelier, 1982; Negishi, 1989).

The place of the Tableau économique in the history of economics has increased in importance dramatically from the 1940s onwards. It has been interpreted either as a forerunner of neoclassical general equilibrium (Samuelson, 1982; Schumpeter, 1954), as a Leontief input–output system and more generally a linear system (see Phillips, 1955; Maitel 1972; Barna, 1975; Bilingsoy 1994), while Marxist authors have interpreted the Tableau as a rationalization of Ancien Régime society (Fox-Genovese, 1976; Gleicher, 1982). The first interpretation, notwithstanding the authority of Schumpeter (and Samuelson!) holds only at the more general level since there is no trace of marginal analysis in Quesnay's economic model. There is much more ground to link the Tableau économique to input–output analysis (for a different opinion, see Pressman, 1994, ch. 5). Indeed, Leontief himself has suggested, if rather cryptically, that Quesnay's work had been an important landmark in the development of his own ideas (Leontief, 1936, p. 105). Moreover, like Leontief, Quesnay was interested in providing both a theoretical and an empirical model of the economy at the same time (Barna, 1975; Meek, 1962, p. 296).

According to the Marxist interpretation, the Tableau économique exemplified the contradiction of Quesnay’s social thought, and more generally of Ancien Régime France, caught between the feudal order, characterized by the prominence of landlords, and the burgeoning capitalist economy, characterized by the role played by the capital investments of farmers. Since the fall of the Berlin Wall in 1989 this interpretation has been on the wane among economists and historians alike.

More recently, the attention of economists interested in Quesnay's economics has turned towards several disequilibrium and underemployment-of-resources equilibrium Tableaux (Barna, 1976; Charles, 2000; Eltis 1984, ch. 2; 1996; Pressman, 1994, chs 4, 6 and 7). These are particularly noteworthy since they are concerned with the possibility of growth or decline and are linked to specific policy issues. There is no place here to detail these different figures (more than 50 in total!), but it may be useful to list the different economic cases investigated which give rise to these Tableaux. First, Quesnay used the Tableau to study the effects of hoarding and of excessive consumption of luxury goods by the landowning class. Second, Quesnay investigated the consequences of an unjust tax system with the case of a tax on the productive sector (in Quesnay's theory tax should be levied on the landowning class) and the case of the Ancien Régime's (costly) taxation system (the fermes générales). Third, Quesnay discussed the joint cases of low agricultural prices due to impediments in external trade and of the economic effects of the establishment of free export in agricultural products (and the rise in prices it causes). Finally, other Tableaux are used to show the consequences of policies encouraging the unproductive industrial sector at the expense of the productive agricultural sector.

All in all, Quesnay's Tableau économique is now considered by most economists as an important landmark in the history of economics and the earliest attempt to provide a calculable model that can be used by governments for policymaking.

taking (eminent domain)

Perry Shapiro
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Compensation for a public taking of private property (typically land) can affect both government's and landowners’ decisions, and compensation rules affect both real and perceived fairness. Arguably, no compensation is efficient; landowners will account for probable loss when making their investment decisions, since such decisions are determined by events outside the discretion of either the landowners or the government (though if the taking decision is made to benefit government or landowners, zero compensation may be inefficient). But zero compensation is unconstitutional (in the United States and Australia) and inequitable. A trade-off between efficiency and equity is therefore normally unavoidable.

Article

The Fifth Amendment of the US Constitution ends with ‘nor shall private property be taken for public use without just compensation’. Similarly, the Australian Constitution, in section 51(xxxi), allows ‘[t]he acquisition of property on just terms …’. Both constitutions give government the power to condemn property for a public purpose and both specify the requirement for compensation. However, they leave unanswered the formula for computing ‘just compensation’. Some dispute that government should be permitted to force the sale of private property through condemnation, but it is widely held that many functions of government, particularly those that require the assemblage of contiguous plots of land, would be impractically complicated without the power of eminent domain. For most, the question is not whether the government should have the right to compulsory acquisition but, rather, what compensation should be paid to the private landowners.

There are two distinct issues when considering compensation for a public taking of private property. The first is that compensation rules can affect the decisions of both government and landowners. The rate at
which landowners must be paid for their condemned property may affect the public's choice of how much land to condemn. In addition, the knowledge of potential compensation can influence landowners' choice of property improvements. If compensation is based on the market value of land, landowners will over-improve their property because they do not consider the possibility of a taking (moral hazard) (Blume, Rubinfeld and Shapiro, 1984); and if improvements increase compensation landowners are inclined to over-invest in their property to favorably affect their settlement with the government (rent seeking) (Fischel, 1995 p. 296).

The second issue is that compensation rules affect both real and perceived fairness, and it is likely that equity is what just compensation is about. In the US Supreme Court 1960 decision on Armstrong v. United States, the majority opinion was that ‘[t]he Fifth Amendment guarantee … [is] designed to bar Government from forcing some people alone to bear public burdens which, all fairness and justice, should be borne by the public as a whole.’ A large group of people, those whose property is not condemned, benefit at the expense of a much smaller minority who must surrender their property. Even when compensation is equal to the pre-taking market value of property, as is most commonly the case, the owners of condemned property lose relative to those escaping condemnation.

Blume, Rubinfeld and Shapiro (1984) use an example of land in a river valley to illustrate potential moral hazard loss. With known probability, $p$, the price of oil will rise to a price sufficiently high that it is in the public interest to dam the river and flood the valley. The structures invested on the land are all lost under the reservoir waters. With known loss probability, $p$, the efficient level of investment on the land equates the expected marginal product (the product of $p$ and the marginal product of capital) with $r$, the market return on capital. If the landowners are fully compensated for both their lost land and immovable capital, the probability of dam-caused flooding will not affect the level of investment on the land. Their investment choice will equate the marginal product of invested capital with the market rate of return (MP=$r$). The result is that an inefficient amount of capital will be invested in the river valley. The conclusion is that no compensation is efficient because landowners will correctly account for probable loss when making their investment decision.

The recommendation for no compensation is based on the presumption that, while uncertain, the decisions whether or not to condemn land and, if so, how much land are determined by events outside the discretion of either the landowners or the government. However, if the taking decision is made to benefit either the government or the landowners, zero compensation induces inefficient decisions (Fischel and Shapiro, 1988; 1989). For instance, if the government represents the interest of a subset of its citizens (for example, the majority) and does not act to maximize social welfare, the need to make compensatory payments to the owners of condemned land will put a beneficial constraint on the government's propensity to condemn an inefficiently large amount of land. However, even if the government is venal and self-serving, it is never efficient to compensate landowners for 100 per cent of lost value. For the sake of social efficiency the landowners, even in the face of bureaucratic venality, must account for the probability of a taking, even if the amount is inefficiently chosen.

Efficiency is only part of the public policy story. While it might be efficient for government to take land without compensation, it nonetheless offends our notion of what is fair. It is unlikely that any policy as draconian as the one suggested would be adopted for the physical acquisition of private property. (Public regulations that restrict the use of private property commonly are not thought to require compensation.) Uncompensated condemnation is not consistent with a constitution that spells out both the powers and the limits of government, as does the US Constitution. Uncompensated condemnation appears as a
bullying big government strong-arming a small minority of landowners. Frank Michelman (1967) proposes a compensation calculus incorporating fairness. Michelman includes an explicit and quantifiable measure he labels ‘demoralization cost’. Demoralization is the personal (psychological) reaction to a government leviathan that runs roughshod over a landowning minority. It is manifest in two different ways: the outpouring of sympathy for the downtrodden, and a concern that the same can happen to you. Citizens empathize with the taken and, simultaneously, worry about the sanctity of their own property rights.

Whether or not Michelman's calculus is used, it is important for real public policy to balance the potential inefficiencies resulting from compensation with the inequities without it. While in most cases it is impossible to achieve efficiency without sacrificing some degree of fairness, or to achieve a fair outcome without sacrificing efficiency, there are special cases for which this is not true. If somehow the interests of the private landowners and the government can be aligned with social welfare, the investment and taking choice can be equitable as well as efficient.

In his discussion of disproportionate impact, Richard Epstein (1985) argues that, if prospective compensation does not affect investment choices, the interests of the landowners and government are the same if takings require full compensation. The case against full compensation is that it induces inefficient investment choices. Without the resource-use concerns, land prices serve to direct government to make only welfare-increasing decisions about condemnation.

For certain types of public projects – those for which changes in land values reflect all the benefits – compensation equal to the post-taking enhanced land value has favorable efficiency and equity consequences. It is equitable because those who lose their property are rewarded equally to those who are lucky enough to escape condemnation. It is efficient because the possibility of condemnation is independent of individual property improvement.

If the benefits of the public taking are specific with measurable market values, it is possible to devise a compensation scheme that achieves both equity and efficiency. However, the dual goals are unattainable when project benefits are diffuse and immeasurable. With these more common cases, it is necessary to consider the trade-off between equity and efficiency. The Michelman calculus is useful in expressing this trade-off if the underlying quantities (discouragement costs) are truly measurable.

Tarbell, Ida Minerva (1857–1944)

Alice H. Amsden

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Fordism; industrial relations; marginalism; scientific management; Tarbell, I. M.; Taylorism

Article

In a profession where women have been denied the liberties of expression otherwise permitted to men of lesser quality, Ida M. Tarbell made her mark as an economic journalist. She had a keen sense of ethical issues, but regrettably, her blend of reformism and conservatism was sometimes bewildering.

Born in 1857 in Erie County, Pennsylvania, Tarbell is best known for her History of the Standard Oil Company (1904), a two-volume attack on the ruthlessness of the oil monopolies (her father was ruined by them). As a muckraker, Tarbell could be expected to favour state intervention in wage setting, then a hotly debated issue. But ironically, whereas the progenitor of marginal productivity theory, J.B. Clark, edged towards arbitration to reduce labour strife, Tarbell embraced Taylorism, whose logic of work atomization builds on the marginalist principle. From 1912 to 1915 Tarbell toured factories she handpicked to study industrial conditions. Favourably struck with Fordism, she wrote a contemporary equivalent of the ‘excellently managed corporation’ entitled New Ideals in Business (1916). The ideals were scientific management, humanistic labour relations and a belief in the fundamental goodness of entrepreneurs.

In her feminist outpourings, Tarbell is better remembered for the way she lived than by what she wrote. Unusual for a woman at the time, Tarbell moved to Paris after college to study women in the French Revolution, as praised by Woodrow Wilson for her ‘common sense’ views on the tariff (which she opposed), attended the Paris Peace Conference, corresponded with notables, including Richard T. Ely, interviewed Mussolini, and shunned marriage for a career. The same Tarbell, however, fought against women's suffrage and in The Business of Being a Woman (1912) advised members of her sex to stay at home.

Abstract

Bhagwati (1965) first demonstrated that if perfect competition prevails in all markets, a tariff and import quota are equivalent in the sense that an explicit tariff reproduces an import level that, if set alternatively as a quota, produces an implicit tariff equal to the explicit tariff, and vice versa. This equivalence breaks down, for example, if the domestic production is monopolized. In this case, replacing an explicit tariff by an import quota set at the level equal to the imports under the explicit leads to a higher implicit tariff. Many other cases of the breakdown of the equivalence also arise.

Keywords

directly unproductive profit-seeking; tariff versus quota; tariffs; uncertainty; voluntary export restraints

Article

The ‘tariffs versus quota’ literature was stimulated by the seminal contribution by Bhagwati (1965). Bhagwati defined the two instruments as equivalent if an explicit tariff reproduces an import level that, if set alternatively as a quota, produces an implicit tariff equal to the explicit tariff and vice versa.

Equivalence and its breakdown

Bhagwati (1965) demonstrated that the tariff–quota equivalence necessarily obtains when perfect competition prevails in all markets. This is shown most simply in the small-country context. By definition, the small country faces a perfectly elastic supply at a given price in the world market. In Figure 1, DD and SS represent the demand and supply curves in this (small) country and $P^*$ fixed world prices. Under free trade, that country produces $Q_0$, consumes $C_0$ and imports $Q_0C_0$. The imposition of an explicit tariff $t$ per unit raises the internal price in the country to $P = P^* + t$ and the output and consumption move to $Q_1$ and $C_1$, respectively. Imports decline to $Q_1C_1$. The consumer surplus declines by the trapezium formed by the sum of the areas marked $b$, $e$, $R$ and $f$. Of this, area $b$ is recovered by producers as extra surplus and area $R$ by the government as tariff revenue. Areas $e$ and $f$ are lost entirely and called deadweight losses. Area $e$ is lost because the marginal cost of production of $Q_0Q_1$ exceeds the world price. Area $f$ is lost because the tariff forces the consumers to stop before the marginal benefit at $P$ exceeds the marginal social cost of obtaining the goods at $P^*$.

Figure 1

Equivalence under perfect competition and non-equivalence under monopoly
If we now replace the tariff by the import quota \( Q_1C_1 \) and auction the quota licences competitively, imports would equal the quota. Subtracting these imports from \( DD \) at each price, we obtain \( D'D' \) as the demand facing domestic producers. The internal price now obtains at the intersection of \( SS \) and \( D'D' \). But by construction, this is \( P=P^*+t \), with \( t \) now representing the implicit tariff. Explicitly, \( t \) is now the price of the licence per unit of imports. The total revenue from the auction of the licences equals \( R \). The outcome is identical to that under a tariff in every way.

Suppose now that a monopoly producer supplies the domestic output with \( SS \) representing his marginal cost curve. Under the tariff \( t \), the monopolist cannot raise the price above \( P^*+t \) so that the outcome is no different from under perfect competition. But if we replace the tariff by import quota \( Q_1C_1 \), with the quota licences auctioned competitively, the monopolist faces the demand curve \( D'D' \). Associated with \( D'D' \) is a marginal revenue curve (which, for the sake of simplicity, is not shown in Figure 1) whose intersection with \( SS \) gives the monopoly output \( Q_M \). The price the monopolist changes at this quantity is \( P_M \), which is higher than \( P^*+t \). The equivalence breaks down. Non-equivalence also obtains if we replace domestic competitive suppliers by an oligopoly rather than a monopoly (Helpman and Krugman, 1992). All these results can be generalized to the large-country case.

Alternatively, non-equivalence obtains if we assume perfect competition in demand and supply but not the allocation of quota. For example, if the holder of the quota licence is a monopolist, he would maximize the quota rents. The solution in this case may involve leaving some licences, thereby raising the domestic price above \( P^*+t \). Retaining perfect competition in all markets, non-equivalence also arises if the quota takes the form of a voluntary export restraint (VER). Under the VER, enforcement of the quota is the responsibility of the exporting country. In this case, the exporting country captures the quota rent, and the welfare loss from the quota to the importing country is larger than under the tariff or direct import quota.

A further case of non-equivalence arises in the presence of uncertainty. This is shown in a simple manner using a construction from Pelcovits (1976). In Figure 2, suppose the import demand by home country is \( MM \) and the world price can be either \( P^*+e \) or \( P^*-e \), each with a probability of one half. Suppose further that we want to restrict expected imports to \( OQ_0 \). Regardless of which world price is realized, an import quota will hit the target exactly with the domestic price given by the height of \( MM \) at \( Q_0 \) and denoted \( P^*+t \). If a tariff is to be used to achieve the same objective, assuming risk-neutral behaviour, we would set the tariff at \( t \). The domestic price in this case could be either \( P^*+t+e \) or \( P^*+t-e \), each with a probability of one half. The reader can verify that the expected welfare losses under the quota and tariff would be different, which implies non-equivalence.

Figure 2
Non-equivalence under uncertainty
Panagariya (1980) considers the equivalence of optimal tariff and quota *structures* in a small-country model with two or more imports. He considers a government wishing to restrict the value (at the world prices) of two or more imports to a pre-specified level. If perfect competition prevails in all markets, the optimal policy is either an explicit uniform tariff on the restricted set of goods or import quotas on them at levels that imply a uniform implicit tariff at the same rate. If domestic production of these goods is monopolized, however, optimal tariffs are still uniform, but optimal import quotas are characterized by implicit tariffs that are generally non-uniform.

In two companion papers, Panagariya (1981; 1982) brings out yet another aspect of tariff–quota non-equivalence in the presence of domestic monopoly. He considers a large-country, general-equilibrium model in which domestic industry is monopolized. He shows that in such a model, exogenous changes in quotas and tariffs lead to qualitatively different outcomes. For example, if quota is the instrument, tightening it always improves the terms of trade. But if tariff is the instrument, raising it may lead to deterioration in the terms of trade.

Finally, Rodriguez (1974) and Tower (1975) have independently considered the outcomes when two countries optimally choose trade interventions in a Nash non-cooperative game within a two-good general-equilibrium model. They show that if the countries choose tariff as the instrument, an equilibrium characterized by finite positive trade between them generally exists. But if the countries employ quotas, such equilibrium does not exist.

**Welfare ranking of tariffs and quotas**

When tariffs and quotas are not equivalent and we use them to target some variable in the economy, a natural question concerns the welfare ranking of the two instruments. For example, if we assume that the domestic production is monopolized but perfect competition prevails everywhere else and the objective is to restrict imports to a specified level at the lowest cost, tariff is superior to quota. This is readily seen in the small-country case in which the tariff forces the monopolist to behave like a competitor whereas the quota allows him to earn positive monopoly rents. Similarly, on the assumption that there is perfect competition on all sides in the product market, if the quota holder is a monopolist, tariff would once
Two additional ranking results are due to Panagariya (1980) and Pelcovits (1976). The former considers the ranking of tariffs and quotas when a small country aims to restrict the value of a subset of imports (at world prices) to a fixed level and these goods are subject to the monopoly distortion. He finds tariffs to be an instrument superior to quotas. Pelcovits considers the welfare ranking in the presence of uncertainty. In the small-country context, on the assumption that the world price is stochastic and the country wishes to constrain the expected imports at a pre-specified level, he asks whether quotas yield higher expected welfare or tariffs. Using a construction similar to that in Figure 2, he shows that the answer is ambiguous.

**Welfare outcomes with pre-existing tariffs and quotas**

A final question of interest is how the welfare outcomes differ when a parameter is altered in the presence of tariffs versus quotas. The first set of contributions in this category comes from the so-called piecemeal trade reforms literature that asks how welfare changes as we relax one trade barrier at a time. Corden and Falvey (1985) demonstrate that in a small country with many imports, if the country restricts trade by quotas only, the relaxation of any quota necessarily improves welfare. Intuitively, the relaxation of the quota reduces the distortion in that good but has no effect on the distortion in the other goods since their imports face the same quota as before. Therefore, the net effect of the change on welfare is positive. This is not true if imports are restricted by tariffs. A reduction in any one tariff directly improves welfare by expanding the imports of that good. But it may indirectly lower welfare by reducing the imports of substitute goods subject to tariff distortions. If the latter effect dominates, the net effect is a reduction in welfare.

Building on the work of Johnson (1967) and Kemp and Negishi (1970), Eaton and Panagariya (1979; 1982) derive conditions under the presence of tariffs on a subset of imports that can lead to an improvement in the terms of trade or growth in a small open economy to result in a loss of welfare. It is readily shown, however, that if import quotas restrict imports instead, improvement in the terms of trade or growth cannot lead to a decline in welfare. Just as in Corden and Falvey, when quotas are in place, their distortionary effect remains unchanged when the terms of trade improve or growth takes place. Therefore, the direct benefits from improved terms of trade or growth determine the final outcome. In the presence of tariffs, tariff distortion worsens if the improvement in the terms of trade or growth is accompanied by a contraction of imports of one or more tariff-ridden goods.

Finally, Bhagwati and Srinivasan (1982) alternatively consider the effect of directly unproductive profit-seeking (DUP) activities in the presence of tariffs and quotas. They show that in the former case the DUP activity may paradoxically raise welfare if it draws resources out of the import-competing good and therefore leads to an expansion of imports of the tariff-ridden good. This cannot happen in the latter case, however, since the imports of the quota-ridden good cannot rise beyond the fixed import quota.

Tariffs are taxes levied on foreign trade: on the importation and, less often, the exportation of goods as they cross the border of a country or other geographical area. Since they are easy to enforce and collect and seem to be (and partly are) paid by foreigners, tariffs have been an important and popular source of government revenue from the earliest times. In early days, the ostensible purpose of tariffs was to pay the government levying them for the protection it afforded to foreign traders on its territory. In modern times, arguments for and against tariffs as well as the determination of their level focus on their impact or supposed impact on the economy. Tariffs nowadays are paid in money and specified either as so much money per unit of merchandise (specific tariffs) or as a given percentage of its value (ad valorem tariffs). With demand a diminishing function of price, tariffs reduce the quantity of dutiable goods imported or exported; and, with the price elasticity of demand also a diminishing function of price, Government's revenue from the tariff (i.e. the
product of its level and the quantity on which it is levied) first increases then diminishes as the tariff rate is raised. Accordingly, there is a rate of tariff that maximizes tariff revenue; but the proper criterion for judging the desirability of tariffs and determining their level is not the amount of revenue they yield but their impact on the whole economy, which is usually discussed under two headings: the protection they provide to domestic producers and their effect on the terms of trade.

**Protective tariffs**

Tariffs on imports raise their domestic prices, thereby shifting demand from imports to their domestic substitutes and increasing the profitability of the latter's production. Import duties also lower the purchasing power of income over imports and import substitutes (collectively known as importables) but add to the money incomes of producers of imports substitutes, their employees and suppliers. Accordingly, the tariff-imposing country's real national income may be raised or lowered, depending on whether the sum of the Government's tariff revenue and the additional incomes generated exceeds or falls short of the loss of purchasing power over importables. That, however, is still only a small part of a full cost-benefit calculation, which must also take into account other costs and benefits of the tariff.

By far the most important among the costs is the danger of retaliation by the foreign countries whose export industries are hurt, or believed to be hurt by the first country's import duties. That cost is especially great when the trade restrictions other countries impose in retaliation to the first country's tariff lead, in their turn, to further retaliations, and so to a general overall reduction in the volume of trade and its gains.

For the impact of import duties is to discourage the imports on which they are levied. It is true that they also stimulate domestic activity and domestic income generation, which, in the long run, may well counteract their restrictive effect on imports, at least to the extent of more or less offsetting the reduction in overall imports. But the combined influence of the restrictive short- and expansionary long-run effects of tariffs would have to keep unchanged not only the overall value of total imports but also their structure by country of origin in order to eliminate the economic justification and pressure for retaliation; whereas even the commodity composition of imports would have to remain unchanged in order to eliminate the political pressure for retaliation as well. Needless to say, those conditions necessary to obviate retaliation are not likely to be fulfilled.

The benefits of import duties include increased employment, an improved balance of trade, the enhanced stability of a more diversified economy, the political and economic advantages of greater self-sufficiency, and the increased efficiency of protected industries when their comparative disadvantages are remediable and can be remedied through learning by doing. Some of those advantages, however, are mutually exclusive. Tariffs, for example, that greatly stimulate the domestic economy are unlikely to improve the balance of trade – a fact that was strikingly brought home to many of the developing countries that engaged in import-substitution policies.

Of the benefits listed, by far the most important is the last-mentioned, which is a permanent benefit secured by temporary tariff protection. It has also received the most attention in the professional literature under the name of the infant industry argument. Trade restriction to nurture budding industries was well known and much practised already during the mercantilist period; but after the advent of economic liberalism, the argument in its favour needed to be reasserted. Its best known and most influential statements in modern times are those of Alexander Hamilton and Friedrich List. Hamilton's.
celebrated ‘Report on Manufactures’ to the US Congress (1791) had a great influence on American tariff policy, and its prediction of the hoped-for consequences of protection turned out to be a remarkably accurate forecast of the country’s subsequent economic development. List’s similar argument half a century later (List, 1841) had even more influence on both US and German foreign-trade policy. The US and German protective tariffs of the 19th century, however, which seem to have been so successful in promoting those countries’ economic development, were very much more moderate than the mid-20th-century import barriers behind which India, Pakistan and the Latin-American and other developing countries pursued their not very successful import-substitution policies (Little et al., 1970). That raises the question of what level and structure of protective tariffs are the most conducive to a country’s economic development. We cannot answer here that much-debated and highly controversial question; but something must be said about effective tariffs, a statistical tool designed to help the search for an answer.

**Effective tariffs**

The height of a tariff levied on imports of a good (also known as the nominal tariff) is not a good measure of the degree of encouragement of its domestic manufacture. For one thing, a manufacturer almost never creates a whole good, only a greater or lesser contribution to it, which is called his value added or effective price; and a given percentage tariff on imports, which enables domestic manufacturers of its substitutes to raise their prices by a like amount, makes a greater, often very much greater *percentage* addition to their value added, in a proportion that is the inverse of the ratio in which their value added stands to price. For example, if the value added in cloth manufacture is 40 per cent of price, then a 20 per cent nominal tariff on imported cloth enables domestic cloth manufacturers to increase their value added by 50 per cent.

For another thing, tariffs are often levied on final, intermediate and primary goods alike; and an import duty on a primary or intermediate good, while encouraging its domestic production, also discourages the domestic manufacture of all those other goods that use it as an input. An import duty on yarn, for example, discourages domestic cloth manufacture by reducing the value added cloth manufacturers can earn.

The concept of effective tariff (ET) is designed to measure the degree of encouragement provided to given productive activities by the combined effect of the nominal tariffs imposed on their outputs and inputs. A simple formula for the effective tariff protection on the manufacture of good $j$ is:

$$ET_j = \frac{t_j}{1 - \sum a_{ij}} - \frac{\sum a_{ij} t_j}{1 - \sum a_{ij}},$$

where $t_j$ is the nominal ad valorem tariff on good $j$, $t_i$ are the nominal tariffs on its several inputs, and the $a_{ij}$ show the share of the cost of input $i$ in the price of good $j$ at free trade prices. Note that the two terms show the contributions of the two factors discussed in the text, note also that the denominator represents
The terms-of-trade effect of tariffs

In contrast to all the attention economists, politicians and the general public have paid to the protection that tariffs provide to domestic industry, the tendency of tariffs to improve the terms on which a country trades its exports for imports, and thereby to increase its share in the gains from international specialization, have been very much neglected. The subject attracted some attention at the end of the last and the beginning of this century, but mainly as a theoretician's intellectual exercise and an economic curiosum.

While protection results from import duties' raising the domestic price that domestic buyers have to pay for importables, they improve the terms on which the duty-imposing country trades its exports for imports, provided that they lower the foreign price that the foreign producers of it receive for them. Similarly, an export duty will also improve a country's terms of trade if it raises the foreign price that foreign buyers of its exports have to pay for them. Accordingly, tariffs improve a country's terms of trade if the foreign supply of its imports or the foreign demand for its exports is less than perfectly elastic; and a given tariff has the greater impact on the terms of trade, the lower are those elasticities (Bickerdike, 1906; Kaldor, 1940).

The advantage of a tariff that improves the terms of trade can be given two interpretations. First, when a tariff changes the foreign price of imports and/or exports to the foreigners' disadvantage, it causes them to pay part of the tariff – a clear and obvious gain for the tariff-imposing country. Secondly, the same gain can also be looked upon as a monopoly or monopsony profit extracted from foreigners by the tariff, which in turn closely resembles the profit margin a monopolist adds on to marginal cost, or a monopsonist subtracts from marginal worth, when he sets his profit-maximizing price. Indeed, when perfect competition among a country's export producers causes them to equate prices to marginal costs and causes its importers to equate the marginal value product of imports to their prices, then export and import duties coincide exactly with a monopolist's and monopsonist's profit margins.

Such a situation resembles a cartel agreement among domestic competitors with respect to their foreign transactions, except that the monopoly or monopsony profits generated accrue to the State in the form of tariff revenue and that the private producers and traders are made worse off than they would be under free trade, because the tariff reduces the volume of their business. From the point of view of the country's national welfare, however, tariffs can be beneficial, in the sense of increasing the sum of the country's private and public real income, just as monopolistic or monopsonistic pricing can increase the monopolist's or monopsonist's profit. Indeed, there are optimum tariffs, which maximize a country's gain from trade, and whose level depends on the price elasticities of the foreign supply of imports and the foreigners’ demand for exports, just as the monopolist's profit maximizing profit margin depends on the price elasticity of demand he faces (Scitovsky, 1942).

Tariffs, like monopoly pricing, redistribute income in favour of those imposing them in a way that inflicts a greater loss on those hurt than the gain they secure for those favoured. For that reason, it is important to prevent competitive tariff impositions and increases, whereby each country retaliates in self-defence to the tariffs imposed by others, and so contributes to a general impoverishment of all or almost all, due to the all-round reduction of international specialization and of the gain it generates. Yet, that happened during the 1930s depression; and it can easily happen when each country believes itself to
have a small enough share in world trade to erect or raise tariffs unpunished and retaliation is effective or believed to be effective in recapturing some of the lost gain of the retaliating country. Free trade therefore is not a stable situation, unless imposed by a dominant country, such as Great Britain in the 19th century or the United States during the period following World War II (Scitovsky, 1942; Kahn, 1947). What happens when free trade is not enforced, which countries gain, which lose from tariffs and retaliatory tariffs, and what is the nature of the path and final outcome of competitive trade restrictions has received considerable attention in the theoretical literature (Kaldor, 1940; Scitovsky, 1942; Graaff, 1949–50; Johnson, 1953–4; Gorman, 1957–8), but is too complex to summarize here.

Also, the subject has remained a theoretical exercise and faded into the background. Yet, it has two aspects that, though largely overlooked in the literature, deserve mention here. One is that tariffs can exploit a country's monopoly or monopsony position in world markets only if that is not already exploited by private firms within the country. The other is that an import duty can be used as countervailing power to prevent a country's being exploited by a foreign exporter's use of his monopoly power.

A country's only large producer of an exportable product or its single importer of a foreign product enjoys, of course, the same monopoly or monopsony position in world markets as does the country as a whole. Accordingly, he can, and usually does, exploit that position to his own – as well as to his country's – advantage by setting the profit-maximizing monopoly or monopsony price. The same is approximately true also if, instead of a single monopolist, a few large firms act in open or tacit oligopolistic collusion in setting monopoly prices. When they do that, tariffs for the purpose of exploiting the country's bargaining position in world markets are not only redundant but harmful, because, added to a producer's monopoly (or subtracted from an importer's monopsony) price, they are liable to push the foreign price beyond its profit-maximizing level, thereby inflicting a loss on domestic exporters or importers that exceeds the government's tariff revenue. In short, tariffs and monopolistic profit margins can substitute one for another, complement each other, but cannot be used to exploit the same monopoly or monopsony position twice over.

That explains, for example, why export tariffs and other export restrictions have been imposed almost exclusively on primary products and only in countries where those are grown by many small growers under competitive conditions. Export duties on coffee and the Ghanaian State monopoly for the export of cocoa are the obvious examples. The industrial countries, which export manufactures, have no need for export duties to exploit their monopoly position in world markets, because the large manufacturers of their exportables are usually able to charge monopoly prices on their own, thus making export duties redundant.

The same argument also explains why Britain practised and preached free trade up to the end of the 19th century. Her heavy manufactures were produced and exported by large, monopolistic firms, her light manufactures (textiles), though produced competitively, were exported by large wholesale merchants, and some of her primary-product imports were also handled by large British firms, most of them able to set prices that exploited their foreign and domestic monopoly positions alike and rendered tariffs superfluous.

We come now to the use of an import duty to offset a foreign exporter's monopoly and diminish or eliminate his monopoly profits. Ross Shepherd has shown (Shepherd, 1978) that a variable import duty which varies, and is expected to vary, directly with the foreign price of an imported good, raises the
country's apparent price elasticity of demand for that import and correspondingly reduces its manufacturer's monopoly power and with it his profit maximizing price. Indeed, under constant cost conditions, a suitable duty will leave unchanged both the volume imported and the domestic price paid for it by domestic consumers, while expropriating the foreign exporter's monopoly profit. Abba Lerner, who seems to have arrived at the same conclusion independently, advocated imposing such a variable duty (which he called 'extortion tax') on oil imports, thereby creating an incentive for OPEC's members to break ranks by reducing price (Lerner, 1980).

In closing, it is worth noting some similarities and differences between the imposition of tariffs and devaluation. A uniform ad valorem duty on all imports combined with a uniform ad valorem subsidy (negative duty) of the same magnitude on all exports is identical to a devaluation of that magnitude in its effects on the balance of trade but leaves unchanged all other international transactions and financial obligations. For that reason, countries anxious not to increase the burden on domestic debtors of foreign debt denominated in foreign currencies have used such and similar policies as means of improving their balance of trade in preference to devaluation. Also, since devaluation worsens a country's terms of trade when the foreign demand for some of its exports is very inelastic, it may be combined with a duty or other restraint on those of its exports (usually primary products), thereby to prevent the deterioration of its terms of trade, or import restriction may be substituted for devaluation.

Tarshis, Lorie (1911–1993)

D.E. Moggridge

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
aggregate supply function; Keynesianism; Tarshis, L.; underinvestment

Tarshis was born in Toronto, Canada, on 22 March 1911. After a commerce degree at the University of Toronto, he went to Trinity College, Cambridge, where he took a BA in 1934 and a Ph.D. in 1939. His years in Cambridge, 1932–6, which coincided with the emergence of Keynes's *General Theory*, shaped much of his subsequent professional life. His notes for Keynes's annual series of eight lectures on his work in progress for the years 1932–5 have become an important source for those interested in tracing the evolution of Keynes's views. The two Cambridge revolutions of the 1930s, Keynes's and imperfect competition, focused the analysis of his Ph.D. dissertation, ‘The Distribution of Labour Income’. From this came two classic articles in 1938 and 1939 which, along with a contemporaneous piece by John Dunlop (1938), forced Keynes to reconsider his generalization that real and money wages moved inversely over the trade cycle and its implications for the assumption of perfect competition that underlay the analysis of the book (Keynes, 1939).

By then Tarshis had moved to the United States, first to Tufts University (1936–9, 1942–6) and subsequently to Stanford (1946–71). While at Tufts, along with his Cambridge classmate R.B. Bryce, he played a significant role in spreading Keynes's ideas among the Harvard community of economists. Then in 1938 he participated with several other economists in the manifesto *An Economic Program for American Democracy*. Only seven of them eventually signed it – R.V. Gilbert, G.H. Hildebrand Jr., A. W. Stuart, M.Y. and P.M. Sweezy, Tarshis and J.D. Wilson – the government or other connections of the rest preventing them from doing so. The *Program* was ‘Keynesian in analysis, stagnationist in diagnosis and all-out in prescription’, and was ‘instrumental’ in driving home to New Deal Washington the need for more spending to overcome the fatal flaw of contemporary capitalism, underinvestment (Stein, 1969, pp. 165–7). His move to Stanford coincided with another effort at Keynesian persuasion, *The Elements of Economics*, the first unashamedly Keynesian introductory textbook. Dogged by controversy over its supposed ‘left wing’ views, it was much less successful than the slightly later

competing text of Paul Samuelson.

During the subsequent 40 years, despite his heavy teaching commitments where he probably left his greatest mark, Tarshis continued to publish regularly. His contributions related to international finance, the microeconomics of Keynes (most notably the aggregate supply function) and contemporary policy issues.

taste-based discrimination

Kerwin Kofi Charles and Jonathan Guryan
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Economists typically account for differences in economic outcomes between ethnic groups with explanations having to do with differences in skill, explanations emphasizing informational problems associated with accurately assessing skill, as in statistical discrimination models, or explanations that rely on the presence of prejudice, the key element of taste-based discrimination models. This article defines taste-based discrimination and briefly outlines the economics of associated models. It discusses empirical implications of these models, and reviews empirical tests from the literature. It speculates about possible avenues for future research likely to enrich the insights forthcoming from the standard taste-based model. Although this article focuses on discrimination arising from racial prejudice, taste-based discrimination subsumes negative preferences towards groups of individuals of many alternative types, including different age, gender or religious groups.

Keywords

discrimination; prejudice; race; segregation; taste-based model; wage levels

Article

1 Becker's taste-based discrimination models

Individual preferences

In his seminal work, Becker (1971; 1st edn 1957) formally demonstrated how negative racial feeling, or prejudice, on the part of individual members of a
majority group (here described as whites) could be related in a market environment to negative outcomes for members of a discriminated-against group (here described as blacks). He chose a representation of racial prejudice which, in addition to being precise and intuitively appealing, lent itself readily to tractable representation in an economic model. Prejudice in Becker's framework is represented as an aversion to cross-racial (or more generally cross-group) contact. Since this aversion renders cross-racial interactions psychically costly, the strength of an agent's aversion can also be thought of as the price the person would be willing to pay to avoid the interaction. Becker studies the effect of prejudice among three distinct types of white agents – employers, employees and customers.

Given the representation of racial prejudice, it follows straightforwardly that, in their market interactions that involve blacks, prejudiced agents act as if the relevant price mediating that interaction is the actual market price plus an amount determined by the agent's level of prejudice. Thus prejudiced employers with a taste for discrimination, \( d_i \), deciding about hiring black workers view themselves as paying not the market wage \( w \) they pay to white workers but rather the price \( w + d_i \). (This functional form assumes the disutility of interaction is linear in the number of black employees. Other functional forms are of course possible.) When the prejudiced person is an employee, holding a taste for discrimination \( \Delta_i \) and contemplating a wage offer of \( \hat{w} \) to work at a firm alongside black workers, he views himself to be working for a wage of \( \hat{w} - \Delta_i \), rather than the wage \( \hat{w} \) he would consider himself to be receiving were all his co-workers white. Finally, in the third example studied by Becker, a prejudiced customer with a taste for discrimination \( \kappa_i \) views himself as paying \( p + \kappa_i \) per unit for goods sold by black sellers, rather than the market price \( p \) he would consider himself to be paying were the sellers white. It should be clear that the parameters \( d_i, \Delta_i \) and \( \kappa_i \) each reflect the disutility that a prejudiced agent receives from interacting with blacks.

**Market implications**

What does individual prejudice as represented above imply about equilibrium wages and prices? Keeping closely to Becker's original presentation, we briefly describe how tastes interact in a market setting, where there is optimizing behaviour and competition, to determine the level of market discrimination for each of the three models.
Employer discrimination

If black \((b)\) and white \((a)\) workers are equally productive and perfect substitutes in production, an employer \(i\) will have utility given by

\[
U_i = f(K, L_a + L_b) - w_aL_a + w_bL_b - d_iL_b
\]

where \(f(.)\) is a constant returns to scale production function, \(w_j\) is the market wage paid to workers from group \(j \in (a, b)\), \(K\) is capital, and \(L_j\) is the number of workers hired from group \(j\). Taste for discrimination, \(d_i \geq 0\), among all employers varies according to some arbitrary distribution \(\Omega\).

Since in this model black and white workers are perfect substitutes in production, each employer simply hires the type of worker who is less costly, at the margin, to him. Thus an employer hires only black workers if \(w_b + d_i < w_a\), and he hires only white workers if the strict inequality is reversed.

Notice that an employer's workforce is strictly segregated by race, unless his racial prejudice \(d_i\) is such that \(w_b + d_i = w_a\).

What is the equilibrium in the short run, when the number and size of firms are fixed? Imagine a central planner choosing black and white wages and allocating black and white workers to employers so that the markets for both types of workers clear. The planner allocates black workers to the least prejudiced employers: that is, to those with \(d_i = 0\) first and then, if necessary, to those with the lowest values of \(d_i\). If the distribution of \(d_i\) is smooth, the last employer to be allocated a black worker must be indifferent between hiring black and white workers. In equilibrium, less prejudiced employers hire blacks, more prejudiced employers hire whites, and the equilibrium black–white wage gap \(w_a^* - w_b^*\) is equal to the prejudice of the employer who is indifferent between hiring blacks and whites at the equilibrium wage, or \(d_i^*\).

The model sharply distinguishes individual prejudice from market discrimination. In particular, the equilibrium black–white wage gap is not determined by the average level of prejudice among employers, but by the prejudice of a marginal discriminator. Even in a market in which some employers are prejudiced, there need be no racial wage gap in equilibrium provided there are non-prejudiced employers to hire all the black workers.
Notice also that since prejudiced employers and black workers have an incentive to avoid interacting, there is market pressure towards segregation, so that segregation and observed discrimination are effectively substitutes. The more segregation there is in equilibrium, the smaller is the wage gap.

In general, the equilibrium black–white wage gap increases as the prejudice of the marginal discriminator increases – either because the fraction of the workforce that is black increases or because of changes in the distribution of prejudice among all employers. In the first case, the presence of more blacks in the market means that market clearance requires that blacks be allocated to ever more prejudiced employers at the margin. In the second case, higher levels of prejudice in the part of the distribution from which the marginal employer is likely to be drawn will increase market discrimination. Since blacks represent a small minority in most markets, the sorting that characterizes the equilibrium guarantees that only higher prejudice among those employers in the left tail of the distribution (below the median) should lower black wages; higher prejudice among the most prejudiced employers in the market should have no effect on the equilibrium wage gap since the marginal employer is very unlikely to be drawn from among these persons.

Employee discrimination

As discussed above, a prejudiced employee behaves as if the wage he is offered by a firm with black workers were the actual offered wage \( \bar{\nu} \) minus the disutility he gets from interacting with blacks at work, \( \Delta \). As in the employer discrimination model, market forces generate a tendency toward segregation. In the employee discrimination case, because of the preferences of their workers, employers have an incentive to segregate their workforces. An employer who hires both black and prejudiced white workers is forced to pay a premium to the whites to induce them to work for him. He does not pay that premium if his workforce is all the same race. Each firm therefore prefers to employ either only white workers or some combination of black and unprejudiced white workers.

If, in equilibrium, firms are able to segregate perfectly by race, there will be no equilibrium wage gap. Only if there are impediments to perfect segregation, large enough to ensure that blacks work with prejudiced co-workers, can employee prejudice lead to wage discrimination. In the likely event these frictions are such that more prejudiced employees are especially unlikely to work with black co-workers, reductions in segregation lead to
increases in the racial wage gap.

**Customer discrimination**

In the third type of taste-based model discussed by Becker, some customers care about the race of workers producing the goods they purchase. They consequently regard the price they pay for goods made by a firm with $l_b$ black workers to be the charged price, $P_b$, plus their disutility which increases with the number of black inputs into production, or $\kappa l_b$. Since all employers are unprejudiced, and since the profits of firms hiring black and white workers must be the same in equilibrium, any per unit price difference in equilibrium must be reflected in a difference in wages paid to black and white workers. ($P_a$ is the price of a good produced exclusively by white workers.) If there is a price difference in the good, the most prejudiced customers will buy goods produced by whites, and the least prejudiced customers will buy goods produced by blacks. The marginal discriminator is that consumer who is indifferent between buying goods made by blacks and those made by whites, given his level of prejudice and the equilibrium prices charged. If there are enough unprejudiced customers relative to the number of blacks in the market, there will be no difference in prices between the two types of goods, and no difference in equilibrium wages by race. If this condition does not hold, then there will be a racial wage gap.

**2 Long-run implications**

**Traditional view**

Much early discussion and criticism about taste-based models centred on the nature of the long run, when firms can freely enter and exit from the market. The employer version of the taste-discrimination model has historically been the focus of this criticism, as it is in this particular prejudice model that the long-run implications appear, at first blush, to be most troubling for the standard model.

To see the essence of the criticism of the employer prejudice model, note that if there is an equilibrium wage gap in the short run, employers that hire only white workers have higher labour costs than do firms that hire only black workers. Since workers are equally productive by assumption, non-discriminating firms earn greater profits. The return to capital is thus different
across firms, and in the long run, capital should flow to those firms with the highest return – those with the least prejudiced employers. With a constant returns to scale production function, this mechanism continues until all employers with $d_i > 0$ shut down and leave the market. In the long-run equilibrium, no prejudiced employer survives and any wage gap caused by prejudice is eliminated. Becker himself originally outlined this argument in his original work, and it was famously and forcefully repeated later by Arrow (1972). The influence of Arrow's criticism was such that it probably discouraged work on taste-based prejudice models, relatively few of which have appeared subsequently in the theoretical literature. At the same time it probably encouraged work on statistical discrimination, which is today the dominant paradigm for the theoretical study of discrimination. Indeed, the earliest versions of statistical discrimination model were presented by Arrow (1972) in the same paper in which his criticism was lodged, followed quickly by Phelps's (1972) seminal work.

**Recent theoretical work**

In recent years a number of authors have presented employer prejudice models of discrimination that modify Becker's original assumptions about competition or the wage-setting process, or introduce job search frictions to resurrect the prediction of long-run racial wage gaps resulting directly from taste-based discrimination.

In an important paper, Black (1995) relaxes the perfect competition assumption, introducing costly job search into a model in which some employers refuse to hire black workers and others are non-discriminatory. Without perfect information, black workers know that some fraction of the employers they randomly encounter while searching would refuse to hire them. Non-discriminatory employers consequently enjoy local monopsony power over their black workers, in the sense that reductions in their wage will not lead all such workers to leave. In equilibrium, the presence of employers that refuse to hire blacks causes blacks to receive, from those employers that do hire them, lower wages than otherwise identical whites.

More recently Lang, Manove and Dickens (2005) described a model in which employers post binding wage offers. Because firms cannot base wage offers on the race of the worker, discriminatory employers exercise their preferences by choosing to hire based on race. Since job search is costly, black workers choose to apply to firms at which they believe they have a good chance of
being hired. These firms are those that post low wage offers. In equilibrium, there is both segregation and a wage gap. Our own recent work (Charles and Guryan, 2007, 2008) calls into question the basic logic of Arrow's critique of the Becker model. The conclusion that discriminatory employers are driven to shut down as a result of competition with non-discriminatory employers is based on an assumption about employers' alternative labor market opportunities, which may be as a worker at a firm. By its reliance on zero profit as the condition for shutting down, this conclusion is implicitly based on the assumption that an employer's outside option is valued only according to the monetary wage paid at that firm, and not according to the race of his potential co-workers. If instead it is assumed that a prejudiced employer takes his distaste for racial contact along with him to his role as a co-worker, then the conclusion is different. Whether a prejudiced employer shuts down then depends on his likelihood of finding a job that does not involve contact with black co-workers. It follows that the ability of the market to segregate is the key mediator between individual discriminatory tastes and market discrimination. In a model with racial preferences that are portable across roles (employer or worker) and in which there is an impediment to segregation, racial wage gaps can persist in the long run even in the face of perfect competition and free entry and exit. Interestingly, we might think of the model described in Charles and Guryan (2007, 2008) as one in which the choice of whether to be an employer or an employee is endogenized. In this case, Becker's worker discrimination model is essentially a generalization of his employer discrimination model. The predictions of this model are essentially the same as those from Becker's short-run employer discrimination equilibrium.

3 Empirical assessment of taste-based prejudice models

There is a vast empirical literature devoted to studying racial gaps in economic outcomes, but very little of that work can be said to test directly the implications of taste-based models. Part of the reason is that it is difficult to establish that observed racial wage differences are truly the result of any form of discrimination and not of unmeasured skill or ability differences across the groups. The suspicion that unmeasured skill differences account in part for observed wage and other differences by race is strengthened by results, such as those from Neal and Johnson (1996), showing that adding rarely used controls like test scores to wage regressions results in a significant reduction
in the amount of the wage gap that is unexplained. Even when it can be reasonably argued that the unexplained gaps are unlikely to be the result of some measure of skill for which the researcher has failed to control, there remains the problem that such results are consistent with forms of discrimination that have nothing at all to do with taste-based prejudice. This is true even of the important and carefully done audit studies in various markets, in which blacks and whites, or their resumes, are sent at random to different employers or firms in analysts, attempts to identify differential treatment. (See for example Heckman, 1998; Bertrand and Mullainathan, 2004.) Charles and Guryan (2008) test the predictions of Becker's model empirically, collecting data on explicit measures of prejudice from the General Social Survey (GSS) to construct indices of the distribution of individual discriminatory tastes. They then compare various measures of prejudice at the labour market (in this US example, state) level, and compare these with the measured black–white wage gap in the market. The results are remarkably supportive of Becker's model. Black–white wage gaps are larger in states with a higher fraction of a black workforce. Racial wage gaps are larger in more prejudiced states, but the relationship holds in a particular way. Black relative wages are negatively related to the degree of prejudice in the left tail of the prejudice distribution, but not to variation in the median or right tail. This finding is consistent with the sorting mechanism that Becker describes, and that tends to make the marginal discriminator someone less prejudiced than the average person. Further supporting the view that the market's ability to segregate is a key mediator between individual tastes and market outcomes, the study found that black–white wage gaps are larger in states where there is more integration of – more contact between – blacks and whites in the workplace.

4 Areas for future work and conclusion

Despite the historical importance of taste-based models in the economics literature on discrimination, we believe there are many areas for future theoretical and empirical work. We briefly discuss only a few of these, listing them in the form of questions.

What precisely is taste-based prejudice?

Becker represents racial prejudice as distaste for interaction, and virtually all subsequent prejudice models have followed Becker's lead. However, racial
prejudice might manifest itself in various other ways, with possible important implications for market outcomes. Prejudice might, for example, affect information processing. In particular, racial prejudice might cause people infected by it not to update negative stereotypes about members of a group, even in the face of contradictory evidence. This representation of prejudice is closely related to work by authors like Loury (2002) and Coate and Loury (1993) about the formation of stereotypes, and to Myrdal's (1944) work on 'vicious cycles'. Much work remains to be done with this representation of prejudice. Nor has much work been done with prejudice represented as a reference for one's own group (nepotism) rather than an aversion to interactions with another group. (See Goldberg, 1982 for an important exception.)

A massive literature in social psychology examines the formation of prejudice and stereotypes, including the question of whether prejudice is a preference towards members of an in-group or dislike of members of an out-group. (It would be impossible to summarize that entire literature in this article, but for a good overview, the interested reader should see Fiske, 1998. An important early study is Allport, 1954.)
The interesting experimental work of Tajfel et al. (1971) suggests that agents care about the utility of their ‘own’ group, but may care more about actions that maximize the difference between their group's outcomes and those of the out-group. Exploring the implications of these and other insights in formal economic models would vastly enrich our understanding of the effect of prejudice.

From where does racial prejudice come?

Are group-based preferences instinctual or learned? What are the root causes of prejudice? Is prejudice the result of ignorance or unfamiliarity? The answers to questions like these are important for designing policies aimed at reducing discrimination, or even the prevalence of the tastes themselves. Research in psychology and sociology, such as that by Tajfel et al. (1971) and the famous ‘Robbers’ Cave' study by Sherif et al. (1961/1988), suggests that the entire notion of in- and out-groups, with associated negative and positive feelings, might even arise among people randomly assigned to groups. At the same time, some of this research suggests that in- and out-group sentiments are especially strong when there is competition over scarce resources. Future work by economists might incorporate these insights to how prejudice could arise endogenously from, say, residential segregation. Or, future work might
assess whether, following sectoral reallocation or local demand shocks, there is a change in the extent to which prejudice varies with competition over scarce jobs.

Is prejudice conscious?

Most analyses of prejudice in economics assume that the prejudiced agent is aware of his prejudicial sentiments. But research suggests that one way that people might conserve their limited cognitive resources is to group objects into categories and then to generate summary beliefs for those groups rather than a separate one for each individual (see e.g. Allport, 1954; Tajfel, 1981; Taylor, 1981). Humans may therefore develop prejudicial beliefs of which they are not overtly conscious. An example of a test of such subconscious prejudice is the Implicit Attitudes Test (Banaji and Greenwald, 1995; Greenwald, McGhee and Schwartz, 1998). Results in the lab (Wittenbrink, Judd and Park, 1997) and in the field (Price and Wolfers, 2007) support the possibility that automatic psychological responses contribute to discriminatory actions. Further investigation of whether prejudice is subconscious and the associated empirical consequences of that being the case would be an obvious useful area for future work.

In addition to answering questions like these, there is clearly a need to subject the various prejudice models to additional empirical tests. Charles and Guryan (2008) is the only paper of which we are aware that tests the basic predictions of the employer discrimination model about the relationship between equilibrium wage gaps and the distribution of prejudice. Clearly there should be more of this type of work, across different areas and over different time periods. To that end, there might be great benefit to economists from collecting data on prejudice themselves rather than relying on data collected by others. For example, no prejudice measure of which we are aware elicits from respondents an answer to the question how much they would be willing to pay to avoid interacting with members of a particular group. Economists collecting such data would naturally cast their prejudice questions in this form, allowing for an almost exact translation between the theoretical construct of interest to economists and the measure used to study it in the data. Similarly, given the central theoretical importance of the nature and frequency of cross-group interaction within firms to observed racial wage gaps in taste-based models, there is likely to be a great deal to be learned from empirical analyses that jointly study wage discrimination and segregation. Here too there would seem to be substantial returns from the collection of new data, as
the available data on actual interactions within firms is coarse and available in very few data sources. Taste-based models were the first models of discrimination written down by economists. While these models almost certainly cannot account for all of the large and durable differences observed in the market across racial, gender and other dimensions, they nonetheless yield valuable insights about why putatively unproductive traits like race or gender might be correlated systematically with worse market outcomes. Although most work on discrimination has focused on explanations like statistical discrimination or systematic differences in unmeasured skill, there is evidence of a resurgence in interest in taste-based models, given the appearance of a number of papers in the recent literature. In our view, renewed interest in, and investigation of, taste-based models will inevitably lead to a richer understanding of the nature and reasons for differences in economic outcomes in the population.

Article

In the current theory of general economic equilibrium, recontracting and tâtonnement (a French word meaning ‘groping’) are used interchangeably to denote a simplifying assumption that no actual transactions, and therefore no production and consumption activities, take place at disequilibria when prices are changed according to the law of supply and demand (Kaldor, 1934; Arrow and Hahn, 1971, pp. 264, 282). Historically speaking, however, this usage is somewhat confusing, since recontracting is originally due to Edgeworth, who developed it in a direction different from that in which Walras developed his tâtonnement (Walker, 1973).

Though different interpretations are given as to whether Walras explicitly excluded disequilibrium transactions from the beginning (Patinkin, 1956, p. 533; Newman, 1965, p. 102; Jaffé, 1967; 1981), it is clear that Walras developed his theory of tâtonnement so as to exclude such transactions. To do this there are at least three methods of tâtonnement. First, we may assume that price-taking traders facing market prices cried by the auctioneer reveal their plans of demand and supply to the auctioneer but do not make any trade contract among themselves until the auctioneer declares that equilibrium is established. Alternatively, traders may be assumed to make trade contracts (Walras, 1926, p. 242, suggested the use of tickets when production is involved) but recontract is assumed always to be possible, in the sense that contract can be cancelled without consent of the other party if market prices are changed. Finally, the effect of past contracts can be nullified by offering new demands (supplies) to offset past supplies (demands), even if it is assumed that past contracts are effective and would be carried out at the current prices when the equilibrium is established (Morishima, 1977, pp. 28–30). Since
any changes in prices make the contract unfavourable to one of the parties which then wishes to cancel the trade contract, there is no difference between the three methods of tâtonnement in the behaviour of demand, supply and prices. Recontracting in this sense of tâtonnement is, however, quite different from that developed in Edgeworth's theory of recontract.

We shall start by the consideration of why this assumption of tâtonnement is necessary for the Walrasian theory of general equilibrium, which is the foundation of neoclassical economic theory. The reason lies in the structure of Walrasian economics, dichotomized between real and monetary theories. Then we analyse formal models of tâtonnement including the original one due to Walras and the modified version developed in modern theories of general equilibrium. It is followed by our assessment of the theoretical achievements and empirical relevance of Walrasian tâtonnement economics. Edgeworth's theory of recontract is reviewed in its relation to the Walrasian theory of tâtonnement. Finally, an evaluation is made on the recent studies of tâtonnement and recontracting, to show in which direction further progress should be made.

Walras (1874–7) insisted that complicated phenomena can be studied only if the rule of proceedings from the simple to the complex is always observed. To understand the fundamental nature of Walrasian economics, it is convenient to make (as did Hicks, 1934) a comparison of Walrasian and Marshallian ways of applying this rule to the study of complicated economic phenomena. Both Walras and Marshall (1890) start with a very simple model of an economy and then proceed to more complex models. There is an important difference, however, between Walrasian general equilibrium analysis and Marshallian partial equilibrium analysis.

Walras first decomposes a complicated economy of the real world into several fundamental components like consumer-traders, entrepreneurs, consumers’ goods, factors of production, newly produced capital goods, and money. He then composes a simple model of a pure exchange economy by picking up a very limited number of such components, that is, individual consumer-traders and consumer's goods, disregarding the existence of all other components. Travel from this simple model to the complex proceeds by adding one by one those components so far excluded, that is, entrepreneurs and factors of production first, then newly produced capital goods, and finally money. In this journey each intermediate model, enlarged from a simpler one and to be enlarged into a more complex one, is still a closed and self-compact logical system. However, each of them is as unrealistic as the starting model, with the exception of the last, into which all the components of a real world economy have been introduced.

Marshall on the other hand studies a whole complex of a real world economy as such. Of course, he also simplifies his study at first by confining his interest to a certain limited number of aspects of the economy. But he does it not by disregarding the existence of other aspects but by assuming that other things remain equal. In this sense most of Marshall's models of an economy, though realistic, are open and not self-sufficient, since some endogenous variables (that is, the ‘other things’) remain unexplained and have to be given exogenously.

The simplest model of Walrasian economics is that studied in the theory of exchange, where goods to be exchanged among individual consumer-traders are assumed simply to be endowed to them and not considered as produced at cost. There exist no production activities in this hypothetical world. The corresponding simplest model of Marshall is that of the market day, in which goods to be sold are produced goods, although the amount available for sale is, for the time being, assumed to be constant. Production does exist in this temporary model, though the level of output is assumed to be unchanged.
that Walrasian model which includes production capital goods are introduced as a kind of factor of production but investment (that is, the production of new capital goods) simply does not exist. On the other hand, in Marshallian short-run theory, which is also a theory of production, investment is actually undertaken though the amount of currently available capital is given. In all of the Walrasian models of exchange, of production and of credit and capital formation there exists no money at all, until it is finally introduced in the theory of circulation and money. In Marshallian models on the other hand money exists from the beginning, though its purchasing power is sometimes assumed to be constant.

In other words, Marshallian theories correspond respectively to special states of the real world economy. The market day (temporary) and short-run models are just as realistic as the long-run model, where capitals are fully adjusted. Thus Marshallian models are practically useful to apply to what Hicks (1934) called particular problems of history or experience. On the other hand, Walrasian models are in general not useful for such practical purposes. They are designed to show the fundamental significance of such components of the real world economy as entrepreneurs and production, investment and the rate of interest, inventories and money, and so on, by successively introducing them into simple models which are then developed into more complex ones. Walras’ theoretical interest was not in the solution of particular problems but in what Hicks called the pursuit of the general principles which underlie the working of a market economy.

From our standpoint we must emphasize that all exchanges have to be non-monetary (that is, direct exchanges of goods for goods) in all the Walrasian theories of exchange, production and capital formation and credit, since money has not yet been introduced. Relative prices (including the rate of interest) and hence consumption and production activities are determined in non-monetary real models without using money, while the role of the model of circulation and money lies only in the determination of the level of absolute prices by the use of the money (Morishima, 1977, ch. 11; Negishi, 1979, ch. 2). Thus Walrasian economics is completely dichotomized between non-monetary real theories and monetary theory, in the sense that all non-monetary real variables are determined in the former and money is neutral, that is it does not matter for the determination of such variables. ‘That being the case, the equation of monetary circulation, when money is not a commodity, comes very close, in reality, to falling outside the system of equations of (general) economic equilibrium’ (Walras, 1926, pp. 326–7).

2. In each of his non-monetary theories Walras tried to show the existence of a general equilibrium in its corresponding self-compact closed model. General equilibrium is of course a state in which not only each individual consumer-trader (entrepreneur) achieves the maximum obtainable satisfaction (profit) under given conditions but also demand and supply are equalized in all markets. In a large economy, how can we make such a situation possible without introducing money? What kind of process of exchange should we consider in order to establish a general equilibrium without using money? Even in the most simple case of an exchange economy, it seems in general almost impossible to satisfy all individual traders by barter exchanges, unless mutual coincidence of wants accidentally prevails everywhere. Walras ingeniously solved this difficulty by his famous tâtonnement, a preliminary process of price (and quantity) adjustment which precedes exchange transactions and/or effective contracts. Suppose that all the individual consumer-traders and entrepreneurs meet in a big hall. Since all of them are assumed to be competitive price takers it is convenient to assume (though Walras himself did not do so explicitly) the existence of an auctioneer whose only role is to determine prices. At the start the auctioneer calls all prices (including the price of a bond) at random. Individual consumers and entrepreneurs make decisions on the supply and demand of all goods, factors of production and of the
bond, assuming that the prices cried by the auctioneer are fixed and that whatever amount they wish can actually be supplied and demanded at these prices. If total demand equals total supply for every good (including the factors of production and the bond) exchange takes place (or contracts are made) at these prices, and the problem is solved. Generally, however, this will not be the case, in which event no exchange transaction should take place at all, even for a good for which total demand is equal to total supply, and every mutually agreed contract should be cancelled. The auctioneer cancels the earlier prices, which failed to establish a general equilibrium, and calls new prices by following the law of supply and demand, that is, raising (lowering) the price of each good for which the demand is larger (smaller) than the supply. The same procedure is repeated until general equilibrium is established. Actual exchange transactions take place and enforceable contracts are made only when every party can actually realize its plan of demand and supply.

Prices change in the process of tâtonnement and it is generally impossible for a single trader to purchase or sell whatever amount he wishes at going prices. Nevertheless, each trader behaves on the assumption that prices are unchanged and that unlimited quantities of demand and supply can be realized at the current prices. This conjecture is justified by the very fact that no exchange transactions are made and no trade contracts are in effect during the tâtonnement, until general equilibrium is established where prices are no longer changed, and every trader can purchase and sell exactly the amount he wishes at going prices.

In a monetary economy of the real world, where of course the tâtonnement assumption cannot be made and some exchange transactions actually take place before general equilibrium is established, even a competitive trader without power to control prices has to expect price changes and to try to sell when the price is high and to buy when the price is low, though he may not always succeed in doing so. This leads to the separation of sales and purchases, a separation which is made possible only by the use of money as the medium of exchange and the store of value. In Walrasian non-monetary real models where the tâtonnement assumption is made, on the other hand, sales and purchases are synchronized when general equilibrium is established so that there is no need for money, and indeed there is no reason why the role of medium of exchange should be exclusively assigned to a single item called money. Since equilibrium prices are already fixed and unchanged almost any non-perishable good can be used if necessary as a medium of exchange.

Walras considered tâtonnement even in his final model, that is, that of circulation and money. Since disequilibrium transactions are thus excluded and there is no uncertainty, there is no room here for money as a store of value. We have to assume therefore that people demand money only for the sake of convenience in transactions. Since all actual transactions are carried out at general equilibrium after the preliminary tâtonnement is over, however, this rationale for the demand for money is not at all convincing. The only role left for money is to determine its own price, that is, the general level of prices.

Walras gave two solutions for general equilibrium of each of his non-monetary real models, as well as his monetary model. The first solution is the demonstration that the number of unknowns is equal to the number of independent equations, which Walras called the scientific or mathematical solution. But how can we find a solution of such equations, particularly when the number of equations is very large? The second solution of general equilibrium given by Walras (1926, pp. 162–3, 170–72) is tâtonnement itself, which is suggested by the mechanism of free competition in markets and is called the practical or empirical solution. Taking the example of the simple model of exchange these two solutions may be
Consider an exchange economy of $m$ goods and denote the price of and the excess demand for the $j$th good by $p_j$ and $E_j$ respectively. One condition for general equilibrium is that demand is equal to supply in all markets, that is

$$E_j(p_1, \ldots, p_m) = 0, \ j = 1, \ldots, m.$$  

(1)

In view of Walras's Law that

$$\sum_j p_j E_j \equiv 0,$$

(2)

only $(m-1)$ equations of (1) are independent, while we can assign the role of numéraire to the $m$th good so that $p_m = 1$ since only relative prices are relevant in a non-monetary economy. Therefore (1) is replaced by

$$E_j(p_1, \ldots, p_{m-1}) = 0, \ j = 1, \ldots, m - 1.$$  

(3)

Equations (1) or (3) are derived from the competitive behaviour of individual consumer-traders. The $i$th consumer-trader is assumed to maximize his utility $U_i(x_{ib}, \ldots, x_{im})$, subject to the budget constraint

$$\sum_j p_j x_{ij} = \sum_j p_j y_{ij}$$  

(4)

where $x_{ij}$ and $y_{ij}$ denote respectively the gross demand for the $j$th good by the $i$th consumer-trader and the given initial holding of the $j$th good of the $i$th consumer-trader. The excess demand for the $j$th good is then defined as
It is to be noted that excess demand is not defined in (1) and (3) explicitly as a function of the \( y_{ij} \)'s. The reason is that the \( y_{ij} \)'s are given constants and are assumed not to change through the process of exchange until the demand plans of all consumer-traders are simultaneously realized when general equilibrium is established. In other words the assumption of tâtonnement is already implicitly made in the mathematical or theoretical solution of general equilibrium.

The original form of Walrasian tâtonnement is the process of successive adjustment in each single market. Suppose the initial set of prices cried by the auctioneer \((p_1, \ldots, p_{m-1})\) does not satisfy the condition (3) of general equilibrium, and we are for example in a situation described by

\[
\begin{align*}
E_1(p_1, \ldots, p_{m-1}) &> 0 \\
E_2(p_1, \ldots, p_{m-1}) &< 0 \\
&\vdots \\
E_{m-1}(p_1, \ldots, p_{m-1}) &> 0.
\end{align*}
\]  

(6)

The price of the first good \(p_1\) is now adjusted by reference to its excess demand \(E\), and increased in the situation (6) until an equilibrium in the first market is established, that is

\[
E_1(p'_1, p_2, \ldots, p_{m-1}) = 0.
\]  

(7)

Here \(E_1\) is assumed to be decreasing with respect to \(p_1\), an assumption which, writing the partial derivative of the excess demand function for the \(j\)th good with respect to the \(k\)th price by \(E_{jk}\), may be symbolized by \(E_{11}<0\).

Under the new price system \(\left(p'_1, p_2, \ldots, p_{m-1}\right)\) the remaining \(m-1\) markets may or may not be in equilibrium. If the second market is out of equilibrium, again under the assumption that \(E_{22}<0\), the price
of the second good is changed from $p_2$ to $\hat{p}_2$ so as to satisfy

$$E_2\left( p'_1, p'_2, p_3, \ldots, p_{m-1} \right) = 0.$$  

(8)

(Generally, this will upset the equilibrium in the first market (7).) Under the price system $$\left( p'_1, p'_2, p_3, \ldots, p_{m-1} \right)$$, then, the price of the third good $p_3$ is adjusted if the third market (where $E_{33} < 0$) is out of equilibrium, upsetting the equilibrium in the second market (8) just established. In this way the last, $m-1$th market, where $E_{m-1,m-1} < 0$, is eventually cleared by changing the price system from $$\left( p'_1, \ldots, p'_{m-2}, p_{m-1} \right)$$ into $$\left( p'_1, \ldots, p'_{m-2}, \hat{p}_{m-1} \right)$$ so as to satisfy

$$E_{m-1}\left( p'_1, \ldots, p'_{m-2}, \hat{p}_{m-1} \right) = 0.$$  

(9)

By this time all the markets except the last, which were once cleared successively, have generally been thrown out of their respective equilibria again. Neither the price system we have just arrived at, $$\left( p'_1, \ldots, \hat{p}_{m-1} \right)$$, nor the initial system, $$\left( p_1, \ldots, p_{m-1} \right)$$, is part of a general equilibrium. The question then is which of the systems is closer to a true general equilibrium that satisfies (3). Walras argued that the former price system is closer to equilibrium than the latter since for example $E_{1}\left( p'_1, \ldots, \hat{p}_{m-1} \right) \neq 0$ is closer to 0 than $E_{1}\left( p_1, \ldots, p_{m-1} \right) \neq 0$. The reason for this, according to Walras, is that the change from $p_1$ to $\hat{p}_1$ which established (7) exerted a direct influence that was invariably in the direction of zero excess demand so far as the first good is concerned. But the subsequent changes from $p_2$ to $\hat{p}_2, \ldots, p_{m-1}$ to $\hat{p}_{m-1}$, which jointly moved the first excess demand away from zero, exerted only indirect influences, some in the direction of equilibrium and some in the opposite direction, at least so far as the excess demand for the first good is concerned. So up to a certain point they cancelled each other out. Hence, Walras concluded, by repeating the successive adjustment of $m-1$ markets along the same lines, that is, changing prices according to the law of supply and demand, we can move closer and closer to general equilibrium.

Walras's argument for the convergence of the tâtonnement process to general equilibrium was intended to be, if successful, the first demonstration of the existence of competitive general equilibrium (Wald, 1936). As we said above, it was merely an argument for the plausibility of such convergence of
the process of tâtonnement, and cannot be considered as a rigorous demonstration of existence of equilibrium. Whether indirect influences of the prices of other goods on the excess demand of a given good cancel each other out will certainly depend on substitutability and complementarity between goods. For example, indirect influences are not cancelled out and the excess demand of a good is increased if the prices of all gross substitutes are raised and the prices of all gross complements are lowered. In addition to the Walrasian stability condition for a single market, that is, \( E_{ij} < 0 \) for all \( j \), therefore, some conditions on the cross-effects of prices on excess demands, that is on \( E_{jk}, j \neq k \), have to be imposed so as to demonstrate convergence.

It was Allais (1943, vol. 2, pp. 486–9) who first demonstrated the convergence of Walrasian tâtonnement by assuming gross substitutability, that is, \( E_{jk} > 0 \) for all \( j \neq k \). To see whether the price system moves closer and closer to the general equilibrium, which he assumes to be at least locally unique, Allais defines the distance \( D \) of a price system from the equilibrium price system as the sum of the absolute values of the value of excess demand for all goods, including the numéraire. The convergence of tâtonnement is then demonstrated by showing that this distance \( D \) is always decreased by changes in prices that are made in accordance with the law of supply and demand. His demonstration may be reformulated in our notation as follows.

The distance to the general equilibrium is defined as

\[
D = \sum_{j} |p_j E_j|
\]

(10)

where the summation runs from \( j=1 \) to \( j=m \), and \( E_j \) is defined as a function of \( p_1, \ldots, p_{m-1} \) as in (3). In view of Walras' Law (2), \( D \) can be replaced either by the summation of positive excess demands

\[
D_1 = \sum_{j} p_j \max(0, E_j)
\]

(11)

or by the summation of negative excess demands

\[
D_2 = - \sum_{j} p_j \min(0, E_j)
\]

(12)
where $\max(0, E_j)$ denotes $E_j$ if it is positive and 0 if $E_j$ is negative, and $\min(0, E_j)$ denotes $E_j$ if it is negative and 0 if $E_j$ is positive. From (2), that is $D_1 - D_2 = 0$, it is clear that

$$D = 2D_1 = 2D_2$$

(13)

so that whether $D$ is increasing or decreasing can be seen by checking whether $D_1$ or $D_2$ (whichever is more convenient) is increasing or decreasing.

Suppose $E_1$ to be positive as in (6) and that $p_1$ is raised following the law of supply and demand. From (12), we have

$$\partial D_2 / \partial p_1 < 0$$

(14)

since $E_{j1} > 0$ for any $j$ such that $E_j < 0$, from gross substitutability. In other words, a change in the price of the first good from $p_1$ to $p_1'$ so as to satisfy (7) decreases the sum of negative excess demands $D_2$ and therefore the distance $D$ to the general equilibrium. Suppose next that $E_{j2} < 0$ for any $j$ such that $E_j > 0$, from gross substitutability. In other words, a decrease in the price of the second good from $p_2$ to $p_2'$ decreases the sum of positive excess demands $D_1$ and therefore the distance $D$ to the general equilibrium. Generally, if $E_j$ is positive and $p_j$ is raised $D$ is decreased, which can be seen from the fact that $D_2$ is decreased. Similarly, if $E_j$ is negative and $p_j$ is lowered again $D$ is decreased, which can be seen from the consideration of the behaviour of $D_1$. Out of the general equilibrium $D$ remains positive and there exists at least one non-numéraire good with non-zero excess demand, so that its price is changing. The distance
to the general equilibrium always decreases out of equilibrium, and therefore we can move closer and
closer to that equilibrium by changing prices according to the law of supply and demand, provided that
gross substitutability is assumed.

Though Walras discussed the behaviour of the process of successive adjustment, he was not against the
consideration of simultaneous adjustment processes in all markets (Uzawa, 1960; Jaffé, 1981). If we
assume that adjustments take place not only simultaneously but also continuously, the tâtonnement
process that each rate of change of price is governed by excess demand can be described by a set of
differential equations,

\[
d \frac{p_j}{dt} = a_j E_j(p_1, ..., p_{m-1}), \ j = 1, ..., m-1,
\]

where \( t \) denotes time and the \( a_j \)'s are positive constants signifying the speed of adjustment in the \( j \)th
market. The study of the behaviour of the solutions of (16), that is prices as functions of \( t \), which was
initiated by Samuelson (1941) is called the study of the stability of competitive equilibrium and has been
extensively carried out by many mathematical economists (Arrow and Hahn, 1971, pp. 263–323;
Negishi, 1972, pp. 191–206). It is well known that gross substitutability is also a sufficient condition for
the convergence of adjustment processes like (16).

5. The idea of tâtonnement was clearly suggested to Walras from the observation of how business is
done in some well organized markets in the real world, like the stock exchanges, commercial markets,
grain markets, fish markets. As a matter of fact, Walras was well informed of the actual operation of the
Paris Stock Exchange where disequilibrium transactions actually did not occur (Jaffé, 1981).

Tâtonnement is therefore not entirely unrealistic as a model of adjustment in such special markets.
However, it is certainly very unrealistic to apply such a model of special markets to the whole economy,
since preliminary adjustments are usually not made before exchange transactions and effective contracts
take place, even in markets where competition, though not so well organized, functions fairly
satisfactorily. Of course, Walras would have admitted this, since tâtonnement was for him not so much a
description of the process of adjustment in the markets of the real world as it was the demonstration of
the existence of general equilibrium, that is a limit to which tâtonnement converges. It should be so
interpreted not only in the case of successive tâtonnement, which reminds us of the Gauss–Seidel
method of solving a set of simultaneous equations, but also in the case of simultaneous tâtonnement
(16), where time \( t \) is not real calendar time, but hypothetical process time. This is no wonder, since
Walrasian non-monetary models are not intended to be faithful descriptions of the real world. They are
designed rather to make clear the significance of each component of the market economy and to uncover
the general principles that underlie its working.

One may feel that such an interpretation of Walrasian tâtonnement is too strict and that the behaviour of
not so well organized markets can be described approximately by the tâtonnement model. Walrasian
tâtonnement may be interpreted as something like the laws of motion, that work strictly speaking only in
the ideal frictionless world but which can be applied approximately to the real world. The law of supply
and demand can certainly be applied even in markets where there is no auctioneer, traders are dispersed, and exchange transactions take place and effective contracts are made before equilibrium of demand and supply is established.

Prices are formed differently in each exchange transaction by negotiation between relevant parties of traders. The law of indifference tends to prevail, however, if the transmission of information is nearly perfect, since atomistic traders know the difficulty of purchasing (selling) at prices lower (higher) than the prices offered by competitors and there are, furthermore, arbitrage activities. If demand falls short of supply, it is suicidal for atomistic sellers to offer a price higher than the average market price, while an atomistic purchaser is unable to consider a price lower than the average market price when demand exceeds supply. With disequilibrium of supply and demand, exchange transactions can take place only if demanders (suppliers) can find suppliers (demanders). If demand is deficient therefore sellers consider cutting prices or increasing marketing costs in order to attract more purchasers, since a drastic increase in sales is expected from slight falls in price or slight increases in marketing costs when information is nearly perfect. By observing such behaviour by the sellers, the purchasers also insist on price cuts. Thus price falls in the face of excess supply. Similarly, market prices rise as the result of a similar process of disequilibrium exchange transactions in the face of excess demand, in which the roles of sellers and purchasers are interchanged from the case of excess supply.

Therefore, we can extend (16) to

\[
\frac{dp_j}{dt} = a_jE_j(p_1, \ldots, p_{m-1}, y_{11}, \ldots, y_{nm}), j = 1, \ldots, m-1,
\]

(17)

where the \(E_j\)'s are again derived from (5) but have now to be considered explicitly as functions of the \(y_{ij}\)'s that is the stock of the \(j\)th good held by the \(i\)th consumer-trader, \(i = 1, \ldots, n\), since the \(y_{ij}\)'s are no longer constants but instead are changed by disequilibrium transactions among the \(n\) consumer-traders. Here we cannot discuss in detail how the \(y_{ij}\)'s are changed as a result of transactions at disequilibria, and have to be content with the general assumption that their rates of change depend on everything, that is, we have

\[
\frac{dy_{ij}}{dt} = F_{ij}(p_1, \ldots, p_{m-1}, y_{11}, \ldots, y_{nm}), i = 1, \ldots, n, j = 1, \ldots, m,
\]

(18)

where the \(F_{ij}\)'s are unknown functions incorporating rules for exchange transactions out of equilibria.

Models of an economy with (17) and (18) are called non-tâtonnement models or non-recontracting models.

Generally, if a non-tâtonnement or non-recontracting process (17) and (18) converges, it does so to an
equilibrium that is different from that arrived at by the tâtonnement process (16), since changes in the $y_{ij}$'s due to disequilibrium exchange transactions have effects on (17) which do not exist in the case of (16). As Newman (1965, p. 102) correctly pointed out, however, the difference can be safely neglected, if the speed of price adjustment in every market is very high (that is, the $a_j$'s in (17) are very large), since then markets arrive at equilibrium prices so rapidly that the effects of disequilibrium transactions are prevented from becoming serious. Although the possibility of disequilibrium transactions is not institutionally excluded and there may well be some, most transactions are actually carried out at equilibrium so that it looks as if the assumption of tâtonnement is satisfied. In this sense, tâtonnement models can be used to describe the behaviour of non-tâtonnement or non-recontracting markets in the real world.

Although the tâtonnement model can be applied to markets that are not so well organized if the transmission of information is nearly perfect and the speed of price adjustment is rapid, the general equilibrium tâtonnement model (16) is still not a realistic description of the real world economy. The reason is that the role of money as the medium of exchange and a store of value is very important in the real world, while as we saw it is highly limited in a model where most exchange transactions are simultaneously carried out at equilibrium. To make our model more realistic so that sales and purchases take place at disequilibria and are separated by the use of money, therefore, we have to get rid of tâtonnement by arguing that the speed of price adjustment is not rapid in (17), so that disequilibrium transactions cannot be ignored.

If the transmission of information is perfect, the law of supply and demand can be applied even in not so well organized markets where no auctioneer exists and disequilibrium transactions take place. This is because every seller (purchaser) perceives an infinitely elastic demand (supply) curve and expects that a drastic increase in sale (purchase) is made possible by a slight reduction (increase) in price. If total demand falls short of total supply in a market, then every trader willingly reduces price or accepts a reduction in it. Similarly, if total demand exceeds total supply in a market every trader willingly raises price or accepts a rise in it.

The transmission of information may not be so perfect, however, in markets where traders are dispersed and so cannot meet in a big hall as they do in the case of Walrasian tâtonnement. Suppose that a market is segmented and transmission of information is perfect among closely related traders, but that it is not so between different segments. Individual traders are assumed to keep contact with current trade partners and not to leave the segment of the market in which they are currently located in search of more favourable trade conditions, unless either they are well informed of such conditions in other segments or trade conditions change unfavourably in the original segment. Possibly because of consideration of cost, traders are constrained by inertia and do not move unless shocked by information on other segments or by changes in the original segment.

Then even an atomistic seller (purchaser) does not perceive an infinitely elastic demand (supply) curve. A seller expects that sales cannot be increased very much by reduction of price since only those purchasers who are currently buying from him are well informed of the price reductions, and this information is not perfectly transmitted to those purchasers who belong to other segments of the market and who are not buying from him. When total demand falls short of total supply and other sellers do not raise the price, it cannot be expected that ‘their’ purchasers leave them in search of cheaper sellers. The same seller has to expect, however, that sales will be drastically reduced if the price is raised, since those customers who are currently buying will be well informed of this and will leave to search for cheaper
sellers, which they can find easily when total demand falls short of total supply and there are many other sellers willing to sell more at the unchanged price.

Atomistic sellers perceive kinked demand curves, with a downward sloping segment for levels of sale higher than the current one, and an almost infinitely elastic segment for levels of sale lower than the current one, when the market is in excess supply. It is very likely then that price does not fall and remains sticky in the face of excess supply (Reid, 1981, pp. 65–6, 96–9; Negishi, 1979, p. 36). It may not pay to reduce price if demand cannot be increased very much. Similarly, an atomistic purchaser perceives a kinked supply curve with an upward sloping segment for levels of purchase higher than the current one, and an almost infinitely elastic segment for levels of purchase lower than the current one, when the market is in excess demand. Since the transmission of information is imperfect and the purchaser cannot attract many sellers by raising price, it may not pay to raise price even if a larger purchase is wanted at the current price. It is very likely, therefore, that price does not rise and remains sticky in the face of excess demand.

Thus prices may be sticky and may not be adjusted quickly by demand and supply in not-well-organized markets in the real world. The speed of adjustment in (17) need not be rapid enough to allow one to ignore the effects of disequilibrium transactions, so that the tâtonnement process (16) cannot then be regarded as a realistic description of adjustment in real-world markets. Walrasian tâtonnement models are, of course, not designed to describe such markets empirically. They are constructed to show how the market mechanism works beautifully under ideal conditions. No one can deny that Walrasian economics succeeded in accomplishing this purpose. The market mechanism, however, does not work so beautifully in the real world. It certainly manages to work somehow but quite often at the cost of prolonged disequilibria in markets, such as involuntary unemployment in the labour market and excess capacity in goods markets. This is why we have to supplement Walrasian economics by launching out into the study of non-Walrasian economics.

7. Recontracting. Since the idea of recontracting is due originally to Edgeworth, who developed it in a way different from Walras's tâtonnement, the implication of Edgeworth's theory of recontract has to be carefully considered in its relation to the theory of tâtonnement in Walrasian economics. These two theories are different from each other in at least two ways, namely with respect to the law of indifference (the uniformity of prices) and to the provisional nature of revocability of trade contracts. The first problem is discussed below, while the second will be considered in the next section.

There have been different interpretations as to whether Edgeworth's Mathematical Psychics (1881) excluded disequilibrium transactions or assumed the irrevocability of contracts (Walker, 1973; Creedy, 1980). Even if we assume that disequilibrium transactions are excluded, however, the theory of recontract in Edgeworth is different from the theory of tâtonnement in Walrasian economics. The law of indifference (that is, the existence of uniform market prices even in disequilibria) is imposed as an axiom in the original Walrasian as well as in modern Walrasian economic theories. This axiom may be justified either through arbitrage activities or by the existence of the auctioneer, and enables individual traders to act as price takers who have only to adjust their plans of supply and demand to the given prices. Such an axiom is not imposed in Edgeworth's recontracting model. To demonstrate his famous limit theorem (Bewley, 1973), Edgeworth starts with a simple two-good two-individual model of exchange, where a trader X offers a good x to a trader Y in exchange for a good y. If we consider the so-called Edgeworth box diagram, any point on the contract curve, where each of two individual traders is not worse off than before exchange, can be a final settlement of trade contract
which cannot be varied by recontract. To narrow down the range of possible final settlements Edgeworth introduces a second X and a second Y, each respectively identical to the first, both in tastes and initial endowments. Since identical traders have to be treated equally in any final settlement, we can still use the same box diagram. Now it can be shown that no final settlement of contract can contain points on the contract curve which give ‘small’ gains from trade to the X traders. Otherwise, it is ‘possible for one of the Ys (without the consent of the other) to recontract with the two Xs, so that for all those three parties the recontract is more advantageous than the previously existing contract’ (Edgeworth, 1881, p. 35).

Similarly, it is possible to exclude as final settlements those points which give ‘small’ trade gains to Y traders.

In this way Edgeworth shows that the range of possible final settlements shrinks as the number of identical traders grows. If there are infinitely many traders the only remaining final settlements turn out to be precisely the points of Walrasian equilibrium, each with a uniform price line, that is the common tangent to indifference curves of X and Y passing through the point of initial endowments. In the terminology of the modern theory of cooperative games, the core of the exchange game (that is, those allocations not blocked by any coalitions of players) consists only of the Walrasian equilibria when the numbers of the Xs and the Ys are each infinitely large. Thus Edgeworth tries to show that the recontracting process in the large economy, where traders obtain a free flow of information through the making and breaking of provisional contracts, leads to the same uniform prices that are given by the auctioneer to price-taking traders in Walrasian equilibria. Though there are no uniform market prices and individual traders are not assumed to be price-takers in Edgeworth’s recontracting process, the resulting equilibrium exchanges are the same as those obtained through Walrasian tâtonnement in a large economy. In such an economy, therefore, where information is perfect, we can safely argue as if there were uniform market prices and as if traders were price-takers. In a sense, Edgeworth justified the Walrasian axiom, since axioms of theories should be assessed not by themselves but by the results derived from them. Even if the Walrasian axiom is not itself realistic, the results derived from it can be as realistic as those derived from more realistic but more complicated axioms.

In later writings Edgeworth confirmed his early position on Walras and the uniformity of prices. Walras describes a way rather than the way by which economic equilibrium is reached. … Walras's laboured description of prices set up or ‘cried’ in the market is calculated to divert attention from a sort of higgling which may be regarded as more fundamental than his conception, the process of recontract. … The proposition that there is only one price in a perfect market may be regarded as deducible from the more axiomatic principle of recontract. (Mathematical Psychics, p. 40 and context: Edgeworth, 1925, vol. 2, pp. 311–23)

We may add that even the existence of a uniform rate-of-exchange between any two commodities is perhaps not so much axiomatic as deducible from the process of competition in a perfect market. (Edgeworth, 1925, vol. 2, p. 453)

8. It is possible to interpret Edgeworth's theory of bilateral exchange (Edgeworth, 1925, vol. 2, pp. 316–19) as a theory of a process where not only the rate of exchange is variable but also contracts are
irrevocable. Starting from a situation with initial holdings, two goods are actually exchanged so as always to increase the utility of each of the two traders. Since exchanges are irrevocable, however, where on the contract curve this process of exchange will terminate depends on the path of exchanges as well as on the initial holdings. Hence it contrasts strongly with Walrasian tâtonnement, the equilibrium of which depends only on the initial holdings. There is no confusion, however, between this theory of Edgeworth and Edgeworth's theory of recontract interpreted in the sense of tâtonnement, since the modern extension of the former theory to the case of multiple traders is rightly called the theory of Edgeworth's *barter* process (Uzawa, 1962; Fisher, 1983, pp. 29–31).

Incidentally, Edgeworth's idea that exchanges necessarily take place only in the direction of increasing utilities can be relevant only in a barter economy. In a monetary economy an exchange of one good against another is decomposed into an exchange of the first good against money and an exchange of money against the second good. Even though the completed exchange of the two goods increases utility, its first half need not do so since in the course of the exchange process one may temporarily receive more money than one plans to keep eventually. In other words, one may impose a rule for non-monetary goods of no overfulfilment of demand and supply plans in the process of exchange, but this cannot be done for money, which has to act both as the medium of exchange and as a store of value beyond the current period.

In view of the current usage of the concept of recontracting in the sense of tâtonnement, what is confusing is the fact that Edgeworth sometimes, and particularly in his later writings, applied his recontracting model to situations where exchange transactions actually take place at disequilibria. To show that his model is of more than academic interest Edgeworth considered the case of a labour market, which each day ends in disequilibrium after exchange transactions have taken place at disequilibrium rates of exchange. From day to day, as the traders’ knowledge of the state of the disequilibrium in the market changes they progressively modify their behaviour, changing the rate of exchange in such a way that the market converges to equilibrium.

Since labour service is perishable within a day and the number and dispositions of the traders are assumed to be unchanged, this process over a sequence of days is formally equivalent to the recontracting process within a day, even though in the former process contracts made on the previous days are irrevocable while in the latter disequilibrium contracts are revocable. Edgeworth insisted that in this example of a process over a sequence of days (Edgeworth, 1925, vol. 1, p. 40) traders do recontract, in the full sense of *Mathematical Psychics*. Since contracts made in earlier days are irrevocable, however, in this case to recontract implies that a new contract is made which is different from that carried out on the previous day. It does not imply the cancellation of contracts already made.

Only a formal similarity exists between these two processes of recontracting, which is due to the assumption that disequilibrium exchange transactions do not really involve a permanent redistribution of wealth. Although labour service is perishable within a day, however, the money paid against labour service certainly is not and it is likely that a redistribution of wealth does take place over a sequence of days. Even from a formal point of view, then, Edgeworth's model of the labour market is rather a pioneering instance of *non-recontracting models*.

9. No one can deny that the rigorous demonstration of the dynamic stability of tâtonnement under certain sufficient conditions has substantially improved on the original argument for the plausibility of its convergence that was made by Walras. More importantly, however, the recent studies on stability have helped us to understand the underlying economic assumptions of the Walrasian tâtonnement
process itself, and made us realize its considerable differences from most price adjustment processes in actual economies. The similar studies of Edgeworth's recontracting process have been helpful in the same way.

As we have shown, Walrasian tâtonnement is a realistic approximation to some actual adjustment processes, provided that the transmission of information is perfect and the speed of adjustment is rapid, as is roughly the case in well organized markets. The problem that remains to be studied, therefore, is the nature of adjustment processes when these conditions are not satisfied, that is, when markets are not so well organized. This is the problem of non-recontracting models in non-Walrasian or disequilibrium economies.

Taussig was born on 28 December 1859 in St Louis, Missouri, and died on 11 November 1940 in Cambridge, Massachusetts. After starting college at Washington University, St Louis, he transferred to Harvard University, where he received the BA (1879), Ph.D. (1883) and LLB (1886). He also studied at the University of Berlin.

Taussig was one of the foremost US economists for half a century. He was on the Harvard faculty from 1885 to 1935, where he was a magisterial teacher and edited the *Quarterly Journal of Economics* from 1896 to 1936. A member of several government commissions, he was the first chairman of the US Tariff Commission, 1917–19, and an adviser to President Woodrow Wilson. He was president of the American Economic Association in 1904 and 1905. His *Principles of Economics* (1911) was the foremost US textbook for generations of economists and non-economists.

Taussig was accurately called ‘the American Marshall’ by Joseph Schumpeter because of his professional stature. He shared with Alfred Marshall an identification with the Ricardo–Mill tradition coupled with a willingness to integrate the ideas of marginalism; a scepticism of the mathematicization of economics; a desire to moderate conflict within the discipline; an understanding that economics was or should be more an organon of analysis, a collection of tools, than a body of doctrine; a sympathy for the working class; and a view that economics was to remain political economy, to include what Schumpeter called ‘economic sociology’. He preferred J.S. Mill’s *Principles of Political Economy* to any modern text, including Marshall’s *Principles*, because in his view it prevented delusions as to economic questions being easy of solution. Like Marshall, too, he considered the Austrian system needlessly complex.

His principal work as an economic theorist lay in wage theory and in international trade theory and
policy. In the former, he attempted to resuscitate a modified version of the wages fund theory, centring on the relative inelasticity of the short-run supply of consumer goods, which he combined with marginal productivity theory. He stressed, however the role of non-competing groups (as part of his great realism in matters of stratification), criticized John Bates Clark's moralistic version of marginal productivity theory and argued that the frequent superior advantage in bargaining of employers meant that marginal productivity was only an upper limit, in the absence of effective competition.

In the field of international trade, in which he was the principal US figure for decades, his major concerns were the complexities of comparative advantage, the role of the specie flow mechanism and the international trade mechanism under non-specie monetary systems, and the history and analysis of protection. His position on protectionism was complex: he affirmed free trade, accepted the infant-industry argument with considerable scepticism of its application in practice, favoured gradual lessening of tariffs and (or but) affirmed a stable tariff system rather than policies of disruptive shifts and shocks. In other policy controversies he strenuously opposed the free coinage of silver as inflationary; criticized unemployment insurance and minimum wages as violating traditional individual initiative; thought progressive taxation less important than the elimination of monopoly and the use of education to diffuse opportunity; and, understanding of worker reliance on unions, blamed labour–management conflict on the failure of management to exercise the responsibilities of wealth and power and to be more understanding of worker interests and ambitions.

Taussig's political economy, or economic sociology, set him off from most other leading orthodox economists. He saw society as both a structure and a struggle for power and privilege, in which an instinct of domination and an impulse of emulation were prevalent if not dominant. These ideas pervaded his Principles, in which he presented, for example, a functional analysis of the leisure class and, in his Inventors and Money Makers (1915b) and (with C.S. Joslyn) American Business Leaders (1932), a further analysis of both the complex psychological bases of economic behaviour and the role of leadership in the successful operation of the market mechanism. Schumpeter wrote that Taussig was ‘among those few economists who realize that the method by which a society chooses its leaders, in what for its particular structure, is the fundamental social function … is one of the most important things about a society, most important for its performance as well as for its fate’ (Schumpeter, 1951, p. 217). In these respects, Taussig's work was compatible with institutionalism, but his establishment position apparently kept those in the later tradition from fully appreciating his contributions. Taussig's ideas here, supplementing those of Friedrich von Wieser, had some influence on Schumpeter himself.

R.H. Tawney was an economic historian and socialist philosopher whose Anglican beliefs lay at the heart of his influential studies of the enduring problem of the ethics of wealth distribution. As Professor of Economic History at the London School of Economics from 1921 to 1958, he became the doyen of a school of thought which defined the subject as the exploration of the resistance of groups and individuals in the past to the imposition on them of capitalist modes of thought and behaviour. In his first book, The Agrarian Problem in the Sixteenth Century (1912) – written to provide an appropriate text for his pioneering tutorial classes for the Workers’ Educational Association – he examined patterns of rural development, protest and litigation surrounding the enclosure of land in Tudor England. After service in the British Army during the First World War – he was severely wounded on the first day of the Battle of the Somme – Tawney returned to his scholarship and developed the arguments which appeared in perhaps his best-known work, Religion and the Rise of Capitalism (1926). Here he showed how alien to the teachings of the Reformation was the assumption that religious thought had no bearing on economic behaviour. Tawney captured in classical prose the clash within religious opinion that preceded that abnegation of the social responsibility of the churches and suggested that ‘religious indifferentism’ was but a phase in the history of Christian thought. In Religion and the Rise of Capitalism Tawney crystallized a number of ideas he had begun to consider in the pre-1914 period. In a commonplace book he kept from 1912 to 1914, Tawney jotted down notes on many of his religious and historical preoccupations. Among them is the simple query, ‘I wonder if Puritanism produced any special attitude toward economic matters’. Over the following decade, he gathered evidence on this subject, and presented preliminary statements in the Scott Holland Memorial Lectures at King’s College, London, in 1922, and in the lengthy introduction he wrote for a 1925 edition of Thomas Wilson’s Discourse on Usury of 1569.
In the notes Tawney left concerning this facet of his historical research, there is no evidence whatsoever that he drew on the celebrated essay of Max Weber, originally published in 1905, on *The Protestant Ethic and the Spirit of Capitalism*. Indeed, a full appreciation of Tawney's Anglican concerns requires a divorce between the two partners of the so-called ‘Tawney–Weber’ thesis.

It is true that both men believed that (in Tawney's words) ‘The fundamental question to be asked, after all, is not what kind of rules a faith enjoins, but what kind of character it values and cultivates.’ They agreed as well that there was in Calvinism a corrosive force which undermined traditional doctrines of social morality in ways which would have shocked the early reformers. And they shared the view that in Protestant teaching there was an important emphasis in religious terms on the ‘inner isolation of the individual’ which reinforced a more general individualism of social and economic behaviour. But what differentiates their work is the uses to which they put their interpretations of Protestantism. Weber's essay was but one part of a comprehensive study of the sociology of religion. It reflects his overriding concern with the development of what he termed the rational bureaucratic character of modern society. In both these facets of his work he charted the progressive, relentless, and irreversible demystification of the world.

Weber's essay helped foster a belief in the bleak permanence of the spirit of capitalism which Tawney laboured to refute throughout his work. *Religion and the Rise of Capitalism* was written precisely to counter the view that social indifferentism in religious thought and individualism in economic thought were unchangeable features of modern life. If Weber's purpose was to describe the demystification of the world, Tawney's was to help in the demystification of capitalism, by stripping it of some of its most powerful ideological supports, derived from one reading of the Protestant tradition.

Anglicanism is, of course, a house of many mansions, in which there is room for reactionaries and socialists alike. The view that capitalism is unchristian because it stultifies the common fellowship of men of different means and occupations has never been more than a minority view. But, at precisely the same time as he was writing *Religion and the Rise of Capitalism*, Tawney joined a number of other influential Anglicans who spoke out against capitalism as a way of life which violated the moral precepts of their faith.

This position was as evident in his essays in political philosophy as it was in his scholarship in economic history. In *The Acquisitive Society* (1921) and in *Equality* (1931), Tawney argued that capitalism was an irreligious system of individual and collective behaviour, since it was based on the institutionalization of distinctions between men based on inherited or acquired wealth. For a Christian, such divisions manifested a denial of the truth that all men are equally children of sin and equally insignificant in the eyes of the Lord. What Matthew Arnold had called the ‘religion of inequality’ was really the obverse of a Christian way of looking at the world.

Tawney's legacy has been particularly pervasive, because his voice had a resonance which appealed to many who did not share his religious outlook. This was in part because he wrote with the moral outrage of Marx and with the grace and eloquence of Milton. His strength lay too in the fact that his was a distinctively English voice. This did not prevent his advocacy of the comparative method in the study of economic history, best evidenced in his book *Land and Labour in China* (1932), written after an eight-month mission to China as an educational adviser to the League of Nations, and in a history of the American labour movement he wrote while adviser to Lord Halifax, British Ambassador to Washington during the Second World War.

But Tawney's influence lies more centrally in his writings on the moral issues posed by capitalist
economic development in Britain. His call for an alternative to the cash nexus – firmly within the tradition of Owen, Ruskin and Morris – has continued to strike a chord among many people not of religious temperament who have sought indigenous answers to the problems of a society crippled by the injuries of class.

Tax competition refers to strategic tax-setting in a non-cooperative game between jurisdictions – whether countries or states or provinces within a federation – with each setting some parameters of its tax system in relation to the taxes set by others. This creates a potential case for international tax coordination, though the revenue impact has as yet been modest (at least in OECD countries). Conflicting national interests make it difficult to design effective coordination schemes.

Article
Tax competition refers to strategic tax-setting in a non-cooperative game between jurisdictions – which can be countries, or states or provinces within a federation – with each setting some parameters of its tax system in relation to the taxes set by others. Broadly read, this definition of tax competition encompasses essentially all tax policy, since every decision potentially requires some view as to the tax strategies formed in other jurisdictions. Typically though, the term is intended to focus on explicit interactions in tax-setting. And the central policy concern to which such interactions point is the potential for efficiency losses (or, as will be seen, gains) – and hence potential gains (or losses) from cooperation – to the extent that each policymaker ignores (or at least attaches less importance to) the impact of its own tax decisions on other jurisdictions, creating fiscal externalities between them.

These cross-border effects might, in principle, lead to taxes ending up too high from a collective perspective, rather than too low, as a result of ‘tax exporting’. Most obviously, countries with power in
the world market for some commodity may find it in their interest to explicitly tax those exports. Similar effects may also be at work in relation to corporate taxation: for example, to the extent that profits arising domestically accrue to foreigners, there is an incentive to tax them heavily (since the well-being of foreigners is presumably less valued than the welfare of domestic citizens).

But the main concern in this area has been with the potential for a ‘race to the bottom’ arising from the possibility that a cut in one country's tax rate will make other countries worse off – losing tax base and/or real economic activity. If each policymaker ignores these harmful cross-border effects, there is a risk of a ‘beggar thy neighbour’ situation in which tax rates end up generally too low in terms of the collective interest.

There are, though, two reasons why this may not pose as great a policy problem as it sounds. First, if policymakers are to some degree self-serving rather than wholly benevolent, then the constraints that tax competition imposes on them may on balance be beneficial for the citizenry. Second, even though governments do not cooperate explicitly, since the tax-setting game between them is played many times, they may find ways to tacitly sustain the cooperative outcome and so avoid inefficiencies.

Tax competition can affect many aspects of tax design, but the policy concerns it raises are naturally greatest where tax bases are most mobile. At an international level, this has meant a focus on the taxation of capital income and excises on such readily transportable and conventionally heavily taxed commodities as cigarettes and alcohol. For brevity, this article follows most of the literature (Wilson, 1999) in focusing on these two, and moreover focuses, within the former, on corporate taxation.

**Excise tax competition**

The international norm is that commodity taxes are levied on the ‘destination principle’, meaning that tax is charged according to the jurisdiction in which consumption occurs: French wine consumed in the United Kingdom, for example, is taxed at the United Kingdom rate. This leaves some room for strategic tax setting (a point developed by Friedlander and Vandendorpe, 1968): prohibited from levying an import tariff on a fellow member of the European Union, the United Kingdom, for example, might be tempted to set a relatively high excise on wine, domestic and imported, so as to dampen import demand and generate a terms of trade benefit or as a means of rent shifting. The scope for tax competition is greatly increased, however, where – as a consequence of legal shopping across borders by consumers and smuggling (for brevity, we refer to both as ‘cross-border shopping’) – the destination principle proves difficult to enforce, so that commodities are in effect taxed according to where they are produced: the ‘origin principle’.

With taxation on an origin basis – at least de facto, and to a potentially significant extent – countries have an incentive to set a relatively low tax rate in order to protect their tax base and perhaps gain base at the expense of others. And there are clearly instances in which cross-border shopping has been a significant influence in tax-setting. The classic example is the reduction in Canadian cigarette taxes in the early 1990s in response to widespread smuggling across the US border. Also, in the United Kingdom cross-border shopping with France has for many years been cited explicitly as constraining the rate applied to alcoholic drink. There is, it should be noted, a further complication with the excises. This is the risk that cigarettes will not even bear the tax charged by a low-tax country, but will simply be diverted to consumption without payment of any tax (Keen, 2002a).
Corporate tax competition

Competition in capital income taxation is potentially most powerful when the tax is levied on a ‘source’ or ‘territorial’ basis (that is, on the income derived in particular jurisdictions) rather than on a ‘residence’ basis (on the income that residents in country derive from their income around the world). This is because under a pure residence system the only way that individuals or companies can take advantage of lower tax rates offered in other countries is by changing their residence: simply by relocating their investments to low-tax jurisdictions, or transfer pricing profits into subsidiaries located there, they would not ultimately avoid the taxes in their country of residence.

In practice, capital income taxes often have a significant element of source taxation even when formally levied on a residence basis. Individuals may simply locate their savings in low-tax jurisdictions and fail to report the proceeds, being especially secure in this when the source country provides a measure of banking secrecy. At corporate level, exemption may be explicit, with outright exemption of corporation's earnings from abroad: this is the case, for example, in the Netherlands and (for countries with which it has a double tax treaty) Canada. Or it may be implicit: while many countries, including the United States and United Kingdom, in principle apply the residence principle, their taxes typically apply only when a multinational's subsidiary abroad pays dividends to the parent, so that those taxes can be deferred (and hence reduced in present value) by delaying repatriation. This brings the system closer to one of de facto source taxation.

Countries that apply the residence principle find it is coming under increasing pressure, particularly for individuals but also for corporations. One sign of this has been the emergence of corporate inversions in the United States and elsewhere, with companies shifting their residence to low-tax jurisdictions. Another is the increased emphasis on controlled foreign corporation (CFC) rules, under which profits of subsidiaries earned abroad, typically in low-tax jurisdictions, may be brought into tax even if not repatriated to the parent.

Importantly, the impact of the corporate tax on business decisions depends on more than just the rate of the tax: it depends on what allowances are available for depreciation, financial costs and other expenses. The question then arises as to precisely which aspects of the corporate tax countries might compete over. There are three candidate tax rates.

First, attention has naturally focused on the headline statutory rate of corporation tax. This is especially relevant to firms’ decisions regarding income shifting, meaning essentially the use of devices other than real investment – transfer pricing, financial arrangements and so on – to shift taxable receipts from countries in which the statutory rate is high to those in which it is low, and deductible expenses in the opposite direction. Statutory rates have fallen substantially since the 1980s. In the Organisation for Economic Co-operation and Development (OECD) countries, the top rate of corporation tax fell from 41 per cent in 1986 to around 27 per cent in 2007. And this reduction in statutory rates has not been confined to developed countries: in sub-Saharan Africa, for example, it fell, on average, by about ten points over the 1990s (Keen and Simone, 2004).

Second, decisions as to the level of investment in a given country depend on the marginal effective tax rate (METR), which is a summary measure of the combined impact of the statutory rate and the allowances available on the return that a firm must earn in order to provide investors with the after-tax return they require. This is an indicator of the effect of the tax system on the incentive to invest at the
margin. If the METR is zero, for example, then the tax system has no impact on the marginal decision to invest even though it may collect revenue by taxing the return infra-marginal investments. Strikingly, for the OECD countries the METR has remained broadly stable over the 1990s (Devereux, Griffith and Klemm, 2002) – which indicates that the reduction in statutory rates has been offset to some degree by a broadening of the corporate tax base.

Third, the choice as to the country in which to locate a given discrete investment (a factory, for example) depends on a comparison of the average effective marginal tax rate (AETR) in each, this quantity reflecting the present value of taxes to be paid – including on infra-marginal profits – over the life of the project. In practice, the AETR often tracks the statutory tax rate quite closely (Devereux and Griffith, 2003), so that it too has fallen substantially over the 1980s.

The overall picture thus suggests that the developed countries have been competing aggressively over the statutory rate of corporation tax, consistent with a desire to benefit from (or prevent) income shifting, but have broadened the tax base sufficiently to leave overall incentives to real investment broadly unchanged.

In what sense is this tax competition?

It could be that these trends simply reflect common developments in a range of countries rather than direct interaction between them – perhaps a common desire to improve incentives by reducing top rates of personal income tax, with the reduction in the corporate tax an adjunct to this, driven by the need to prevent disincorporation. Or – consistent with the basic notion of tax competition above – it could be a form of ‘yardstick competition’, with governments perceiving that their electorates assess them in part by comparing them with neighbouring countries, and so use the tax system to signal a supportive attitude to business or wider competence in economic management. Distinguishing empirically between these two hypotheses – correlation due to competition for tax base or real investment, versus correlation due to common shocks or yardstick competition – is not easy. Brueckner (2003) provides a review of the empirical literature in this area. In the international context, the emerging empirical evidence does seem to suggest that tax competition in pursuit of tax base or investment is important: Devereux, Lockwood and Redondo (2003), for example, find that the correlation between corporate tax rates became greater as capital controls became weaker, which would not be the case if the correlation were due to common domestic shocks. More anecdotally, one recent sign of tax competition closer to yardstick form than to competition for mobile base may be the spread, in the last few years, of ‘flat tax’ systems characterized by low tax rates on personal income: while one can see an argument for a low corporate tax rate to attract mobile capital, it is hard to see a similar base gain from setting the tax rate on labour income at the same, low rate.

This account of developments in the various corporate tax rates suggests that the pattern of any corporate tax competition has been quite complex. Why is it that countries have apparently competed over the tax rate but not over the base? One possibility is that this enables them to attract the more mobile and profitable investments without overly jeopardizing revenue from the less mobile corporate tax base. But there is no direct evidence for this, so the pattern of competition remains something of a puzzle.
There has been much talk of tax competition leading to the erosion – perhaps the elimination – of revenue from the corporate tax, and from capital income taxes more generally. For the developed countries as a group, however, this has not happened. Indeed, for them corporate tax revenues since the 1990s have if anything increased. In the EU15, for example, corporate tax revenues rose from 2.5 per cent of GDP in 1990 to 3.2 per cent in 2004. Country experiences vary, however. In Japan, corporate tax revenue has decreased over the same period from 6.5 to 3.8 per cent of GDP, and in Germany from 2.3 to 0.6 per cent. While these revenue figures need to be interpreted with great caution, there is no sign (as of 2007) of a collapse.

Quite why revenue has held up in the developed countries is not fully understood. Base-broadening measures have in many cases been adopted alongside the reduction in statutory rates, as seen above, but it is not clear that these have been sufficient to provide a full explanation. For the United Kingdom, there is evidence (Devereux and Klemm, 2005) that while base-broadening played some role, the buoyancy of corporate tax revenues has reflected also growth of the corporate sector, especially the financial sector, that did not seem to be largely attributable to the tax itself. It may well be that in other countries too – though not, it seems, all – an increase in the share of profits in GDP is part of the reason. For the United States, Auerbach (2006) argues that the resilience of corporate tax revenue reflects increased volatility of profits: the asymmetric treatment of positive and negative profits (the former taxed, the latter attracting no rebate but only carry forward) implies that this would lead to an increase in expected tax revenues. It is by no means clear, of course, that any such trends – and, hence, the resilience of corporate tax revenues – can be expected to continue.

There is tentative but emerging evidence of quite a different story in developing countries. These, too, have seen a marked reduction in statutory rates of tax. But this has not been offset by an expansion of the base – revenues in relation to GDP appear to have been falling, by about one-fifth in the poorest of them since the 1990s. Given their pressing needs for revenue and greater reliance on corporate taxes – around 13 per cent of total revenues at the start of the 1990s, compared to about nine per cent for the high-income countries – it may be that corporate tax competition is a more pressing concern for developing countries than for developed.

Basic welfare concerns

The policy concern raised by tax competition is that the failure to coordinate – each jurisdiction attaching relatively little importance to the impact of its decisions on others – will lead to a worse outcome than could be obtained from some form of cooperation in tax-setting. The fear is that the revenue pressures which emerge will lead either to reduced government expenditure or reliance on other tax instruments, notably taxes and social contributions on labour income, that are more distortionary and/or less coherent with equity objectives. In the limit (and leaving aside location-specific rents, most classically from natural resources), the corporate tax, for instance, would be reduced to a benefit tax – that is, one which simply charges companies for the value of the services they receive. Competition for mobile capital may also distort the composition of public spending, as well as its level, with too much focus on public infrastructure complementary with capital and too little on public expenditure on items...
of benefit to consumers: too many airports, not enough libraries. The argument is developed by Keen and Marchand (1997), and there is emerging evidence to suggest it is of some real importance.

Winners and losers

This lack of coordination does not mean, however, that all countries will be worse off as a result of tax competition. The literature strongly suggests, in particular, that small countries are likely to set particularly low tax rates, and in doing so to be better off than they would be under schemes of cooperation that do not explicitly involve the large countries paying them transfers (Kanbur and Keen, 1993). This is because in setting low tax rates they have little to lose in terms of revenue from their domestic tax base but a lot to gain (both in revenue terms and, perhaps, for the scale and profitability of their financial sector) from attracting tax base initially located abroad. And of course many tax havens are indeed small jurisdictions.

Thus coordination is not necessarily Pareto-improving: inducing all countries to participate may require transfers to those who win from tax competition and/or the exercise or threat of some form of punishment for non-cooperation.

Tax competition may be good: ‘taming the beast’

Some see tax competition as a good thing, providing a market discipline that serves to limit the size of government, supplementing inadequate constitutional and electoral constraints. In this view, developed first by Buchanan and others taking the view of government as ‘Leviathan’, the inefficiencies from non-coordination reduce the welfare of the policymakers themselves but increase that of the citizenry. There is another more subtle argument to the effect that tax competition may be beneficial even when policymakers are wholly benevolent. This is because the possibility of capital flight to low-tax countries provides a way in which others can commit not to impose heavy ex post taxes on savings once they have been made (so overcoming a basic time consistency problem in taxing capital income): see Kehoe (1989).

Much of the policy debate on the desirability or otherwise of tax competition quickly becomes a sterile statement of ideology, with it being seen as either wholly bad or wholly good. But there is a strand of the literature that has sought to better understand the trade-off at issue, between improved efficiency of the tax system as a result of coordination and the possibility that some or all of the additional revenue this can be used to generate will be wasted. One model leads to a simple test: a coordinated increase in tax rates from the non-cooperative equilibrium increases the citizens’ welfare if and only if \( \lambda < \text{MDL}/(1 + \text{MDL}) \), where \( \lambda \) is the proportion of public expenditure that is wasted and \( \text{MDL} \) is the marginal deadweight loss from raising an additional euro of revenue (Edwards and Keen, 1996). This at least enables one to narrow down the scope of policy disagreement. Suppose, for example, it is agreed that the marginal deadweight loss from taxation is at least 15 cents per euro. Then all those who believe that government wastes no more than 13 cents per euro of its spending, at the margin, should agree that a small coordinated increase in the corporate tax rate would be beneficial. The key difficulty remains, however, of determining what proportion of spending is ‘wasted’ – or indeed what ‘waste’ means in this context, since different people may clearly take different views, for example, of the social value of
spending that is essentially redistribitional. Besley and Smart (2007) provide a more subtle analysis of these political economy issues in a model of electoral competition, in which candidates may be either Leviathans or benevolent. The results that emerge are more nuanced, but include, importantly, the observation that intensified tax competition is likely to be beneficial to the citizenry only if pure Leviathans are sufficiently rare: otherwise the electoral process offers them little respite from exploitation.

**Quantification**

There have been a few attempts to estimate the welfare costs of tax competition, using computable general equilibrium models. On the corporate tax side, Parry (2003) finds the loss to be relatively small: about three per cent of capital tax revenues, and even less when a modest degree of ‘Leviathanism’ is present. Sørensen (2004a) also finds relatively small gains: less than one per cent of GDP. On the excises, Keen (2002a) stresses the difficulty of inferring the extent of any problem from the extent of observed cross-border shopping: tax competition could be so fierce, for example, that this is zero in equilibrium and yet a welfare loss is suffered from the inefficiently low equilibrium tax rate. But illustrative calculations in this case also suggest a relatively modest welfare loss: rarely more than two per cent of tax revenue.

**Ensuring that all participating countries gain**

The first problem in coordinating taxes is to ensure that all participants gain. For the EU, this is explicit in the unanimity rules; in other contexts, it is implicit in the national sovereignty of potential participants. In principle, the inefficiency being addressed implies that all could gain from coordination if accompanied by compensating transfers to some participants. This means, more specifically, making payments to any countries that gain from tax competition. This appears unlikely in practice, because of the appearance of rewarding those who are gaining at the expense of others. It may be that the best way to deal with this is by combining coordination with other measures, perhaps not in the tax area, that tend to benefit the winners: this is the ‘Hicksian optimism’ that by adopting a series of reforms that are potentially Pareto-improving one will arrive at an actual Pareto improvement. The alternative is the exercise of threat.

**The ‘third country’ problem**

Coordination among a subset of countries may be undermined if other countries do not also participate, a point that has been explicit, for example, in the negotiations leading to the EU Savings Directive. This raises the same issues of compensation and cajoling just discussed. The third country problem does not mean that coordination among that subset alone would actually leave them worse off (Konrad and Schjelderup, 1999). Simulation exercises do though suggest that, when capital mobility is high, the welfare gains may be far smaller when only a subset of countries participate (Sørensen, 2004a).
Full harmonization

There are circumstances in which harmonization – a term that has come to mean complete uniformity not only of rates but also of bases (especially problematic for the corporate tax, but not a trivial issue for the excises either) – is collectively beneficial. Keen (1989), for example, shows that starting from a Nash equilibrium in the setting of destination-based commodity taxes, convergence to an appropriately weighted average of the initial tax rates is Pareto-improving. This result supposes, however, that taxes are used only for strategic reasons: by adding a revenue motive the conditions for Pareto gains become much stronger, as shown in Lockwood (1997). In practice, moreover, such full convergence is not only politically unlikely but is overly restrictive as a means of dealing with coordination failure. The search has been for looser measures of coordination.

A minimum tax rate

Minimum rates are in principle an attractive way of limiting any ‘race to the bottom’, leaving potentially considerable leeway for national discretion in tax-setting. Even those countries initially below the minimum, and so required to raise their tax rates, may benefit from the adoption of a minimum tax: this is because when they raise their rates, countries above the minimum will be less threatened by their low rates and so will tend to set higher rates than they otherwise would. This increase in the rates set by those above the minimum reduces the damage to those forced to raise their rates, and may even cause the latter to gain (Kanbur and Keen, 1993). In this way, imposing a minimum rate may be Pareto-improving.

All this assumes, however, that countries compete only over the statutory rate of tax. That may be a reasonable assumption in relation to excise taxation (for which the EU has indeed adopted minimum rates), since there is relatively little scope for game-playing on the base itself. For the corporate tax, however, the danger is that unless there is also agreement on a common base for the corporate tax, countries may instead compete by narrowing their tax bases, offering more generous allowances for investment, and so on. Tax competition would thus simply manifest itself in a different form.

Formula apportionment

This refers to a corporate tax system – of the kind operated by the states in the United States and the provinces of Canada – under which the profits earned by multi-jurisdictional enterprises are allocated across those jurisdictions by means of some formula intended to capture the extent of its activities in each, and each jurisdiction then taxes the profits allocated to it at whatever rate it chooses. The advantage of such a scheme is that it eliminates the incentive for multinationals to move profits between jurisdictions by transfer-pricing or financial arrangements, since these have no effect on aggregate profits and hence also no effect on the taxes charged in each jurisdiction. This in turn means that the jurisdictions have no incentive to set low tax rates in order to encourage such income-shifting. Companies will have an incentive to distort their activities across jurisdictions, however, in so far as this affects the weights by which their profits are allocated across jurisdictions. This makes it important, for example, that (in contrast to common practice in the United States) the capital stock should not enter the...
tax competition: The New Palgrave Dictionary of Economics

If it does, companies will have an incentive to invest in jurisdictions with a low tax rate; and there will be an incentive to offer low tax rates in order to attract such investment. Indeed, the net effect could be that tax competition is actually worse under formula apportionment than under separate accounting (Sørensen, 2004b): encouraging a firm to invest a little more in a country produces revenue proportional to the marginal return on that investment under separate accounting, but proportional to the firm's average profit under formula apportionment. Since average returns tend to exceed marginal, this makes it more tempting to attract capital by offering a low tax rate. The general difficulty here is that under formula apportionment the corporate tax becomes to some degree a tax on whatever is used to define the weights. Thus, similar but perhaps less problematic effects arise with using sales and some measure of employment in the weights, these being the other main candidates.

Ring-fenced corporate tax regimes: good or bad?

A recurrent theme in attempts to identify especially ‘harmful’ aspects of corporate tax competition is the idea that special schemes which are ‘ring-fenced’ in the sense of being restricted to particular investors or sectors are especially damaging. This may not be correct (Keen, 2002b; Janeba and Smart, 2003). Allowing countries to compete very aggressively over particularly mobile aspects of the corporate tax base while maintaining higher rates on the rest may lead to an outcome that is better for all concerned than one in which they are required to set the same tax rate on all parts of the base. The reason is simple: it may ultimately be less damaging for countries to compete very aggressively over a narrow base than to compete less aggressively over a wider one.

Codes of conduct

The attempt to prevent the spread of, and to roll back, particular practices by means of non-binding rules of the game has been a remarkable development in international taxation over recent years, with such a code of conduct being adopted in the EU and a similar approach being adopted as part of the OECD's harmful tax practice project. The question arises as to how much further such an approach can be pushed. For by focusing on special schemes and excluding general levels of corporate taxation – and even putting aside the possible reservation on ring-fencing just mentioned – the codes arguably miss the central issue: too low a general level of corporate taxation.

Information sharing: reinforcing destination and residence principles

A quite different strategy is to limit the scope for tax competition by seeking to strengthen the application of the destination and residence principles (for commodity and income taxes respectively). The former is difficult to do given the general trend towards seeking fewer border formalities rather than more, an effect amplified by the increased importance of international services that cannot be taxed as they cross the border. For the income tax, strengthening resident taxation would involve, in particular, limiting the scope for deferral of taxes by leaving earnings aboard, in turn entailing an extension and firmer enforcement of CFC rules.
Another key measure that has been the focus of much attention in recent years is the strengthening of international information exchange on tax matters. In relation to capital income, this is a key element of the EU savings directive (which requires member states to either provide information to others on the interest income earned by their residents or levy a withholding tax, most of the proceeds being transferred to the country of residence) and the OECD's harmful-tax project.

It may seem obvious that low-tax countries can only lose from sharing information, through a reduction in their tax base and associated activities. Bacchetta and Espinosa (1995), however, show that they may benefit from a strategic effect of such sharing: for the higher-tax countries will then be inclined to set higher rates than they otherwise would (prospective outflows being diminished by the prospect of discovery abroad), which also enables the low-tax country to raise its tax rate too. Building on this insight, Huizinga and Nielsen (2003) explore the choice between information sharing and the use of withholding taxes in a repeated game, while Keen and Ligthart (2006) show that, if the difference in country size (and hence non-cooperative tax rates) is large enough, then sharing some of the revenue raised as a result of shared information with the source country (contrary to standard practice) has an adverse impact on total revenue raised but provides a device for securing a Pareto gain. How powerful the strategic effects of information exchange are likely to be, and indeed how effective such measures are likely to be in a technical sense (given, not least, the absence of common taxpayer identification numbers across countries) remains to be seen.

**Tax competition in federations**

The discussion so far has been concerned with ‘horizontal’ tax competition, in the sense that the interaction has been between jurisdictions with their own distinct tax bases. In federal systems, however, different levels of government commonly share tax bases: this may be explicit – in the United States, for example, corporate income is taxed at both federal and state level – or implicit (the base of a federal income tax, for instance, would overlap substantially with that of a state sales tax). The latter gives rise to ‘vertical’ tax competition, which in itself might be expected to lead to taxes that are too high from the collective perspective: a lower-level government that increases its own tax rate is liable to take less than full account of the impact on federal revenues of the consequent contraction of the shared tax base.

Two aspects of vertical tax externalities have received particular attention. First, how does tax-setting at the two levels interact? Theory leaves this indeterminate: intuitively, the optimal tax rate set by a lower-level jurisdiction is likely to depend (inversely) on the elasticity of the base, the effect of a change in the federal tax rate is in principle typically unclear (see, for example, Keen, 1998). Empirically, Hayashi and Boadway (2001), for example, find that higher federal rates of corporate taxation in Canada are associated with lower provincial tax rates. Second, how does the interplay between horizontal and vertical externalities play out (with the former pointing in most models to tax rates being too low, and the latter to their being too high)? In a model of capital income tax competition, Keen and Kotsogiannis (2002) show that this turns on the relative magnitudes of the elasticities of the demand for capital (which shapes the aggressiveness of horizontal tax competition) and of the supply of savings (shaping the responsiveness of the shared tax base). In a model of excise taxation, capturing both directions of externality, Devereux, Lockwood and Redoano (2007) show that the balance between the two depends on the ease of cross-border arbitrage and the price elasticity of demand. Using data for the US states,
they also find evidence of significant vertical interactions in the setting of gasoline taxes, with the federal tax tending to be positively associated with state taxes.

Conclusion

The marked reduction in statutory corporate tax rates over the 1980s, which seems to be largely if perhaps not entirely attributable to international tax competition, has not been matched by a similar reduction in corporate tax revenues – at least in developed countries. Quite why remains something of a puzzle, and the possibility of more marked reductions in the future cannot be ruled out. The welfare significance of these developments also remains a matter of dispute, most fundamentally because the view that tax competition may provide a useful discipline on government has not been developed to a point at which it has firm empirical substance. The case for coordination thus remains uneasy, and is perhaps strongest in developing countries given both the more apparent impact on revenues and the clearer need there for stronger revenue mobilization. If coordination is sought, the key difficulty is to ensure that it takes a form from which all participants gain – in the absence of explicit transfers, this is not easy to assure, and may require packaging measures within some broader agreement. Recent policy initiatives have focused more on administrative measures than on substantive policy restrictions: it remains unclear how effectively these will deal with the underlying problems that motivate their use.

Tax compliance and tax evasion

Joel Slemrod

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Tax evasion is widespread, always has been, and probably always will be. Variations in duty and honesty can explain some of the across-individual and, perhaps, across-country heterogeneity of evasion. But the stark differences in compliance rates across taxable items that line up closely with detection rates suggest strongly that deterrence is a power factor in evasion decisions. Although the normative theory of taxation has been extended to tax system instruments such as the intensity of enforcement, the empirical knowledge for operationalizing these rules is sparse.

Keywords

civic virtue; deterrence; reciprocity; tax compliance; tax evasion; tax incidence

Article

No government can announce a tax system and then rely on taxpayers’ sense of duty to remit what is owed. Some dutiful people will undoubtedly pay what they owe, but many others will not. Over time the ranks of the dutiful will shrink, as they see how they are being taken advantage of by the others. Thus, paying taxes must be made a legal responsibility of citizens, with penalties attendant on noncompliance. But even in the face of those penalties, substantial tax evasion exists – and always has.

Determining the extent of evasion is not straightforward, for obvious reasons. Because tax evasion is both personally sensitive and potentially incriminating, self-reports are vulnerable to substantial underreporting. Moreover, the dividing line between illegal tax evasion and legal tax avoidance is blurry. Under US law, tax evasion refers to a case in which a person, through commission of fraud, unlawfully pays less tax than the law mandates. Tax evasion is a criminal offence under federal and state statutes, subjecting a person convicted to a prison sentence, a fine, or both. An overt act is necessary to give rise to the crime of income tax evasion; therefore, the government must show wilfulness and an affirmative act intended to mislead. Some tax understatement is, however, inadvertent error, due to ignorance of or confusion about the tax law (as is some overpayment of taxes). Although the theoretical
models of this issue generally refer to wilful understatement of tax liability, the empirical analyses
cannot precisely identify the taxpayers’ intent and therefore cannot precisely separate the wilful from the
inadvertent. Nor can they, in complicated areas of the tax law, precisely distinguish the illegal from the
legal.

The most careful and comprehensive estimates of the extent and nature of tax noncompliance anywhere
in the world have been made for the federal taxes that the US Internal Revenue Service (IRS). The IRS
comes up with its estimates by combining information from random intensive audits with information
obtained from ongoing enforcement activities and special studies about sources of income, such as tips
and cash earnings of informal suppliers like nannies and housepainters, that can be difficult to uncover
even in an intensive audit.

The latest tax gap estimate, released in February 2006 (IRS, 2006) but pertaining to the 2001 tax year,
estimated the overall gross tax gap estimate to be 345 billion dollars, which amounts to 16.3 per cent of
estimated actual (paid plus unpaid) tax liability. Of the 345 billion dollar estimate, the IRS expects to
recover 55 billion dollars, resulting in a ‘net tax gap’ – that is, the tax not collected – for tax year 2001
of 290 billion dollars, which is 13.7 per cent of the tax that should have been reported.

About two-thirds of all underreporting happens on the individual income tax; the corporation income tax
makes up slightly more than ten per cent and the payroll tax gap makes up about one-fifth of total
underreporting. For the individual income tax, understated income, as opposed to overstating of
exemptions, deductions, adjustments, and credits, accounts for over 80 per cent of underreporting.
Business income, rather than wages or investment income, accounts for about two-thirds of the
understated individual income. Taxpayers who were required to file an individual tax return, but did not,
accounted for slightly less than ten per cent of the gap.

There are wide variations in the rate of misreporting as a percentage of actual income by type of income
(or offset). Only one per cent of wages and salaries and four per cent of taxable interest and dividends
are underreported. In large part this is because wages and salaries, as well as interest and dividends,
must be reported to the IRS by those who pay them; in addition, wages and salaries are subject to
employer withholding. Self-employment business income is not subject to information reports or
withholding, and its estimated noncompliance rate is sharply higher. An estimated 57 per cent of non-
farm proprietor income is not reported – 68 billion dollars – which by itself accounts for more than a
third of the total estimated underreporting for the individual income tax. All in all, over half of
underreporting is attributable to the underreporting of business income, of which non-farm proprietor
income is the largest component.

All in all, there is substantial evidence that the extent of evasion for sole proprietor income is high
compared to such income sources as wages, salaries, interest and dividends, and may be more than half
of true income. Other components of taxable income for which information reports are nonexistent or of
limited value, such as other non-wage income and tax credits, also have relatively high estimated
misreporting rates. The IRS reports (IRS, 2006) that the net misreporting rate is 53.9, 8.5, and 4.5 per
cent for income types subject to ‘little or no,’ ‘some,’ and ‘substantial’ information reporting,
respectively, and is just 1.2 per cent for those amounts subject to both withholding and substantial
information reporting.

Little is known about how the level of noncompliance, and its proportion to actual income, varies by
income class. One study based on IRS audit data for 1988 suggested that higher-income people evade
less, in relation to the size of their true income, than those with lower incomes, but for a number of
tax compliance and tax evasion: The New Palgrave Dictionary of Economics

reasons this study is not conclusive. Other studies suggest that married filers, taxpayers younger than 65, and men have significantly higher average levels of noncompliance than others. Within any group defined by income, age, or other demographic category, there are some who evade, some who do not, and even some who overstate tax liability. It is not known to what extent this heterogeneity is explained by different ‘tastes’ for evasion or different opportunities to evade.

Noncompliance is also a factor with businesses, both in their role as withholding agents for taxes that are not statutorily levied on businesses, and also for taxes that are levied on businesses, such as the corporation income tax. Based largely on operational data, the IRS estimates that noncompliance with the corporation income tax in 2001 was 30 billion dollars, which corresponds to a noncompliance rate of 17 percent. Of this 30 billion dollars, noncompliance by corporations with over 10 million dollars in assets make up 25 billion. But the estimated noncompliance rate of the larger companies is lower, 14 per cent compared to 29 per cent for corporations with less than 10 million dollars of assets. Because these estimates are largely based on deficiencies proposed by the examination teams of operational audits, and because most big corporations are routinely audited, these tax gap estimates are subject to several caveats. Because of the complexity of the tax law, exactly what is actual tax liability – and therefore what is actual tax noncompliance – is often not clear. In any given audit, some noncompliance may be missed, and there will also be mistakes in characterizing as noncompliance what is legitimate tax planning. Knowing that the resolution of the ultimate tax liability is often a long process of negotiation, the tax liability according to the originally filed return, as well as the initial deficiency assessed by the examination team, may be partly a tactical ‘opening bid’ that is neither party's best estimate of the ‘true’ tax liability.

It is difficult to compare the magnitude and nature of tax evasion in the United States with other countries, in part because no other country has undertaken a broad-based analysis of tax evasion like that undertaken in the United States. Based on less extensive analysis, the Swedish Tax Agency has estimated the total gap as a percentage of taxes at eight per cent in 2000. Although no official estimate for the United Kingdom has been released, a government document has speculated that it is likely that the United Kingdom has a tax gap of a similar magnitude to that of Sweden and the United States. Many studies suggest that noncompliance rates in developing countries are considerably higher.

Economics models have tried to put these facts into a coherent model. The standard economics framework for considering an individual's choice of whether and how much to evade taxes is a deterrence model in which taxpayers make these decisions in the same way they would approach any risky decision or gamble – by maximizing expected utility – and are influenced by possible penalties no differently than any other contingent cost. Optimal tax evasion depends on the chance of getting caught and penalized, the size of the penalty for evasion, and the individual's degree of risk aversion.

Attempts to empirically verify the predictions of the deterrence model of tax evasion have focused on the effect on evasion of enforcement intensity and the level of tax rates, but have been plagued by the same measurement issues that arise in assessing the magnitude of tax noncompliance. Perhaps the most compelling empirical support for the deterrence model is the cross-sectional variation in noncompliance rates across types of income and deductions. Line item by line item, there is a clear negative correlation between the noncompliance rate and the presence of enforcement mechanisms such as information reporting and employer withholding. A striking example of the link from a lack of deterrence to tax compliance involves state use taxes, which are due on sales purchased from out-of-state vendors but consumed in the state of residence. These taxes are largely unenforceable (except perhaps for some
tax compliance and tax evasion: The New Palgrave Dictionary of Economics

expensive items like cars), and noncompliance rates are in the range of 90 per cent. The effect on noncompliance of the penalty for detected evasion, as distinct from the probability that a given act of noncompliance will be subject to punishment, has not been compellingly established empirically. Although the deterrence model has dominated the economics literature, some have argued that it predicts a compliance rate much lower than what we actually observe, and that factors such as duty and reciprocal altruism can explain this. Some have argued that many taxpayers comply with tax liabilities because of ‘civic virtue’, and that more punitive enforcement policies may crowd out such intrinsic motivation by making people feel that they pay taxes because they have to, rather than because they want to. Others argue that tax evasion decisions depend on perceptions of the fairness of the tax system or what the government uses tax revenues for. But such individual judgements can be complex; for example, expenditures on warfare might be tolerated in a patriotic period, but rejected during another period characterized by anti-militarism. These patterns suggest that a form of reciprocal altruism may be at work where taxpayer behaviour depends on the behaviour, motivations, and intentions not of any subset of particular individuals, but of the government itself. In support of this view, surveys show a positive relationship across countries between attitudes towards tax evasion and professed trust in government.

There is, however, no clear evidence that tax compliance behaviour can be easily manipulated by the government to lower the cost of raising resources. Appeals to patriotism to induce citizens to pay their taxes (and, often, buy war bonds) are common; the US Secretary of Treasury during the First World War, William Gibbs McAdoo, referred to these campaigns as ‘capitalizing patriotism’. That such campaigns are successful during ordinary (non-war) times in convincing taxpayers to forego the cost-benefit calculus and comply has not been compellingly demonstrated. Recent randomized field experiments in the state of Minnesota and in Switzerland have found no evidence that appeals to taxpayers’ consciences, stressing either the beneficial effects of tax-funded projects or conveying the message that most taxpayers were compliant, had a significant effect on compliance.

The difficulties of separating out whether people pay their taxes because they feel they ‘ought to’ or whether they fear the penalties attendant to not doing so is well illustrated by some evidence from a recent survey sponsored by the Internal Revenue Service (IRS Oversight Board, 2006). While 96 per cent of those surveyed in 2005 mostly or completely agreed that ‘It is every American’s civic duty to pay their fair share of taxes’, 62 per cent also said that ‘fear of an audit’ had a great deal or somewhat of an influence on whether they report and pay their taxes ‘honestly’.

Tax evasion has policy implications because it affects the distribution of the tax burden as well as the resource cost of raising taxes. Variations in compliance rates by income class can to some extent be offset by adjustments in the rate schedule, but it is practically impossible to offset variations within an income class, so that evasion creates horizontal inequity because equally well-off people end up with different tax burdens.

Tax evasion also imposes efficiency costs. The most obvious are the resources taxpayers expend to implement and camouflage noncompliance, and the resources the tax authority expends to address this. In addition, when the tax system is otherwise close to optimal it provides a socially inefficient incentive to engage in those activities for which it is relatively easy to evade taxes. For example, because the income from house painting can be done on a cash basis and is therefore harder to detect, this occupation is more attractive than otherwise. Although a supply of eager and cheap house painters undoubtedly is greeted warmly by prospective buyers of that service, the work of the extra people drawn to house
painting, or any activity that facilitates tax evasion, would have higher value in some alternative occupation.

The same argument applies to self-employment generally, as the enhanced opportunity for noncompliance inefficiently attracts people who would otherwise be employees. The opportunity for noncompliance can distort resource allocation in a variety of other ways, such as causing companies that otherwise would not find it attractive to set up a financial subsidiary, or set up operations in a tax haven, to facilitate or camouflage abusive avoidance or evasion.

The mere presence of tax evasion does not imply a failure of policy. Just as it is not optimal to station a police officer at each street corner to eliminate robbery and jaywalking, it is not optimal to completely eliminate tax evasion. Recognizing tax evasion introduces a new set of policy instruments whose optimal setting is at issue, such as the extent of audit coverage, the strategy for choosing audit targets, and the penalty imposed on detected evasion. It also invites a rethinking of standard taxation problems.

One important issue is how many resources to devote to enforcing the tax laws. One superficially intuitive rule – increase the probability of detection until the marginal increase of revenue thus generated equals the marginal resource cost of so doing – is incorrect. Although the cost of hiring more auditors, buying better computers and the like is a true resource cost, the revenue brought in does not represent a net gain to the economy, but rather a transfer from private (noncompliant) citizens to the government.

The correct rule equates the marginal social benefit of reduced evasion, which is not well measured by the increased revenue, to the marginal resource cost. The distinction suggests that unregulated privatization of tax enforcement, in which profit-maximizing firms would maximize revenue collection net of costs, would lead to socially inefficient overspending on enforcement. The social benefit is related to the reduced risk bearing that comes with reduced tax evasion and a reduction in the resource misallocations generated by evasion. Some have suggested that the basic framework of social welfare maximization is inappropriate, and have argued that there should be a specific social welfare discount applied to the utility of those who are found to be guilty of tax evasion and thus are known to be ‘antisocial’; the standard normative model applies no such discount, so that noncompliant taxpayers do not per se receive a lower social welfare weight than compliant taxpayers.

No one has yet compellingly translated this theoretical characterization of optimal enforcement into a statement about how much evasion should be tolerated. But its implication for interpretation of the tax gap is clear and was stated by former IRS Commissioner Lawrence Gibbs, who said that the tax gap estimates are not intended to be measures of the potential for additional enforcement yields because some would not be ‘cost-effective’ to collect. An economist would substitute the term ‘socially optimal’ for ‘cost-effective,’ but the spirit of Gibbs's remark is essentially correct. Just as there is an important difference between oil reserves and ‘economically recoverable’ oil reserves, there is a difference between tax evasion and economically (read optimally) recoverable tax evasion.

The normative theory has not yet made much progress in guiding policy regarding the key tools of tax administration, especially the role of information reporting by arms-length parties. The ability of the IRS to rely on reports by firms about wages and salaries paid to employees explains why the (optimal) noncompliance rate of labour income is so much lower than for self-employment income, for which no such information reports exist. The ability to match firm-to-firm sales is touted by advocates as a major administrative advantage of value-added taxes, and the difficulty of monitoring firm-to-consumer sales and to distinguish them from firm-to-firm sales has been noted as the Achilles heel of administering a retail sales tax. Overall, when relatively disinterested third parties can be required to provide
information, as they are with wages and salaries, high compliance rates can be achieved at fairly low cost. But when there are only interested parties involved, an alternative mechanism must be found – such as the requirement in an invoice-credit value added tax that taxes on input purchases can be deducted only if the seller produces an invoice for taxes remitted – or else compliance will be low in the absence of costly auditing.

The ubiquity and importance of evasion call into question one of the canons of undergraduate public finance textbooks – that the incidence and efficiency of taxes does not in the long run depend on which side of the market the tax is levied. Once the reality of tax evasion is recognized, the incidence and efficiency of a tax system may depend critically on which side of the market remits the tax to the government and which side must report its transactions to the government. A uniform value-added tax and a uniform national retail sales tax may look identical in a world of no evasion or administrative costs, but have very different effects in the real world.

Tax evasion is widespread, always has been, and probably always will be. Variations in duty and honesty can explain some of the across-individual and, perhaps, across-country heterogeneity of evasion. But the stark differences in compliance rates across taxable items that line up closely with detection rates suggest strongly that deterrence is a powerful factor in evasion decisions. Given the current state of theory and evidence on tax evasion, it is not clear in what way or how much enforcement might be most efficiently increased. Although the normative theory of taxation has been extended to tax system instruments such as the intensity of enforcement, the empirical knowledge for operationalizing these rules is sparse.

Labelling certain provisions in the tax law as tax expenditures has been criticized for lacking an ‘agreed conceptual model’ for distinguishing between integral tax rules and interpolations reflecting spending rather than tax policy. However, the tax expenditure concept can be reformulated as relying on a distinction between (a) the distributional goals that might underlie the use of a tax base such as income or consumption, and (b) allocative goals such as encouraging particular activities or investments. Tax expenditure estimates could be prepared using both measures, including negative tax expenditures (that is, tax penalties) as well as positive ones.

Article
The practice of labelling certain provisions in the tax law as ‘tax expenditures’ is widely attributed to Stanley Surrey, the longtime Harvard law professor and, from 1961 to 1969, Assistant Secretary of the Treasury for Tax Policy in the United States. Surrey introduced the term in a 1967 speech, in which he urged official measurement of the revenue cost of all tax expenditures, which he defined as ‘special’ benefits in the income tax law. Surrey argued that publication of a tax expenditure budget would encourage and facilitate treating special tax rules on a par with similarly motivated direct spending rules. This proposal had earlier antecedents, having been part of the federal budgetary process in Germany since at least 1959. In the United States, however, it proved more controversial, reflecting Surrey's use of it as a tool, not just of budgetary policy, but also in tax policy debate, where he was well-known as an advocate of progressive, comprehensive income taxation. In keeping with his tax policy views, Surrey, after leaving the Treasury, pressed the argument that tax expenditures should generally be eliminated from the US income tax, with any that served meritorious social goals being replaced by direct...
appropriations. Surrey's advocacy may have encouraged some with different tax policy views to regard the tax expenditure budget as special pleading for his views, merely masquerading as anodyne budgetary reporting.

Concern that the tax expenditure budget unduly served Surrey's particular views became more widespread with the rise in tax policy circles, beginning in the 1970s, of support for replacing the US federal income tax with a consumption tax. Various tax expenditures from an income tax standpoint, such as the exclusion of interest from bonds issued by state or local governments, are correct from a consumption tax standpoint. If 'tax expenditures' should be eliminated presumptively, then using a normatively controversial income tax standpoint to define them could be viewed as unduly aiding those who favour moving the current 'hybrid' US system closer to the income tax pole rather than to the consumption tax pole.

In the face of these criticisms, Surrey arguably won the battle concerning tax expenditure analysis, but lost the war. The Congressional Budget and Impoundment Control Act of 1974 made tax expenditure estimates mandatory both in the President's annual budget and in certain reports by Congressional committees. These estimates generally are static, measuring the level of utilization of a given provision, rather than how much revenue would be raised by repealing it. The tax expenditure concept has remained intellectually controversial, however. Moreover, it has not noticeably discouraged the use of 'special' tax benefits, other than perhaps temporarily if it helped to inspire the landmark Tax Reform Act of 1986.

What is a tax expenditure?

In official US estimates, tax expenditures are defined as pro-taxpayer departures from a 'normal' income tax base. This is not uncommon, although practices vary around the world. The normal income tax base has a number of features that depart from theoretically pure Haig–Simons income taxation. For example, it features a realization requirement under which unrealized gains and losses have no immediate tax consequences, includes double taxation of corporate income, and makes no adjustments for inflation. It also treats as tax expenditures some items whose preferentiality is controversial – for example, the itemized deductions for medical expenses and for state and local income taxes paid.

Criticism of tax expenditure analysis has focused both on what some view as the arbitrariness of the normal income tax base in any of its currently used variants, and on the lack of any 'agreed conceptual model' (Bittker, 1969, p. 258) for identifying special tax benefits. Such a model is needed to support the view that a particular provision, although located in the tax code, is actually a spending rule. A deeper problem is that 'taxes' and 'spending' cannot meaningfully be distinguished, even though the former involves cash flow to the government while the latter involves cash flow from the government. By way of illustration, consider US federal income taxation of Social Security benefits, which was introduced during the Reagan administration and increased during the Clinton administration. While both administrations classified the changes as benefit cuts, Republican critics of the Clinton proposal argued that it was a tax increase. Arguably, these critics were formally correct, in that the reduction in net benefits was accomplished via income tax payments. However, if exactly the same reduction in net benefits had been accomplished by reducing gross benefits (that is, the amounts paid out by the Social Security administration), it evidently would have been a 'spending cut'. Tax expenditure analysis requires discerning a substance to distinction between taxes and spending that does not depend in this
way on form, or else by definition everything in the tax code would be a tax rule. Still, the intuition underlying tax expenditure analysis is hard to dismiss. Suppose, for example, that the US Congress decided to replace $1 billion of military spending with a $1 billion tax credit, offered to the same taxpayers who would have received the direct appropriation in exchange for the same goods or services. Nominally, this switch would lower both ‘taxes’ and ‘spending’ by $1 billion. In substance, however, little would have changed. Tax expenditure analysis would treat the credit as ‘spending’ through the tax code, thus preventing the change in form from being misperceived as a change in substance.

Distribution and allocation

The distinction that tax expenditure analysis draws between tax and spending rules can be restated in terms of Richard Musgrave’s (1959, p. 5) conceptual division between the public sector’s distribution and allocation functions. Apportioning the burden of paying for government through a measure of ability to pay, such as income or consumption, is conceptually a distributional enterprise. Thus, a rule within the income tax law, such as the hypothetical military suppliers’ credit, that appears to serve primarily allocative purposes (furnishing goods and services for military use) can logically be viewed as extraneous to the distribution function, even if its placement in the tax code is desirable (for example, on administrative grounds). The same reasoning applies in reverse if a set of tax rules serving primarily allocative purposes includes provisions that appear to serve primarily distributional aims. Thus, suppose a Pigouvian pollution tax offered rebates to low-income polluters. One could extend this reasoning to cover clearly distinguishable allocative or distributional functions as well – for example, the inclusion of education subsidies, such as lower tax rates for pollution by schools, in a Pigouvian pollution tax. In each of these cases, the extraneous provision could be termed a tax expenditure, albeit without any necessary implication that it should be eliminated or moved. The reason for this linguistic exercise might be to increase public understanding of the provision at issue, and in particular to prevent ‘tax cuts’ from being distinguished from ‘spending increases’ on purely formal grounds where their substance is identical.

While this restatement of the distinction that Surrey attempted to draw between taxes and spending can go a long way to rationalize tax expenditure analysis, it does not support all aspects of current practice. For example, in the USA child tax credits are classified as tax expenditures, but personal exemptions (deductions for dependents, including children) are not. Yet the two provisions have similar effects, and both could be viewed as relating to a distributional goal of having tax burdens depend on family size. Thus, neither the distinction between them nor the treatment of either as a tax expenditure is highly robust.

Income tax base versus consumption tax base

The distinction between distribution and allocation functions does not address the issue of how to handle distinctions between the income and consumption tax bases, as illustrated by the question of whether the US exclusion for state and local government bond interest is a tax expenditure. Here the answer would depend on whether the distribution branch was assumed to follow income or consumption tax norms.
Under the latter norm, the anomalous result would be taxing other interest income, rather than exempting municipal bond interest. From either distributional perspective, however, the distinction in the tax treatment for interest depending on who paid it is likely to seem anomalous, even if desirable for allocative reasons. One possible solution discussed in recent US government budgets is to prepare alternative tax expenditure listings, one from an income tax baseline and the other from a consumption tax baseline.

Administrative departures from a pure income tax or consumption tax

One reason for the practice of computing tax expenditures relative to a ‘normal’ income tax base, rather than Haig–Simons income, is the notion that the provisions being analysed are substitutes for direct spending. Thus, if the main reason for not taxing unrealized asset appreciation is administrative, the legislature is unlikely to be choosing between alternative implementations of the resulting allocative policy. However, if administrative considerations limit the departures from a given theoretical base that are treated as tax expenditures, a system with those departures may easily be confused with one that actually implemented the theoretical ideal. One possible response to this dilemma is to create a separate category in tax expenditure analysis for departures from a given theoretical base that appear to be primarily administratively motivated (Shaviro, 2004, p. 218).

Negative tax expenditures (tax penalties)

Under current practice, tax expenditure analysis is limited to measuring the static revenue effect of departures from a given baseline that favour the taxpayer. Departures that disfavour a taxpayer are ignored, rather than being treated as negative tax expenditures or tax penalties. However, the rationale for measuring departures in one direction arguably should apply symmetrically. An example of an unmeasured tax penalty in the current US income tax is the disallowance of business expense deductions for bribes. However socially desirable the disallowance rule may be, it reflects a departure from simply measuring net income in cases where the bribe was economically motivated. The practical importance of measuring tax penalties would increase if income tax rules were being analysed from a consumption tax as well as an income tax baseline, since this would cause a variety of common income tax features, such as taxing particular kinds of interest income, to constitute tax penalties.

Tax havens are low-tax jurisdictions that offer businesses and individuals opportunities for tax avoidance. The 45 major tax haven countries in the world today are small, affluent, and generally well governed. They attract disproportionate shares of world foreign direct investment, and, largely as a consequence, their economies have grown much more rapidly than the world as a whole since the 1980s. The effect of tax havens on economic welfare in high-tax countries is unclear, though the availability of tax havens appears to stimulate economic activity in nearby high-tax countries.

**Article**

Tax havens are low-tax jurisdictions that offer businesses and individuals opportunities for tax avoidance. There are roughly 45 major tax havens in the world today. Examples include Andorra, Ireland, Luxembourg and Monaco in Europe, Hong Kong and Singapore in Asia, and the Cayman Islands, the Netherlands Antilles, and Panama in the Americas. These tax havens are generally small and affluent, in total comprising just 0.8 per cent of world population, though accounting for 2.3 per cent of world income (Hines, 2005). Low-tax jurisdictions are also common within countries, at various times taking the form of special economic zones in China, offshore possessions and local enterprise zones in the United States, and tax-favoured regions including eastern Germany, southern Italy, eastern Canada, and others. Tax havens are widely used by international investors; in 1999, 59 per cent of US multinational firms with significant foreign operations had affiliates in one or more tax havens (Desai, Foley and Hines, 2006b).
Countries offer low tax rates in the belief that, by doing so, they attract greater investment and economic activity than would otherwise have been forthcoming. Countries with low tax rates permit investors to retain most of their locally earned pre-tax income; other considerations equal, therefore, countries with lower tax rates should be expected to offer a broader range of attractive opportunities, and therefore draw larger volumes of foreign investment, than countries with higher tax rates.

The possibility of using tax havens to facilitate avoidance of taxes that would otherwise be owed to governments of other countries adds to the attractiveness of tax haven investments. For individuals, who are taxed by their home governments on income earned in tax havens, tax avoidance typically entails wilful income misreporting. For businesses, tax avoidance can be accomplished by the use of financial arrangements, such as intrafirm lending, that locate taxable income in low-tax jurisdictions and tax deductions in high-tax jurisdictions. In addition, firms are often able to adjust the prices at which affiliates located in different countries sell goods and services to each other. Most governments require that firms use arm's-length prices, those that would be used by unrelated parties transacting at arm's length, for transactions between related parties, in principle thereby limiting the scope of tax-motivated transfer price adjustments. In practice, however, the indeterminacy of appropriate arm's length prices for many goods and services, particularly those that are intangible, or for which comparable unrelated transactions are difficult to find, leaves room for considerable discretion. As a result, transactions with tax haven affiliates can be used to reallocate income from high-tax locations to the tax haven affiliates themselves or else to other low-tax foreign locations. This, in turn, increases the appeal of locating investment in foreign tax havens.

As a result of these incentives, American firms exhibit unusual activity levels and income production in foreign tax havens (Hines, 2005). Of the property, plant and equipment held abroad by American firms in 1999, 8.4 per cent was located in tax havens, considerably more than would be predicted strictly on the basis of the sizes of tax haven economies. Employment abroad by American firms was likewise unusually concentrated in foreign tax havens, with 6.1 of total foreign employee compensation, and 5.7 per cent of total foreign employment, located in tax haven affiliates. American firms located 15.7 per cent of their gross foreign assets in the major tax havens in 1999; the major foreign tax havens accounted for 13.4 per cent of their total foreign sales, and a staggering 30 per cent of total foreign income in 1999. Much reported tax haven income consists of financial flows from other foreign affiliates that parent companies owned indirectly through their tax haven affiliates.

Tax haven countries have enjoyed very rapid economic growth rates that coincide with dramatic inflows of foreign investment. Tax havens averaged 3.3 per cent annual per capita real GDP growth from 1982 to 1999, whereas the world averaged just 1.4 per cent annual real per capita GDP growth over the same period. Controlling for country size, initial wealth, and other observable variables, does not change the conclusion that the period of globalization has been favourable for the economies of countries with very low tax rates (Hines, 2005).

The policy of offering foreigners very low tax rates is potentially costly to tax haven governments, if doing so reduces tax collections that might otherwise have been used to fund worthwhile government expenditures. It is far from clear, however, that tax haven countries face significant trade-offs of this nature. Governments have at their disposal many tax instruments, including personal income taxes, property taxes, consumption or sales taxes, excise taxes, and others, that can be used to finance
expenditures. Furthermore, even very low rates of direct taxation of business investment may yield significant tax revenues if economic activity expands in response. In fact, the public sectors of tax haven countries are of comparable sizes to those of other countries, though there is evidence that they may be somewhat smaller than would have been predicted on the basis of their populations and affluence alone (Hines, 2005).

Characteristics of tax havens

Tax havens are small countries, commonly below one million in population, and are generally more affluent than other countries. In addition, tax havens score very well on cross-country measures of governance quality that include measures of voice and accountability, political stability, government effectiveness, rule of law, and control of corruption. Indeed, there are almost no poorly governed tax havens. Poorly governed countries, of which the world has many, almost never become tax havens (Dharmapala and Hines, 2006).

An important reason why better-governed countries are more likely than others to become tax havens is that the potential returns are greater: higher foreign investment flows, and the economic benefits that accompany them, are more likely to accompany tax reductions in well-governed countries than they are tax reductions in poorly governed countries. Evidence from the behaviour of American firms is consistent with this explanation, in that tax rate differences among well-governed countries are associated with much larger effects on US investment levels than are tax rate differences among poorly governed countries (Dharmapala and Hines, 2006).

Impact on other countries

Tax havens are viewed with alarm in parts of the high-tax world, where there are concerns that the availability of foreign tax haven locations may divert economic activity from countries with higher tax rates, and erode their tax bases. Alternatively, tax havens could encourage investment in other countries, if the ability to relocate taxable income into tax havens improves the desirability of investing in high-tax locations, or if low tax rates reduce the cost of goods and services that are inputs to production or sales in high-tax countries. In fact, the evidence indicates that foreign tax haven activity appears to stimulate activity in nearby high-tax countries, a one per cent greater likelihood of establishing a tax haven affiliate being associated with two-thirds of a per cent greater investment and sales in nearby non-haven countries (Desai, Foley and Hines, 2006a).

The empirical regularity that tax havens stimulate economic activity in high-tax countries does not resolve the impact of tax havens on the welfare of high-tax countries. Tax avoidance carries mixed implications for governments of nearby countries, since it may erode tax bases and therefore tax collections, implying that the greater economic activity associated with nearby tax havens might come at a high cost in terms of forgone government revenues. One possibility is that countries would prefer to subject mobile international companies to lower tax rates than they do other firms, but are prevented from doing so by political considerations or the practical difficulty of distinguishing multinational from domestic firms. In such a setting, countries might benefit from permitting multinational firms to obtain tax reductions by using affiliates in tax havens, thereby implicitly subjecting these mobile firms to lower
tax havens: The New Palgrave Dictionary of Economics

tax burdens than other taxpayers. In 1998, the Organization for Economic Co-operation and Development (OECD) introduced its Harmful Tax Practices initiative, the purpose of which was to discourage OECD member countries and certain tax havens from pursuing policies that were thought to harm other countries by unfairly eroding tax bases. As part of this initiative, the OECD produced a List of Un-Cooperative Tax Havens, identifying countries that have not committed to sufficient exchange of information with tax authorities in other countries. The concern was that the absence of information exchange might impede the ability of OECD and other countries to tax their resident individuals and corporations on income or assets hidden in foreign tax havens. As a result of the OECD initiative, along with diplomatic and other actions of individual nations, many countries and jurisdictions outside the OECD have committed to improve the transparency of their tax systems and to facilitate information exchange. While there remain a few tax havens that have not made such commitments, the vast majority of the world's tax havens rely on low tax rates and other favourable tax provisions to attract investment, rather than using the prospect of local transactions that will not be reported.

**tax incidence**

Gilbert E. Metcalf  
Edited by Steven N. Durlauf and Lawrence E. Blume

**Abstract**

Tax incidence is the study of who bears the burden of a tax. It distinguishes between statutory incidence (the legal requirement to remit a tax) and economic incidence (the change in real income or wealth resulting from a tax). Considerable advances have been made since the mid-1980s in our understanding of the burden of taxes in imperfectly competitive models as well as in intertemporal models. In particular, analysing lifetime tax burdens can give markedly different results for many taxes. Increases in computing power and the availability of large-scale data-sets have also enriched our understanding of tax incidence.

**Article**

Tax incidence is the study of who bears the economic burden of a tax. Broadly put, it is the positive analysis of the impact of taxes on the distribution of welfare within a society. It begins with the very basic insight that the person who has the legal obligation to pay a tax may not be the person whose welfare is reduced by the tax. The statutory incidence of a tax refers to the distribution of tax payments based on the legal obligation to remit taxes to the government. Thus, for example, the statutory burden of the payroll tax in the United States is shared equally between employers and employees. Economists, quite rightly, focus on the economic incidence, which measures the changes in economic welfare in society arising from a tax. The standard view of the economic burden of the payroll tax in the United States is that it is borne entirely by employees. Economic incidence differs from statutory incidence because of changes in behaviour and consequent
changes in equilibrium prices. Consumers buy less of a taxed product, so firms produce less and buy fewer inputs – which changes the net price of each input. Thus the job of the incidence analyst is to determine how those other prices change, and how those changes affect different kinds of individuals.

The distributional impact of a tax (or system of taxes) depends in part on how the question is framed. An absolute incidence analysis considers the burden of a change in taxes without regard to the use of proceeds. A differential incidence analysis carries out a revenue-neutral change in tax by raising one tax while lowering another. Typically, a lump-sum tax is changed to effect revenue neutrality. A balanced budget incidence analysis considers the burden of a change in taxes along with an equivalent change in spending. In his classic analysis of the US tax system, Pechman (1985) carried out a differential incidence analysis and concluded that the total system of taxes in the United States was broadly proportional. Taking into account government transfers financed by taxes, on the other hand, Browning and Johnson (1979) argued that the US tax system was progressive.

In addition to framing the incidence question precisely, incidence results can depend on the time frame for analysis. Pechman's analysis ranks households by their annual income. It is well known that annual income can be a poor proxy for measuring the well-being and consumption potential of a household, because of measurement error and lifetime income considerations. Lifetime income considerations are particularly important for assessing the distributional implications of a consumption tax, since consumption to annual income ratios are very high in the lowest annual-income deciles. Fullerton and Rogers (1993) replicate the Pechman analysis using a lifetime income framework, and conclude that the overall incidence of the US tax system is similar to that obtained in Pechman's annual income framework, though the forces driving incidence results differ somewhat.

In a perfectly competitive partial equilibrium framework, the economic incidence of a tax is unaffected by which side of the market the tax is levied on. Thus the statutory requirement to share the payroll tax in the United States equally between employer and employee has no bearing on the ultimate incidence of the tax. Second, the economic burden of a tax is borne more heavily by the side of the market that is less elastic (in absolute value). Thus, the share of the payroll tax borne by the employee is, to a first-order approximation, equal to $\frac{\varepsilon_D}{(\varepsilon_S + \varepsilon_D)}$ where $\varepsilon_S$ ($\varepsilon_D$) is the labour supply (demand) elasticity.

This burden share formula suggests that no more than 100 per cent of the tax can be shifted to a party. In an imperfectly competitive market, commodity tax overshifting can occur (in the sense that the consumer price rises by more than the tax rate). Moreover, ad valorem and excise taxes, which have equivalent burden impacts in a competitive market when set to collect the same revenue, now can have different burden impacts. Delipalla and Keen (1992) show that in markets with oligopoly supply ad valorem taxes are less likely to lead to overshifting than excise taxes. Once one allows for imperfect competition, many counter-intuitive results can obtain, including a commodity tax reducing the consumer price (for example, Cremer and Thisse, 1994). Fullerton and Metcalf (2002) develop the analysis of tax incidence under imperfect competition further and provide some hypothetical results.

Harberger (1962) is the progenitor of the modern field of general equilibrium incidence analysis. In addition to providing a framework for analysing the corporate income tax, Harberger's approach can be used to analyse a wide array of taxes. He models the corporate income tax as a partial factor tax, that is, a tax on the use of one factor in one sector. The tax thus affects relative factor prices and relative output prices. Harberger concludes that capital is likely to bear approximately the full burden of the corporate income tax. Capital mobility means that the burden is on all capital, not just corporate capital.
Harberger's analysis assumed a closed economy. In a small open economy with international capital mobility, corporate tax drives capital abroad so that domestic savers earn the same net return as before the tax is imposed. This drives down the domestic capital stock, and thus the domestic wage rate, and the burden of the tax falls on labour (as an immobile factor). While the immobile local factor bears a burden from the tax, Bradford (1978) shows that worldwide capital in the aggregate suffers a loss exactly offset by gains to immobile factors in the rest of the world, resulting from the outflow of capital from the country imposing the tax. In contrast, Gravelle and Smetters (2001) argue that imperfect substitutability of domestic and foreign products can limit or even eliminate the incidence borne by labour, even in an open economy model. They find that the tax is borne by domestic capital, as in the original Harberger model.

While Harberger's analysis (and subsequent work) showed the importance of general equilibrium effects, it lacked a fully dynamic characterization of savings and investment, channels through which important burden shifting could occur. Feldstein (1974), for example, argues that much (if not all) of the burden of a tax on capital income is shifted to workers in the form of lower wages as a result of decreased investment reducing the capital–labour ratio.

Once investment is considered, the incidence of a tax in a dynamic model can also be affected by the distinction between old and new capital. Old capital is capital in place prior to a tax change. For example, Auerbach and Kotlikoff (1987) show that a consumption tax and a wage tax – two approaches to exempting capital income from taxation – differ only in their tax treatment of old capital. In the absence of transition rules, the former subjects old capital to a lump-sum tax, while the latter does not. In addition to distributional implications, the presence of old capital complicates the attribution of economic incidence. Consider a new property tax that has been in place for many years in a community. Carrying out an incidence analysis today, we might allocate the burden of the tax to current owners based on their property values. This approach would be consistent with the ‘old’ view of property taxation (see Fullerton and Metcalf, 2002, for more on the incidence of the property tax). But with capitalization effects the tax burden should properly be allocated to the property tax owners at the time of the enactment of the tax: more precisely, it would be allocated to the owners at the time that potential buyers and sellers of property in the community become aware that the tax would be enacted. Without offsetting benefits from the property tax revenues, potential homeowners will be willing to pay less for housing. In equilibrium, housing values would fall by the present discounted value of the stream of future tax payments at the time of enactment, and the owners at that time would bear the entire burden of the tax.

To return to the corporate income tax, an increase in the tax rate generates lump-sum taxes on previously installed capital through capitalization effects. As Auerbach (2005) emphasizes, the tax treatment of corporate capital is sufficiently complicated to ensure that assigning its burden is a hazardous exercise, but both in the short and the long run it is probably the case that some portion of the tax falls specifically on shareholders due to the tax on old capital, among other factors.

Careful tax incidence analysis is essential to understanding the distributional implications of a country’s tax system. The field of incidence analysis has progressed dramatically since the mid-1980s, as new research has yielded fresh insights into the burden of taxes in imperfectly competitive models and in intertemporal models. The increase in computing power and the availability of large-scale data-sets have also enriched our understanding of tax incidence. Despite all the advances that have occurred, the topic
of tax incidence will probably continue to be an area of productive research, yielding further insights in the years to come.

tax shelters

David A. Weisbach
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Tax shelters take advantage of unintentional gaps in the tax base often caused by subtle mismatches in complex tax rules. The optimal line between allowable tax planning and illegitimate tax shelters depends on the cost of closing these gaps compared with the revenue raised, relative to the efficiency costs of other sources of funds. The definition of illegitimate tax shelters, therefore, depends on parameters such as the tax base and rate structure as well as the expected taxpayer response to different possible definitions.

Keywords

elasticity of taxable income; tax avoidance; tax base; tax compliance; tax evasion; tax rules; tax shelters

Article

The term ‘tax shelters’ generally refers to any tax reducing activity other than outright evasion or traditionally modelled responses to taxation, such as changes in labour supply or savings. The term sometimes includes investing in explicitly tax-favoured assets such as homes, life insurance or tax exempt bonds. At other times, however, the term is used to mean only tax-reducing activities inconsistent with the intent of the tax law, in which case it may not include these activities. The concept is closely related to, but usually thought to be narrower than, the notion of tax avoidance.

To define the term more precisely has proven to be impossible. The US Treasury Department (1999) observed that tax shelters come in the ‘guises of Proteus’ and argued that no single definition was appropriate. The tax law itself defines shelters for purposes of certain penalties as a plan or arrangement, a significant purpose of which is the avoidance or evasion of federal income tax, a definition sufficiently broad as to be almost meaningless. Rather than attempt to define shelters, Treasury (1999) has listed factors common to many shelter transactions, including (1) lack of economic substance; (2) inconsistent financial and accounting treatment; (3) presence of tax-indifferent parties; (4) complexity; (5) unnecessary steps or novel investments; (6) promotion or marketing; (7) confidentiality; (8) high
tax shelters: The New Palgrave Dictionary of Economics

transaction costs; and (9) risk reduction arrangements. The Joint Committee on Taxation (1999) took a similar approach, recommending the use of tax shelter indicators or factors for purposes of triggering enhanced disclosure requirements or penalties. Other investigations have defined tax shelters as complex transactions, marketed by sophisticated professionals, used by corporations or wealthy individuals to obtain significant tax benefits in a manner never intended by the tax law (Levin, 2003; GAO, 2003). Perhaps the most pithy definition, by Michael Graetz, is that a tax shelter is ‘a deal done by very smart people that absent tax considerations, would be very stupid’ (Herman, 1999).

The definition of tax shelters matters for two related reasons. First, it points to behavioural responses to taxation that are left out of the usual analysis of labour/leisure or investment distortions and that are also not included in many analyses of tax evasion. Tax evasion, for example, is usually modelled as a report/non-report decision that imposes risk on the individual but otherwise has no direct affect on behaviour. Tax shelters, in contrast to evasion, normally involve actual although subtle changes to behaviour, such as leasing rather than owning, using a different organizational form, or using hybrid financing instruments. A less than optimal use of legal forms can produce social losses beyond merely the risk of audit. Analyses of investment distortions normally compute marginal effective tax rates on different activities. Tax shelters can significantly reduce effective tax rates on certain activities, which means that the distortions might be substantially larger than otherwise thought. Second, the definition has a set of legal consequences, such as disallowance of tax benefits, penalties, disclosure rules, and additional audits.

The appropriate legal consequences of the definition of tax shelters and an analysis of the economic effects of sheltering need to be tied together. In particular, the scope of activities that should be subject to various policies must be determined based on an analysis of the consequences of such policies, not a definition. There is no clear line between various tax-reducing activities, ranging from working less, being paid in tax-free fringe benefits, investing in tax-favoured assets, entering into traditional shelters, and false reporting. The treatment of a class of these activities as tax shelters, others as criminal evasion, and others as allowable should depend on which activities are optimally subject to a given set of policy instruments.

This approach means that, to define shelters, we need a general theory of tax instruments, including the tax base, the penalty structure, the drafting of legal rules, reporting regimes, and the audit rate. As emphasized by Feldstein (1995; 1999), given some tax base and set of audit, penalty, and similar policies, the private marginal cost of all tax reducing activities will be equal. Therefore, the elasticity of taxable income can be used as a summary measure of the efficiency of the tax system. Slemrod and Kopczuk (2002) observe that the elasticity of taxable income is, in part, a policy variable rather than a preference because policymakers can control the size of the tax base, auditing mechanisms, penalties, and other variables that affect opportunities to reduce taxable income. First order conditions for an arbitrary tax instrument (assuming an optimal linear income tax) set the marginal administrative cost of the instrument equal to sum of marginal (indirect) utility from the change in the instrument and the marginal revenue. Marginal revenue is made up of two components: revenue directly from the change in taxation of the item at issue with the elasticity held constant, and revenue from the change in the elasticity of taxable income.

Viewed in this way, tax shelters are similar to any other gap in the tax base, and appropriate responses to shelters (and definition of shelters) depend on relative cost of obtaining that source of funds. Although
tax shelters: The New Palgrave Dictionary of Economics

This general formulation does not tell us anything about the particular definition of tax shelters or which particular mix of instruments is optimal, it does focus attention on the relevant factors. For example, it seems clear that there should be substantial sanctions for fraud because any other rule would produce a very high elasticity of taxable income – without such sanctions, any increase in the tax rate, starting from zero, would produce substantial reductions in reported income. A similar conclusion holds for many shelters. If they became well known and inexpensive, the elasticity of taxable income becomes unduly high. Similarly, an important effect of imposing a tax on a shelter is reducing the elasticity of taxable income rather than raising revenue directly from the tax on the shelter activity. Because few would engage in the shelter activity without the tax benefits, any revenue from a direct tax on that activity is likely to be small. Most important, the elasticity measure emphasizes that the optimal definition of tax shelters depends on what other instruments are in use, such as the scope of the tax base, the rates, and the audit and evasion rules. For example, ceteris paribus, the higher the tax rates, the broader the optimal definition of shelters is likely to be.

Another approach, more grounded in law than in economics, is to focus on the drafting of tax rules. The primary cause of shelters, in this view, is the imperfect interactions of statutory rules. Treasury (1999) referred to these interactions as discontinuities. Given limited resources, drafters of tax rules can cover only general cases. Taxpayers have a private incentive to find unusual interactions of otherwise reasonable rules and structure transactions to take advantage of them. Weisbach (1999) argued that the solution to this problem, long followed by US law, involves general rules for common behaviours and ambiguous standards, so-called anti-abuse rules, that prevent intentional use of unintended, tax-reducing interactions in the general rules. This approach balances the uncertainty of the ambiguous standards (and the potential principal–agent problems of a revenue-maximizing tax agency overusing the standards) with the benefit of tax rules that need to cover only general cases and, therefore, that can be simpler. A related approach is to focus on the industrial organization of the tax shelter industry. The designing and implementation of tax shelters takes significant resources. While privately beneficial, most of this expenditure of resources has no social benefit. On the other hand, advice about compliance (as opposed to shelters) does have a social benefit. The regulatory problem is to distinguish these activities. Various approaches have been considered, such as limiting the use of contingency fee arrangements based on tax savings, requiring disclosure by advisors of client lists, and direct sanctions, including criminal penalties, for giving inappropriate tax advice.

Reliable estimates of the number or size of tax shelters are difficult to obtain because of their secrecy and because of the ambiguity in the definition of shelters. There is no tax shelter equivalent to the measurements of the tax gap (which is a measure of non-compliance). Shelters have long been considered a problem in the tax law, and anecdotal evidence of sheltering activity has frequently driven tax policy. Important Supreme Court decisions on shelters date back to the 1930s or earlier. In 1934, the Treasury Department attempted to prosecute the former Secretary of the Treasury, Andrew Mellon, for tax evasion. Although the grand jury refused to indict, Mellon was eventually ordered to pay $400,000 in back taxes for what might be considered shelters. As Secretary, Mellon had solicited from Internal Revenue Service ‘memorandum setting forth the various ways by which an individual may legally avoid tax’ (Brownlee, 1996). In 1969, an outgoing Secretary of the Treasury revealed that in 1967 no income taxes were paid on 155 tax returns with gross incomes of 200,000 dollars or more, including 21 of returns of millionaires (Zelizer, 1998). This revelation led immediately to a variety of tax law changes to prevent the use of shelters.
The late 1970s and early 1980s saw a significant rise in tax shelter activity. In 1980, the Commissioner of the Internal Revenue Service stated that ‘about 200,000 individual tax returns representing about 18,000 shelter schemes are now at various stages of the examinations’ process’ (Kurtz, 1980). In 1985, there were over 20,000 tax shelter cases pending in the tax court, and, as of 1982, these cases made up approximately one-third of the court's docket (Collinson, 1985). Limitations on tax shelter losses that were part of the Tax Reform Act of 1986 were estimated to raise almost $53 billion over the five-year revenue window. Birnbaum and Murray (1987) report that these provisions were central to the compromise that allowed the 1986 Tax Reform Act to pass.

Notwithstanding the tax shelter limitations enacted in the 1986 Act, tax shelter activity was thought to rebound significantly in the 1990s. A Senate Subcommittee investigation reported that a single major accounting firm had more than 500 tax shelter products in its inventory and that it sold these products aggressively to individuals and corporations (Levin, 2003). Some 19 lawyers or accountants associated with these shelters were indicted in the largest criminal tax case in US history. Graham and Tucker (2006) study 44 instances of tax shelters by examining reported cases (which should represent only a small fraction of actual shelters). They find that typical tax shelter deduction was more than one billion dollars per firm and that the median shelter produced a deduction sufficient to shield income of approximately nine per cent of asset value. Settlements from a single type of shelter, known as ‘Son of Boss’ sold largely to individuals produced more than $3.7 billion in additional taxes in 2005.

Tax treaties coordinate how signatories tax transnational income flows to avoid double taxation and prevent fiscal evasion. Treaties affect the division of tax revenues and signal commitment to international ‘rules of the game’. Most of the 2,000 plus extant bilateral tax treaties are based on the OECD Model Tax Convention. Residence countries avoid double taxation of foreign-source business income by exempting it or providing credits for source-country taxes. Source-countries typically reduce withholding taxes on interest, dividends and royalties. Despite apparent differences, the economic effects of taxing worldwide income, with credits for foreign taxes, may resemble those of exempting it.

Article

The term ‘tax treaties’ is commonly used – as here – to describe bilateral treaties that coordinate how signatories apply their taxes on income and capital to transnational economic activity. (A few multilateral treaties addressing broader objectives, for example, that establishing the European Union, deal to a limited extent with these or other taxes, as do some treaties – notably the multilateral General Agreement on Tariffs and Trade – that deal primarily with other forms of taxation.) The primary
objectives of tax treaties are avoidance of double taxation and prevention of fiscal evasion. Secondary objectives include the division of tax revenues between treaty partners and signalling that signatories will abide by international ‘rules of the game’. Avoidance of double non-taxation has recently received increased attention. While treaties generally regulate taxation of both individuals and legal entities, the latter are by far the more important and the focus of this article.

Over 2,000 bilateral tax treaties are currently in force. Because tax treaties require several years of negotiation, they are expected to remain in force for several decades, and their wording is rather general, to allow reinterpretation. The vast majority of tax treaties are based on the OECD Model Tax Convention (OECD, 2005), whose origins can be traced to the work of the League of Nations during the 1920s (see Graetz and O'Hear, 1997). The ‘Commentary’ that accompanies and interprets this Model Convention, often also called the OECD Model Tax Treaty, is frequently revised to deal with unforeseen issues (for instance, those involving electronic commerce discussed below). Developing countries generally prefer the United Nations (UN) Model Tax Convention, which is more favourable to their interests as source countries. Although they have historically had difficulty getting more powerful developed countries to accept its terms, this has changed recently (see Kosters, 2004). Some countries, including the United States, publish their own model treaties. Although based on the OECD Model, these models deal with special concerns or features of the country's tax system, such as the US concern with ‘treaty shopping’ considered below. The OECD website discusses many issues covered here.

Avoiding double taxation

Nations have the legal right to tax both income arising within their borders and the income of their residents, whatever its geographic source. In the absence of treaties, there is a risk of ‘double international taxation’ by the ‘source country’ where income arises and the ‘residence country’ of the taxpayer, even though domestic legislation may unilaterally provide relief from double taxation. Moreover, because of differences in definitions of residence or source, more than one country may impose either a residence- or a source-based tax. Double taxation impedes transnational transactions and investment flows.

Tax treaties commonly assign to source countries the primary right to tax business income resulting from direct investment, but to residence countries the primary right to tax other forms of income, including that from portfolio investment. Treaties generally provide one of two methods that residence countries can use to avoid double taxation of foreign-source business income, including dividends from subsidiaries: exemption of foreign-source income and credits for taxes paid to source countries. By comparison, they typically provide that source-country withholding taxes on interest, dividends, and royalties will be reduced reciprocally, sometimes to zero. The latter provisions have given rise to ‘treaty shopping’, the practice of establishing subsidiaries in a country solely for the purpose of benefiting from its treaties. The United States now insists on a ‘limitations of benefits’ provision that eliminates most treaty shopping.

Treaties specify rules for the characterization of income (for example, as business profits, dividends, interest, royalties, capital gains and service income) and the geographical ‘sourcing’ of each type of income. The former task is particularly challenging in cases such as income from the provision of computer software, which might reasonably be characterized as business profits from the sale of goods, royalties or service income.
Treaties limit source-country taxation of business profits to income earned by a permanent establishment (PE), indicated by the presence of a fixed place of business or a dependent agent in the country. This provision has important implications for the division of revenues between source and residence countries. Having its origin in a world of physical products, the definition of a PE, and especially its application to modern business models such as electronic commerce that may not require a physical presence in the source jurisdiction, has recently been the subject of considerable controversy. Treaties generally provide that arm's length prices – prices that would prevail in transactions between unrelated parties – are to be used in valuing transactions (including financial transactions) between related parties. While determining transfer prices is relatively straightforward for some homogeneous commodities that are widely traded (such as oil and wheat), it is difficult – or even conceptually impossible – for many unique intangible assets that have no market outside a given multinational corporation. The OECD has issued guidelines for the determination of transfer prices, some of which rely on formulas, but has steadfastly refused to sanction formulary apportionment (OECD, 1995). Countries may disagree over the proper transfer prices, despite treaty provisions for mutual agreement procedures intended to resolve these and other conflicts in interpreting and applying treaties (for example, the residence of a taxpayer). In such cases double taxation may occur.

Preventing fiscal evasion

To prevent fiscal evasion, tax treaties provide for the exchange of information between tax authorities. For example, if a person deposits funds in a foreign bank, but does not report the resulting interest income, the fiscal authorities of that country could report the interest to their counterparts in the taxpayer's country of residence. In fact, exchange of information has been less useful than this description suggests. First, the fiscal authorities of the country of residence must identify the suspected tax cheat (‘no fishing’) and cannot require provision of information not collected in the normal course of operations or in violation of domestic law. Tax evaders can utilize legal entities whose identities are not known to the tax authorities of their country of residence to make investments. Tax havens – low-tax jurisdictions that have bank secrecy and related laws that allow ownership of assets to be concealed – pose a particularly important threat to tax compliance. Since tax havens generally do not participate in treaty networks and resist exchange of information, it has been relatively simple to evade taxes by channelling investments to or through them. During the 1990s the OECD undertook a project on ‘harmful tax competition’ that included pressure on tax havens to exchange information.

Signalling

Some developing countries and countries in transition from socialism deviate from widely recognized standards for taxing business profits, for example by not allowing deductions for all business expenses or enacting tax laws that favour domestic taxpayers over foreigners. The existence of a tax treaty provides a signal to potential investors that the signatories will play by the internationally accepted ‘rules of the game’, including taxation of net business income and non-discrimination, and assurance that their country of residence will defend them in the event of deviations from those rules. (A taxpayer
may ordinarily appeal to the ‘competent authority’ of its country of residence to insure that both countries are abiding by the terms of the treaty.) For example, by concluding a tax treaty with Canada (its first), Mexico demonstrated readiness to join the OECD, the North American Free Trade Association and the World Trade Organization. Also, non-discrimination rules prevent source countries from levying higher taxes on non-resident investors than on local investors, in order to benefit from the availability of foreign tax credits offered by the residence country.

**Multilateral treaties**

Some advocate a World Tax Organization analogous to the World Trade Organization. Such a body might foster harmonization of income tax bases, far-reaching cooperation among tax administrations, or even equalization of tax rates. Harmonization of tax bases – and especially of tax rates – is unlikely to occur soon, if ever, because, inter alia, defining the tax base and setting tax rates are important aspects of sovereignty, there is no benchmark for the ideal income tax base, and the laws of nations exhibit numerous complex differences.

**Economic issues**

At first glance the two methods of preventing double taxation of business profits have quite different economic consequences. If all residence countries employed the exemption method, all income from foreign investment in a particular source country would bear only the tax of the source country and *capital import neutrality* would prevail. On the other hand, if all residence countries taxed all foreign-source income currently and allowed credits for all source-country taxes, all investment made by residents of a particular country would bear the same tax and *capital export neutrality* would prevail.

There are, however, at least three reasons why the economic effects of taxing worldwide income, with credits for foreign taxes, may resemble those of an exemption system.

First, the parent's tax on most income of foreign subsidiaries is deferred until the income is distributed. (The primary exception occurs when the residence country taxes the undistributed income of certain controlled foreign corporations currently, commonly as an anti-abuse technique.) Thus systems that ostensibly tax the worldwide income of residents and systems that exempt foreign-source income produce similar results.

Second, foreign tax credits are commonly limited to the average tax rate paid on both foreign and domestic-source income. When ‘excess foreign tax credits’ exist, not all taxes levied by high-tax nations can be credited, again producing results similar to those of exemption systems.

Third, the tax treaties of some nations (but not the United States) allow credits for taxes that developing countries choose not to collect, because of tax incentives such as holidays and investment incentives. Such ‘tax sparing’ implies that tax incentives benefit investors, as under an exemption system, rather than being neutralized by higher taxes in the residence country.

taxation and poverty

John Karl Scholz
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Low-income US households typically pay Social Security payroll taxes, state and local sales taxes, and possibly, state income taxes. Federal income taxes in the United States and the United Kingdom, among other countries, provide tax subsidies to low-income working families, particularly those with children. These ‘in-work benefits’ raise the incomes of poor families, modestly increase employment, and have negligible effects on hours of work. The design and effectiveness of these provisions depend on details of the tax system, such as the unit of taxation, the degree to which people file tax returns, and the ability of the tax authority to enforce tax rules.

Article

Tax systems around the world can have substantial effects on the income available to families with low-skill workers. Key factors affecting the tax burdens of poor families include the set of taxes used in the economy, the specific exemptions and deductions contained in the system, and the special provisions targeting low-income households. To discuss these issues, this article focuses primarily on the experiences of the United States, but much of the discussion applies to tax systems in other developed and developing countries. For a broader treatment of taxation in developing economies, see, for example, Burgess and Stern (1993) and Gordon and Li (2005).

The primary taxes borne by low-income US households are the Social Security payroll tax, state and local sales taxes, and in some states, state income taxes. Roughly 41 per cent of US families pay more in payroll taxes than individual income taxes. If we (appropriately) assume the employer's share of payroll
taxes are borne by workers, payroll taxes exceed income taxes for 71 per cent of US families. For most low-earning individuals, the net present value of Social Security benefits still exceeds the present discounted value of taxes paid (Liebman, 2002), but these families are much more likely than others to be intertemporally credit constrained, so, if the payroll tax is fully borne by workers, the 14.2 per cent combined employer–employee tax results in a substantial reduction in after-tax resources available for consumption. (14.2 per cent is the sum of the employer and employee shares of payroll taxes, which equals 15.3 per cent, divided by market earnings increased by the employer's tax share – 1.0765 – with the idea that, without the payroll tax, employers would increase wages by their share of the tax.) The perceived regressivity of the Social Security payroll tax was one factor leading to the adoption of the Earned Income Tax Credit in the mid-1970s.

Sales taxes and their international cousins, value-added taxes (VAT), also raise concerns among policymakers that they impose inappropriate burdens on low-income households. Consequently, these taxes frequently exempt items such as food, clothing, and medicine that are thought to typically compose larger shares of poor families’ budgets than is the case for other families. Zero-rating (excluding) items raises a fundamental issue in taxation. Should tax systems be designed to raise the revenues necessary for the operation of government in the most efficient way possible, leaving expenditure policy to address distributional concerns, or should taxes be designed to address equity issues directly? Exempting (or zero-rating) items in a VAT or consumption tax reduces efficiency (for example, see Ballard, Scholz and Shoven, 1987). Whether policymakers deem the exemptions as being necessary depends on political considerations and the strength of other available institutions to redistribute resources to poor families. The federal individual income tax is conspicuously absent from my list of taxes reducing the incomes of poor families. Until around 1974, the federal income tax imposed positive average and marginal tax rates on families with incomes at the US poverty line, so, along with payroll and sales taxes, income taxes (at both the federal and, in some circumstances, the state level) reduced the incomes of low-income working families. In the absence of other tax provisions targeting low-income families or individuals, the threshold at which families began to pay income taxes was determined largely by the size of the standard deduction and exemptions, and whether these provisions were indexed for inflation. In 1974 the difference in average tax rates, combining income and payroll taxes, between a one-adult, two-child family with income at the poverty line and a two-adult, two-child family with income three times the poverty line was 9.2 percentage points, or the difference between 13.2 per cent and 22.4 per cent. By 2005 the difference was 36.9 percentage points, or the difference between –15.3 per cent and 21.6 per cent. (These calculations are made with the NBER's TAXSIM model: see Feenberg and Coutts, 1993 for a discussion of TAXSIM.)

By far the most important factor affecting the tax treatment of low-income families in the United States since 1977 has been the development and expansion of tax provisions targeted to low-income taxpayers that are ‘refundable’ – the Treasury pays out the value of the credit regardless of whether the taxpayer otherwise has positive tax liability. The most important of these is the Earned Income Tax Credit, though in recent years a portion of the child credit has also been made refundable. Refundable credits can result in negative average tax rates for working poor families with children. The antecedent for current tax provisions targeting low-income families is negative income tax (see Moffitt, 2004, for a nice discussion). The negative income tax (NIT) was to provide a basic income guarantee that would be clawed back as earnings increase. In the mid-1970s US policymakers came
close to enacting a NIT, and its labour market and family formation effects were studied extensively in a series of closely watched, widely publicized social experiments (see, Robins, 1985; Cain and Wisoker, 1990 for further details).

The United States implemented an Earned Income Tax Credit (EITC) in 1975. The EITC provides a subsidy to earnings up to a specific income threshold. For example, in 2004 the EITC gave a 40 per cent earnings subsidy up to 10,750 dollars to a family with two or more children. Taxpayers with earnings between 10,750 and 14,040 dollars received the maximum credit of 4,300 dollars. The maximum credit for families with one child is 2,604 dollars; for childless workers it is 390 dollars. The credit was reduced by 21.06 per cent of earnings between 14,040 and 34,458 dollars. Hence, there are three distinct ranges of the EITC: the subsidy, flat and phase-out ranges of the credit.

The political appeal of the EITC, and similar programmes in other countries such as the Working Tax Credit in the United Kingdom and an EITC-like earnings subsidy to be implemented in South Korea, rests on at least two factors. First, earnings subsidies like the EITC are thought to encourage work and they are sometimes justified as part of a set of policies to ‘make work pay’. There is considerable evidence that this perception is accurate: the EITC has positive employment effects so, in contrast to many alternative ways of redistributing income from higher- to lower-income families, the EITC does not substantially harm labour market incentives. Second, by adding the EITC to an existing individual income tax, implementation costs are relatively low, particularly compared with programmes that require their own bureaucracy.

The static labour supply model implies the EITC will have an unambiguous, positive incentive effect on employment. The empirical evidence is consistent with these incentive effects: the EITC has a statistically significant and large effect on labour force participation of single women with children. Grogger (2003), for example, concludes that the EITC ‘may be the single most important policy measure for explaining the decrease in welfare and the rise in work and earnings among female-headed families in recent years’ (2003, p. 408). For more on the EITC, see Dickert, Houser and Scholz (1995); Eissa and Liebman (1996); Keane and Moffitt (1998); Ellwood (2000); Meyer and Rosenbaum (2000, 2001); and Hotz, Mullin and Scholz (2005). Eissa and Hoynes (2004) focus on the employment and hours decisions of secondary workers in married families and find small, negative effects of the credit on work. Hotz and Scholz (2003) survey EITC research.

The static labour supply model implies an ambiguous incentive effect of the EITC on hours in the phase-in range of the credit and unambiguous negative incentive effects on hours in the flat and phase-out ranges. Studies estimating the effects of the EITC on hours of work for working households find no bunching of taxpayers at the beginning and end of the phase-out range, as might be expected if the EITC significantly affects hours and taxpayers are cognizant of the discontinuities in implied marginal tax rates generated by the credit (Liebman, 1997). It is not surprising that negative effects on hours for people already in the labour market are small, since the precise relationship between the EITC and hours worked is likely to be poorly understood by most taxpayers. Most EITC recipients pay a third party to prepare their tax returns, and it is difficult to infer the implicit tax rates embodied in the credit from the look-up table that accompanies the EITC instructions. This confusion is less likely to mitigate positive participation effects, since, for these to be operative, taxpayers need only to understand that there is some tax-related bonus to work. Abundant anecdotal evidence indicates that taxpayers have this understanding (see, for example, DeParle, 1999).
The UK Working Tax Credit has an interesting design feature when compared with the EITC. Instead of phasing in, it imposes an hours threshold that triggers eligibility, thereby increasing the number of households receiving positive employment and hours incentives in relation to a credit on the first dollar of earnings. All households working fewer than 16 hours will see an increase in the after-tax return to work (and, since they do not receive any credit if they have fewer than 16 hours of work, there is no incentive to ‘buy’ more leisure). Hours limits impose a potentially significant additional administrative burden – because hours information is typically not required to implement an income tax – so their desirable labour market incentive effects must be balanced against the additional costs that arise from administering the hours requirement. Blundell and Hoynes (2004) find the EITC seems to have a larger effect on employment than the WTC predecessor, even though average EITC benefits are somewhat smaller. This may in part be because the incentive effects of in-work benefits in the United Kingdom are dulled by integrations with the rest of the tax and benefit system.

The unit of taxation in most countries around the world is the individual, not the family as is the case in the United States. Most policymakers (including those in the United Kingdom), however, believe that it is essential to target tax benefits on the basis of family income, since it is widely believed that families pool resources when making economic decisions. UK tax authorities meet this goal by having taxpayers claim eligibility by submitting a form to the tax authorities during the year, while the claim is recalculated at the end of the year based on family income. The UK experience shows that it is possible to have a credit with family-based eligibility in a tax system where individuals are the unit of taxation.

Less is known about the effects of the EITC on other aspects of behaviour. Dickert-Conlin and Houser (2002) and Eissa and Hoynes (2004) provide some evidence that the EITC encourages the existence of female-headed families. Heckman, Lochner and Cossa (2002) examine the effects of the EITC on skill formation. While they emphasize that much more needs to be done, they reach a tentative conclusion that the EITC has little impact on average skill levels in the economy. The EITC appears to reach those who are eligible – participation rates among eligible taxpayers is high (Scholz, 1994). Lastly, the EITC also suffers from high rates of non-compliance (Internal Revenue Service, 2002): many taxpayers who are not eligible end up claiming and receiving the credit. There is probably a trade-off between a policy with low administrative costs, like the EITC, and high rates of non-compliance.

taxation of corporate profits

Alan J. Auerbach
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Corporate profits taxes account for a relatively small share of revenues in leading industrial countries but represent a potentially important source of economic distortion. The incidence of corporate taxes has traditionally been assigned to owners of capital, but more recent theories have suggested that many other groups, from shareholders to owners of other domestic factors of production, may share the burden, and that the burden itself may be overstated. Although commonly described as taxes on income, corporate profits taxes may have quite different bases, making the economic effects potentially quite different from those of a tax on corporate source income.

Article

Industrial countries commonly levy a tax on the earnings of corporations. Corporate income taxes account for a relatively small share of revenues in these countries. As of 2000, the share of total government revenues accounted for by the corporate tax (OECD, 2002, Table 13) reached a high among the G-7 countries in Japan, at 14 per cent, and a low in Germany, at five per cent. In a number of these countries, this share had dropped substantially from the 1960s. For example, the US share stood at 16 per cent of revenues in 1965, almost double its 2002 value of nine per cent. The decline in importance of corporate tax revenues has been attributed to a variety of overlapping factors,
including tax policy, shifts in business activities out of corporate form, more aggressive tax avoidance behaviour, financial innovation, and increasing tax competition and capital mobility among jurisdictions. In sorting through these potential explanations, economists continue to develop models of corporate tax incidence and efficiency effects and to consider the rationale for a separate tax on corporate income. The US corporate tax dates at least to a corporate profits excise tax in 1909, four years before a constitutional amendment cleared the way for the 1913 introduction of a general income tax that included a corporate profits tax. In the years since, two key measures have been the relative taxation of distributed and retained earnings and the relative taxation of corporate and non-corporate capital income. The original US income tax imposed a ‘normal’ one per cent tax rate on both retained and distributed earnings but also imposed a graduated individual income surtax of up to six per cent on a tax base that excluded retained corporate earnings, leaving retained earnings subject to a much lower overall tax rate than distributed earnings and leaving corporate income as a whole facing a lower tax rate than income from non-corporate sources, which could not escape the surtax. Through the years, however, although the tax rate on retained earnings generally remained below that on distributed earnings, increases in the corporate level tax caused both rates to rise relative to tax rates on non-corporate income (Bank, 2006).

By the post-Second World War era, the corporate income tax was viewed as imposing an extra tax burden on activities within the corporate sector, even with the favourable treatment of retained earnings. This set the stage for the extremely influential analysis by Harberger (1962 and 1966, respectively) of the incidence and efficiency effects of the corporate income tax.

Harberger’s contributions

Dividing the US economy into two sectors according to whether production was predominantly carried out by corporate or non-corporate businesses, Harberger (1962) characterized the corporate tax as an additional tax levied on capital income originating in the corporate sector, layered on top of the individual income tax collected on capital income from both sectors. He then estimated incidence through the changes in factor prices and product prices that would result from a small increase in the corporate tax. Harberger’s main conclusion was that, under reasonable assumptions regarding the two sectors’ production elasticities of substitution and consumers’ elasticity of substitution between the two sectors’ products, the corporate income tax was borne fully by owners of capital, economy-wide. This finding has two important elements. First, capital bears the entire tax; it is not shifted to labour or consumers. Second, it is all capital, not just corporate capital, that bears the tax.

Harberger’s second contribution (1966) is his estimates of the inefficiency resulting from the higher tax imposed on corporate capital. As a result of the corporate tax, he saw the social (before-tax) rate of return as higher in the corporate sector. Real national income would increase if the tax distortion were eliminated and capital were reallocated to equalize rates of return across sectors. Harberger estimated the deadweight loss of the tax differential between corporate and non-corporate investment to be about seven per cent of the taxes collected on corporate earnings.

Harberger’s analyses spawned a vast literature that extended and challenged his initial results. The simplicity of Harberger’s technique – comparative static analysis of small changes in a two-sector model – proved not to be a major source of concern given that similar findings resulted from analysis using a multi-sector computable general equilibrium model (Shoven, 1976). But Harberger also relied on several
other simplifying assumptions including: (a) free mobility of factors across sectors; (b) that the corporate tax can be viewed as an add-on tax on capital income originating in the corporate sector; (c) no risk; (d) competitive markets and constant returns to scale; (e) a closed economy; and (f) fixed economy-wide factor supplies. These and other assumptions have been examined in the literature.

**Dynamics**

It is reasonable to think of the shifts predicted by the Harberger model as occurring over time with after-tax returns to capital slowly equalizing in the two sectors and with corporate assets initially dropping in value to reflect the gap in after-tax returns, consistent with the $q$-theory of investment envisioned by Tobin (1969) and developed by Hayashi (1982), Summers (1981) and others. Thus, a corporate income tax with gradual adjustment to Harberger's long-run outcome would be borne partially by current owners of corporate capital, through an initial drop in asset values, and partially by future investors in corporate and non-corporate capital, through lower rates of return. The inefficiency of the corporate tax would be changed by gradual adjustment, with weaker responsiveness to tax changes translating into smaller present-value deadweight losses.

**Investment provisions**

As modelled by Harberger, the base of the corporate income tax equals income from all corporate capital. In particular, income from capital goods of different vintages is taxed at the same rate. In reality, capital goods of different ages receive different treatment, even though they are subject to the same statutory corporate tax rate, because of differences in depreciation provisions and other incentives provided to new investment. With accelerated depreciation and investment incentives, new assets are more attractive than old ones of the same productivity. Put another way, the effective tax rate on new investment may be lower than the effective tax rate on existing capital. The differential should be capitalized into the value of existing assets.

Calculations in Auerbach (1983) found that the value ratio of old to new corporate fixed capital in the United States should have been around 0.8 in the early 1980s, with a reduction in both investment incentives and the statutory corporate rate reducing capitalization substantially by the next decade (Auerbach, 1996). Thus, there is a second component of the corporate tax borne by corporate asset holders rather than by capital, and potentially lower deadweight loss as well to the extent of the tax wedge being shifted from new capital to existing assets. Auerbach (1983) found the marginal effective corporate tax rate in the United States to be well below the average effective corporate rate.

**Corporate financial policy and taxation**

With corporations having the option to issue debt, the interest payments which are deductible at the corporate level, and to retain earnings, thereby trading off current dividends for capital gains on which taxes may be lower and can be deferred, how much ‘double taxation’ does corporate capital actually face? In the extreme, if corporations finance all their investment by borrowing, there is no corporate tax imposed on investment; indeed, corporate tax liability is reduced, because nominal interest payments – a
portion of which simply compensates lenders for a loss in purchasing power – are tax deductible. Based on these attributes, Stiglitz (1973) concluded that firms should pay no dividends, retain all their earnings, and meet any additional financing needs by issuing debt. While this theory explains why some equity would exist, it fails to explain why so much equity exists. Here, the theory of Miller (1977) comes in. Miller focused on the heterogeneity of individual investors, arguing that, under a progressive tax system, there may be some investors in high enough tax brackets that the extra taxation at the corporate level is more than offset by the preferential individual tax treatment of equity income. Under Miller's theory, investors with a tax preference for equity would hold equity, those with a tax preference for debt would hold debt, and corporations would be indifferent between the two, issuing enough of the two securities to satisfy the demands of investors.

Even with investor heterogeneity, is it plausible that a significant share of investors will have a tax preference for equity? A very low effective equity tax rate would be required, and this seems inconsistent with the fact that a substantial share of equity earnings comes to investors as fully taxed dividends. One potential explanation is that many countries provide some form of dividend relief, either through reduced taxation at the corporate level (through a lower rate of corporate tax on distributed earnings or a deduction for dividends paid) or at the investor level (through a lower rate of tax on dividends received or a shareholder imputation credit for taxes paid at the corporate level). An alternative explanation comes from the ‘new view’ of dividend taxation (Auerbach, 1979; Bradford, 1981; King, 1977), under which the effective rate of individual tax on equity income may be the capital gains rate, adjusted for deferral – a very low rate – even if dividends are distributed, when retained earnings are the source of equity finance, as they are for most large corporations. This view stands in stark contrast to the ‘traditional’ view, under which the effective individual tax rate on equity earnings is a weighted average of the tax rates on dividends and capital gains, the weights reflecting the shares of corporate earnings distributed and retained.

The new view, which also attempts to explain why mature firms pay dividends, is based on the intuition that existing equity funds are ‘trapped’ within the firm, unable to get out easily without being subject to a tax rate on dividends. As a consequence, the dividend tax rate (or, more precisely, the excess of the dividend tax rate over the effective individual capital gains tax rate on retained earnings) will be capitalized into share values, having no effect on the incentive to distribute earnings or on the effective tax rate on equity-financed investment. Through the years, different empirical strategies have been used to test the relative validity of the traditional and new views of the impact of equity taxation. One approach, based on the *q*-theory investment model, appeared to provide strong support for the traditional view when based on UK data (Poterba and Summers, 1985) but equally strong support for the new view when based on US data (Desai and Goolsbee, 2004). Other approaches focusing on rates of return (Auerbach, 1984) and the source of investment funds (Auerbach and Hassett, 2003) have suggested the presence of firm heterogeneity, with the new view more relevant for ‘mature’ firms with ample internal funds.

Regardless of whether there are investors with a sufficiently low tax rate on equity, another serious challenge to the Miller model is that investors clearly do not specialize. Tax-exempt institutional entities invest substantially in equity, and higher-income individuals hold at least some corporate bonds. As discussed by Auerbach and King (1983), the Miller model breaks down when assets are risky and investors must balance the objectives of diversification and tax minimization. Tax preferences will
influence portfolios – those in higher brackets will still gravitate more towards assets, like equity, with more favourable individual tax treatment. This modification of the model implies that the incidence conclusions based on the simple Miller model are overly strong; while high-bracket investors suffer more from an increase in the corporate tax, even tax-exempt investors will also bear some of the burden.

Risk

Since the work of Domar and Musgrave (1944), economists have noted that taxes on capital income provide insurance as well as imposing burdens. As has been established in the literature, a proportional tax system that provides a full loss offset (that is, the same tax rate applies whether income is positive or negative) imposes a burden on investors only to the extent that the safe return is taxed. This result, combined with the empirical observation that the real, safe rate of return is very close to zero, led Gordon (1985) to suggest that the corporate income tax imposes few economic distortions and has little incidence, although it collects tax revenue on average (that is, in expected value). Gordon's conclusion was challenged by Bulow and Summers (1984), who argued that, while the government shares in the income risk of a corporate investment, much of the investment risk is associated with fluctuations in the price of capital goods, and the corporate tax base excludes accruing capital gains and losses on fixed capital. Likewise, the corporate tax's risk-sharing is reduced by imperfect loss offsets, which also raise the effective tax rate. Thus, even if a pure, symmetric tax on accruing corporate income caused few distortions, this is unlikely to be true of actual corporate tax systems that consistently raise substantial revenues from corporations.

Imperfect competition

Harberger's conclusions on incidence were challenged by the econometric results of Krzyzaniak and Musgrave (1963), who, on the basis of time-series analyses of American manufacturing, reached the startling conclusion that after-tax profits rose in the short run in response to increases in the corporate tax rate. The Krzyzaniak–Musgrave contribution was criticized by a number of writers, but their empirical finding is possible under certain forms of imperfect competition. The study's methodology does not allow one to identify the nature of corporate responses, but corporations behaving in an oligopolistic manner need not maximize joint profits, and therefore might increase before-tax profits, and possibly even after-tax profits, by reducing output and hence increasing prices in response to an increase in the corporate tax.

The international economy

Unlike in the purely domestic context, there is a distinction between where income is earned and where its owner resides, and the concept of residence, itself, is applied not only to individuals but also to corporations. Countries may seek to tax corporate income on a source basis, a residence basis, or some combination of the two, and most countries follow this last approach, taxing at least some income at source at the corporate level, even if the corporation is owned abroad, and taxing at least some portfolio income of domestic residents on holdings of foreign assets.
As in the analysis underlying the Miller model, an equilibrium with individuals possessing different relative tax preferences for different assets leads to specialization of the highest-bracket investors in the most tax-favoured assets (Gordon, 1986), but the number of possible allocations of assets among investors is increased by the fact that individuals may hold foreign assets in many countries and in a variety of ways (for example, portfolio investment versus direct investment), and corporations (and, to a lesser extent, individuals) can change the location not only of their investments but also of their tax residence.

Among the key results in the international tax context is that a corporate income tax will be partially shifted to non-capital domestic factors of production, the more so the smaller is the taxing jurisdiction (Kotlikoff and Summers, 1987). Also, with many taxing jurisdictions, the possibility of ‘tax competition’ arises, with governments setting their corporate tax rates strategically in response to the tax policies of other countries. In this context, a ‘race to the bottom’ is a possible, though by no means a certain, outcome. But the reductions in corporate tax rates in recent decades provide some evidence for a strengthening of tax competition (Devereux, Griffith and Klemm, 2002).

The long run

One of the Harberger model’s most important omissions is the impact of corporate income taxes on capital accumulation. We would expect an increase in the effective tax rate on new saving and investment to reduce capital accumulation. The resulting decline in the capital–labour ratio would increase before-tax returns to capital and lead to a fall in wages, thus partially shifting the tax burden from capital to labour, with much the same effect as capital flight in the open economy. This analysis would apply to the corporate tax as well, but only to the extent that the corporate income tax represents a tax on new saving and investment.

Taxation of foreign income entails the taxation by one country of income that its residents earn in another country. While most countries exempt active foreign business income from taxation, several large capital exporters subject foreign income to taxation but permit taxpayers to claim credits for taxes paid to foreign governments. There is extensive empirical evidence that the taxation of foreign income influences the magnitude of foreign investment and the tax avoidance activities of investors. Neutral taxation of foreign income entails considerations not only of the volume and location of investment, but also the effects of taxation on capital ownership.

Article

Taxation of foreign income entails the taxation by one country of income that its residents earn in another country. Most countries subject some types of foreign income to taxation. Since this income is also typically taxed by the foreign countries in which it is earned, there is considerable scope for ruinous double taxation. For example, in the 1970s the corporate tax rate in the United States was 48 per cent while the corporate tax rate in Germany was 56 per cent; without some attenuation of double taxation, the combined tax rate of 104 per cent would probably have discouraged (profitable) American corporate investment in Germany.

International practice since the dawn of taxation is that countries tax income earned within their borders, whereas countries in which taxpayers are resident grant tax relief for foreign income in order to reduce...
or eliminate double taxation. There are two primary alternative methods by which residence countries grant relief, the first being to exempt foreign income from taxation, and the second being to permit residents to claim credits for taxes paid to foreign governments. Many countries combine these systems, exempting active foreign business income from taxation while subjecting foreign personal income to taxation but permitting individuals to claim credits for income taxes paid to foreign jurisdictions.

The nature of international commerce is such that most foreign income is earned by businesses rather than individuals. Many countries largely exempt active foreign business income from taxation, though a number of major capital exporting nations, including the United States, the United Kingdom and Japan, tax foreign income while granting credits for taxes paid to foreign governments. With such a system of taxing foreign income, and a home-country corporate tax rate of 35 per cent, a corporation that earns 100 in a foreign country that imposes ten per cent tax rate pays taxes of 10 to the foreign government and 25 to its home government, since its home-country corporate tax liability of 35 is reduced to 25 by the foreign tax credit of ten. Since foreign tax credits are intended to alleviate international double taxation, credits are limited to home-country taxes due on foreign income; taxpayers are not permitted to use taxes paid to foreign governments to reduce home-country tax liability on domestic income. In addition, countries that tax active foreign income permit taxpayers to defer home-country taxation of certain business profits earned and reinvested abroad; that income is taxed only when repatriated to the country of residence.

Effects of taxing foreign income

The taxation of foreign income and the tax laws of other countries have the potential to influence a wide range of corporate and individual behaviour, including, most directly, the location and scope of international business activity. Studies of behavioural responses to international tax rules find that multinational firms invest less in high-tax countries than they do in otherwise-similar low-tax countries. This is most evident from the disproportionate shares of financial and real investment in tax haven countries (Hines, 2005), but also appears in cross-sectional econometric estimates of the determinants of foreign investment. Controlling for income levels and other observable characteristics of host countries, foreign direct investment levels are negatively associated with local corporate tax rates, the implied elasticity of investment with respect to the tax rate generally lying close to –0.6 in data covering the 1980s (Hines and Rice, 1994), and increasing in magnitude to –1 or greater in evidence data since the 1990s (Altshuler, Grubert and Newlon, 2001). High rates of local taxes other than corporate income taxes are likewise associated with reduced levels of foreign investment (Desai, Foley and Hines, 2004a). There is extensive evidence that firms arrange financial flows and intrafirm sales to reallocate taxable income from high-tax countries to low-tax countries. This reallocation is commonly accomplished by concentrating corporate borrowing, and therefore interest deductions, in high-tax countries (Desai, Foley and Hines, 2004b), and by adjusting prices paid for intrafirm financial transactions and sales of goods and services to minimize income reported in high-tax countries (Clausing, 2003). As a consequence, multinational firms report significantly higher profit rates in low-tax countries than in high-tax countries (Desai, Foley and Hines, 2003), and the ability to reallocate taxable income only increases the attractiveness of investing in low-tax countries.

Taxation of foreign income, together with provision of foreign tax credits, dampens incentives to earn
income in low-tax countries, since lower foreign tax payments reduce available foreign tax credits and thereby create greater home-country tax obligations. Foreign investment in the United States is consistent with these incentives, in that investors from countries that exempt foreign income from taxation concentrate their investments more heavily in low-tax states than do investors from countries that tax foreign income (Hines, 1996). The taxation of foreign income restricts the attractiveness of investment in low-tax countries to situations either in which ample foreign tax credits are available, or in which investors can profitably defer home-country taxation. In practice, American firms are much more likely to reinvest foreign profits earned in low-tax locations, since immediately returning these profits to the United States would produce significant tax obligations (Desai, Foley and Hines, 2001).

The impact of home-country taxation is illustrated by the practice of granting ‘tax sparing’ credits for investments in certain developing countries, thereby permitting taxpayers to claim credits for normal rates of foreign taxes, whether or not these have been actually paid. Evidence indicates that Japanese investors are much more likely to receive local tax concessions in countries with which Japan has ‘tax sparing’ agreements than they are elsewhere, and that Japanese investment is concentrated in these countries as a result (Hines, 2001). Finally, the taxation of foreign income has even encouraged some individuals and multinational firms to expatriate, effectively changing their places of tax residence to avoid home-country taxation of lightly taxed foreign income (Desai and Hines, 2002).

Neutral taxation of foreign income

International tax rate differences may encourage inefficient allocation of economic activity; consequently, considerable effort has been devoted to understanding the properties of tax systems that create neutral incentives.

Capital export neutrality (CEN) is the doctrine that an investor's income should be taxed at the same total rate regardless of the location in which it is earned. If a home-country tax system satisfies CEN, then a firm seeking to maximize after-tax returns has an incentive to locate investments in a way that maximizes pre-tax returns. This allocation of investment promotes global economic efficiency under certain circumstances. The CEN concept is frequently invoked as a normative justification for taxation of foreign income with provision of foreign tax credits (Richman, 1963), though in practice, countries limit foreign tax credits and commonly defer taxation of unrepatriated active business income. The same logic implies that governments acting on their own, without regard to world welfare, should want to tax the foreign incomes of their resident companies while permitting only deductions for foreign taxes paid. Such taxation satisfies what is known as national neutrality, discouraging foreign investment by imposing a form of double taxation, but doing so in the interest of the home country, which disregards the value of tax revenue collected by foreign governments. From the standpoint of the home country, foreign taxes are simply costs of doing business abroad, and therefore warrant the same treatment as other costs. This line of thinking suggests that countries fail to advance their own interests in permitting taxpayers to claim foreign credits, or worse, in exempting foreign income from taxation. A third neutrality principle is capital import neutrality (CIN), the doctrine that the return to capital should be taxed at the same total rate regardless of the residence of the investor. Pure source-based taxation at rates that differ between locations can be consistent with CIN, since different investors are taxed at identical rates on the same income. In order for such a system to satisfy CIN, however, it is also...
necessary that individual income tax rates be harmonized, since CIN requires that the combined tax burden on saving and investment in each location should not differ between investors. While CEN is commonly thought to characterize tax systems that promote efficient production, CIN is thought to characterize tax systems that promote efficient saving (Horst, 1980).

The importance of ownership for productivity, and the reality that much foreign investment consists of acquisitions of existing assets by new owners, has prompted analysis of the features of tax systems that do not distort ownership of capital. Capital ownership neutrality (CON) is satisfied if every country taxes foreign income similarly, thereby avoiding tax-based ownership clienteles (Desai and Hines, 2003). From the standpoint of capital ownership, a country fails to advance world welfare by adopting a tax system that promotes CEN, if most capital exporters exempt foreign income from taxation. The same circumstances that make CON desirable from the standpoint of world welfare also imply that countries acting on their own have incentives to exempt foreign income from taxation, regardless of what other countries do. The reason is that additional outbound foreign investment does not reduce domestic activity, since reduced home-country investment by domestic firms is offset by greater investment by foreign firms. Home-country welfare rises with the productivity of domestic factors, and is maximized by ownership patterns produced by exempting foreign income from taxation. Tax systems that exempt foreign income from taxation are therefore said to satisfy national ownership neutrality. Hence it is possible to understand why so many countries exempt active foreign business income from taxation, and it follows that, if every country did so, capital ownership would be allocated efficiently, to the benefit of global productivity.

taxation of income

Alan J. Auerbach
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Income taxes are the single most important source of revenue for most countries, although there is an active debate about the relative attractiveness of alternatives such as broad-based consumption taxes. In practice, the income tax base deviates from a comprehensive income measure in several important respects, by excluding non-market activities, limiting refunds for losses, and including capital gains on realization rather than on accrual. Each deviation introduces additional distortions of taxpayer behaviour. Defining the family unit for purposes of income taxation remains a complex issue, as does the optimal degree of tax progressivity.

Article

Despite its current prominence as a government revenue source, the income tax's first appearance is relatively recent in the historical evolution of government finance. Evidence of a serious national income tax is difficult to find before the end of the 18th century, when William Pitt achieved the passage in Great Britain of the Act of 1799, which imposed a comprehensive income tax, complete with exemptions and abatements for dependents, on all residents of Great Britain. Introduced to maintain the British government's solvency during the Napoleonic Wars, the income tax was dispatched once the French had been. Seligman (1911, p. 113) quotes a contemporaneous source as stating that the repeal of the tax by Parliament 'was declared amidst the greatest cheering and the loudest exultation ever witnessed within the halls of the English Senate'. It was only decades later that the
income tax reappeared in Britain. This pattern of introduction during wartime, followed by repeal and eventual, permanent reinstitution is found in the experience of other countries, as well. In the United States, for example, the first income tax was introduced during the civil war in 1862, being abandoned in 1872. It reappeared in 1894 in similar form, but was almost immediately declared unconstitutional by the Supreme Court, which found it to be a ‘direct’ tax not apportioned among the states according to population. The 16th amendment to the constitution was required before the income tax could be imposed again in the United States, in 1913.

Over time, the income tax has grown in importance so that it now represents the single most important revenue source in most developed countries. In 2000 (according to OECD, 2002, Table 9), for example, taxes on income and profits among the G-7 countries (the United States, Japan, Germany, France, United Kingdom, Italy, and Canada) accounted for between roughly one quarter and one half of all revenues, with the United States relying the most on the income tax (51 per cent) and France the least (25 per cent).

Being a direct tax on individuals, rather than an indirect tax on transactions, the income tax requires a more developed government infrastructure than other revenue sources. This distinction also provides the key to understanding both why the income tax was seen as a fairer way to raise revenue and why it was so vehemently opposed. Through assessment of individuals, the income tax was better suited to the achievement of a progressive, broad-based tax structure than the agglomeration of indirect taxes and duties that preceded it. At the same time, this focus on individuals instead of transactions brought with it the perception of a challenge to individual liberty, both because of the exposure to the government of the individual's economic behaviour and the ability of government to levy arbitrarily high taxes on small groups of taxpayers (see, for example, Blum and Kalven, 1953).

The measurement of income

Dating back almost to the introduction of the income tax itself is the question of how income should be measured. What has come to be called the ‘Haig–Simons’ measure of income is now generally accepted as the appropriate base for an income tax (Haig, 1921; Simons, 1938). As expressed by Simons (1938, p. 50), ‘Personal income may be defined as the algebraic sum of (1) the market value of rights exercised in consumption and (2) the change in the value of the store of property rights between the beginning and end of the period in question.’ One may justify the Haig–Simons approach on grounds of both fairness and efficiency, the former because it treats individuals with different sources of income uniformly and the latter because it does not distort decisions of how to devote resources to the generation of income. Yet actual income taxes vary from this definition, for reasons of both administration and politics.

Market versus non-market activities

A range of activities generates imputed income that, by the Haig–Simons definition, should be included in the income tax base. Some sources of imputed income, such as imputed rent from owner-occupied housing, have been seriously considered for inclusion in the tax base. At the other extreme are various home production activities such as cleaning and home repair. The inability and unwillingness of governments to tax income from non-market activities introduces a
distortion of taxpayer choices, for it encourages the taxpayer to substitute non-market for market
activities. Such substitution may be entirely legal, as in the purchase or cleaning of one's own home, or
illegal, as in the establishment of professional cooperatives wherein members provide services to other
members ‘for free’.

Realizations versus accruals

The Haig–Simons measure does not distinguish between realized and unrealized increases in wealth. Yet
most income tax systems include capital gains in the tax base only when they are realized, if at all. This
outcome is traceable in part to the difficulty of measuring unrealized gains, although this can hardly be a
problem for the vast wealth held in marketable securities. A related difficulty, often ascribed to farmers
and the owners of small businesses, involves illiquid assets which would have to be sold below their
going-concern values were their owners subject to taxes on associated accrued gains. Finally, property
rights to capital assets may be sufficiently vague or disputed that it is difficult even to attribute
ownership until gains have actually been realized. A variety of proposals to tax such accrued gains
retrospectively upon realization (for example, Vickrey, 1947; Auerbach, 1991) have attracted little more
than academic attention.

This favourable treatment of capital gains facilitates the accumulation and transmission of wealth. It has
therefore been viewed as mitigating the progressivity of the income tax system, leading some (for
example, Kaldor, 1955) to favour an individual expenditure tax on grounds of equity. At the same time,
others have argued that favourable capital gains treatment serves to encourage risk-taking, which is
otherwise discriminated against by the income tax system (see the discussion below).

Nominal versus real income

Income has been viewed as an appropriate measure of the individual's ability to pay, but this ability is
generally viewed in real rather than money terms, an individual being no better off with twice the
income at twice the price level. Price-level indexation of the income tax requires two types of
corrections: to the rate structure and to the base itself. The first is required because of the progressivity
of marginal tax rates, the second because capital income is measured incorrectly in the presence of
inflation.

When the income tax structure has marginal tax rates that rise with nominal income, increases in the
price level raise both the marginal and the average tax burden on a given real income level. Correction
for inflation involves indexing tax brackets to the price level, a practice implemented only in 1985 in the
United States, after a period of relatively high inflation.

Capital income is generally mismeasured in an inflationary environment because changes in the real
value of capital goods that are due to inflation are generally treated incorrectly by the tax system. This
has led to four problems identified by the literature (see, for example, Aaron, 1976); the understatement
of costs of goods sold from inventories, the understatement of the depreciation expenses associated with
the use of durable capital goods, the overstatement of income received from bonds and other nominal
commitments, and the overstatement of realized capital gains. In all cases, the problem arises from a
failure to apply the Haig–Simons approach to changes in the value of capital assets. There have been
few attempts to ameliorate these distortions in practice. In fact, some economists have suggested that maintaining these apparently gratuitous distortions serves a positive purpose, namely, to weaken government’s appetite to pursue inflationary policies (Fischer and Summers, 1989).

**Losses**

There is no logical reason why the income tax base for an individual cannot be negative, but treating losses as gains are treated would call for a negative tax payment, that is, a government refund. This outcome is rarely observed in practice, in part perhaps because restricting the use of losses imposes some limit on the extent to which taxpayers can fraudulently under-report income. Instead, individuals with currently negative tax bases are permitted to average the current base retrospectively or prospectively with the aim of achieving a net positive number. In the case of forward averaging (called ‘carrying forward’) this still amounts to the penalty of having to wait for the refund until future taxes are due without any interest to compensate for this deferral.

A closely related outcome occurs under a progressive tax structure when income is positive in every year, but fluctuates from year to year. Since marginal rates are higher in good years than bad (a milder version of what occurs when negative tax bases face a tax rate of zero), taxpayers face a higher tax in present value than if they received the same present value of income, but in a smooth stream over time. As with the treatment of losses, tax systems typically provide some imperfect form of averaging of incomes over several contiguous years to lessen this problem.

This treatment of losses and risky incomes has been viewed as discouraging the taking of risks (for example, Domar and Musgrave, 1944), and has been one of the more valid reasons for favouring the preferential treatment normally accorded capital gains. At the same time, there is no general presumption that income taxation, in itself, discourages the taking of risks, since it reduces not only the returns to risky investments but also the risks. In fact, the reduction in risk may increase private risk-taking (Domar and Musgrave, 1944; Tobin, 1958), but this outcome may be reversed if government cannot reduce the risk of its resulting revenue stream (Gordon, 1985).

**Defining the unit of taxation**

In addition to these problems of income measurement, ambiguities have arisen concerning the delineation of the taxpaying unit. Questions have concerned how broadly to define a unit at a given date, and over what time interval to measure the income accruing to that unit.

**Tax treatment of the family**

Tax systems vary in their treatment of related individuals. The method of treatment of family members affects the tax burden on a family because of the progressivity of the rate structure. Two individuals will generally be assessed a different tax bill if considered separately than if taxed jointly as a couple, regardless of how the rate structure is adjusted, since the total tax bill under separate taxation will depend on the distribution of taxable income between the individuals while under joint taxation it will not.
Even if families can be identified and grouped for purposes of taxation, the problem remains in deciding how to vary the tax schedule with family size. For this, one must have a measure of how to normalize income by family size to obtain a measure of the family’s ability to pay. Such questions have been addressed but not often applied to the design of tax schedules. Finally, how the family is grouped also matters if the tax-free transfer of resources through gifts and bequests is not allowed. The strict Haig–Simons approach would include gifts and bequests in the tax base of the recipient, but such transfers might not be observed if occurring within the unit of taxation.

**Tax treatment over time**

In Simons’s own description of the appropriate measurement of income, the element of time plays a crucial role, since accretions to wealth must be defined over some interval. Indeed, the difference between a tax on income and a tax on expenditures amounts to a different choice of time interval over which to measure income for purposes of taxation. If, instead of annual income, we assessed taxes on lifetime income, then individuals would pay taxes in excess of lifetime consumption only to the extent that they accumulated resources over their lifetimes. Taking the further step of assessing families rather than individuals, we might ignore even the lifetime resource accumulation that would go to finance the consumption of subsequent generations.

This point has not been missed by advocates of the expenditure tax, who argue that, from a lifetime perspective, individual expenditures are a better measure of ability to pay than annual income. Under the annual income tax, individuals who consume their resources later in life face a heavier lifetime burden, paying taxes when income is initially earned and again when interest on the saved capital is received in later years. This outcome led to the charge that the annual income tax imposes unfair ‘double taxation’ of savings, an argument made by early proponents of a consumption tax (for example, Fisher, 1939; Kaldor, 1955). More recent arguments in favour of consumption taxation have focused on considerations of economic efficiency. The central point of this literature has been that, notwithstanding the government’s inability to avoid all tax-induced distortions, a system including capital income taxation, which imposes greater and greater distortions on consumption as the time horizon lengthens, cannot be optimal (Chamley, 1986; Judd, 1985).

**On the optimal progressivity of the income tax**

As soon as the income tax became ensconced as a revenue source, economists began to consider how progressive it should be. Early researchers in the utilitarian tradition focused on how rapidly the tax burden should rise with income so as to exact an equal sacrifice from each individual given the particular utility function with which people were assumed to be endowed. The answer also depended on whether one was seeking equal absolute sacrifice, equal proportional sacrifice, or equal marginal sacrifice, all measured in units of the interpersonally comparable individual utilities (Musgrave, 1959, pp. 99–105).

Perhaps the most disquieting result from this line of investigation was that the achievement of equal marginal sacrifices required the equalization of incomes across individuals, if utility function were the same (Edgeworth, 1897). A missing element that would have altered this finding was the distortionary
impact of taxes on economic behaviour. The high marginal tax rates needed to approach equality of after-tax incomes (100 per cent in the extreme case of complete equality) would undoubtedly become self-defeating, in that the after-tax incomes of all individuals would begin to fall as tax revenues ceased increasing with increases in marginal tax rates. Such an outcome would be inconsistent with any evaluation of social welfare that had Pareto efficiency as a necessary condition for an optimum.

There followed, eventually, a line of research that sought to reconcile the utilitarian aim of equal marginal sacrifice with the disincentive effects of marginal taxation. The seminal paper here is that of Mirrlees (1971), who found optimal marginal rates to be relatively low. Subsequent research has also shown that marginal tax rates should eventually approach zero at the highest incomes, a result that is not only dependent on various assumptions but also less politically controversial than one might first expect once it is recognized that it applies to marginal, not average, tax rates, and possibly only at very high incomes.

Further research on the distortions of the income tax has focused on its efficiency relative to other tax bases, such as labour income and consumption expenditures. A key result here is that of Atkinson and Stiglitz (1976), who showed that, under a relatively plausible restriction on preferences, government could not improve on a progressive tax on labour income using differential consumption taxes. If one interprets different commodities as consumption at different dates, then the implication is that a tax on labour income, or equivalently a tax on lifetime consumption, is the optimal progressive tax. Many complications limit the direct application of this result in the determination of actual tax policy, but the lesson has been helpful in what remains an active area of research. One notable complication is that tax policy evolves over time. This evolution makes comparisons of tax systems different from evaluations of a transition from one tax system to another, in which the treatment of assets accumulated under the previous tax system must be taken into account in performing welfare analysis (Auerbach and Kotlikoff, 1987).

taxation of the family

James Alm
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

In administering an individual income tax, a country must decide what constitutes an ‘individual’. This choice has traditionally been seen as one between making either the family or the individual the ‘unit of taxation’. The choice between the family and individual as the unit of taxation in the income tax – indeed in any tax or transfer programme – is not clear-cut, and involves difficult trade-offs between competing and worthwhile goals. This article examines some of the issues that countries face in choosing the unit of taxation, or what is often referred to as ‘taxing the family’.

Keywords

community property laws; equity; horizontal equity; income splitting; labour supply; marriage and divorce; marriage tax; progressive and regressive taxation; tax compliance costs; taxation of income; taxation of the family; vertical equity; women’s work and wages

Article

Nearly all countries around the world impose an individual income tax. In administering this tax, each country must decide what constitutes an ‘individual’, that is, each country must choose the ‘unit of taxation’. This choice has traditionally been seen as one between the family and the individual. In the former case, the incomes of all members of a family are aggregated, and the income tax (with all of its relevant provisions) is then imposed on total family income. In the latter case, each individual is taxed only on his or her own individual income, even if he or she is a member of a family unit in which other members have taxable income.

The choice between the family and individual as the unit of taxation is not clear-cut, and involves difficult trade-offs between competing and worthwhile goals. With the dramatic increase in recent years of different household ‘types’ – cohabiting but not legally married couples, extended families, same-sex couples, unrelated individuals living together – these issues have become even more complicated. The
presence of numerous other tax and transfer programmes whose magnitude is determined by family status complicates these issues still more.

This article examines some of the issues that countries face in choosing the unit of taxation, or what is often referred to as ‘taxing the family’.

**Some goals and principles in taxing the family**

Countries have a variety of goals in choosing the structure of the individual income tax. Such a tax is usually viewed as balancing the various desirable attributes of taxation: taxes must be raised (adequacy) in a way that treats individuals fairly (equity) and in a way that minimizes interference in economic decisions (efficiency). See Boskin and Sheshinski (1983) and Apps and Rees (1999) for an analysis of the optimal taxation of the family.

Defining equity is quite difficult. One notion of equity requires that taxpayers with greater income pay greater amounts of taxes. It is generally felt that a progressive rate structure is best able to achieve vertical equity, sometimes referred to as the progressivity goal of taxation.

Another notion requires that taxpayers who are equal in all relevant respects pay equal amounts of taxes. The difficulty here lies in defining ‘equals’. Equals can be defined in terms of married couples with equal income, but also as any ‘household’ with equal income. If a married couple is seen as the relevant household type for defining equals, then achieving the goal of horizontal equity across households requires that married couples with equal incomes pay equal taxes. However, if a household is defined more broadly, then achieving this goal requires that any households with equal income pay the same amount of taxes, requiring the additional and separate goal of equal payments by singles and couples. This goal can easily be broadened to apply to all household types.

Still another goal is marriage neutrality, which requires that a couple's combined income tax liability remain unchanged with marriage. However, there is substantial evidence that many couples pay more in taxes as a married couple than their combined taxes as single individuals; this is often referred to as a ‘marriage tax’ or ‘marriage penalty’. There is also evidence that marriage can reduce tax liabilities, in which case the reduction in taxes is called a ‘marriage subsidy’ or ‘marriage bonus’. As discussed later, it is well documented that the US individual income tax is not marriage neutral, and exhibits a large and variable marriage penalty – and marriage bonus – whose magnitude has changed over time. There is also evidence that the income tax is not marriage-neutral in many other countries.

In general, any income tax can create a marriage penalty or subsidy if two conditions are satisfied: the tax is based on household income, and the tax imposes different marginal tax rates at different levels of income (Steuerle, 1999). Many tax and transfer programmes meet these conditions, so that that marriage non-neutrality exists throughout the fiscal system in almost all countries. For the United States, the General Accounting Office (1996) identified 59 provisions in the individual income tax code that contribute to a marriage penalty or subsidy, and over 1,000 federal laws in which marital status is a factor in the determination of taxes or transfers, ranging from income tax and welfare provisions to programmes involving veterans’ payments, immigrant benefits, and other social insurance programmes.

It is now well-known that no individual income tax can achieve the simultaneous goals of horizontal equity across families, equal payments by singles and couples, progressivity, and marriage neutrality. Choosing the features of the individual income tax therefore requires that countries must face trade-offs
in their pursuit of worthwhile goals. Countries have made very different choices in this regard.

**Worldwide practice in taxing the family**

In the case of the United States, the tax treatment of the family has varied over time (Bittker, 1975; Berliant and Rothstein, 2003). The basic unit of income taxation was initially the individual. However, after the Second World War a growing number of states instituted community property laws, which allowed married couples to divide their income equally and file separate tax returns, thereby giving a significant tax advantage to couples living in community property states. In response, the Revenue Act of 1948 changed the unit of taxation from the individual to the family with the adoption of ‘income splitting’ for married couples, in which all couples were allowed to aggregate and to divide in half their income for federal tax purposes. Due to the progressive nature of the individual income tax, a couple's joint tax liability fell with marriage (for example, a marriage bonus).

This marriage bonus grew over the next two decades. Public pressure to remedy this disparity led to the adoption of the Tax Reform Act of 1969, which established a new, separate tax schedule for single individuals that insured that single persons would incur a maximum tax liability of 120 per cent of a married couple with equal income. However, a side effect of this reform was the creation, for the first time, of a marriage tax or penalty for many married couples, especially for couples with similar earnings. Since then, various tax and demographic changes have markedly affected the potential for a marriage penalty or subsidy, as well as the magnitude of each. In the longer run, the size of the marriage penalty will be heavily influenced by the alternative minimum tax.

Other countries have made very different choices in taxing the family (Alm and Melnik, 2005). In most OECD countries (as of 2002 tax laws), the individual is the unit of taxation, and joint filing for couples is not permitted. Joint filing is required in only seven countries (Belgium, France, Greece, Luxembourg, Portugal, Switzerland, and the United States), while six countries allow couples to select the filing status (Germany, Iceland, Ireland, Norway, Poland, and Spain). A total of 17 OECD countries use only the individual as the unit of taxation, and, as noted, another six countries in which the taxpayer can choose between single or joint taxation. Not every country that permits or requires joint filing allows joint assessment (for example, income splitting between the spouses). For instance, Greece, Norway, and Spain all have provisions for joint filing, but income splitting does not apply, which means that joint filing is not meaningfully different from single filing, except when joint filing allows a couple to use different personal exemptions. Income splitting is present in some form in only nine of the 32 OECD countries. In most countries that allow income splitting, the income of the spouses is simply aggregated, so that the tax system does not differentiate between households with equal combined incomes based on how the income is distributed within the couple. However, there are exceptions to this as well. For example, Belgium allows only limited income splitting, which applies only to those couples in which there is a significant differential between the spouses’ incomes.

Income splitting in the presence of a progressive tax rate structure creates a tax benefit to couples when spouses earn different incomes, as evidenced quite clearly by the US experience. Furthermore, the tax benefit is a function of the difference in those incomes and the marginal tax rate structure. For instance, Luxembourg has narrowly defined marginal tax rate brackets, and a relatively small differential can translate into a significant tax saving for a married couple as opposed to two single taxpayers with similar incomes, as long as neither spouse falls into the highest income bracket. In contrast, in Iceland
and Ireland a much larger difference in incomes may have no impact on tax liability due to the marginal
tax rate structure.
Many OECD countries also have special tax provisions that apply to single-earner couples, in an attempt
to provide some form of tax relief to these couples. The most common provision is some form of credit,
deduction, allowance, or rebate (for example, Australia, Austria, Canada, the Czech Republic, Denmark,
Iceland, Italy, Japan, the Republic of Korea, and the Slovak Republic). Another popular provision is
income splitting, used in Belgium, France, Germany, Ireland, Luxembourg, Poland, Portugal, and the
United States.
In general, the dominant practice of individual income taxation in OECD countries is to choose the
individual rather than the family as the unit of taxation, and thereby to tax individuals on their own
income even if they are married. As a result, the individual income tax is largely marriage neutral in
these countries. This practice of taxing the individual is one that has tended to emerge since the mid-
1970s in these countries. Even so, there remains much diversity in how OECD countries choose to tax
the family.

Some effects of taxing the family

Defining the taxable unit as the family rather than the individual is controversial. The principal
arguments revolve around equity issues. However, there are also efficiency issues, as well as revenue
effects.
The basic economic model of marriage indicates that income taxes may affect the gains to marriage via
two paths. First, differential income tax treatment of married couples may alter the total taxes paid by
the couple relative to taxes paid as single individuals. If total taxes paid increase (decrease) with
marriage, ceteris paribus, then the gains to marriage unambiguously fall (rise). Second, marriage may
change the marginal tax rate faced by the couple relative to that faced as singles. A higher marginal tax
rate with marriage increases the tax liability of the couple and so lowers the benefits of marriage;
however, a higher marginal tax rate also lowers the after-tax wage rates of the individuals, thereby
reducing the opportunity cost of household production work and increasing the gains from marriage. The
tax system therefore both creates incentives for those marriages that involve traditional gender roles and
discourages those marriages with two wage earners.

Much recent empirical work has attempted to disentangle the effects of income taxes on marital
decisions, with most of this work focusing on the United States. See Whittington and Alm (2003) for a
summary of many of these studies. This work has tended to find that the marriage tax has a small but
statistically significant impact on marriage and divorce probabilities. The income tax may also affect the
timing of the marriage decision, and several studies have found that couples in the United States and in
Canada, England and Wales have timed their marriages to avoid one year of the tax penalty. There is
some evidence that income tax influences the likelihood that individuals live together as a legally
married versus as a cohabiting couple. Even so, in most instances the magnitude of the tax impact is
relatively small. For example, Alm and Whittington (1999) find that at mean values a ten per cent rise in
the marriage penalty leads to a 2.3 per cent reduction in the possibility of first marriage, and Alm and
Whittington (1997) estimate that doubling the tax penalty increases the probability that a couple delays
its marriage to the next tax year by one per cent but that the tax penalty subsidy has no impact on the
Marriage penalties and subsidies also affect the labour supply decisions (both participation and hours) of married individuals. Consider the secondary earner of the family. With the family as the unit of taxation, the secondary earner in a couple will be taxed at the marginal tax rate faced by the family on its combined income, and this tax rate is likely to be much higher than the tax rate that the individual would face if single. Taxing the family thereby discourages both labour force participation and hours worked of the secondary earner. Recent estimates of labour supply elasticities indicate that female labour force participation is especially responsive to marginal tax rates, particularly for women in high-income couples. See Kniesner and Ziliak (2008) for a comprehensive survey.

In sum, this recent research clearly demonstrates that the marriage penalty/subsidy distorts some individual decisions, even if these effects are not always large.

A number of other studies have attempted to calculate the actual penalties or subsidies in the US individual income tax. Although the precise estimates differ, their broad outlines are generally the same. For example, Feenberg and Rosen (1995) use individual tax returns to compute the US marriage penalty for 1994. They find that 51 per cent of married couples paid an average marriage penalty of about $1,200, 38 per cent received an average marriage subsidy of $1,400, and 11 per cent were unaffected. Couples more likely to incur a marriage penalty were two-earner families (especially with similar incomes), families with children, families with higher family income, and older families; single-earner couples generally received a marriage bonus. However, there was much dispersion in the size of the penalty/bonus across households. In total, income taxes were $6 billion higher than otherwise. Studies by Alm and Whittington (1996), the Congressional Budget Office (1997), and Bull et al. (1998) give comparable results.

The marriage penalty/bonus affects families at different levels of income very differently. For example, Alm and Whittington (1996) find that families in the highest family income quintile had an absolute tax penalty that was unambiguously larger than that borne by low- or middle-income couples but that, as a percent of income, the penalties and subsidies were much larger for low-income families. The Congressional Budget Office (1997) estimates that the average tax penalty for a family with less than $20,000 in adjusted gross income (AGI) was 7.6 per cent, compared with 1.6 per cent for families with AGI greater than $50,000. However, the level of family income does not unambiguously determine the magnitude of the marriage penalty/bonus. Rather, it is the distribution of income between husband and wife that largely determines the magnitude and the sign of the change in taxes with marriage. Overall, these differential tax treatments of individuals and families introduce large, variable, and capricious inequities due to unequal treatment of taxpayers based solely on their marital status:

- between married couples with one earner (who get a bonus relative to what they would pay as singles) and those with two earners (who pay a penalty), even if each type of couple pays the same taxes as a married couple;
- between married couples and cohabiting couples – individuals may choose to live together as unmarried cohabiters because of the income tax savings that unmarried status gives them;
- between married couples and single households (for example, the so-called ‘singles tax’); and
- between married couples and extended households (for example, non-marital cohabitation in same-sex households, in households with related individuals, in households with unrelated
As Steuerle (1999) has noted, the marriage tax is almost like a voluntary tax, imposed on those who have decided voluntarily to marry.

Conclusions

What do we want an individual income tax to achieve? There is today an enormous, and increasing, diversity of family structures in many countries. In the 1950s, the ‘traditional family’ was typically a single-earner household with a stay-at-home spouse. Now, many individuals choose to live alone, two-earner families are the norm, non-marital cohabitation among opposite and same-sex couples is common, extended families are increasing in numbers, and there are widespread instances of unrelated individuals living together. These newer types of households are, by many definitions, ‘families’. However, they are treated very differently, and often much less favourably, than the traditional households once envisioned as the norm by the tax codes in many countries.

If concern with the marriage penalty/bonus is an overriding issue, it is certainly possible to move the individual income tax toward marriage neutrality. One obvious method here is to make the individual the unit of taxation. However, it is also possible to move closer to neutrality even while retaining the family as the unit of taxation, by such piecemeal reform options as increasing the standard deduction for married couples, expanding the tax brackets facing married couples, establishing a secondary earner deduction, expanding the phase-out range of transfer programmes, flattening overall rate structures, or allowing optional individual filing. More fundamental reform options include eliminating progressivity (for example, a flat rate tax) or even eliminating the individual income tax and replacing it with a national sales tax or a value-added tax.

However, these reform options would only reduce the marriage penalties (and bonuses) in the individual income tax. There would still be marriage penalties and bonuses throughout other parts of the tax and transfer system. Moreover, suppose the individual is made the unit of taxation, as many OECD countries have chosen to do. This choice is not without its own efficiency, equity, and adequacy problems. An important justification for the use of the family as the unit of taxation is the notion that families with equal family income should pay equal taxes. There is no question that making the individual the unit of taxation would violate this goal of horizontal equity across families, as well as equal payments by singles and couples. There are also significant administrative and compliance issues from individual taxation. How are itemized deductions split between partners? How is unearned (or capital) income split between partners? Who claims the tax benefits from children? How do the tax enforcement agencies verify the legitimacy of these declarations? What are the compliance costs of individual filing? Many other such issues naturally arise, and the ways in which these issues are resolved vary greatly across countries.

It may well be that the importance of the traditional family unit still justifies its favourable tax treatment. This is clearly the avenue that the United States has chosen, and it seems unlikely that this choice will change anytime soon. However, it may also be time to recognize that a diverse society can no longer treat one family structure so differently from the others. Making the individual the unit of taxation would eliminate the marriage tax/subsidy (and the singles tax), and would also re-establish the principle of horizontal equity, broadly defined to apply to individuals and not to families or to couples. Many
countries have in fact chosen to make the individual the unit of taxation. There are no easy choices here, and it is inevitable that the goals of taxation are often conflicting. Taxing the family requires facing these difficult trade-offs directly.

taxation of wealth

Alan J. Auerbach
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

One of the oldest forms of taxation, wealth taxes may take the form of annual taxes based on property or net worth, or assessments collected at less regular intervals, on estates or inheritances or in the form of emergency capital levies. Wealth taxes are still prominent but have become less important than income taxes as a source of revenue. Although wealth taxes are related in structure to taxes on capital income, their economic effects depend on their form. In addition to explicit taxes on wealth, governments impose implicit capital levies through changes in tax policy.

Article

Wealth taxation is one of the oldest methods of government revenue collection, having been used at least since the time of the ancient Greeks. According to Seligman (1895, p. 34), Athens levied a general property tax not only on land and houses, but also on slaves, cattle, furniture, and money. The succeeding centuries have seen many types of wealth taxation tried and others proposed, with perhaps no other form of taxation being the subject of such heated debate.

Wealth taxes are in some sense taxes on capital income. All assets have value because of the returns they generate, though the returns need not be in explicit form (as with business assets) but may be implicit (as with owner-occupied housing or gold). Taxing wealth on an annual basis may therefore be viewed as equivalent to taxing its return at a rate sufficient to produce the same tax revenue. However, a number of factors make wealth taxation and capital income taxation different in practice.
First, governments often levy taxes on very particular forms of wealth (such as land), while income taxation has more typically been broad-based. Second, taxes on income have usually been confined to income explicitly realized. This is, for example, the nearly universal approach to capital gains taxation. Wealth taxes, such as property taxes on owner-occupied real estate, have not followed the same principle. Thus, it has been possible for taxpayers with very little liquidity but substantial wealth to be burdened with taxes well in excess of their explicit income. Moreover, wealth is generally even more unevenly distributed among the population than realized capital income. Finally, while it is natural to expect that income taxes would not exceed 100 per cent of income, there is no comparable upper bound on wealth taxes short of the entire stock of wealth. The perception that wealth taxes threaten the rights of individual citizens through the possibility of discriminatory or unfair taking of assets is undoubtedly a factor in the controversy that has often surrounded wealth taxation.

As of 2000, wealth taxes accounted for five per cent of tax revenues for the average OECD country, although the share was ten per cent or more in several countries, including the United States, the United Kingdom, Canada and Japan (OECD, 2002, Table 23).

Types of wealth taxation

In discussing the history and economic effects of wealth taxation, it is useful to distinguish the primary forms of wealth taxation that have been used. There are four that may be considered important.

Property taxation

This is the oldest form of wealth taxation, dating from antiquity. It is characterized by a tax at regular intervals (for example, yearly) on particular forms of private wealth, most commonly land, but also other forms of property. Originating in an era when land ownership was a much better measure of one's ability to pay than is currently so, property taxes have gradually been replaced and supplemented by other forms of taxation. In the United States, for example, where property taxes are still relatively important, the fraction of government revenue coming from property taxation fell to ten percent or so in the years after the Second World War, compared with around 40 per cent during the first three decades of the 20th century (Carter et al., 2006, Figure Ea-c).

Estate and inheritance taxation

Taxes on bequests and inheritances first appeared long after general property taxes. They differ from property taxes in that they are assessed only once, at death, and typically apply to most assets bequeathed. Estate taxes are typically quite complicated and not particularly successful either at revenue collection or wealth redistribution. Some have referred to the estate tax as a ‘voluntary tax’ because there are so many tax-planning devices available to reduce or eliminate the tax burden imposed on transfers to wealth.

Net worth taxation

As discussed above, net worth taxation, which applies to assets net of liabilities, is very similar in effect to a tax on capital income, differing primarily in its coverage of assets which do not generate substantial current realized income. Whereas property taxes and taxes on estates or inheritances are quite common, only a handful of developed countries currently supplement their revenue collections with broad-based annual taxes on net worth. At the end of the 20th century, only two OECD countries, Iceland and Spain, reported non-negligible revenues from taxes on net worth, although even for these two countries such taxes still accounted for less than one half of one per cent of total revenues (OECD, 2002).

Capital levies

In wartime, countries need vast resources over short periods of time. The preferred method of raising such funds has been the issuance of national debt, but several countries resorted in the 20th century to the capital levy, a ‘one time only’ tax on existing wealth, more burdensome than annual net worth taxes but ostensibly temporary. Such levies were imposed in the First World War by Germany, Czechoslovakia, Austria and Hungary, and prior to the Second World War by Italy and Hungary (Hicks, Hicks and Rostas, 1941). Naturally, fully unanticipated, one-time wealth taxes are non-distortionary if not particularly fair, but the appearance of one country more than once in the above list indicates the difficulty of using capital levies unexpectedly, a problem popularly known as ‘dynamic inconsistency’.

The economic effects of wealth taxation

One may start an analysis of the effects of wealth taxation by noting its similarity to the taxation of capital income, with its coincident discouragement of saving. In practice, however, different forms of wealth taxation may have different or additional effects because of their design. For example, the capital levy may be less distortionary to the extent that it is unanticipated.

The ‘single tax’

In *Progress and Poverty* (1882), Henry George argued for the use of a tax on the rent of unimproved land as the chief source of government revenues. Though some contemporary authors disagreed, it is fairly clear that George's tax, in hitting the return to a productive factor in extremely inelastic supply, would have imposed minimal distortions of economic behaviour. Of course, the ‘single tax’ movement that followed for many years after was invested with a fervour based on much more than the desire for Pareto efficiency.

Taxation and risk-taking

Many authors (for example, Domar and Musgrave, 1944; Stiglitz, 1969) have noted the potentially different impact on risk-taking occurring under capital income and wealth taxes because of the failure of the latter to vary with the asset returns actually realized. But this distinction is more apparent than real once investors have taken the opportunity to scale their asset holdings up or down in response to
Tobin (1958) showed, a tax on risky capital income has no effect on individual welfare and private risk-taking when the safe rate of return is zero. It may further be shown (Gordon, 1985) that, when social risks are efficiently traded, neither does social risk-taking change when such a tax is levied. These results are quite easily extended to the case when the safe rate of return is positive and the tax is on capital income in excess of this safe return on assets. Thus, if we view a tax on all capital income as one on the safe return to capital and one on the excess returns that compensate for risk, only the former component has economic impact. Hence, a capital income tax may be seen as equivalent to a tax levied on asset values multiplied by a fixed, safe rate of return, in which case it is obviously equivalent to a tax on wealth (Kaplow, 1994). Note that this equivalence requires efficient risk-bearing. Otherwise, capital income taxation may be preferred because it allows the government to pool risks that individual investors have not been able to pool privately.

The Tiebout hypothesis

In the United States, property taxes are used primarily to pay for local public services, and are the dominant source of finance for such services. This connection means that, if communities differ in their property tax burdens, one cannot ignore the implied differences in public services if it is necessary to live in a community to partake of its public services, such as education, trash removal, and police and fire protection. In the absence of such a connection, one would expect property tax differentials to be reflected in land prices. However, with government using the taxes to pay for desired public outputs, one might expect a different result.

This notion was formalized by Tiebout (1956), who sketched a theory in which different communities levy different taxes and provide different bundles of public services, the result being a Pareto-optimal allocation with individuals choosing their place of residence according to the bundle of local public goods and services desired. Aside from the difference between such an entrance fee and the actual property tax, there are many other issues that arise in considering the validity of the Tiebout model (Mieszkowski and Zodrow, 1989). Nevertheless, local wealth taxes, with competing jurisdictions, are clearly different in their impact from national wealth taxes.

Bequests and the estate tax

If annual wealth taxes discourage saving in a way similar to annual capital income taxes, one might presume the same result for estate taxes, with the large anticipated one-time burden having an important impact on lifetime saving. However, this presupposes an economic model of bequests that is by no means well accepted, that is, that they are the manifestation of a desire to leave resources to heirs, and that they are influenced by the ‘price’ of an after-tax dollar in the heir's hands. At least one factor leading to bequests is the absence of efficient annuities markets, inducing the need for elderly individuals to engage in precautionary saving to provide for unanticipated health expenses or a longer than predicted lifetime. Such saving would not be influenced at all by taxes imposed after death. Hence, one might view estate taxes as being potentially less distortionary than wealth taxes on the living, but this benefit has not been enough to overcome administrative complexity and popular opposition to strong estate taxes.
Policy changes and implicit wealth taxes

In addition to any taxes they explicitly impose on wealth, governments also use implicit wealth taxes whenever tax policies alter the attractiveness of different assets. For example, under a switch in the individual tax base from income to consumption, investors receive a higher after-tax return on new investments but are saddled with unanticipated taxes on the decumulation of existing assets for consumption purposes (Auerbach and Kotlikoff, 1987). Implicit wealth taxes of this sort are potentially much larger in magnitude than formal wealth taxes themselves.

Taylor rules

Athanasios Orphanides

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Taylor rules are simple monetary policy rules that prescribe how a central bank should adjust its interest rate policy instrument in a systematic manner in response to developments in inflation and macroeconomic activity. This article reviews the development and characteristics of Taylor rules in relation to alternative monetary policy guides and discusses their role for positive and normative monetary policy analysis.

G. K.

Article

Taylor rules are simple monetary policy rules that prescribe how a central bank should adjust its interest rate policy instrument in a systematic manner in response to developments in inflation and macroeconomic activity. They provide a useful framework for the analysis of historical policy and for the econometric evaluation of specific alternative strategies that a central bank can use as the basis for its interest rate decisions.

A perennial question in monetary economics has been how the monetary authority should formulate and implement its policy decisions so as to best foster ultimate policy objectives such as price stability and full employment over time. It is widely accepted that well-designed monetary policy can counteract macroeconomic disturbances and dampen cyclical fluctuations in prices and employment, thereby
Taylor rules: The New Palgrave Dictionary of Economics

improving overall economic stability and welfare. In principle, when economic growth unexpectedly weakens below the economy's potential, accommodative monetary policy can stimulate aggregate demand and restore full employment. Likewise, when inflationary pressures develop, monetary restriction can restore the central bank's price stability objective. In practice, however, given the limited knowledge that economists have about the macroeconomy – for example, about macroeconomic dynamics, about the monetary transmission mechanism, and even about the measurement of fundamental concepts such as the natural rates of output, employment and interest – there is substantial disagreement about the scope of stabilization policy and about policy design.

One approach is to decide upon what seems to be the best policy on a period-by-period basis, without appeal to any specific policy guide. A seeming advantage of this approach is that it gives policymakers the discretion to use their judgement period by period. However, a basic tenet of modern research is that systematic policy – that is, policy based on a contingency plan or policy rule – has important advantages over a purely discretionary policy approach. By committing to follow a rule, policymakers can avoid the inefficiency associated with the time-inconsistency problem that arises when policy is formulated in a discretionary manner. Following a rule allows policymakers to communicate and explain their policy actions more effectively. Policy based on a well-understood rule enhances the accountability of the central bank and improves the credibility of future policy actions. Also, by making future policy decisions more predictable, rule-based policy facilitates forecasting by financial market participants, businesses, and households, thereby reducing uncertainty.

Various proposals for monetary policy rules have been made over time, and a vast literature continues to examine the relative advantages and drawbacks of alternatives in abstract theoretical terms, in the context of empirical macroeconometric models, and in terms of the practical experience accumulated from past policy practice. To appreciate the appeal and limitations of Taylor rules, it is useful to relate their development to other proposals for systematic monetary policy.

Development of monetary policy rules

Some proposals suggest postulating a rule in terms of the main objectives of monetary policy, for example ‘maintain economic stability’ or ‘maintain a constant aggregate price level’. (See Simons, 1936, for early arguments favouring price-level targeting over discretionary policy.) One important practical difficulty with these proposals, however, is that the concepts involved are not under the control of the central bank and thus the proposals are not operational. In essence, these proposals fail to draw a clear distinction between the objectives of monetary policy and the policy instruments that are at least under the approximate control of the central bank. As a result, the suggested rules are only implicit in nature and are difficult to monitor and to distinguish from discretionary policy in a meaningful manner.

To be useful in practice, policy rules must be simple and transparent to communicate, implement and verify. This requires a clear choice of what should serve as the policy instrument – for example the money supply, $m$, or the short-term interest rate, $i$ – and clear guidance as to how any other information necessary to implement the rule – for instance recent readings or forecasts of inflation and economy activity – should be used to adjust the policy instrument.

Perhaps the simplest example of a policy rule is the proposal that the central bank maintain a constant rate of growth of the money supply – Milton Friedman's $k$-percent rule (Friedman, 1960). The rule draws
Taylor rules: The New Palgrave Dictionary of Economics

on the equation of exchange expressed in growth rates:

\[ \Delta m + \Delta v = \pi + \Delta q \]

(1)

where \( \pi \equiv \Delta P \) is the rate of inflation and \( p, m, v, \) and \( q \) are (the logarithms of), respectively, the price level, money stock, money velocity, and real output. Selecting the constant growth of money, \( k \), to correspond to the sum of a desired inflation target, \( \pi^* \), and the economy's potential growth rate, \( \Delta q^* \), and adjusting for any secular trend in the velocity of money, \( \Delta v^* \), suggests a simple rule that can achieve, on average, the desired inflation target, \( \pi^* \):

\[ \Delta m = \pi^* + \Delta q^* - \Delta v^*. \]

(2)

Further, if the velocity of money were fairly stable this simple rule would also yield a high degree of economic stability. An early illustration of this rule appeared in 1935 in the work of Carl Snyder, a statistician at the Federal Reserve Bank of New York. After estimating that the normal rate of growth of trade in the United States was about four per cent per year at the time and observing that the velocity of money was stable, Snyder argued that 'the highest attainable degree of general industrial and economic stability will be gained by an expansion of currency and credit … at this rate [four per cent]' (Snyder, 1935, p. 198). During the 1960s and early 1970s, Milton Friedman's recommendation that the Federal Reserve control the rate of money growth to equal four per cent per year was similarly based on the assumption that potential output growth in the United States roughly equalled four per cent – the prevailing estimate at that time.

Another way to interpret this policy rule is in terms of the growth of nominal income, \( \Delta x = \pi + \Delta q \). With the economy's natural growth of nominal income defined as the sum of the natural growth rate of output and the central bank's inflation objective, \( \Delta x^* = \pi^* + \Delta q^* \), a rule for constant money growth can be seen as targeting this natural growth rate. An advantage of a constant money growth rule is that very little information is required to implement it. If velocity does not exhibit a secular trend, the only required element for calibrating the rule is the economy's natural growth of output. In addition, while the calibration of this rule does not rest on the specification of any particular model, the rule is remarkably stable across alternative models of the economy. In this sense, the policy of maintaining a constant growth rate of money is arguably the ultimate example of a rule that is robust to possible model misspecification.

Simple modifications allowing for some automatic response of money growth to economic developments have also been proposed as simple rules that could deliver improved macroeconomic
Taylor rules: The New Palgrave Dictionary of Economics

performance (see, for example, Cooper and Fischer, 1972). Among the simplest such alternatives is the rule associated with Bennett McCallum (1988; 1993):

$$\Delta m = \Delta x^* - \Delta \nu^* - \psi \Delta x (\Delta x - \Delta x^*).$$

(3)

McCallum showed that, if a rule such as this (for example, with $\psi \Delta x = 0.5$) had been followed, the performance of the US economy likely would have been considerably better than actual performance, especially during the 1930s and 1970s – the two periods of the worst monetary policy mistakes in the history of the Federal Reserve.

A factor that complicates the use of the money stock as a policy instrument is the potential for instability in the demand for money due either to temporary disturbances or to persistent changes resulting from financial innovation. In part for this reason, central banks generally prefer to adjust monetary policy using an interest rate instrument.

A policy rule quite as simple as Friedman's $k$-percent rule cannot be formulated with an interest rate instrument. As early as Wicksell's (1898) monumental treatise on *Interest and Prices*, it was recognized that attempting to peg the short-term nominal interest rate at a fixed value does not constitute a stable policy rule. (Indeed, this was one reason why Friedman, 1968, and others expressed a preference for rules with money as the policy instrument.) Wicksell argued that the central bank should aim to maintain price stability, which in theory could be achieved if the interest rate were always equal to the economy's natural rate of interest, $r^*$. Recognizing that the natural rate of interest is merely an abstract, unobservable concept, however, he noted: 'This does not mean that the bank ought actually to *ascertain* the natural rate before fixing their own rates of interest. That would, of course, be impracticable, and would also be quite unnecessary.' Rather, Wicksell pointed out that a simple policy rule that responded systematically to prices would be sufficient to achieve satisfactory, though imperfect, stability: 'If prices rise, the rate of interest is to be raised; and if prices fall, the rate of interest is to be lowered; and the rate of interest is henceforth to be maintained at its new level until a further movement in prices calls for a further change in one direction or the other' (Wicksell, 1898, p. 189, emphasis in the original). In algebraic terms, Wicksell proposed what is arguably the simplest reactive monetary rule with an interest rate instrument:

$$\Delta i = \theta \Pi.$$

(4)

Wicksell's simple interest rate rule did not attract much attention in policy discussions, perhaps because of its exclusive focus on price stability and lack of explicit reference to developments in real economic activity.
Taylor rules: The New Palgrave Dictionary of Economics

The classic Taylor rule and its generalizations

The policy rules that are commonly referred to as Taylor rules are simple reactive rules that adjust the interest rate policy instrument in response to developments in both inflation and economic activity. An important advance in the development of these rules can be identified with the policy regime evaluation project reported in a volume published by the Brookings Institution (Bryant, Hooper and Mann, 1993). The objective of the project was to identify simple reactive interest rate rules that would deliver satisfactory economic performance for price stability and economic stability across a range of competing estimated models. The Brookings project examined rules that set deviations of the short-term nominal interest rate, $i$, from some baseline path, $i^*$, in proportion to deviations of target variables $z$, from their targets, $z^*$:

$$i - i^* = \theta(z - z^*).$$

(5)

The collective findings pointed to two alternatives as the most promising in delivering satisfactory economic performance across models. One targeted nominal income, while the other targeted inflation and real output:

$$i - i^* = \theta_\pi(\pi - \pi^*) + \theta_q(q - q^*).$$

(6)

The potential usefulness of this particular rule as a benchmark for setting monetary policy was further highlighted in the celebrated contribution by John B. Taylor at the Fall 1992 Carnegie-Rochester Conference on Public Policy. Taylor developed a ‘hypothetical but representative policy rule’ (1993, p. 214) by using the sum of the equilibrium or natural rate of interest, $r^*$, and inflation, $\pi^*$, for $i^*$ and setting the inflation target and equilibrium real interest equal to two and the response parameters to one half. The result was what became known as the classic Taylor rule:

$$i = 2 + \pi + \frac{1}{2}(\pi - 2) + \frac{1}{2}(q - q^*).$$

(7)
Taylor noted that, if one used the deviation of real quarterly output from a linear trend to measure the output gap, \((q - q^*)\), and the year-over-year rate of change of the output deflator to measure inflation, \(\pi\), this parameterization appeared to describe Federal Reserve behaviour well in the late 1980s and early 1990s.

The confluence of the econometric evaluation evidence supporting the stabilization properties of this rule and its usefulness for understanding historical monetary policy in a period generally accepted as having good policy performance generated tremendous interest, and numerous central banks began to monitor this policy rule or related variants to provide guidance in policy decisions. These developments also greatly influenced monetary policy research and teaching. By linking interest rate decisions directly to inflation and economic activity, Taylor rules offered a convenient tool for studying monetary policy while abstracting from a detailed analysis of the demand for and supply of money. This allowed the development of simpler models (see the survey in Clarida, Gali and Gertler, 1999, and papers in Taylor, 1999) and the replacement of the ‘LM curve’ with a Taylor rule in treatments of the Hicksian IS–LM apparatus. (It should be noted, however, that this abstraction is overly simplistic when the short-term interest rate approaches zero. At the zero bound, the stance of monetary policy can no longer be measured or communicated with a short-term interest rate instrument; see, for example, Orphanides and Wieland, 2000). Subsequent research (see Orphanides, 2003b, for a survey) suggested that a generalized form of Taylor's classic rule could provide a useful common basis both for econometric policy evaluation across diverse families of models and for historical monetary policy analysis over a broad range of experience:

\[
i = (1 - \theta_i)(r^* + \pi^*) + \theta_i \pi_{t-1} + \theta_{\pi}(\pi - \pi^*) + \theta_q(q - q^*) + \theta_{\Delta q}(\Delta q - \Delta q^*). \tag{8}
\]

The generalized Taylor rule (8) nests rule (6) as a special case but introduces two additional elements. First, it allows for inertial behaviour in setting interest rates, \(\theta_i > 0\), which proves particularly important for policy analysis in models with strong expectational channels (Woodford, 2003). Second, it allows the policy response to developments in economic activity to take two forms: a response to the level of the output gap, \((q - q^*)\), or its difference, which can also be restated as a response to the difference between output growth and its potential, \((\Delta q - \Delta q^*)\). The generalized Taylor rule also nests another simplification of special interest, \(\theta_i = 1\) and \(\theta_q = 0\), which yields a family of difference rules similar to Wicksell's original proposal:

\[
\Delta i = \theta_{\pi}(\pi - \pi^*) + \theta_{\Delta q}(\Delta q - \Delta q^*). \tag{9}
\]
These difference rules are also of interest because, like money-growth rules, their implementation does not require estimates of the natural rate of interest or the level of potential output (and the output gap) but only of the growth rate of potential output. Indeed, these rules may be viewed as a reformulation of money-growth rules in terms of an interest rate instrument. To see the relationship of (9) to money growth targeting, note that, by substituting the money growth in rule (3) into the equation of exchange, that rule can be stated in terms of the velocity of money:

$$
\Delta v - \Delta v^* = (1 + \psi\Delta x)(\Delta x - \Delta x^*).
$$

To reformulate this strategy in terms of an interest rate rule, consider the simplest formulation of money demand as a (log-) linear relationship between velocity deviations from its equilibrium and the rate of interest. In difference form this is

$$
\Delta v - \Delta v^* = a\Delta i + e,
$$

where $a > 0$ and $e$ summarizes short-run money demand dynamics and temporary velocity disturbances. An interest-rate-based strategy that avoids the short-run velocity fluctuations, $e$, may be obtained by substituting the remaining part of (11) into (10). This yields

$$
\Delta i = \theta(\Delta q - \Delta q^*)
$$

for some $\theta > 0$, which, as can be readily seen, has the same form as rule (9).

In light of this flexibility in nesting a wide range of alternative monetary policy strategies and the relative simplicity of the form (8), Taylor rules have been used to discuss a variety of policy regimes, from money growth targeting (see, for example, Clarida and Gertler, 1997) to inflation targeting (see, for example, Orphanides and Williams, 2007).

A crucial element for the design and operational implementation of a Taylor rule is the detailed description of its inputs. This requires specificity regarding the measures of inflation and economic activity that the policy rule should respond to, whether forecasts or recent outcomes of these variables...
are to be employed, and the source of these data or forecasts. In addition, the source of information and updating procedures regarding the unobservable concepts required for implementing the rule must be stipulated. Specificity in these dimensions is essential for practical analysis because there is often a multitude of competing alternatives and a lack of consensus about the appropriate concepts and sources of information that ought to be used for policy analysis. This situation is particularly vexing in regard to the treatment of unobservable concepts, such as the output gap. Unfortunately, econometric policy evaluation exercises suggest that inferences regarding the performance of a particular Taylor rule often depend sensitively on assumptions regarding the availability and reliability of these inputs. Differences in underlying assumptions complicate comparisons across studies and often explain differences in reported findings.

An illustrative example of this sensitivity relates to improper treatment of information regarding the current state of the economy. A common pitfall in theoretical policy evaluation exercises is to assume that the current state of the economy – for example, the current output gap – can be perfectly observed. Under this assumption, a Taylor rule with a vigorous response to the output gap is often recommended as ‘optimal’ in model-based policy evaluations. However, naive adoption of such recommendations would be counterproductive. Available real-time estimates of the output gap are imperfect, and historical experience suggests that the mismeasurement is often substantial. Under these circumstances, better stabilization outcomes would result if policy did not respond to the output gap at all or if it responded to output growth instead (Orphanides, 2003a). If the natural rate of interest is also unknown and its real-time estimates are subject to significant mismeasurement, the difference variant of the Taylor rule, (9), proves considerably more robust than the Brookings variant, (6), reversing the ranking of the two alternatives that is implied under perfect knowledge (Orphanides and Williams, 2002).

Another example of such sensitivity relates to the use of forecasts in the Taylor rule. Because of lags in the monetary policy transmission mechanism, pre-emptive policy reaction is generally recommended, especially with respect to inflation. But inferences regarding the performance of forecast-based policy are sensitive to the quality of the forecasts. In some models, Taylor rules responding to several-quarters-ahead forecasts of inflation appear more promising for stabilization than rules focusing only on near-term conditions. However, this conclusion is not robust and is overturned once the potential unreliability of longer-term forecasts due to model misspecification is factored into the analysis (Levin, Wieland and Williams, 2003).

As already noted, Taylor rules have proven valuable for historical policy analysis. Following Taylor (1993), numerous authors have examined historical monetary policy in the United States using either calibrated or estimated versions of Taylor rules (8). Studying the characteristics of policy in periods associated with good or bad economic performance helps identify aspects of policy that may be associated with such differences in performance. A complicating factor is the need for real-time data and forecasts for proper inference (Orphanides, 2001). The pitfall of using ex post revised data and retrospective estimates of unobserved concepts in estimating Taylor rules is not uncommon. However, interpretations of historical policy based on information that was unavailable to policymakers when policy decisions were made is of questionable value. Policy prescriptions from a fixed rule are distorted as the inputs to the rule are revised from those originally available to policymakers, and therefore counterfactual comparisons of alternative policy rules can be misleading when they are based on revised data.
Despite these challenges, some useful elements of policy design emerge from historical analysis of Taylor rules. First, and arguably most important, good stabilization performance is associated with a strong reaction to inflation. Second, good performance is associated with policy rules that exhibit considerable inertia. Third, a strong reaction to mismeasured output gaps has historically proven counterproductive. Fourth, successful policy could still usefully incorporate information from real economic activity by focusing on the growth rate of the economy. To be sure, such broad principles provide insufficient guidance for identifying the precise policy rule that might be ideal in a specific context. But this is not the objective of policy design with Taylor rules. Rather, the goal is the identification of simple guides that are robust to misspecification and other sources of error experienced over history.

In summary, Taylor rules offer a simple and transparent framework with which to organize the discussion of systematic monetary policy. Their adoption as a tool for policy discussions has facilitated a welcome convergence between monetary policy practice and monetary policy research and proved an important advance for both positive and normative analysis.

Taylor made his chief contribution to economic theory in his 1928 presidential address to the American Economic Association, in which he laid out the basic principles of market socialism (Taylor, 1929). He argued that rational allocation of resources could be achieved in a socialist state if three conditions are met: citizens obtain income from the state in exchange for services; income is freely spent on goods offered for sale by the state at given prices; prices are set at full costs of production. The third condition can be met through a trial-and-error method in which prices of factors of production are set at levels that clear the market. Given these costs and consumer demand, markets for finished products can be cleared by adjusting levels of output and inventories. Such a system could achieve results similar to those of a competitive private enterprise economy.

Taylor's doctorate was in philosophy from the University of Michigan (1888). He taught at Albion College 1879–92, and in the Department of Economics at Michigan from 1892 to 1929. A strong advocate of laissez-faire policies and the gold standard, Taylor was a noted expositor of economic theory, with emphasis on Marshallian partial equilibrium analysis, analytic rigour and a libertarian ideology. His Principles textbook (Taylor, 1911) went through nine editions from 1911 to 1925.

Taylorism

A.L. Friedman

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

scientific management; soldiering; Taylor, F. W.; Taylorism; time study

Article

Taylorism refers to the system of management developed by Frederick Winslow Taylor. Taylor called his system ‘scientific management’. Scientific management is clearly described in Taylor's two most famous works, Shop Management (1903) and The Principles of Scientific Management (1911). Scientific management is based on the following principles:

1. 1. Management gathers and systematizes all the workers’ traditional knowledge.
2. 2. All possible ‘brainwork’ is removed from the shop and centred in the planning or layout department.
3. 3. The work should be divided into its simplest constituent elements: the tasks. Management should try to limit individual ‘jobs’ to a single task as far as possible.
4. 4. Managers should specify the tasks to be done in complete detail. These tasks should be presented to the worker in written form. They should note not only what is to be done, but also how it is to be done and the exact time allowed for doing it.
5. 5. The work should be monitored closely.

Taylor's techniques for gathering information about work was time study, the measurement of elapsed time for each component operation of a work process. Taylor also recommended that the foreman's job should be divided into more simplified task collections. Shop-floor foremen should be divided into the setting-up boss, speed boss, quantity inspector and repair boss. However, the main division was to separate work-design and manning-level decisions away from shop-floor foremen and to the planning department.

The purpose of Taylor's system was to eliminate ‘soldiering’, or low worker effort. This could either take the form of natural soldiering, the natural instinct and tendency for men to take it easy, or
systematic soldiering, the calculated reduction of effort arising from actions and communication among groups of workers. The ultimate cause of both forms of soldiering for Taylor ‘lay in the ignorance of the management as to what really constitutes a proper day’s work for a workman’ (1911, p. 53). Once this was determined ‘scientifically’, workers would be forced to comply with this standard by careful monitoring of their performance and by a differential piecework payment system. A target rate of work would be determined by work study. If workers exceeded this target, they would receive a bonus, but bonus payments would reach a ceiling between 30 per cent and 100 per cent of the standard work rate. If workers failed to meet their targets, they would lose earnings.

There is a wide range of opinions as to the importance of Taylorism. For some, Taylorism represents the dominant theory and practice of 20th-century management (Drucker, 1954; Braverman, 1974). For others, Taylorism is viewed as having widespread ideological impact, but not much influence on practice because it was successfully resisted by workers and was too expensive for managers (Edwards, 1979). Finally, there are those who view Taylorism as an expression of important changes in management practices, but that moves towards Taylorism have not been universal. The application of Taylorism is contingent on environmental factors (Friedman, 1977; Littler, 1982).

teams

Roy Radner
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

A team consists of a number of decision-makers, with common interests and beliefs, but controlling different decision variables and basing their decisions on (possibly) different information. The economic theory of teams is concerned with (1) the allocation of decision variables and information among the team members, and (2) the characterization of efficient decision rules, given the allocation of tasks and information. The theory of teams thus addresses a middle ground between the theory of individual decision under uncertainty and the theory of games, and provides a natural framework for the analysis of mechanisms for decentralization, including market-like mechanisms.

Article

The economic theory of teams addresses a middle ground between the theory of individual decision under uncertainty and the theory of games. A team is made up of a number of decision-makers, with common interests and beliefs, but controlling different decision variables and basing their decisions on (possibly) different information. The theory of teams is concerned with (1) the allocation of decision variables (tasks) and information among the members of the team, and (2) the characterization of efficient decision rules, given the allocation of tasks and information.

For example, in the pre-computer age, airline companies had a number of ticket agents who were authorized to sell reservations on future flights with only partial information about what reservations had been booked by other agents. A team-theoretic issue would be the characterization of best rules for those agents to use under such circumstances, taking account of the joint probability distribution of demands for reservations at the different offices, the losses due to selling too many or too few reservations in total, and so forth. A second issue would be the calculation of the increase in expected profit that would
be obtained by providing each agent with better information about the status of reservations at all offices, or by increased centralization of the reservation process. To calculate this increase in expected profit – the value of the additional information – one of course needs to know something about the best decision rules with and without the additional information. However, providing this additional information would require additional communication, transmission, processing, and storage, all of which would be costly. The value of the information puts an upper bound on the additional cost that should be incurred. The value – and cost – of the information will depend on its structure and on the structure of the team's decision problem, and not just on some simple measure of the 'quantity' of information. (For a study of the airline reservation problem, and other models of sales organization, from a team-theoretic point of view, see Beckmann, 1958 and McGuire, 1961, respectively.)

In this entry we shall sketch a formal model of team theory, the characterization of optimal team decision functions, and the evaluation of information in a team. The theory will be illustrated with a discussion of decentralized resource allocation, followed by concluding remarks on the incentive problem.

A formal model

We consider a team and $M$ members. Each member $m$ controls an action, say $a_m$. The resulting utility to the team depends on the team action,}

$$a = (a_1, \ldots, a_M),$$

and on the state of the environment. (Since the team members have common interests, there is a single utility for the whole team.) The state of the environment comprises all the variables about which team members may be uncertain before choosing their actions. It is determined exogenously, i.e. is not subject to the control or influence of the team members. If we denote the state of the environment by $s$, then we can denote the utility to the team by $u(a, s)$; the function $u$ will be called the payoff function for the team. Before choosing an action, each team member $m$ receives an information signal, $y_m$. This information signal is determined by the state of the environment, say $y_m = \eta_m(s)$. (This includes the case of 'noisy' information, if the description of the state of the environment includes a description of the noise.) We shall call $\eta_m$ the information function for member $m$, and the $M$-tuple $\eta = (\eta_1, \ldots, \eta_M)$ will be called the information structure of the team.

Each team member $m$ will choose his action on the basis of the information signal he receives, according to a decision function, say $\alpha_m$. Thus

$$a_m = \alpha_m(y_m) = \alpha_m(\eta_m[s]).$$

(1)
If we use the symbol $\alpha$ to denote the \textit{team decision} function, i.e., the $M$-tuple of individual decision functions, then the utility to the team, in state $s$, of using the information structure $\eta$ and decision function $\alpha$ can be expressed as

$$U(s) = u[\alpha(\eta[s]), s],$$

To express the team's uncertainty about the state of the environment, we suppose that $s$ is determined according to some probability distribution, $\phi$, on the set $S$ of possible states. This probability distribution may be interpreted as ‘objective’ or ‘personal’; in the latter case it represents the beliefs of the team members (Savage, 1954). It is part of the definition of a team that its members have common beliefs, as well as common utility functions.

With the state $s$ distributed according to the probability distribution $\phi$, the utility $U(s)$ in (2) is a random variable. We shall assume that the team chooses its decision function so as to maximize the (mathematical) expectation of this utility,

$$E[U(s)] = \sum_s \phi(s)U(s) \equiv \omega(\alpha, \eta, \phi).$$

As a special case, suppose that the information functions of the team members are identical. In this case, the team decision problem is formally identical to a one-person decision problem in which the same person controls all of the actions. An alternative interpretation of this case is that the information is \textit{centralized}. By contrast, if at least two team members have essentially different information functions, then we may say that the information is \textit{decentralized}. With this definition of (informational) decentralization, we see that all organizations but the very smallest are likely to be decentralized to some extent.

The expected utility for the team depends on the team members’ decision function, the team information structure, and the probability distribution of states of the environment, as well as on the ‘structure’ of the decision problem, i.e. the way in which the utility (2) depends on the members’ action and the state of the environment. This is brought out by the notation in (3). If we want to compare the usefulness of two different information structures, we have to associate with them some corresponding decision function $\alpha$ and probability distribution $\phi$. Since the probability distribution (sometimes called the ‘prior distribution’) represents either objective probabilities or the team members’ common beliefs before they receive further information, it is natural to take it as a datum of the problem. On the other hand, since the decision functions can be chosen by the team, it is natural to associate with each information structure
the corresponding team decision function that maximizes its expected utility (given the information structure). Thus the optimization problem for the team may be posed in two stages: (1) for a given information structure, characterize the optimal team decision function(s); (2) optimize the information structure, taking account of the costs of – or constraints on – making the information available, and with the proviso that for each information structure the team uses an optimal decision function. More will be said below about each of these stages of the problem. However, it should be emphasized here that the choice of information structure comprises most of the organizational design choices that are not concerned with conflicts of interests or beliefs among the organization's members. The information structure is, of course, affected by the pattern of observation and communication in the team. In addition, the allocation of tasks within the team is expressed by the information structure. To see this, suppose that each member of the team were assigned an information structure; then a reassignment of decision variables to team members would be formally equivalent to reassigning information functions to decision variables.

Optimal decision functions

We shall now consider the characterization of team decision functions that are optimal for a given structure of information. It will be useful to recall here the corresponding problem for a single-person decision problem (see, e.g., Marschak and Radner, 1972, ch. 2). We may use the same model and notation as in the previous section, but remembering that there is only one member of the team. The following statement provides a general characterization of the optimal decision function: For each information signal, choose an action that maximizes the conditional expected utility given the particular signal.

This characterization is easily derived from equations (2) and (3). In equation (3), group the terms in the sum according to the information signal associated with each state; this gives us

\[ E[U(s)] = \sum_y \sum_{\eta(s) = y} \varphi(s) U(s). \]

(4)

From (2), if \( \eta(s) = y \), then the resulting utility in that state is

\[ U(s) = u[\alpha(y), s]. \]

(5)

For each signal \( y \), the decision-maker can choose an action \( a = \alpha(y) \). Hence, combining (4) and (5) we see that, for each signal \( y \), the decision-maker should choose \( a = \alpha(y) \) to maximize
Let $\psi(y)$ denote the probability of $y$, and let $\phi(s|y)$ denote the conditional probability of $s$ given $y$. By definition,

$$\psi(y) = \sum_{y=\eta(s)} \phi(s),$$

and if $y = \eta(s)$,

$$\phi(s|y) = \frac{\phi(s)}{\psi(y)},$$

or

$$\phi(s) = \psi(y) \phi(s|y).$$

Hence (6) can be written as

$$\psi(y) \sum_{\eta(s)=y} \phi(s|y) u(a, s),$$

so that maximizing (6) is equivalent to maximizing
which we recognize as the conditional expected utility using the action \(a\), given the signal \(y\). This proves the above characterization of the best decision function. (Notice that we have implicitly assumed that the signal has positive probability. There is no loss of generality in doing so; we can simply exclude from consideration all signals that have zero probability, since they do not affect the expected utility.)

The characterization of optimal single-person decision functions can be extended to the case of a team, but in a restricted way. Consider a particular team member \(i\). If a team decision function, say \(\alpha\), is optimal, then surely \(i\)'s decision function \(\alpha_i\) is optimal given that each other member \(j\) uses \(\alpha_j\). Hence \(i\) is faced, so-to-speak, with a one person decision problem in which the other members’ decision functions form part of \(i\)'s ‘environment’. The following is therefore a necessary condition for a team decision function to be optimal:

**Person-by-person-optimality condition**

For each member \(i\), and for each signal \(y_i\) with positive probability, the corresponding action \(\alpha_i(y_i)\) maximizes the team's conditional expected utility given the signal, \(y_i\) and the decision functions of the other members.

Although person-by-person-optimality is necessary for optimality, it need not be sufficient. However, one can prove the following:

**Theorem 1:** If each member's action is a real finite-dimensional vector chosen from some open rectangle, and if for each state \(s\) the team's utility is a concave and differentiable function of the team action, then any team decision function that is person-by-person-optimal is also optimal. (For a proof of this theorem, and an example in which a person-by-person-optimal decision function fails to be optimal, see Marschak and Radner, 1972, ch. 10, s. 3.; for a more complete treatment, see Radner, 1962.)

The person-by-person-optimality condition can be applied to yield more detailed characterizations of optimal team decision functions for special cases, e.g., in which the utility function is quadratic or piecewise-linear (see Marschak and Radner, 1972, ch. 10). A few such applications are illustrated below.

**The evaluation of information**

As noted at the beginning of this discussion, many of the most interesting qsts in organizational design concern the comparison of alternative information structures. One information structure is better than another to the extent that it permits better decisions; on the other hand, this improvement can be obtained only at some additional cost.

We first consider the case in which the utility from the decisions is additively separable from the cost of the information structure; we shall call this the *separable case*. In this case, one is justified in defining
the gross value of an information structure as the difference between (1) the expected utility derived from its best use and (2) the maximum utility obtainable using no information (beyond that contained in the prior probability distribution of states).

If the team has no information (the null information structure), then its decision function reduces to a single team action. The maximum expected utility that the team can obtain with the null information structure is

$$V_0(\varphi) = \max_a \sum_s u(a, s).$$

(9)

Hence in the separable case, the gross value of an information structure $\eta$ is defined as

$$V(\eta, \varphi) = \max_\alpha \omega(\alpha, \eta, \varphi) - V_0(\varphi).$$

(10)

(Cf. equation (3).)

Note that the value of an information structure depends on the prior distribution, as well as on the entire structure of the decision problem (available actions, utility function, etc.). This should make one suspect that there is no way to tell whether one information structure is more valuable than another just by examining the two information structures alone.

To examine this question more carefully, it is useful to introduce another representation of information. Consider again for the moment the single-person case; an information structure then consists of a single function from states to information signals. For any given signal, there is a set of states that give rise to that signal. This correspondence between signals and sets of states determines a partition of the set of states; each element of the partition is a set of all states that lead to a particular signal; denote this partition by $(S_y)$. It is obvious that any two information structures that give rise to the same partition are equivalent from the point of view of the decision-maker, and in particular must have the same value. In other words, the names or labels of the signals are unimportant.

Suppose now that the set $S$ of states of the environment, the number $M$ of team members, and the set $A$ of team actions are fixed. Consider the family of all team decision problems that can be formulated with the given triple $(S, M, A)$. In other words, consider the set of all pairs $(u, \varphi)$, where $u$ is a utility function for the team, and $\varphi$ is a prior distribution, compatible with $(S, M, A)$. We shall say that one information structure is as valuable as another information structure if the value of the first is greater than or equal to the value of the second for all team decision problems compatible with $(S, M, A)$. (Value is defined by equation (10).)

The following criterion provides a simple test for the relation ‘as valuable as’. Of two partitions of the
set \( S \), we shall say the first is as *fine* as the second if every element of the first partition is a subset of some element of the second (the first can be obtained by ‘refining’ the second). Let \( \eta = (\eta_1, \ldots, \eta_M) \) and \( \chi = (\chi_1, \ldots, \chi_M) \) be two team information structures. We shall say that \( \eta \) is as fine as \( \chi \) if for every team member \( m \), \( \eta_m \) is as fine as \( \chi_m \). One can prove (see Marschak and Radner, 1972, Ch. 2, Sec. 6):

Theorem 2: Assume that every team member has at least three alternative actions; then the information structure \( \eta \) is at least as valuable as the information structure \( \chi \) if and only if, for each member \( m \), \( \eta_m \) is as fine as \( \chi_m \).

Theorem 2 can be extended to deal with ‘noisy’ information (see, e.g., McGuire, 1972). Since two partitions of a set need not be ranked by the relation ‘as fine as’, it is clear from Theorem 2 that the relation ‘as valuable as’ is only a partial ordering of information structures. This implies, in particular, that there is no numerical measure of ‘quantity of information’ that can rank all information structures in order of value, independent of the decision problem in which the information is used.

If the utility of the team decision and the cost of information are not additively separable, then an alternative definition of value of information must be used. For example, suppose that the outcome of the team decision and the cost of the information structure are both measured in dollars, and the team is not risk-neutral, so that the team utility is some (nonlinear) function of the outcome and the cost. Then we can define the value of the information structure as the ‘demand price’, i.e., the smallest cost that would make the team indifferent between using the information structure and having no information beyond the prior distribution. (For further discussion of the comparison of information structures, see McGuire, 1972. For more on the value of and demand for information, see Arrow, 1972.)

**Decentralization**

We have used the term informational decentralization to refer to a structure of information in which not all members have the same information function. In an economic organization the information structure is generated by processes of observation, communication, storage, and computation. For example, suppose that each team member \( m \) starts by observing a different random variable, say \( \zeta_m(s) \). If there were no communication among the members before actions were taken, then each member's information would be the same as his observation – an extreme form of decentralization. On the other hand, if there were complete communication of their observations among the members, then their information functions would be identical, namely \( \zeta = (\zeta_1, \ldots, \zeta_M) \). Alternatively, the latter information structure could be generated by having all members communicate their observations to a central agency, which would then compute the team action and communicate the corresponding individual action to each member. In the last two cases, we would say that the information structure is completely centralized, because all of the members’ actions were based on the same information.

Rarely does one encounter in a real organization the extremes of no communication or complete communication just described. Rather, one finds that numerous devices are used to bring about a partial exchange of information. The usefulness of such devices is measured by the excess of additional value (expected utility) they contribute over the costs of installing and operating them. Examples of such devices are the dissemination of reports and instructions, the formation of committees and task forces, and ‘management by exception’. Formal models and a comparative analysis of some of these devices are
given in (Marschak and Radner, 1972, ch. 6). In particular, this methodology is used to elucidate the value of two different forms of management by exception.

**Allocation of resources in a team**

For many economists, the purely competitive market represents the ideal model of economic decentralization. Indeed, in some economic literature, ‘decentralization’ and ‘pure competition’ are synonymous. The potential usefulness of market-like mechanisms to decentralize economic decision-making in a socialist economy has also been discussed by students of socialism (Lange and Taylor, 1938; Lerner, 1944; Ward, 1967).

The theory of teams provides a natural framework for the analysis of market mechanisms as a device for decentralization. For example, consider the problem of allocating resources to productive enterprises. Suppose that some resources are initially held centrally by a ‘resource manager’. Before any exchange of information, the resource manager observes the supplies of centrally available resources, and each enterprise manager observes his respective local conditions of production: technology, supplies of local resources, etc. The action of the resource manager is to allocate the central resources among the enterprises. The action of an enterprise manager includes (say) the choice of techniques and the levels of inputs of local resources. The state of the environment comprises the total supplies of central resources and the local conditions.

At one extreme, the team action could be taken without any communication. In particular, the central resources would be allocated based only on the prior probability distribution of local conditions. Regarding the supplies of central resources, each enterprise manager would know only the prior probability distribution of such supplies, and the allocation rule to be used by the resource manager. We might call the resulting information structure ‘routine’.

At the other extreme (complete centralization), each enterprise manager might be required to report to the resource manager all of his information about local conditions. The resource manager would then compute both the optimal decisions of the enterprises and the optimal allocation of resources. Accordingly, the resources would be allocated and the enterprise managers would then be ‘instructed’ by the resource manager as to what actions they should take.

In a market mechanism, the resource manager would announce prices (of central resources), and the enterprise managers would respond with demands. In the literature on allocation and price-adjustment mechanisms it is usually assumed that this exchange of messages is iterated until an equilibrium of supply and demand is reached (this may require infinitely many iterations!). In a real application of such a mechanism, only a few iterations would typically be feasible, and equilibrium would not be reached. Thus one could not appeal to the theory of optimality of the equilibria of such processes. Nevertheless, the exchange of information produced by even a few iterations might be quite valuable, i.e., the information structure might be much more valuable than the ‘routine’ structure, and possibly close in value to that of complete centralization.

Indeed, research done to-date on models of such processes suggests that price and demand signals are strikingly efficient in conveying the information needed for good allocation decisions, even out of equilibrium (Radner, 1972; Groves and Radner, 1972; T.A. Marschak, 1959, 1972; Arrow and Radner, 1979; Groves and Hart, 1982; Groves, 1983; Hogan, 1971).
Incentives in teams

The model of a team assumes that the team members have identical interests and beliefs. Thus no special incentives are required to persuade the individual members to honestly implement the given information structure or to take the decisions prescribed by the optimal team decision function. A full-fledged theory of economic organization should, of course, take account of conflicting interests and beliefs, and the resulting problems of incentives.

This article is not the place to review the growing literature on this subject, but a few comments may be useful here. In general, it is not possible to solve the ‘incentive problem’ costlessly. (For exceptions to this generalization, see Groves, 1973; Green and Laffont, 1979.) Thus, in an economic organization, there will be two sources of efficiency loss: (1) decentralization of information, having the effect that individual actions will be based on information that is less complete than the information jointly available to the organization as a whole; (2) conflicts of interests and beliefs among the decision-makers, leading to distortions of information and action (‘game-playing’). In fact these two sources are not so easily disentangled. For example, under conditions of uncertainty and limited information, it will typically be difficult for a supervisor (or organizer) to determine whether a particular decision-maker is providing correct information or following a prescribed decision rule, since to achieve this would require the supervisor to have all of the information that is available to the subordinate. In other words, informational decentralization leads to de facto decentralization of authority. (For references to the literature on incentives and decentralization in economic organizations see Arrow, 1974; Hurwicz, 1979; Radner, 1975, 1986; and Stiglitz, 1983.)

technical change

S. Metcalfe
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Successive transformations of economic society from agricultural to industrial form and beyond to the service economy have consolidated a process of economic change with its own inner logic of tremendous power, a logic which harnessed continual technical and organizational innovation to the pursuit of profit. The intertwining of emergent knowledge and economic adaptation within the instituted frame of modern capitalism is at the core of economic self-transformation. This article treats this topic in three parts: the relation between new knowledge and economic transformation; some consequences of technical change; and the residual productivity debate.

Article

The successive transformations of economic society since the 14th century from agricultural to industrial form and beyond to the service economy have consolidated a process of economic change with its own inner logic of tremendous power, a logic which harnessed continual technical and organizational innovation to the pursuit of profit. At the core of the new logic is the intertwining of emergent knowledge and economic adaptation to its hidden possibilities that has been the basis for the sustained increase of aggregate output per person employed – the chief proximate source of increased standards of
living in the Western world – the progressive mechanization and automation of production methods, and the continuous development of the economic structure (Kuznets, 1977; Mokyr, 1990; 2002). The gains in material welfare, in length of human life, in life experience and functioning have been beyond anything achieved before the 18th century, yet knowledge-driven progress comes at a price. It is necessarily uneven in its incidence across space and time, and the ensuing disparities of performance can do impose heavy human adjustment costs as old ways give ground to the new. Skills are devalued, capital assets lose the capacity to generate income, while there is little prospect of the losers receiving compensation. If the balance sheet speaks to progress, it does so in a tangled way. This is the ethic of competition, and nowhere is this unevenness more apparent than in the seemingly unavoidable differences in economic performance between advanced and developing countries. Knowledge-driven economic growth is never a smooth, balanced affair of proportional expansion with each activity advancing in step. Rather, as Schumpeter insisted, it involves disharmony and fierce competition between new and old activities and places, a diversity of growth rates and profit rates and continual reallocation of labour and capital between and within activities. It is occasionally useful to study such processes as if structural change were absent, but to do so courts the danger of missing the substance and therefore the process and significance of technical and economic change. For the very process of uneven adjustment is a powerful stimulus to the development of further knowledge. This is the Faustian bargain accepted by the Western world with its origins in Reformation and Renaissance and its consolidation in the 19th and 20th centuries.

What was the nature of this emergent combination of knowledge-generating system and market system of economic adaptation? All productive activity involves the transformation of materials and energy, in a purposeful, intelligent and information-dependent fashion to add value to the materials and energy. These transformations are of physical form, or of spatial location, or of availability in time; indeed, the history of technical change is a history of invention and innovation directed to providing new inanimate energy sources, to providing means to control the application of energy, and to providing new, synthetic materials on which to work. What economists see from one perspective as the substitution of capital for labour in more roundabout methods of production is from this perspective the substitution of non-human for human energy, a process that was well established through the use of water power in the early middle ages and went on to be revolutionized by innovations in steam power, internal combustion and ultimately electricity. All existing industries were affected by the new power sources, (textiles, iron and steel, mining in particular) in the first Industrial Revolution, but new industries emerged, too, to produce the machines of increasing sophistication and specialization to harness the new power sources and to extend their application to transport and communication. That much product innovation was required to exploit the new possibilities warns us that the relation between product and process technology is usually close. That new forms of business organization were needed to deal with increased capital intensity and new risks tells us that technical and organizational change were seldom far removed from each other. The increasing incentives to exploit the material base of the planet and the ability to synthesise materials not found as natural compounds gave further licence to the innovation process with oil, aluminum, plastics and pharmaceuticals, each becoming commonplace in the 20th century. But it would be a mistake to focus attention on the great, traditional industries alone, whether producing capital goods, consumer goods or intermediate products; trends of a different nature reflected the deeper ways in which new knowledge was working its transformative effects. Superficially this is seen in terms of the displacement of manual labour as an energy supply, but this misses the point that the human role was
moving increasingly into one of the management and coordination of information that is essential for any rational activity. Within business enterprises, within public bureaucracies and within markets, greater human effort was required to manage and coordinate the flows of information demanded by economic growth and its handmaiden – a richer and deeper division of labour. That this could be possible only in the presence of a productivity-enhancing revolution in information generating, storing and communicating activities should be obvious at least from our position in the early 21st century. In this regard, the innovation sequence and economic adaptations associated with the printing press proved to be of profound importance: for it eliminated a long-standing constraint on the exact reproduction of information, and made possible its transmission over generations (storage), and its more ready transport. Written communication increased in relative importance compared with face-to-face conversation, the costs associated with codification declined dramatically and, consequentially, the organization of a spatially distributed but deeply connected process of the growth of science and technology became possible (Eisenstein, 1979). The subsequent developments of telegraph and telephone, of information-processing machines, of television and radio, and now of the Internet are amplifications of the revolution begun by printing. Since all societies are knowledge based, that epithet counts for little: what matters is the form of information society that prevails, and the way in which inanimate energy and its harnessing machinery has been applied progressively to further transform the production, transport and storage of information is a development at least as significant as the discovery of economical steam power in Watt's day. The growth in the productivity of information activities made possible in manufacturing, transport and communication, and now service activities, is accepted by all commentators as immense, for it has economized on scarce mental capacity, not just on limited human strength. Quite remarkably, total employment has continued to rise even though its occupational composition, like the composition of economic output, is continually shifting in response to new technological possibilities, despite the prognostications of less confident observers of modern capitalism. Modern capitalism appears, by accident no doubt, to have evolved a set of institutional rules which not only promotes the efficient use of what is known to further specific human ends but serves also to greatly stimulate the production of further new knowledge. The solution of one problem through the speculative deployment of imagination serves only to open up further problems, while the future direction and outcomes of this process remain necessarily hidden from view. Knowledge and economy are deeply intertwined, and the restless nature of the one reinforces the restless nature of the other. This is the nature of that Faustian bargain between a knowledge system and the market process.

As the above sketch might warn the reader, the economic analysis of technical progress is not a straightforward matter. The familiar tools of equilibrium economics are best suited to discussing the long-run effects of new products and methods of production; they are not well suited to analysis of the disequilibrium processes by which new technologies are generated, improved and absorbed into the economic structure. All these processes take time, operate with different velocities and are subject to complicated interactions and feedback effects. It has been traditional to divide the analysis of technical change into three branches: invention, the creation of new products and processes; innovation, the transfer of invention to commercial application; and diffusion, the spread of innovation into the economic environment. Unfortunately, this has provided a somewhat fragmented approach to the study of technical change in which an understanding of interdependence and feedback between the stages has been hidden, together with important elements which emphasize the continuity of advance. A more unified approach is possible if we place the growth of knowledge and its instantiation in novel
innovations in the context of a competitive market process, in which firms seek to differentiate themselves and gain commercial advantages by introducing new products/services and processes. That the market system is a defining instituted feature of modern capitalism goes a long way to explaining its experimental proclivities and thus the importance to it of enterprise. It is an open system in which, in principle, all existing constellations of resources are open to challenge by rival, entrepreneurial conjectures according to their anticipated profitability. Innovations (like breakthroughs in science) are always statements of disagreement, in this case about the efficacy of the prevailing allocation of resources. Thus there is an important boundary in play, to work the system needs order and agreement, to progress it needs disorder and disagreement, it is the institutions of capitalism that contribute to keeping the two in balance. Of course, firms are not the only important source of new knowledge; they are only one element in a more comprehensive system of public and private research institutes of many kinds; but with respect to innovation (as distinct from invention) they play a virtually dominant role as the one combinatorial agency bringing together the different kinds of problem solving and exploiting resources needed to create wealth from knowledge. The way in which they combine internal with external innovation resources is an important aspect of their innovative ability, as Marshall knew well; external organization, connecting to customers, suppliers and other sources of knowledge, is as much a part of a firm's productive capital as is its internal organization. The three questions which arise from this viewpoint are: (a) by what processes is technological variety generated?; (b) by what processes do different varieties acquire economic weight?; and, (c) by what mechanisms does the process of acquiring economic weight shape the development of technological variety? 

To the first question belongs the study of a firm's strategy in changing its knowledge base and articulating new and improved products and processes. The role of science in modern invention, the organization of R&D activity, and the links between a firm and other knowledge-generating institutions each play a role with respect to variety and its generation. But no individual variety of product or process is significant until it acquires economic weight, and the greater the weight the greater the impacts of the new technology upon its environment. In regard to the second question, innovations acquire economic significance because they are superior either from the point of view of users or from the point of view of their producers or both. Clearly, however, the more profitable it is to use new products and processes and the more profitable it is to supply them, the more quickly will they acquire economic weight and displace existing products and processes. The dynamics of adjustment to new opportunities depend on how different the new technologies are from established forms, and how the economic environment evaluates those differences relative to the standards of value and cost. The third question contains some of the most complex questions of all, relating to the inducement mechanisms which generate and shape technological variety. Clearly there are important non-economic factors at work. However, different environments for market exploitation do make it profitable to develop a technology in different directions, and the experience of exploiting a technology in a given environment, more often than not, gives rise to important learning effects which indicate an agenda for subsequent development and applications in other areas of activity. Technologies do not emerge into the economic sphere fully fledged but typically in immature form, and evolve very much according to the bottlenecks and incentives to development which arise in their application. Progress thus tends to be localized around a canalized path of advance and to be contingent on factor prices and the values consumers place on different combinations of functional features. The same technological opportunity exploited in different environments would in all probability develop in different directions. By a similar token, a
technology which is mature in one environment may be developing rapidly in another. Maturity is at root an economic concept applicable to situations where the expected benefits fall short of the expected costs of further advancing technology.

Within the development of economic thought, the study of technical change has never played a major role. Indeed, from Adam Smith onwards, and with the exceptions of Marx and Marshall, it was progressively written out of classical economic analysis. Thus, despite Smith's emphasis on the division of labour as a form of induced technological and organizational change, little of his remarkably productive insight survived in subsequent writings, apart from the maintained separation of the agricultural and manufacturing sectors as different loci of progress and increasing returns. Not surprisingly, no classical writer foresaw that technical progress in agricultural methods would dispel the niggardliness of nature and banish the spectre of the stationary state. By the time Robbins came to write his methodological characterization of the neoclassical scheme in 1932, not only had technical progress been handed over to the psychologists and engineers, but the very nature of the questions posed by economists had changed fundamentally. Gone was the emphasis on accumulation and progress and in its place stood the analysis of the allocation of given resources under given technical conditions and, moreover, subject to a definition of competition as a state of equilibrium quite incompatible with the increasing-returns implications of the division of labour. The analysis of an organic process became instead the search for the solution of a given jigsaw puzzle. Only Schumpeter (1911) provided a clear way forward. He insisted that technical progress be viewed as a transformation arising from within the capitalist system, that it was an integral part of the competitive process and that a key role was played by the entrepreneur and entrepreneurial profits in the process by which technologies acquire economic weight. Orthodox equilibrium theory, it will be noted, had found no room for the entrepreneur. It has been left to the post-1945 generation of economists to reassert the importance of technological change. So far they have done so in a piecemeal, empirical fashion with little attempt to reintegrate the phenomena back into a formal framework of accumulation and structural change. The writings of Pasinetti (1981) and of Nelson and Winter (for example, 1982) can be said, from quite different perspectives, to make this step and have stimulated many others to follow their lead and develop an evolutionary approach to technical change (Dosi, 2000; Nelson and Winter, 2002; Witt, 2003).

Some consequences of technical change

If the process of technical change remains difficult to handle, we can still make limited progress with an analysis of its consequences using long-period methods of analysis. Here, one of the most compelling features of production in modern industrial societies is its roundabout nature. The Industrial Revolution placed modern economies on a path of increasingly roundabout production arrangements in which resources are devoted to elaborate chains of production where raw materials (mineral or agricultural) are worked into intermediate commodities for further processing into final commodities and services with the aid of complex tools and machinery. Specialization and the division of labour are the natural features of such roundabout, mechanized methods, as Adam Smith made clear. When discussing technical progress it is particularly important to recognize that the majority of changes occur within the structure of input–output relations and not only in the activities producing final commodities for consumption (Pasinetti, 1981). A framework which treats this structure as a black box into which primary inputs flow...
and final outputs emerge will not be a useful foundation for the study of technical progress and its
effects.

To illustrate some possibilities we employ the following analytic device. Consider a self-contained
component of an economic system; we call it a subsystem, which produces a single consumption good,
cloth, via three separate, constant returns to scale activities. A lathe is produced with inputs of labour
and itself, a loom is produced with inputs of labour and the lathe, and final output, cloth, is produced
with labour and the loom. The lathe and the loom are produced means of production; they are outputs of
one activity and inputs into another productive activity (Kurz and Salvadori, 1995). Imagine this
subsystem to be embedded in a competitive capitalist economy, and that it is analysed in long-period
equilibrium conditions in which capital invested in each activity in the subsystem supports a common
rate of profits, \( r \), and grows at the common rate, \( g \). There is no structural change taking place in the
relative importance of the three activities. Given the profits rate, there will be a unique pattern of relative
production prices of the three commodities and a unique level of the real wage, \( w \) (ratio of money wage
to the price of cloth). Similarly, given the growth rate there is a unique pattern of employment within the
subsystem and a unique level of consumption per worker, \( c \) (ratio of cloth output to total employment in
the subsystem). Now it is well known that higher values of \( r \) are related to lower values of \( w \), while
higher values of \( g \) are related to lower values of \( c \). The corresponding so-called wage–profit and
consumption growth frontiers are downward sloping, satisfy the dual property that \( r = g \) when \( w = c \), and
have a common, finite maximum value for \( r \) and \( g \), corresponding to zero \( w \) and zero \( c \), respectively.

These frontiers are a convenient vehicle with which to explore the effects of technical change.

Starting from a position in which only one production process is available in each activity, consider
the long-run equilibrium effects of technical change. Two basic categories of change may be considered, in
each case involving changes in one or more input–output coefficients in the subsystem: first,
improvements, which imply no qualitative change to any output or input and require only that less of at
least one existing input is used within at least one of the processes; and second, inventions, which do
imply qualitative change, a physically different output (for example, a new lathe or loom) is produced by
an entirely new process.

Whatever the precise changes in input–output coefficients, inventions and improvements can always be
classified into three groups by comparing the long-period properties of the new bundle of processes with
those of the existing bundle. Dominant technical changes are those which are economically superior
over the entire range of profit rates consistent with the existing technology. At the ruling real wage and
relative price structure associated with the ‘old’ method, the new process supports a higher rate of profit,
and this is the basis for its superiority and – we must here conjecture – its adoption in the subsystem. By
similar reasoning, redundant technical changes are those which are economically inferior for all possible
wage and price constellations; they constitute failed inventions. Finally, conditional changes are those
whose superiority or otherwise do depend on the prevailing relative price structure. For the invention or
improvement to become an innovation, it must be economically superior when evaluated at the
prevailing price structure. Only dominant changes and the superior set of conditional changes satisfy this
condition and can have an economic effect – that is, become innovations.

The long-period effects of innovations depend on the nature of the change in technology and the position
of the corresponding process in the input–output structure. In particular, changes in the machine
producing processes have quite different consequences from changes within the cloth activity. The more
important consequences may be summarized as follows. An improvement or invention in a machine

process will alter the entire relative price structure of the subsystem. At the ruling rate of profits, the
closest the commodity whose method is improved is reduced relative to the price of all other produced
commodities, while the price of all commodities which use the output of the improved process are
reduced relative to the money wage. The further down the chain of input–output relations lay the
improvements, the greater is the breadth of the consequences of the technical change. Consequently, the
simplest case involves an improvement to the cloth activity: cloth falls in price but the relative prices of
lathes and looms are unaffected. The corollary of these effects is that any technical change increases the
real wage consistent with the ruling rate of profits. Corresponding to the changes in price relations are
changes in the structure of employment within the subsystem. A labour-saving technical improvement in
a machine activity reduces the proportion of total subsystem employment absorbed by that activity, but
how it redistributes employment among the other activities depends on the particular nature and location
of the change in question. Any improvement in cloth making, by contrast, has no effects on the
equilibrium employment structure. All technical changes will increase the level of consumption per head
consistent with the ruling growth rate. Naturally, the magnitude of these effects depends on the ruling
values of the growth rate and rate of profits. It is often convenient to summarize the effects of technical
change in terms of the associated differences in w–r and c–g frontiers before and after the technical
change. In brief, all dominant changes give rise to new frontiers which lie above the ones associated
with the old methods. In the case of conditional changes, the old and new frontiers intersect at least
once. Nothing clear-cut can be established about the effects of technical change on the aggregate degree
of mechanization, whether measured by the value capital–labour or the value capital–output ratio.
Depending on the basis of valuing the capital stock, capital intensity may increase or decrease and the
different measures may even move in opposite directions. The concept of neutral technical progress has
traditionally been a focus of attention in relation to the effects of progress upon the distribution of
income. As an example, the traditional case of Harrod-neutral technical progress (no effect on the value
capital–output ratio at the ruling r and g) is achieved, trivially, with an improvement in labour
productivity confined to the final consumption activity but, more generally, requires that labour
productivity increase in equal proportionate amounts in each and every process. Such Harrod-neutral
changes leave the structure of employment and relative commodity prices unchanged. There is little
doubt that neutral progress of any kind is not to be expected in practice, nor is it a particularly interesting
analytic category. Indeed, at given r and g values, Hicks's neutral technical progress (no effect on the
capital–labour ratio) is logically impossible in an input–output subsystem of the kind discussed here
(Steedman, 1985). More interesting in terms of technological interdependence are the induced technical
changes known as trigger effects (Simon, 1951; Fujimoto, 1983). Where technical progress occurs in a
machine activity, it may so alter the relative profitability of other activities in which that good is an input
that it becomes profitable to adopt different processes within those other activities. In this way the
effects of technical change in any machine activity may trigger changes in production methods far
beyond the activity in question.

In summary, even under the hypotheses of long-run equilibrium conditions the consequences of
technical progress are complex, and are associated with changes in relative prices, real incomes and
physical patterns of employment of all inputs. Unless attention is confined to progress in consumption
goods, the full ramifications of technical progress can be understood only within an input–output
framework. A fortiori one can only understand the inducements to change technology within such a
framework of technological interdependence.
The residual debate

A central focus for the literature on technical progress has been provided since the early 1950s by a debate on the measurement of total factor productivity and the implications which follow for our understanding of the growth process. Within the neoclassical tradition, the sources of economic expansion were considered to be population growth and thrift, with growth in labour productivity dependent upon the substitution of capital for labour. Despite the early protests of Schumpeter (1911) that these mechanisms were of negligible significance in explaining long-term growth of capitalist economies, it was not until a series of studies demonstrated the apparent independence of output growth from accumulation that debate could be engaged. The ingenious methods of Abramovitz (1956), Solow (1957) and Kendrick (1973) showed beyond reasonable doubt that the modern growth of the US economy was in proportionate terms at least three-quarters due to increased efficiency in the use of productive inputs and not to the growth in the quantity of resource inputs per se. The implication was quite devastating: an adequate explanation of economic growth appeared to lie outside the traditional concerns of economists, to constitute a residual hypothesis.

From these early studies followed a lengthy sequence of extensions and amendments (that continues unabated today) creating a rich tapestry of data on the growth of the major industrialized and developing nations, and their constituent activities. For our purposes it is the framework employed to identify the contributing sources of economic growth which is of primary interest. For the measured quantities of inputs and outputs are brittle constructs easily swayed by errors of measurement or aggregation, and particularly marked by a failure to allow for quality change in consumption and capital goods, the disamenities of modern growth and the valuation to be placed on enhanced leisure time. Despite the sophisticated efforts to refine measures of the productive input, taking detailed account of the effects of education on labour quality (Denison, 1962) and on the measurement of capital goods and their services (Jorgenson and Griliches, 1967), agreement on the size of the so-called residual element in growth remains as elusive as ever. Here lies a paradox: the importance of new skills and of inventions and quality improvements in capital and intermediate goods increases with the rate of technical progress, as the effects of the information revolution confirm; thus the faster the rate of progress the more the difficulty in measuring its contribution to economic growth. The rise of the service economy and its intangible outputs and inputs certainly adds to these difficulties, and it has become commonplace to suggest that the increased importance of services will reduce the possibilities for further growth in total factor productivity, let alone its accurate measurement (Griliches, 1992). Certainly these considerations increase the merits of attempts to measure productivity growth at the level of more finely defined activities and take advantage of new micro data-sets (Bartlesmann and Doms, 2000). We cannot explore this further here, other than to point to the fact that aggregate productivity growth is now to be treated as a combination of improvements within activities and the structural changes that reallocate output and resource inputs between activities. Productivity change in this frame takes on a more evolutionary hue, as sketched above and premised on the unevenness of progress and adaptation to it (Nelson, 1989).

The central organizing concept behind the early studies was the aggregate production function and the separation of observed growth in output per worker into two independent and additive elements: capital–labour substitution, reflected in movements around a given production function; and increased efficiency.
in resource use, as reflected by shifts in this function. To maintain additivity, the analysis had to be
confined to marginal changes in output and input, and could not be applied cumulatively to longer
periods without introducing an interaction term between capital substitution and increased efficiency.
Within this framework all inputs, the factor services, stand on an equal footing, and constant returns
alloverd with universal perfect competition allow marginal productivity pricing to identify the
contribution which the growth or relative decline of each input makes to the growth of output per
worker. To identify the growth of total factor productivity in a short time interval one need only subtract
from the growth of output the growth in total factor input, itself a factor-price-weighted sum of the
growth rates of the individual inputs. The sensitivity of such a procedure to errors of measurement in
inputs, outputs and relative prices will be obvious.

Some difficulties, immediately apparent from the controversy over capital and distribution, now enter
the picture. From the point of view of the long-run supply of productive services, all inputs do not stand
on an equal footing. In particular, the flow of capital services depends on the stocks of usable capital
instruments and thus on the ability of the economic system to maintain and augment such stocks in
quality and quantity. But these capital instruments are produced and reproduced by productive activities
which themselves are subject to technical progress over time. Thus, to treat independently increases in
efficiency and increases in the stock of capital goods is at least misleading, unless one maintains that
technical progress occurs only in consumption activities. The consequences of this for the measurement
of total factor productivity are severe (Rymes, 1971). To illustrate, consider an economy growing at a
constant rate over time with a constant saving ratio, with the rate of increase in labour productivity the
same in all activities, and the capital–output ratio constant. In such an economy the rate of increase in
efficiency due to technical progress is exactly measured by the rate of increase in productivity per
worker, and not by the measured increase of total factor productivity; which is of a smaller magnitude
since it wrongly deducts the effects of induced capital–labour substitution. Increased efficiency makes it
easier to reproduce capital goods, such that all the observed rate of increase in the capital–labour ratio
(equal to the growth of output per worker) is induced by the enhanced efficiency in the processes
producing capital goods. There is no independent capital deepening to contribute to the growth of labour
productivity. It is not surprising that when we identify labour as the only primary input then the natural
measure of increased efficiency is the rate of increase of labour productivity. Capital goods are after all
instruments made by labour too, indeed in some traditions of thought they are described and analysed as
so much ‘stored-up labour’. All this, of course, leaves untouched a second aspect of the capital
controversy, namely, the severe conditions which have to be imposed to generate an aggregate
production function along which output per worker is positively associated with the quantity of capital
per worker, and for which input prices may be claimed to measure the corresponding marginal products
of factor services (Bliss, 1975; Harcourt, 1972). It is perhaps for this reason that studies of residual
productivity have become more prominent at the industry level with as detailed a specification as
possible of the relevant physical flows of factor services. But disaggregation does not avoid the problem
and the fact that the capital inputs of one activity are derived from the outputs of other activities. The
growth of labour productivity in any one activity depends not only upon its own increase in efficiency
but upon increased efficiency in the activities supplying it with capital goods, materials and energy.
Thus we are back in the world of input–output interdependence in which the results of enhanced
efficiency are imported and exported between activities in the way outlined in the previous section.
There can be no doubt as to the value of the residual productivity debate; it awakened interest in the
The origins and effects of technical progress and stimulated several new lines of research. However, it never did attempt to answer the questions about the constitution and generation of residual productivity growth. These remain the dominant questions as we seek to further understand the complex mechanisms that link technical change to the growth of wealth in modern capitalism.

technology

Joel Mokyr
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Technology is the utilization of natural phenomena and regularities for human purposes. Propositional knowledge – sets of statements about natural regularities and phenomena – provides the epistemic base of technology, whose width largely determines society's ability to generate technology. The high social rate of return to technology leads to underinvestment in new technology, justifying some government subsidization. Only since the 18th century have producers and scientists been systematically linked, allowing technology to flourish. Technology is the main factor driving economic growth; the scope for technology transfer ensures it will continue to be so, as long as the appropriate institutions are in place.

Article

Technology may be defined as the utilization of natural phenomena and regularities for human purposes. It is a matter of debate whether the manipulation of regularities in human behaviour by firm management should be properly classified as technology, or whether technology should be defined more narrowly as the harnessing of physics, chemistry and biology. Either way, it has become a distinctive feature of homo sapiens, and the success of the species in expanding technology has had momentous consequences for our planet, both physically and biologically.

In standard neoclassical economics, technology is regarded as a mapping from inputs to outputs. However, such definitions inevitably assign technology to a ‘black box’ category (Rosenberg, 1994). Yet the economic approach illustrates the many aspects of technology relevant to social science. Much
of this is captured in the concept of the isoquant, which is a summary description of the mapping. The isoquant displays the three important economic aspects of technology. One is the basic constraint that human knowledge imposes on what people can do. The lowest isoquant – that is, the fewest inputs that combine to produce a unit of output – denotes that limitation to human knowledge at any given moment. There is no implication that a more efficient production is not possible in some metaphysical sense, but rather that conditional on the state of knowledge in time $t$ this is the best that can be done. Second, the isoquant map indicates that not all producers are necessarily producing at best-practice technology. The entire set above the lowest isoquant is feasible, and while these techniques are by definition less efficient than best practice, there may be many good reasons why average practice is often considerably below best practice. Finally, the fact that the isoquant is a curve and not a point indicates one of the fundamental features of technology, namely, that there are many ways to skin a cat. One of the deepest issues in economics is the choice of technique from the available menu and how that choice is affected by economic parameters. The shape of the isoquant, moreover, tells us a great deal about the nature of the technology available, the degree to which factors are substitutes for one another, the rate at which the marginal products of factors are declining, and so on.

The production function approach only implicitly allows recognition of technology's fundamental nature, namely, that it is, above all, knowledge. By writing the function to include a shift factor, we allow for the growth of knowledge to enable an economy to do things it could not do previously. That technology is first and foremost human knowledge is not always fully recognized. Needless to say, in order to result in production, this knowledge in the vast majority of cases requires some strongly complementary inputs (tools, materials and energy), which economists define as capital and intermediate inputs. Yet in the deepest sense technology exists in the knowledge defining how certain actions plus certain inputs lead to outcomes we deem desirable.

For that reason, the fundamental unit of technology can be regarded as the technique, a concept close to Nelson and Winter's ‘routine’ (Nelson and Winter, 1982). A technique is basically a set of instructions on how to produce, much like a simple recipe. Some techniques may, of course, be hugely complicated, with many conditional and nested statements, but their syntax remains prescriptive. Hence the term ‘prescriptive’ knowledge, which contains anything from baking a cake to driving instructions to engineering handbooks. The master-set of all techniques available in society is what Joan Robinson (1956) once called ‘the book of blueprints’ and it constitutes a monstrous menu from which firms and economists make selections. Two types of questions about this menu suggest themselves: how do agents really learn the contents of the menu and make selections, and how did the menu get written in the first place?

The full meaning of technology can be realized by adding the concept of competence. Competence concerns the execution of the instructions in the technique by agents. Instructions can be codified (in writing or orally), but no set of instructions is ever complete: they need to be read, interpreted, and carried out. If it were possible to write a complete set of instructions that would be wholly self-contained and self-explanatory, competence would be irrelevant and production could be entirely carried out by automatons. It is clear, however that all techniques contain implicit or ‘tacit’ components that require the agency of a human to interpret and carry out the instructions. The size of the ‘tacit’ component varies over time and from field to field, but can never be reduced to zero (Cowan and Foray, 1997). It consists of a certain savoir-faire that comes with experience or imitation, but is hard to learn from codified information.
Technology and knowledge

To understand why and how technology contains what it does at any given time, we need to consider more carefully where it comes from. Many standard definitions of technology refer to ‘science’ as an essential ingredient. Thus the Oxford English Dictionary defines technology as ‘1. the application of scientific knowledge for practical purposes. 2. the branch of knowledge concerned with applied sciences’. Such a definition is patently ahistorical: the close association between ‘science’ (in the modern sense of a consensual, formal, and analytical understanding of natural phenomena) and technology is a product of the past two centuries. For many centuries, people had been employing technology in a variety of fields, yet it is hard to think of a medieval blacksmith, a peasant in biblical Palestine, or a miner in ancient Roman Spain as relying on ‘science’. Technology is therefore part of production in whatever form we observe; science came into the picture only very recently.

As an alternative to the somewhat anachronistic emphasis on science, I have proposed for historical purposes the concept of propositional knowledge (Mokyr, 2002). Propositional knowledge is a set of statements about natural regularities and phenomena. These may be expressed in terms of firm regularities such as the laws of thermodynamics or purely in terms of description, measurement, and cataloguing. The distinction between propositional and prescriptive knowledge seems obvious: the planet Neptune and the structure of DNA were not ‘invented’; they were there prior to discovery, whether we knew it or not. The same cannot be said about diesel engines or aspartame. Polanyi (1962, p. 175) notes that the distinction is recognized by patent law, which permits the patenting of inventions (additions to prescriptive knowledge) but not of discoveries (additions to propositional knowledge). He points out that the difference boils down to the observation that prescriptive knowledge can be ‘right or wrong’ whereas ‘action can only be successful or unsuccessful’.

The main point is that this knowledge supports the prescriptive knowledge that is the essence of technology. This support is the epistemic base of technology. This base can be narrow or wide, depending on how much of the natural regularities of the technique is known. But it was common for things to be invented despite a narrow or negligible epistemic base. Through luck and serendipity, through dogged trial-and-error, or through an intuitive sense that defies precise analysis, inventors stumbled upon things that worked and worked well, without actually understanding why and how they worked. Such concepts are of course relative. It may seem to us, for example, that Alessandro Volta, who built the first working electrical battery in 1800, did not know quite how and why his ‘pile’ worked, but our own understanding of this, while broader than his, may still be quite limited compared with what may be known about the subatomic nature of electricity in the future.

The width of the epistemic base determines to a great extent the effectiveness of the process whereby society creates new technology. Hit-and-miss experimentation or a ‘try-every-bottle-on-the-shelf’ method may well yield new techniques that work, but they will tend to be one-off advances, which soon enough reach the upper bound of their capacity. Further adaptation and tweaking following an invention is far more effective if the basic modus operandi is understood. Moreover, if one does not understand why something works, it will be hard to know what does not work. Enormous amounts of human energy were misallocated, largely by highly talented individuals, in research on alchemy, astrology, attempts to build perpetuum mobile machines, and similar impossibilities. Advances in propositional knowledge
eventually terminated these programmes. In other words, the lack of propositional knowledge greatly increased the costs of research and development, and until about 1750 most new technical advances soon ran into diminishing returns in terms of their further improvement and development. Lack of an adequate epistemic base also often curtailed the effectiveness of existing technology. For instance, in agriculture, the knowledge that fertilizer increased yields had existed for thousands of years but, until 19th-century organic chemistry widened the epistemic base, basic distinctions between nitrates, phosphorus and potassium were not made, and thus often enough the quantities and kinds of fertilizers used were poor. Better understanding allowed these to be calibrated exactly, which brought about huge improvements in yields.

Technology as an economic good

Much of modern growth theory relies on ‘endogenous technology’ in which technology is being produced by inputs within the economy and responds to prices and costs (Aghion and Howitt, 1997). This literature has successfully dealt with many of the uncomfortable characteristics of technology in models of a growing economy. Of those, a number stand out. One is that like all forms of knowledge it is a purely non-rivalrous good. By giving it away for free, the original owner loses no knowledge of his own, but his capability to exploit this knowledge for commercial ends is reduced. Moreover, by giving it away he loses control over its diffusion since it is normally hard to prevent the new owner from giving it to a third. Second, new knowledge is the ultimate example of increasing returns, a good that is fixed and of no marginal cost to produce. Third, much technology is inappropriable in the sense that, once one person has it, others can often easily imitate or reverse-engineer the technique. Fourth, techniques are hard to exactly quantify, since they often have complex relations with other techniques, ranging from the purely complementary to the pure substitute. Hence, attempts to somehow ‘count’ the number of techniques in a society and to relate them to inputs seems ill-fated and to violate Einstein's dictum that some things that count cannot be counted and a more axiomatic way of measuring technology is needed (Olsson, 2000). Fifth, the process of technology generation is subject to far more uncertainty than any other economic activity. Moreover, this is uninsurable risk. Each invention is made only once, so that there is only a limited amount one can learn from the experience of other inventions. The risk is not only that the technique an inventor is trying to write may not be feasible (or at least not feasible for her), it is also that even if the search is successful someone else may have got there first or the technique may not be commercially exploitable (Rosenberg, 1996). Finally, much of the underlying propositional knowledge, the foundation and essential input of inventive activity, is available at no charge from scientific literature. Yet accessing it may be rather costly all the same.

The production of new technology has changed dramatically over past centuries. Until late in the 19th century, the lone inventor slaving away in a small workshop or lab was the paradigmatic creator of new technology. Some of the more successful ones may have worked on commission (such as the great Richard Roberts, the foremost mechanical engineer in Britain in the first half of the 19th century), but basically they were individuals working on their own account. Some of them were professional inventors who hoped – often in vain – to find the ‘killer ap’ that would make them rich. Others did not bother about the money, and made their inventions for their own satisfaction or for the benefit of mankind, and demonstratively refused to take out patents. Since the late 19th century an increasing share of inventive activity has become part of ‘corporate R&D’, an organized and often bureaucratized form
of activity, often systematic and always driven by a corporate bottom line. The corporate research lab first emerged in the big German chemical concerns in the late 19th century, but the system was soon adopted in other industrialized nations. The individual inventor working in the proverbial garage has not been quite eliminated, and even today it happens that some lone wolf will come up with an idea that the huge research labs of large corporations did not think of. The agility and creativity of the single human mind may not altogether perish in the dark-suited world of corporate profits, but it is also clear that, when such an invention is successful, the road to riches usually leads to control by or a merger with a larger company with access to credit, marketing networks, and development facilities.

Despite the many market failures in the knowledge industry, however, there is a market for technology since it is clearly valuable (Arora, Fosfuri and Gambardella, 2004). One form this market takes is technical consulting, through which firms purchase expertise not otherwise available to them. This practice can be easily traced back to the early 18th century, and by the time the Industrial Revolution came along consulting engineers of a variety of kinds was common among technologically advanced firms. Another way the market for technology operated was through licensing. Licences were bought and sold commonly in countries in which the patent system worked effectively to protect intellectual property rights, and they are as close as we can get to seeing how technological knowledge was valued (Khan and Sokoloff, 2001). Patent protection of one form or another was quite common in 18th- and 19th-century America and Europe, and firms could buy technology owned by another firm, a practice that has continued into our own time. Once a patent expires, however, the technique becomes common access. For that and other reasons, some industries elected to protect their techniques by secrecy, of which the best-known example is the still secret recipe for Coca Cola, code-named ‘Merchandise 7X’, kept under lock and key in a vault in the Sun Trust Bank Building in Atlanta, Georgia.

From a social point of view, it still seems to be the consensus that most societies seriously underinvest in the creation of new technology. This largely reflects the high social rate of return, which is widely regarded to be higher than the private rate of return resulting from the difficulty of appropriating and exploiting all the benefits of new technology and spillovers from one industry to another as well as across different countries (Mansfield et al., 1977). Such rates of return are notoriously hard to compute, and differ substantially among industries, to say nothing of the difficulty in distinguishing between average and marginal rates. But overall these rates are significantly higher in innovation than in other investment projects. The production of ‘knowledge’ is thus widely regarded as a market requiring some form of government intervention through the subsidization of pure scientific research and the support of some technologies with high rates of spillover.

Technology as a historical force

Simple models that relate complex social systems to a single technological advance or to a number of them have been proposed by some historians, but have not found a large following. These models include Lynn White’s suggestion that the feudal system followed from the adoption of the horse stirrup, and Karl Wittfogel's notion that oriental despotisms had their origins in hydraulic technology and the need to coordinate water control (Smith and Marx, 1994). Economists, too, have felt that at times technological developments did affect economic performance and that certain key inventions such as printing with moveable fonts or navigational techniques developed in the 15th century did have major
effects on history, although in most cases they are non-committal about what the real exogenous variable is. What is missing from the historical record before 1750 is much evidence that technology was ever powerful enough to bring about sustained economic growth such as to make a significant difference in living standards within a reasonable time. This is not to say that the episodes of high technological creativity in Song China or Renaissance Europe did not lead to major qualitative changes in the control that people had over their resources or their daily lives. But, in so far as they led to economic growth, the effects were limited in time and space, and were often offset by population responses.

Beyond that it should be noted that most societies that ever existed were not technologically creative (Mokyr, 1990). Even societies that can take credit for substantial cultural or artistic achievements, such as Greek, Hellenistic, or Jewish societies, were often not terribly inventive. Indeed, to take a global look at human history, the miracle is that technology actually changed as much as it did. Until quite recently, inventors were widely regarded as dangerous. This was in part because every act of invention is in some sense an act of rebellion and disrespect towards earlier generations and their know-how. For societies that held the wisdom of their forefathers in deep respect, such as Judaism and late Islam, inventors were little different from heretics. Moreover, inventions often threatened to reduce the value of existing human or physical capital by making it obsolete and in some cases redundant. Many governments saw disequilibrium caused by technological shocks as a threat to the status quo, and took a ‘make-no-waves’ approach toward new technology. Entrenched interests often took a Luddite attitude towards innovation, blocking it where they could. While Enlightenment Europe started to challenge every conventional wisdom and embarked on a new path, three literate and sophisticated empires – the Ottomans, Ch’ing China, and Tokugawa Japan – each in its own way closed off most innovation and chose stasis over progress. Second, in most societies, there was a deep social gap between, on the one hand, educated and informed people who studied nature and mathematics and, on the other, those who did the grunt work in the fields, mines, or workshops. Many improvements that were seemingly within reach of Roman society, such as casting iron and eyeglasses, were not achieved. The conventions and social class structure that prevented this kind of communication were slowly bridged in medieval Europe by monks, who were simultaneously the educated class and deeply interested in applying new technology such as windmills and mechanical clocks. But not until 18th-century Europe was there an organized and concerted effort to bring those who knew things and those who made things in direct contact with one another. Only after that happened could producers access and use the propositional knowledge of the natural philosophers (as they were called then), while at the same time the needs of manufacturers and farmers began to affect the research agendas of those in charge of expanding knowledge.

Modern science and technology

After 1820 or so, the connections between science and technology become slowly tighter, but it is unclear which of the two was the dog and which the tail. The relation between the two varied substantially from industry to industry and from technique to technique. In some areas the science came first and then informed the technology (which in turn may then have led to a further sophistication of the science). This was surely true in a field like telegraphy, in which Oersted's famous discovery of electromagnetism in 1819 led scientists to speculate that an electromagnetic telegraph was possible. It was equally true in medicine after 1870 when scientists demonstrated that bacteria were the cause of many infectious diseases, leading to a series of techniques in preventive hygiene. But in other areas the
technology came first and science followed, often at a distance. Consider materials technology: steel had been made for centuries before some of Lavoisier's students finally realized in 1786 what gave it its special properties. Even after that, the great breakthroughs in steel-making of the 1850s and 1860s were only marginally informed by the metallurgy of the time. In energy technology the gap was even larger: it took the world almost a century and a half after Newcomen's first successful engine in 1712 to finally nail down the principles that made it work.

Any simple statement about the sequencing of science or technology is in any case likely to be false. The two complemented and reinforced one another, theory and practice working cheek by jowl. Technology often operated as a ‘focusing device’ for scientists, showing them a well-defined problem they could then try to solve. In many cases, technology confirmed or inspired theoretical work. Heinrich Hertz's work on oscillating sparks in the 1880s and the subsequent development of wireless communications by Oliver Lodge confirmed Maxwell's purely theoretical work on electromagnetic fields. The success of the Wright brothers at Kitty Hawk in 1903 resolved the dispute among physicists on whether heavier-than-air machines were feasible at all. Following their successful flight, Ludwig Prandtl published his magisterial work on how to compute airplane lift and drag using rigorous methods.

The simple ‘linear model’ in which pure science leads to applied science and from there to technology is further undermined by the important feedback from technology to science that has been called ‘artificial revelation’. In many fields science has been constrained by technology: astronomy depended on telescopes, microbiology on microscopes, chemistry on electrical batteries. In our own time, fast computers have become an indispensable tool for virtually every field of research. In many cases, significant scientific progress occurs when the tools to measure, to observe, or to analyse were significantly improved (Price, 1984). In that way, it could be argued, technology has become self-reinforcing, and the historical models in which technology shocks have no persistence and eventually asymptote off to a new equilibrium have become irrelevant. This is particularly true because modern technology increasingly has the capability to combine and hybridize techniques with other, seemingly unrelated, techniques. Some techniques, indeed, have had such strong and so many complementarities with others that they have been dubbed ‘general purpose technologies’ – steam, electricity, steel, and lasers all come to mind (Bresnahan and Trajtenberg, 1995). Such hybridizing technology can grow at a dazzling pace, even if no pure new knowledge is added, simply through a growing number of combinations and recombinations (Weitzman, 1996). Moreover, modern communications and access technology make it much easier for inventors to scan what is available and find the ‘right’ match to create ever more sophisticated hybrids.

Technology and growth

The exponential growth in technological capabilities is responsible for the emergence of modern growth. However, not all growth derives from improved technology: improved allocations and scale economies account for some proportion of it. But growth based on knowledge is different in some important respects from other forms of growth. One is that it seems much harder to reverse. Whereas wealth based on the gains from trade can be quickly lost due to political turmoil or war, knowledge is much like the proverbial genie that cannot be placed back in the bottle. Although there are historical cases of knowledge actually being ‘lost’, they tend to be rare and in a modern economy quite hard to imagine. More controversial is the question of whether the accumulation of knowledge will ever run into
diminishing returns through the exhaustion of technological opportunities or the proliferation of knowledge beyond our capability to contain and control it even with the very best access technology. Concerns that ‘everything that can be invented has been invented’ have been made repeatedly in the past and been held up to ridicule as often by historians of technology. Indeed, technological progress often requires more and better new technology simply because many techniques have unforeseen consequences that require modification or replacement. Internal combustion engines were one of the defining inventions of the 20th century, but their impact on the environment has increasingly emphasized the need for an alternative approach. Similar instances of technological ‘bite-back’ can be observed in a host of other modern techniques and, while not all of them necessarily have a technological ‘fix’, better knowledge surely is part of the solution to any problems caused by new techniques. Similarly, technological successes create new needs, which themselves create an endogenous demand for new techniques. Thus the unprecedented increase in life expectancy requires an entire new set of techniques catering to the needs and wishes of people in advanced age brackets, who were a negligible proportion of the population only a century ago.

What is striking about the history of technology is that change has as often as not been competence-reducing rather than competence-increasing. Much effort has gone into making modern technology easy to operate and maintain, with the ingenuity being frontloaded in the design. Once the design is perfected, it can be mass-produced and operated by workers of relatively low skill, and increasingly by automatons, a process Marx termed ‘deskilling’. While this is surely not true across the board, it is increasingly the case not just in manufacturing but in services as well. Such routinization of technology suggests a possible bifurcation in the demands for competence. On the one hand, new techniques will be devised by highly skilled scientists and engineers, whose access to the appropriate propositional knowledge is almost immediate, and whose ingenuity will drive continuous progress. However, their numbers are sufficiently small that their supply is not really a serious constraint. They can be drawn from the elite applicants to the top technological universities in the world, picked by their mathematical skills and creativity. It is a small elite of original, skilled, and driven minds that drives technological progress, as it always has. The fact that their designs can be implemented and maintained by workers whose skills may be quite limited means that the progress of technology is not really constrained much by the supply of human capital. Technology transfer is a concept that captures the very real possibility that knowledge invented in one society can in the end be utilized effectively in another, if the institutional parameters are properly lined up. There seems, hence, little reason to believe that technology-driven growth is a temporary phenomenon.

Technology and institutions

Technology is the key to worldwide economic growth, though it is clear that in many Third World nations the lack of good institutions stands in the way of the adoption of more productive new technology. The payoff structure, both for the generation of new and for the adoption of existing technology, is determined by institutions, and this sets the stage for technological outcomes. The analysis of economists has tried to segment growth between technological achievements that push the product possibility frontier out and institutional achievements that move the economy closer to that frontier. Yet the interactions between the two make such decompositions hazardous. Economists have long realized that inventors, just like everybody else, respond to incentives. So, for that matter, do the
natural philosophers and mathematicians who provide them with the epistemic base for their new techniques. Yet the exact nature of the proper payoff for those who add to the stock of useful knowledge is the subject of some debate.

Whatever the rewards for successful invention, society needs above all to ensure that those who experiment and research are not penalized, even if their research appears absurd or offensive to most others. Penalizing people because their ideas are eccentric or ‘heretical’ has become rather rare in our age but, with the intensification in the resistance of such ideological organizations as animal-rights or anti-nuclear groups, and the rise of public concern about sensitive areas such as human cloning and stem cells, certain fields of research may be in jeopardy. In the absence of sticks, what the optimal carrots are is far from agreed upon. The most widely used reward is patents, but historically patents have been quite ambiguous as a tool to encourage technological progress (Jaffe and Lerner, 2004). The alternatives to patents all have advantages and drawbacks. Secrecy, of course, is the most costly since the social marginal costs of sharing information are zero. Moreover, any system of intellectual property rights based on secrecy discriminates against those techniques that lend themselves to reverse-engineering or obvious imitation. Awarding the three p’s (prizes, pensions, patronage) to successful inventors has coexisted in many places with the fourth (patents). In ancien régime France, the Royal Academy was authorized to award such distinctions to inventions that benefited the realm. That such decisions were highly subjective at best and open to nepotism and corruption at worst seems obvious, but no creative society has ever been able to avoid them: Samuel Crompton and Edmund Cartwright, two of the most successful inventors of the British Industrial Revolution, were voted substantial awards by the British Parliament because they had failed to secure patent protection. The South Carolina legislature awarded Eli Whitney $50,000 for his invention in 1794 of the cotton gin, which was easy to imitate. Our own age awarded the Nobel Prize for physics to inventor Jack Kilby in 2000 for the research that led to the integrated circuit.

Yet it should be recognized that contributions to knowledge require more complex incentives than mere property rights. No academic economist should be surprised by a statement that the payoff to successful research is more than just a financial compensation or rewards correlated with it. While the 20th century was the age of profit-driven corporate research, it also witnessed unprecedented flourishing of open-source activity, in which participants were incentivized in ways that transcended simple profit-maximizing behaviour. This is not only the case in certain software-writing enterprises such as Linux or Mozilla. It holds for much of the university- or government-driven programme of scientific research, in which academic researchers increased the body of propositional knowledge by a huge multiple while rarely getting rich in the process. The centrality of university research, supported by government grants in the emergence of many of the major technologies of the late 20th century, should serve as evidence of the complexities of the motivations of those who add to the stock of propositional knowledge. In research, the name of the game is credit, not profit. Researchers want property rights to their work, but normally prefer peer recognition to a cheque. The results of their work, through complex interactions with technology, have been the cheapest lunch in human history.

Technology and institutions co-evolve, but they obviously follow very different evolutionary dynamics and selection processes; it cannot be expected that their joint evolution will ever result in an optimal environment for technological progress (Nelson, 1994). At the same time, the corporate and government sectors have emerged as key players in the creation of new technology. The government sets most of the rules of the game (patent laws and enforcement, antitrust, licensing) as well as some priorities (for
example, military and space research, national institutes for health), while corporations in an oligopolistic market maximize profits subject to the institutional structure, and rely on the epistemic bases created mostly by people at universities or research institutions. The net result is imperfect on many levels (especially the now quite problematic patent system). And yet it has produced and will continue to produce a dynamic, innovative society in which technological progress and economic growth have become the rule rather than the exception (Baumol, 2002). From a long-term historical point of view, that is quite a miracle.

temporal equilibrium

J.-M. Grandmont
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Temporary general equilibrium views the dynamic evolution of an economy as taking place sequentially in calendar time, with decisions being made and equilibrium being achieved at each date in the light of the traders’ expectations about the future. The article surveys the contributions of the field to the microeconomic foundations of macroeconomics, in particular to the analysis of monetary phenomena, non-clearing markets, imperfect competition and the foundations of Keynesian unemployment, as well as the study of economic dynamics and (in)stability of self-fulfilling expectations under various learning schemes, in relation in particular with ‘excess volatility’ of financial markets.

Article

The conceptual framework

The fact that trade and markets take place sequentially over time in actual economies is a trivial observation. It has nevertheless far-reaching implications. At any moment, economic units have to make decisions that call for immediate action, in the face of a future that is as yet unknown. Expectations about the unknown future play therefore an essential role in the determination of current economic
variables. On the other hand, the expectations that traders hold at any time are determined by the information that they have at that date on the economy, in particular on its current and past states. Observed economic processes are thus the result of a strong and complex interaction between expectations of the traders involved and the actual realizations of economic variables. Economists have long recognized that such an interaction should be at the heart of any satisfactory theory of economic dynamics. The temporary equilibrium approach was indeed designed quite a while ago by the Swedish school (Lindahl, 1939) and J.R. Hicks (1939; 1965), with the intent to establish a general conceptual framework that would enable economists to cope with the study of dynamical economic systems, and in particular to incorporate in their models the subtle interplay between expectations and actual realizations of economic variables that seems factually so important. Economic theorists have employed this framework in a systematic way since then, using in particular the powerful techniques of modern equilibrium and/or game theory; this effort has yielded important improvements of our understanding of the microeconomic foundations of macroeconomics.

Before reviewing briefly a few of these important advances, it may be worthwhile to make clear what the basic characteristics of the temporary equilibrium approach are, and to compare it with others. To fix ideas, let us assume that time is divided into an infinite, discrete sequence of dates. We may envision first a specific institutional set-up, that was called a futures economy by Hicks (1939), and later generalized by Arrow and Debreu. Let us assume that markets for exchanging commodities are opened at a single date, say date 0; assume further that at that date, markets exist for contracts to deliver commodities at each and every future date \( t \geq 0 \). The specification of a ‘commodity’ will then involve not only the physical characteristics of the good or service to be delivered, but also the location and the circumstances (‘state of nature’) of the delivery. One gets then what has been called a ‘complete’ set of futures markets at the initial date \( t = 0 \) (Debreu, 1959, ch. 7).

It is clear that this framework is essentially timeless. Once an equilibrium is reached at date 0 (this equilibrium may be Walrasian or the result of any other game theoretic equilibrium notion), production and trade do take place sequentially in calendar time. But the coordination of the decisions of all traders is achieved at a single date through futures markets. There is no sequence of markets over time, and no role for expectations, money, financial assets, or stock markets.

Let us consider next another, more dynamic, type of organization, in which markets do open in every period. In this framework, traders would exchange at every date commodities immediately available on spot markets, promises to deliver specific commodities at later dates on futures markets, as well as money, financial assets and/or stocks (of course markets must be ‘incomplete’ in the sense of Arrow–Debreu at every date, otherwise reopening markets would serve no purpose). To convey the following discussion most simply, let us assume away all sources of uncertainty and consider the case where the state of the economy at any date can be described by a single real number. To simplify matters further, let us assume that the state of the economy at \( t \), say \( x_t \), is completely determined by the forecasts \( x_{i,t+1} \) made by all traders \( i = 1, \ldots, m \) at date \( t \) about the future state, through the relation

\[
x_t = f (x_{1,t+1}, \ldots, x_{i,t+1}, \ldots, x_{m,t+1})
\]
The temporary equilibrium map $f$ describes the result of the market equilibrating process at date $t$ – be it Walrasian or not – for a given set of forecasts. Of course, in the study of any particular economy, the map $f$ will be derived from the ‘fundamental’ characteristics of the economy: tastes, endowments, technologies, the rules of the game, the policies followed by the government.

The foregoing formulation does seem to take into account the observed fact that markets unfold sequentially in calendar time. It is, however, incomplete since no specification of the way in which forecasts are made at each date has been offered at this stage.

We must first discuss a concept that was introduced by Hicks himself, that of an *intertemporal equilibrium*, with self-fulfilling expectations, and that has been extensively used recently in a variety of contexts. Such an intertemporal equilibrium is defined formally, in the present framework, as an infinite sequence of states $\{x_t\}$ and of forecasts $\{x^e_{i,t+1}\}$ satisfying (1) and

$$x^e_{i,t+1} = x_{t+1} \tag{2}$$

for all dates. Although time appears explicitly in this formulation, it should be clear that this particular equilibrium concept is also intrinsically *timeless*. Indeed all elements of the sequences of equilibrium states $\{x_t\}$ and of equilibrium forecasts $\{x^e_{i,t+1}\}$ are determined simultaneously by an outside observer: present and future markets are equilibrated all at the same time.

The preceding discussion shows how we must proceed to describe a sequential adjustment of markets, in calendar time. We *must* add to the temporary equilibrium relationship (1) a specification of the way in which traders forecast the future at each date as *a function of their information on current and past states of the economy*. If we assume, for the simplicity of the exposition, that the information available to traders at date $t$ is represented by the sequence $(x_t, x_{t-1}, \ldots)$, that means that we have to add to (1), $m$ expectations functions of the form

$$x^e_{i,t+1} = \psi_i(x_t, x_{t-1}, \ldots) \tag{3}$$

The equations (1) and (3) describe then in a consistent way a sequential adjustment of markets – a sequence of *temporary equilibria* – in which time goes forward, as it should. Given past history $(x_{t-1}, x_{t-2}, \ldots)$, (1) and (3) determine the current temporary equilibrium state and forecasts. Once such a temporary equilibrium is reached, production and exchange takes place at date $t$, and the
The temporary equilibrium approach, as sketched in the formulation (1) plus (3) is the general formulation, in fact the only sort of formulation that is allowed, if one wishes to describe the evolution of the economy as a sequence of markets that adjust one after each other. One should expect accordingly the approach to include self-fulfilling expectations as a special case. Indeed choose a particular intertemporal equilibrium. Then the associated sequence of states, say \( \{ \bar{x}_t \} \), is a solution of the difference equation

\[
\bar{x}_t = F(\bar{x}_{t+1})
\]

(4)

in which \( F(x) = f(x, \ldots, x) \) for all \( x \). Consider now the economy at date \( t \), and assume that past states have been \( (\bar{x}_{t-1}, \bar{x}_{t-2}, \ldots) \). Assume that the traders know the characteristics of the economy, or at least the map \( F \), and further that the map \( F \) is invertible (we are voluntarily vague about the domain of definitions of the functions under consideration, to simplify the present methodological discussion, but these technical details can be fixed up). The traders are then able to infer that the recurrence satisfied by current and past states, that is, \( x_t = F^{-1}(x_{t-1}) \), will obtain in the future as well, their forecasting rule may be viewed as the result of iterating twice that relation, or of inverting \( x_{t+1} = F^2(\bar{x}_{t-1}) \), for all \( i = 1, \ldots, m \)

\[
\psi_i(\bar{x}_t, \bar{x}_{t-1}, \ldots) = F^{-2}(\bar{x}_{t-1}).
\]

(5)

If this relation holds, \( \bar{x}_t \) is indeed a temporary equilibrium state (that is, it solves (1) and (3)) at date \( t \), given past history \( (\bar{x}_{t-1}, \bar{x}_{t-2}, \ldots) \).

As we have just shown, the temporary equilibrium method includes self-fulfilling expectations as a special case. This shows incidentally that the opposition often made in the literature, between self-fulfilling expectations, that are claimed to be ‘forward looking’, and ‘backward looking’ expectations as in (3), is presumably misleading. The temporary equilibrium approach is indeed much more general, since it permits to incorporate in the analysis the fact that traders usually learn the dynamics laws of their environment only gradually, and thus to study in principle how convergence toward self-fulfilling expectations may or may not obtain in the long run.

The preceding discussion was carried out in a simple one-dimensional world operating under certainty. It should be clear nevertheless that the qualitative conclusions we obtained hold as well in a more complex, multidimensional world operating under uncertainty.

When the evolution of the economy is described as a sequence of temporary equilibria, at each date, the
current equilibrium states are determined by past history. In this framework, a number of issues arise naturally. First, one has to find the conditions under which the dynamic evolution of the economy is well defined. In other words, when does a temporary equilibrium exist? Second, does the corresponding dynamical system have long-run equilibrium states, such as deterministic stationary states or cycles, and/or stationary stochastic processes, along which expectations are self-fulfilling? Under which conditions, in particular on the formation of expectations, do the sequences of temporary equilibria so generated converge to such a long-run equilibrium? This is precisely the sort of questions that have attracted the attention of modern economic theorists working in temporary equilibrium theory.

Overview

We turn now to a brief appraisal of this research effort, referring the interested reader to more extensive and more technical surveys that already exist in the literature, see for example Grandmont (1977; 1987; 1998).

Money and assets in competitive markets

Considering a sequence of markets opens immediately the possibility for traders to hold money and more generally, assets of various kinds for saving, borrowing, transactions purposes and/or insurance motives. The application of the modern techniques of temporary equilibrium theory to the study of monetary phenomena has led to a major reappraisal, in the 1970s, of classical and neoclassical monetary theories in competitive environments. It has permitted in particular to solve an old problem that had puzzled economic theorists for some time (Hahn, 1965), namely, why fiat money, which has no intrinsic value, should have a positive value in exchange in competitive markets. The answer provided by traditional neoclassical theory relied essentially upon unit-elastic price expectations and the presence of real balance or wealth effects (Patinkin, 1965). Modern temporary equilibrium methods have shown that sort of answer to be surely incomplete and presumably mistaken: intertemporal substitution effects have to play an important role, and this can be achieved only by abandoning the hypothesis of unit-elastic expectations and by introducing some degree of inelasticity of expectations with respect to current observations (an example of such a condition was used in (5) above, where the forecast was made to depend on past states but not on the current state). The reappraisal of monetary theory by means of the temporary equilibrium method clarified greatly many confusing debates of the preceding literature: the relations between Walras's and Say's Law, the meaning and the validity of the classical dichotomy and the quantity theory of money, the possibility of monetary authorities to manipulate the interest rates or the money supply, the existence of a ‘liquidity trap’ (Grandmont, 1983). The introduction of cash-in-advance constraints in temporary competitive equilibrium models of money (Grandmont and Younès, 1972; 1973) yielded important insights into the relations between its respective roles as a store of value and as a medium of exchange, and time preference, and permitted to make precise the microeconomic foundations of Milton Friedman's theory of optimum cash balances (1969; see also Woodford, 1990). Such models of money using cash-in-advance constraints have been popular in modern macroeconomics, following the contribution of R.E. Lucas, Jr. (1980). Capital market imperfections that
make explicit the essential role of money in exchange have since been central to the modern analysis of monetary theory and policy (see Wallace, 2001).

The introduction of assets of various kinds in competitive markets leads also to the possibility of speculation and arbitrage in capital markets. Different persons with different tastes or expectations will then be willing to trade such assets. An important question is to study the conditions ensuring the existence of a temporary equilibrium in that context. A neat answer to that problem was provided by J.R. Green (1973) and O.D. Hart (1974): there must be some agreement between the traders’ expectations about future prices.

Temporary equilibria with non-clearing markets and imperfect competition

A temporary equilibrium need not be Walrasian. One may consider cases where prices and/or wages are set through monopolistic or oligopolistic competition at the beginning of each elementary period and remain temporarily fixed within that period. A temporary equilibrium corresponding to these prices is then achieved at each date by quantity rations that set upper or lower bounds on the traders’ transactions. It had been known for some time that traditional Keynesian macroeconomic models of unemployment involved, explicitly or implicitly, the assumption of temporarily fixed prices and/or wages, as noted by Hicks himself (1965). The choice-theoretic structure of these models was rather unclear, however, which was a source of some confusion. The systematic study of temporary equilibrium models with quantity rationing undertaken in the 1970s produced deep insights on this issue, and unveiled the hidden but central role played by quantity signals, as perceived by the traders in addition to the price system, to achieve an equilibrium in such models.

One major outcome of this research programme was the discovery that different types of unemployment could obtain, and even co-exist. ‘Keynesian unemployment’ corresponds to a situation where there is an excess supply on the labour and the goods markets. In such a situation, firms perceive constraints on their sales because demand is too low. Keynesian policies aiming at increasing aggregate demand may work in such a case. But unemployment may co-exist with an excess demand on the goods markets. In such a regime, called ‘classical unemployment’ by Malinvaud (1977), the source of unemployment is rather the low profitability of productive activities. Keynesian policies may not work in that case; one has to resort to policies that restore profits, such as lowering real wages. In that respect, these results achieved a remarkable synthesis, within a unified and clear conceptual framework, between two paradigms that appeared fundamentally distinct beforehand.

The research on this topic proceeded very early on to endogenize prices and wages and yielded numerous insights of the connections between Keynesian models of unemployment and price or wage making in monopolistic or oligopolistic models of competition (see Barro and Grossman, 1976; Benassy, 1982; 1986; Grandmont and Laroque, 1976; Hart, 1982; Malinvaud, 1977; Negishi, 1979). It has since become a cornerstone building block of the modern reformulation of so-called ‘new Keynesian macroeconomics’ (Benassy, 2002; Dreze, 1991; Mankiw and Romer, 1991). While early formulations focused on temporary equilibria with non-clearing markets due to exogenously staggered price and wage setting (see Taylor, 1999, for a survey), more recent research seeks to explain such staggering of price and wage changes as the rational reaction of agents under the gradual diffusion of ‘sticky information’ (Mankiw and Reiss, 2003).
Learning and (in)stability

The temporary equilibrium approach includes self-fulfilling expectations as a particular case, and is in fact more general, since it can incorporate learning in the formation of the traders’ expectations. An important issue, that has been early on the agenda of that research programme (Fuchs and Laroque, 1976), is then to know whether the sequences of temporary equilibria that are associated to given learning processes or expectations functions converge eventually to a long-run equilibrium along which forecasting mistakes vanish. The question arises of course for long-run equilibria that are simple, such as steady states, or more complex, such as deterministic cycles (Grandmont, 1985). The general lesson that seems to come out the research works done on the topic appears to be some kind of ‘uncertainty principle’ (Grandmont, 1998). Learning generates local instability of self-fulfilling expectations whenever agents are on average uncertain about the local stability of the system, and thus ready to extrapolate a wide range of regularities (trends) out of past deviations from equilibrium, and when the influence of expectations on the dynamics is significant. On the other hand, learning may generate locally stable dynamics when either expectations do not matter much or traders extrapolate a restricted range of stable trends out of past deviations from equilibrium.

The above principle arises in a wide variety of learning processes, in particular in ‘error learning’ models, least squares and Bayesian learning. Of course, if one is willing to restrict the range of learning schemes, one may be able to produce sharper stability criteria (see in particular the concept of ‘E-stability’ developed by Evans and Honkapohja, 1999, for a particular class of learning processes). Local learning instability due to the above ‘uncertainty principle’ may explain why markets in which expectations are thought to play a significant role, such as markets for financial assets, durable goods, capital or inventories, display more volatility than others. In a similar vein, Brock and Hommes (1997) have shown local instability in a cobweb model, and convergence to more or less complex cyclical or chaotic long-run equilibria, when agents choose in variable proportions among different more or less efficient (and costly) learning schemes, and have sought to apply this approach to explain ‘excess volatility’ in financial markets.

term structure of interest rates

Burton G. Malkiel
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The term structure of interest rates concerns the relationship among the yields of bonds that differ only with respect to their terms of maturity. This article explains the three traditional explanations of the term structure. 1. The expectations theory considers the long rate to be an average of current and future short rates. 2. The liquidity-preference theory posits that illiquid, risky long-terms bonds must yield a premium over expected short rates. 3. The hedging-pressure theory stresses the influence of the preferred habitats of different investors. A survey of empirical work on the term structure including affine yield models concludes.

Article

The term structure of interest rates plays a critical role in the decisions of individuals and corporations and in the conduct of monetary policy. Individuals deciding between an adjustable and a fixed-rate mortgage, and corporations deciding whether to finance their operations with short- or long-term debt, can make sensible decisions only if they understand the factors that determine the relationship between short- and long-term rates. Central banks, which are considered to have substantial control over short-term interest rates, need to understand the likely effect on long rates from their activities in the short-term market. During 2005, in his final year as Chairman of the Federal Reserve, Alan Greenspan referred to the
behaviour of long-term rates as a ‘conundrum’ (Greenspan, 2005, p. 8). The US central bank had raised short-term rates at eleven consecutive meetings but the long-term government-bond rate actually declined over the period. This article examines the Greenspan conundrum and presents the traditional theories offered by economists to explain the relationship between short- and long-term interest rates. Consider a one-year zero coupon bond that makes a single known payment at maturity, which is \( F \), the face value of the bond. The bond's price is \( P \) and the investor's return is \( R, 1 \), which is the bond's simple (one-year) yield to maturity:

\[
P = \frac{F}{(1 + R, 1)}.
\]

Assuming annual compounding, the yield to maturity of an \( N \)-year bond, we can find \( R, N \) by solving the equation

\[
P = \frac{F}{(1 + R, N)^N}.
\]

The term structure of interest rates concerns the relationship among the yields of (zero coupon) default-free securities that differ only with respect to their term to maturity. The relationship is more popularly known as the shape of the yield curve, which is pictured by plotting the various yields to maturity (Rs) on the vertical axis against the different years to maturity (Ns) on the horizontal axis. Explaining the shape of curve has been a subject of intense examination by economists for over 60 years. Historically, three competing theories have attracted the widest attention. These are known as the expectations, liquidity preference, and hedging-pressure (or preferred habitat) theories of the term structure.

**The expectations theory**

According to the expectations theory, the shape of the yield curve can be explained by investors’ expectations about future short-term interest rates. I use the term ‘interest rate’ to refer to the yield to maturity of a zero coupon bond of a specific term to maturity (\( N \)). This proposition dates back at least to Irving Fisher (1896), but the main development of the theory was done by Hicks (1939) and Lutz (1940). More recent versions of the theory have been developed by Malkiel (1966), Roll (1970; 1971), and Cox, Ingersoll and Ross (1981).

Suppose, for example, that investors believe that the prevailing level of interest rates is unsustainably high and that lower rates are more probable than higher ones in the future. Under such circumstances, long-term bonds will appear to investors as more attractive than shorter-term issues if both sell at equal yields. Long-term bonds will permit an investor to earn what is believed to be an unusually high rate
Over a longer period of time than short-term issues, whereas investors in shorter bonds subject themselves to the prospect of having to reinvest their funds later at the lower yields that are expected. Moreover, longer-term bonds are likely to appreciate in value if expectations of falling rates prove correct. Thus, if short and long securities sold at equal yields, investors and arbitrageurs would tend to bid up the prices (force down the yields) of long-term bonds while selling off short-term securities, causing their prices to fall (yields to rise). Thus, a descending yield curve with short issues yielding more than longer ones can be explained by expectations of lower future rates. Similarly, an ascending yield curve, with longer issues yielding more than shorter-term ones, can be explained by expectations of rising rates.

Under the assumptions of the perfect-certainty variant of the expectations theory, there are no transactions costs, and all investors make identical and accurate forecasts of future interest rates. The theory then implies a formal relationship between long- and short-term rates of interest. Specifically, the analysis leads to the conclusion that the long rate is an average of current and expected short rates.

Consider the following simple two-period example, where only two securities exist (a one-year and a two-year zero coupon bond), and investors have funds at their disposal for one or two years. Let capital $R_s$ stand for actual market rates (yields), while lower-case $r_s$ stand for expected or forward rates. Prescripts represent the time periods for which the rates are applicable, while postscripts stand for the maturity of the bonds. Thus, $t, R, 2$ indicates today's actual two-year rate, while $t + 1, r, 1$ stands for the expected one-year rate in period $t + 1$.

If investors are profit maximizers, it follows that each investor will choose that security (or combination of securities) that maximizes his return for the period during which his funds are available. Consider the alternatives open to the investor who has funds available for two years. The two-year investor will have no incentive to move from one bond to another when he can make the same investment return from buying a combination of short issues or holding one long issue to maturity. If such an investor invests one dollar in a one-year security and then reinvests the proceeds at maturity (that is, $1 + t, R, 1$) in a one-year issue next year, his total capital will grow to $(1 + t, R, 1)(1 + t + 1, r, 1)$ at the end of the two-year period. Alternatively, if he invests his dollar in a two-year zero coupon issue, he will have at maturity $(1 + t, R, 2)^2$. In equilibrium, where the investor has no incentive to switch from security to security, the two alternatives must offer the same overall yield, namely,

$$\begin{align*}
(1 + t, R, 2)^2 &= (1 + t, R, 1)(1 + t + 1, r, 1).
\end{align*}$$

Thus, the two-year rate can be expressed as a geometric average involving today's one-year rate and the one-year rate of interest anticipated next year:

$$\begin{align*}
(1 + t, R, 2) &= [(1 + t, R, 1)(1 + t + 1, r, 1)]^{1/2}.
\end{align*}$$
If eq. (2) holds, then the holding-period return for the one-year investor will also be the same whether he buys a one-year bond and holds it to maturity or buys a two-year bond and sells it after one year. If eq. (2) does not hold, say because the two-year rate was lower than the average of the current and prospective one-year rate, an arbitrageur could make a sure profit by selling the two-year issue short and purchasing a series of one-year securities. It is in this sense that the expectations theory fulfills a no-arbitrage condition.

In similar fashion, the rate on longer-term issues must turn out to be an average of the current and a whole series of future short-term rates of interest. Only when this is true can the pattern of short and long rates in the market be sustained. The long-term investor must expect to earn through successive investment in short-term securities the same return over his investment period that he would earn by holding a long-term bond to maturity. In general, the equilibrium relationship is,

\[
(1 + t, R, N) = [(1 + t, R, 1)(1 + t + 1, r, 1) \ldots \times (1 + t + N - 1, r, 1)]^{1/N}
\]  

The expectations theory can be extended to a world of uncertainty and it can account for every sort of yield curve. If short-term rates are expected to be lower in the future, then the long rate, which we have seen must be an average of those rates and the current short rate, will lie below the short rate. Similarly, long rates will exceed the current short rate if rates are expected to be higher in the future. Notice that the expectations theory is capable of explaining the Greenspan conundrum. Suppose that the central bank's aggressive raising of short-term rates was expected to lower future inflation and weaken future economic activity, thus leading to expectations of lower future short-term rates. In such a case, the long rate could fall because, while the current short rate was higher, the entire set of future short rates would be lower than was previously expected.

The liquidity-preference theory

The liquidity-preference theory, advanced by Hicks (1939), accepts that expectations are important in influencing the shape of the yield curve. Nevertheless, it argues that, in a world of uncertainty, short-term issues are more desirable to investors than longer-term issues because they are more liquid. Short-term issues can be converted into cash at short notice without appreciable loss in principal value, even if rates change unexpectedly. Long-term issues, however, will tend to fluctuate widely in price with unanticipated changes in interest rates and hence ought to yield more than shorts by the amount of a risk premium.

If no premium were offered for holding long-term bonds, it is argued that most individuals and institutions would prefer to hold short-term issues to minimize the variability of the money value of their portfolios. On the borrowing side, however, there is assumed to be an opposite propensity. Borrowers
can be expected to prefer to borrow at long term to assure themselves of a steady source of funds. This leaves an imbalance in the pattern of supply and demand for the different maturities – one that speculators might be expected to offset. Hence, the final step in the argument is the assertion that speculators are also averse to risk and must be paid a liquidity premium to induce them to hold long-term securities. The arbitrage described in the exposition of the expectations theory is not riskless. Thus, even if interest rates are expected to remain unchanged, the yield curve should be upward sloping, since the yields of long-term bonds will be augmented by risk premiums necessary to induce investors to hold them. While it is conceivable that short rates could exceed long rates, if investors think that rates will fall sharply in the future, the ‘normal relationship’ is assumed to be an ascending yield curve. Formally, the liquidity premium is typically expressed as an amount that is to be added to the expected future rate in arriving at the equilibrium-yield relationships described in eqs. (1) through (3). If we let \( L, 2 \) stand for the liquidity premium that should be added to next year's forecasted one-year rate, we have

\[
(1 + t, R, 2)^2 = (1 + t, R, 1)(1 + t + 1, r, 1 + L, 2)
\]  
(4)

and

\[
(1 + t, R, 2) = [(1 + t, R, 1)(1 + t + 1, r, 1 + L, 2)]^{1/2}.
\]  
(5)

Thus, if \( L, 2 \) is positive (that is, if there is a liquidity premium), the two-year rate will be greater than the one-year rate even when no change in rates is expected. It has also been customary to assume that \( L, 3 \), the premium to be added to the one-year rate forecast for two years hence (that is, period \( t + 2 \)), is even greater than \( L, 2 \), so that the three-year rate will exceed the two-year rate when no change is expected in short-term rates over the next three years. In general, the liquidity-premium model may be written as

\[
(1 + t, R, N) = (1 + t, R, 1)(1 + t + 1, r, 1 + L, 2)\ldots\ldots(1 + t + N - 1, r, 1 + L, N)]^{1/N}.
\]  
(6)

On the assumption that \( L, N > L, N - 1 > \ldots > L, 2 > 0 \), the yield curve will be positively sloped even when no changes in rates are anticipated. Another potential explanation of the Greenspan conundrum is consistent with the liquidity-preference theory. The prompt actions of the central bank to insure that future inflation is contained could engender
Term structure of interest rates: The New Palgrave Dictionary of Economics

expectations of greater future economic stability and thus lower risk premiums throughout the economy.

The hedging-pressure or preferred habitat theory

Other critics of the expectations theory, including Culbertson (1957) and Modigliani and Sutch (1966), argue that liquidity considerations are far from the only additional influence on bond investors. While liquidity may be a critical consideration for a commercial banker considering an investment outlet for a temporary influx of deposits, it is not important for a life insurance company seeking to invest an influx of funds from the sale of long-term annuity contracts. Indeed, if the life insurance company wants to hedge against the risk of interest-rate fluctuations, it will prefer long, rather than short, maturities. Long-term investments will guarantee the insurance company a profit regardless of what happens to interest rates over the life of the contract.

Many pension funds and retirement savers find themselves in a wholly analogous situation. A retirement saver who has funds to invest in bonds for n periods will find an n-period pure discount (zero coupon) bond to be the safest investment. It is assumed that, if investors are risk averse, they can be tempted out of their preferred habitats only with the promise of a higher yield on a bond of any other maturity. Of course, other investors such as commercial banks or corporate investors will hedge against risk by confining their purchases to short-term issues. These investors will need higher yields on longer-term issues to induce them to invest in such securities. Under this hedging-pressure theory, however, there is no reason for term premiums to be necessarily positive or to be an increasing function of maturity. Under an extreme (and somewhat implausible) form of the argument suggested by Culbertson, the short and long markets are effectively segmented, and short and long yields are determined by supply and demand in each of the segmented markets.

One of the popular explanations of the Greenspan conundrum was that many long-term investors, such as pension funds, were moving money out of the stock market and into the long-term bond market in order to ‘immunize’ their long-term liabilities. Such buying creates additional demand for long-term bonds, driving the yields of such securities down.

Empirical analysis of term structure theories

The chief obstacle to effective empirical analysis of the determinants of the term structure of interest rates has been the lack of independent evidence concerning expectations of future interest rates. Consequently, the first step in most empirical tests of the pure form of the expectations theory has been to set up some mechanism by which expectations may reasonably have been formed by market participants. Since people usually estimate the future by relying, at least in part, on historical information, this procedure has often involved the generation of forecasts of future interest rates from past values of these rates. Then investigators have sought to determine whether empirical yield curves have been consistent with these hypothetical forecasts and with the premise that investors, in fact, behave as the expectations theory claims. Thus, in essence, two theories were tested jointly: first, a theory of expectations formation, and second, a theory of the term structure. Of course, it is important to realize that any inability to confirm the expectations theory may be due to a failure to specify properly an expectations-forming mechanism rather than a failure of the theory to offer a correct explanation of
The expectations-forming mechanisms utilized in empirical studies have been varied and inventive. They have included an error-learning mechanism (Meiselman, 1962); distributed lags on past rates (Modigliani and Sutch, 1966) or on inflation (Modigliani and Shiller, 1973; Fama, 1976); use of ex post data under an assumption that market efficiency and rationality require that ex post realizations do not differ systematically from ex ante views (Roll, 1970; 1971; Fama, 1984a; 1984b); and survey data assumed to reflect the actual expectations of market participants (Kane and Malkiel, 1967; Malkiel and Kane, 1969; Kane, 1983). While affirming the general importance of expectations in influencing the shape of the yield curve, empirical studies have generally rejected the pure form of the expectations hypothesis. There does appear to be an upward bias to the shape of the yield curve, indicating that term premiums do exist. But, contrary to the liquidity-preference theory, term premiums do not increase monotonically over the whole span of forward rates. Moreover, such term premiums vary over time. In addition, there appear to be seasonal patterns in the forward rates calculated from the short end of the yield curve.

Campbell (1995) points out that the pure expectations hypothesis implies that, whenever long yields exceed short yields, short yields should tend to rise in the future. It also implies that long yields must rise in the future so as to produce the capital losses that equate the short-term holding period returns between long and short maturities. He finds, instead, that mean excess returns on long bonds are positive. But excess returns on longer-term bonds do not rise throughout the maturity spectrum. The excess returns on zero coupon two-month bonds over one-month bills are positive, and excess returns over short bills rise with maturity at first, but after one year begin to decline and actually become negative for 10-year zero coupon bonds. And when the long-short yield spread is high, long yields have tended to fall, thus amplifying the yield differential between long and short bonds. Note that it is precisely this behaviour that Chairman Greenspan referred to as a ‘conundrum’ during 2005.

Affine yield models

More recent work on the term structure of interest rates has focused directly on how the shape of the term structure changes over time. The literature has evolved mostly in continuous time, and it is assumed that the future dynamics of the term structure depend on the evolution of some single factor or multiple factors that follow a stochastic process. The models are rooted in a framework consistent with the risk-adjusted expectations theory where arbitrage opportunities are not possible in equilibrium and where (log) bond yields are functions (which are often ‘affine’) of a single state variable that describes movements in future short-term rates or in a set of state variables related to the workings of the economy and the formation of expectations.

The pioneering models of this type were presented by Vasicek (1977) and Cox, Ingersoll and Ross (1985). These early papers developed single-factor models where the specific factor was the very short-term (instantaneous) default-free interest rate. Thus, all the information that is relevant for the determination of long-term rates was compressed into one stochastic process for very short rates. The process is a continuous time analogue to an autoregressive process where there is a fixed ‘normal’ short-term rate that can serve as an anchor for mean reversion. Once the diffusion process for short rates is...
The term structure of interest rates: The New Palgrave Dictionary of Economics

specified, arbitrage is relied upon to explain the observed yields of bonds of different maturities. The models described above are special cases of the affine class of term structure models. The models that followed have employed multiple factors but maintained the assumption that (log) bond prices are linear functions of the state variables. Duffie and Kan (1996) and Singleton and Dai (1999) presented models where the factors are the yields of \( n \) various fixed maturity bonds. Litterman and Scheinkman (1999) show that at least 95 per cent of the variation in yield changes can be explained by three latent factors, and interpret these factors in terms of the ‘level’ of yields, the ‘slope’ of the yield curve, and the ‘curvature’ of the curve. Further work has made significant strides in identifying and relaxing the restrictive assumptions of these models and in improving estimation techniques. Dewachter and Lyrio (2006) have jointly modelled the term structure as well as the dynamics of various macroeconomic variables. Their paper provides a macroeconomics interpretation of the Litterman–Scheinkman latent factors. They interpret the ‘level’ of yields factor as representing inflation expectations, the ‘slope’ of the yield curve factor as representing business-cycle conditions, and the ‘curvature’ factor as representing an independent monetary policy factor. Note that these factors are exactly those referenced earlier in an attempt to explain the Greenspan conundrum. A full discussion of affine yield models is contained in a survey article by Piazzesi (2006).

terms of trade

Ronald Findlay
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article describes the various approaches that have been made to the ‘terms of trade’, the question of determining and measuring the rate at which countries that engage in international trade divide the benefits between them. It traces the evolution of the relevant ideas, beginning with the pioneering contributions of David Ricardo, John Stuart Mill and Alfred Marshall.

Keywords

balance of trade; barter; commodity terms of trade; comparative advantage; double factorial terms of trade; gains from trade; gross barter terms of trade; immiserizing growth; income terms of trade; index numbers; international trade theory; Marshall, A.; Marshall–Lerner condition; Mill, J. S.; North–South economic relations; offer curve; optimal tariffs; Prebisch, R.; reciprocal supply and demand; Ricardo, D.; shadow pricing; Singer, H.; single factorial terms of trade; stationary state; terms of trade; transfer problem

Article

The two most basic questions about international trade are, ‘What goods will each country export?’ and ‘What will be the ratios at which the exports of one country exchange for those of its trading partners?’ The first problem is that of ‘comparative advantage’; the second that of the ‘terms of trade’, which is the subject of the present article. David Ricardo, in Chapter 7 of the Principles (1817), gave a definitive answer to the first question and went a long way towards the solution of the second, though it was John Stuart Mill and Alfred Marshall who eventually gave the complete answer.

In the following discussion it will be convenient to assume, for simplicity, that there is only a single good exported and imported, and sometimes even that there is only a single factor of production, such as labour of a given quality. In practice, of course, we would have to use index numbers for unit values and physical volumes of exports and imports, giving rise to all the familiar problems (see index numbers).
There are a number of alternative concepts and associated statistical measures of the terms of trade. The most prominent are listed below.

1. The commodity or net barter terms of trade is by far the most common meaning of the term, and is usually what is meant when the expression is used without any qualifying prefix. In principle, this is the relative price of the ‘exportable’ in terms of the ‘importable’, the number of units of the latter obtainable for each unit of the former. It has the dimensions of ‘nine waistcoat buttons for a copper disc’ in the words of Lewis Carroll’s ‘Song of the Aged, Aged Man’ in Through the Looking Glass, words that D.H. Robertson (1952, ch. 13) used as the motto for a delightful essay on the terms of trade. In statistical practice, the commodity terms of trade are calculated as changes in the ratio of an export price index to an import price index, relative to a base year.

2. The gross barter terms of trade is a concept introduced by F.W. Taussig. It is the ratio of the volume of imports to the volume of exports. It coincides with the commodity terms of trade when trade is balanced, that is, there are no international loans or unrequited transfers. A deficit in the trade balance would cause the gross barter terms to be more favourable than the commodity or net barter terms, and vice versa. This should not, of course, be understood to mean that a trade deficit is necessarily preferable to balanced trade, since the additional imports now may have to be paid for by future trade surpluses.

3. The income terms of trade, sometimes also referred to as ‘the purchasing power of exports’ corresponds to the commodity terms of trade multiplied by the volume of exports. This is equal to the volume of imports under balanced trade, and exceeds or falls short of it if there is a surplus or deficit, respectively, in the balance of trade. In other words, it is the level of imports in real terms that can be sustained by current export earnings.

4. The single factoral terms of trade refers to the marginal or average productivity of a factor in the export sector, evaluated in terms of the imported good at the commodity terms of trade. The concept is meaningful for any single factor or production taken separately, though it is sometimes defined in a non-operational fashion in the literature as referring to ‘units of productive power’.

5. The double factoral terms of trade is an attempt to go behind the international exchange of commodities to the productive factors that are ‘embodied’ in them. Thus, if units are chosen, to the effect that a unit of labour in England produces a unit of cloth and a unit of labour in Portugal produces a unit of wine, commodity terms of trade of say five wine to one cloth would mean that a unit of English labour exchanges implicitly for five units of Portuguese labour in international trade.

The first three concepts of the terms of trade are all measurable in practice, subject to the usual index number problems. The commodity terms of trade are routinely calculated for most countries in the world by international agencies such as the United Nations (UN), the World Bank and the International Monetary Fund (IMF). The gross barter and income terms of trade have also been calculated for several countries.

The single factoral terms of trade, for any particular factor, can also be computed. Indeed it corresponds exactly to the concept of ‘shadow prices’ for primary inputs that has recently been developed in the literature on cost–benefit analysis in distorted open economies. Thus it could indicate what the value of a worker or an acre of land, engaged say in the coffee export sector, was worth in terms of imported food at the commodity terms of trade. This could serve as a valuable guide to resource allocation if a
The double factorial terms of trade, however, is either misleading if it is computed for any particular single factor in a world of more than one scarce input, or non-operational if defined amorphously as applying to units of ‘productive power’. This concept has been regarded by more than one economist as the fundamental one, and no less an authority than D.H. Robertson, in the essay referred to above, called it the ‘true’ terms of trade. Equally eminent authorities, such as Haberler (1955) and Viner (1937), have, however, been more sceptical, and rightly so.

The concept has recently come to the fore again, after many decades of neglect, in connection with the theories of A. Emmanuel (1972) on ‘unequal exchange’ in trade between high-wage and low-wage countries, which he regards as a form of ‘exploitation’ of the latter by the former. It is possible to interpret Emmanuel as saying that it is only when the double factorial terms of trade are equal to unity that there is no unequal exchange. As Emmanuel himself acknowledges, however, his argument requires equal capital intensity in the export sectors of the trading partners. We may all agree with Robert Burns that ‘A Man's a Man for a’ That’ in terms of dignity and spiritual worth. It is another thing, however, to say that skill or physical capital, both accumulated at some cost, should count for nothing, and that the only ‘fair’ exchange is one that takes place according to the simple labour theory of value.

Furthermore, it is clear that the commodity terms of trade can improve while the factorial terms worsen, and vice versa. Thus suppose that, initially, one day's labour in ‘North’ and ‘South’ produces a unit of steel and coffee, respectively, and that the commodity terms of trade was one unit of steel for one unit of coffee. Suppose now that one worker in the North produces three steel, while his counterpart in the South still produces only one coffee. Let the commodity terms of trade now be two units of steel for one of coffee. The commodity terms have doubled in favour of the South, while its factorial terms have deteriorated to two-thirds instead of unity. Which situation would the South prefer?

**Fundamental determinants**

Ricardo did not determine the terms of trade explicitly in his analysis in Chapter 7 of the *Principles*. He was only able to show that the equilibrium value would be between the comparative cost ratios of the two countries, specified by the linear technologies. It was John Stuart Mill (1844) who solved the problem by his numerical example of ‘reciprocal supply and demand’, later refined by Marshall (1930) through the geometric device of the ‘offer curves’ showing the excess supplies and demands of the two goods in each country as functions of the terms of trade, the equilibrium value of which would be determined by setting world excess supply equal to zero. Marshall demonstrated the possibility of multiple equilibria and also established a criterion for stability of equilibrium that is in use to this day, in the form of the so-called Marshall–Lerner condition that the sum of the import demand elasticities has to be greater than unity.

In modern terms it is the preferences of the consumers that have to be introduced to close the model. Once these are introduced the equilibrium value(s) of the terms of trade are determined as a function of these preferences, the labour endowments and the technical coefficients of production. The subsequent development of the literature has generalized Ricardo's analysis to any number of goods, factors and countries and to variable instead of fixed technical coefficients. The determination of the terms of trade is thus technically nothing other than that of finding the equilibrium vector(s) of relative prices for
general equilibrium models in which there is a world market for tradable goods and internationally mobile factors, and national markets for non-traded goods and internationally immobile factors. In addition to constituting a central problem for the theory of international trade in its ‘positive’ aspect, the terms of trade plays if anything an even more critical role in the ‘normative’ dimension of evaluating the ‘gains from trade’. It is crucial to keep these two facets of the terms of trade conceptually distinct, though of course they are both involved in almost every theoretical or policy problem. Another essential distinction is between the terms of trade as an exogenously determined parameter, as in the ‘small’ open economy models, and as an endogenously determined variable, the equilibrium value of which is altered by some change in circumstances or parameters, such as factor endowments, technology or tastes. Much confusion has been caused in the literature by failure to bear these basic distinctions in mind at all times. In the realm of positive theory, the terms of trade generally appear in comparative static exercises as the key dependent variable, upon which the effect of some exogenous shock is sought. As an example, consider the effect of a switch in the composition of home demand in favour of the imported commodity. At constant terms of trade this would create an excess demand for the imported good. On the assumption of Walrasian stability, this must lead to a deterioration of the home country's terms of trade for the world market to return to equilibrium.

The famous ‘transfer problem’ is another example of this sort of comparative static exercise. The transfer of purchasing power at constant terms of trade would lead to an excess supply in the world market of the transferor’s exportable, if the home propensity to consume this good is greater than that of the recipient country (the so-called ‘classical presumption’). Thus the terms of trade of the transferor would deteriorate, given Walrasian stability, imposing a ‘secondary burden’ on the transferor. Finally, we may consider the effects of economic growth, in the form of exogenous changes in factor endowment or technical innovations in either sector, a literature that was stimulated by Hicks's (1953) inaugural lecture on the ‘dollar shortage’. Here again the analysis consists in finding the effect of the change on excess supply or demand at constant terms of trade, and thus obtaining the direction of movement in the terms of trade necessary to clear the market, assuming stability in the Walrasian sense.

Welfare effects

All these exercises in positive theory of course have welfare consequences for both trading partners. In the case of the two-country transfer problem the transferor is worse off, even if the terms of trade were to move in its favour, while the recipient is better off, even if the terms of trade were to turn against it. In the case of a shift in the composition of home demand towards imports the welfare of the trading partner will rise under normal conditions (see below) as a result of this improvement in its terms of trade. If growth in one country creates an excess demand for imports at constant terms of trade, its passive partner will also benefit from the resulting increase in the relative price of its export. In the last two cases a country experiences an exogenous improvement in its terms of trade, with no alteration in its own preferences, technology or factor endowment. Must its welfare necessarily increase as a result? The answer in general is ‘yes’, unless there are domestic distortions such as monopoly or monopsony in product or factor markets, exogenous wage differentials or real factor–price rigidities. A simple example of how it is possible for a country to experience a loss in welfare as a result of an improvement in its commodity terms of trade can be constructed as follows. Suppose that domestic production is completely specialized on the export good and that the real wage is fixed in terms of the
imported good. At constant employment, and therefore constant marginal physical productivity of labour in terms of the exported good, the real wage would be lower in terms of the imported good because of the improvement in the terms of trade. This will induce a decline in employment and output until the marginal physical product of labour rises in the same proportion as the relative price of the imported good has fallen, so that the original level of the real wage is restored. The terms of trade improvement, given employment and output, increases welfare, but the contraction in these variables induced by the change in the terms of trade reduces welfare. This negative effect can clearly be sufficient to outweigh the positive effect of the terms of trade gain considered in isolation, since the counteraction can be very sharp if the marginal productivity of labour schedule is assumed to be sufficiently elastic.

Haberler (1955, p. 30), in a characteristically penetrating and judicious discussion of the subject, has stated that ‘other things being equal an improvement in the commodity terms of trade does imply an increase in real national income’. As our analysis of the example in the previous paragraphs shows, however, even such a cautious formulation needs to be interpreted with care. It would obviously be a mistake to compound the welfare effects of an exogenous shift in the terms of trade with the direct welfare effects of some independent shock. In our example, however, the terms of trade change was the sole shift in the data, the contraction of employment and output being induced by this very change in the terms of trade itself.

When the change in the terms of trade is a consequence of some exogenous shock, such as a change in tastes, technology or factor endowment, it is clearly erroneous to infer the total change in welfare solely from the direction of change in the terms of trade. Technological progress in the export sector that causes deterioration in the terms of trade can obviously leave a country better off in spite of the deterioration, even though it would of course have been still better off if the terms of trade had remained unchanged. It is this sort of consideration that has led to the introduction of concepts such as the factoral terms of trade, since these measures could show an improvement even when the commodity terms of trade deteriorate. In general, however, it is a mistake to expect any single concept of the terms of trade to be an unambiguous indicator of changes in the gains from trade when there are shifts in the fundamental determinants of tastes, technology and factor endowments.

The welfare effects of such changes can be broken into two parts: first, the effect at unchanged terms of trade and second, the effect of the associated change in the terms of trade. The net effect on welfare may thus be positive or negative and need not correspond with the direction of the change in the terms of trade. Bhagwati (1958) established the possibility that the net effect on welfare of the country experiencing economic growth can be negative, a phenomenon that he termed ‘immiserizing growth’.

Finally, we may consider the terms of trade as an objective of policy, when the country has some degree of monopoly power in international markets. The consideration of a rational policymaker, ignoring the possibility of retaliation, would be to restrict trade to such an extent as to equate at the margin the benefit resulting from the improvement in the terms of trade with the loss of welfare resulting from the decline in the volume of trade. This is the famous ‘optimum tariff’ argument, the level of which varies inversely with the elasticity of foreign demand for imports.

**Secular tendencies**

In addition to comparative static analyses of the type considered up to now, the literature also contains some more speculative hypotheses about secular tendencies in the terms of trade. In the Ricardian
tradition, capital accumulation and technical progress lead to a steady expansion in the supply of manufactures, while the supply of primary products is always constrained by the limited availability of 'land' and other natural resources. Ricardo's theorem for a closed economy – that growth would raise the relative price of food and therefore the rent of land until a 'stationary state' is approached – has been extended to the world economy in the form of a presumption that there would be a tendency for the terms of trade to move against manufactures and in favour of primary products. Keynes, Beveridge, Robertson and E.A.G. Robinson all took part in a long-running debate on this issue. The story that W.S. Jevons kept enormous stocks of coal in his basement is a bizarre manifestation of this phobia. W.W. Rostow (1962, chs 8 and 9) gives a very interesting review and analysis of this literature, which foreshadows the views associated with the Club of Rome on the depletion of exhaustible natural resources.

Discussions of the secular tendencies of the terms of trade since the Second World War, however, have been dominated by the view of Raul Prebisch (1950) and Hans Singer (1950) that the historical record shows a long-run tendency for the commodity terms of trade of the less developed countries to deteriorate. The evidence was a series showing an apparent long-run improvement in Britain's terms of trade between 1870 and 1940. Theoretical reasons given for the alleged tendency have been lower income-elasticity of demand for primary products than for manufactures, technical progress that economizes on the use of imported raw materials and monopolistic market structures in the industrial countries combined with competitive conditions in the supply of primary products. The general consensus on the statistical debate that has arisen on this issue is that there has not been any discernible secular trend for the commodity terms of trade of the developing countries to deteriorate (see Spraos, 1980, for a summary and assessment of the evidence; Lewis, 1969, presents an interesting alternative theoretical and empirical analysis of this problem). Hadass and Williamson (2001) provide a useful recent summary and critique of the ongoing debate on the Prebisch–Singer thesis.

The Prebisch–Singer hypothesis and the more general concerns of the ongoing North–South dialogue have also spawned a number of so-called 'North–South' models, in which the interaction of an advanced industrial region with a less developed and structurally dissimilar, labour-abundant, primary producing region is studied in a dynamic context. The terms of trade play a key role in these models, since the growth rate of the South is linked to this variable through dependence on capital goods imported from the North. This and other analytical issues related to secular trends in the terms of trade are further discussed in Findlay (1980; 1984), Taylor (1981) and Darity (1990).

terrorist, economics of

S. Brock Blomberg and Gregory D. Hess
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article provides a comprehensive study of the economic determinants of domestic and transnational terrorism and the role that the economy plays in fostering a more peaceful world. We describe the research associated with the microfoundations of terrorist groups and how they organize. We also analyse models of conflict resolution to investigate the relative importance of macroeconomic factors for domestic and transnational terrorism. We describe a number of data-sets employed by researchers in the field and end by describing the most recent research which investigates the linkages between terrorism, democratization, globalization and development.

Keywords

civil conflict; democratization; development; foreign direct investment; globalization; gravity models; international trade; terrorism, economics of; war and economics

Article

Since the prominent post-2000 terrorist incidents in high-income cities such as New York, Madrid and London, and the persistent incidence of terrorism in Middle East countries such as Israel and Iraq, both academia and the media have become involved in a careful examination of its causes. Terrorism is, however, neither new nor novel – indeed, the very origin of the term points to a long history, dating back to the late 1700s. (The word ‘terrorism’ apparently first appeared in the English language in reference to the ‘reign of terror’ associated with the rule of France by the Jacobins from 1793–94. The first incidence was actually reported in first century bc when Jewish terrorists, Zealots-Sicarri, incited a riot which led to a mass insurrection against the Roman Empire. See Laqueur, 1977, pp. 7–8.) While terrorism has been present for longer than one might realize, research on the economics of terrorism has a shorter history. The literature has primarily focused on two areas: the microfoundations of terrorism – understanding why organizations employ terrorist tactics – and the macroeconomic causes and
consequences of these tactics. The latest wave of research highlights the relationship between terrorism, globalization and democratization.

Microeconomics of terrorism

Microeconomic-based (or at least economic-sympathetic) research in terrorism generally concludes that terrorist organizations behave rationally (see, for example, Bueno de Mesquita, 2005). So, while at key junctures terrorists initiate futile, high-cost (to terrorists’ own selves) insurgencies and lose sight of whether the tactics really bring them closer to their political goals, for example, the behaviour is likely more driven by the clandestine nature of organizations and the daily struggle to maintain operational security by distorting rebels’ understanding of the world outside their organization (see Bell, 1990; 2002). This also points to the utility of propagating ideological movements in terrorism.

To whit, Hudson's review (1999) shows that for every study finding a purported psychological regularity, or social psychology, there exist a contradictory study. This is consistent with Krueger and Maleckova's (2003) finding that terrorists do not come from the poorer or uneducated segments of society. Given that organizations prefer to send competent terrorists, and thus select for the highest qualified, these results are best interpreted as showing that irrationality and individual oppression are not the underlying causes of terrorist incidents.

Moreover, if ideology plays a role in terrorist recruitment, its focus has clearly evolved. With respect to the spreading of revolutionary ideologies, there has been a change in the motive of terrorists since the November 1979 takeover of the US embassy in Tehran, the Iranian capital. Up to that point, terrorism had been primarily motivated by revolutionary and separatist ideologies – for example, the Red Army or Shining Path (see Wilkinson (2001). Since then, religious-based fundamentalism has played a more primary role. For example, the share of religious-based terrorist organizations had grown from four per cent to over 50 per cent by 1995 (Hoffman, 1997).

However, it is misguided to search for the causes of terrorism in ideologies such as radical Islam. Rather, researchers such as Mishal and Sela (2002), Wilhelmsen (2004) and Brynjar and Hegghammer (2004) and Pape (2005) document that rational calculations rather than fundamentalist fury guide terrorist organizations’ decision-making. From the perspective of leadership, the evidence is strong that terrorists strategically choose targets to best realize their political agenda. (In turn, Enders and Sandler, 2002, analyse the government's response to the innovations in the supply of terrorism.)

Macroeconomics of terrorism

Given that terrorist behaviour can be described within a rational choice framework, many researchers have constructed models in order to evaluate the macroeconomic costs and consequences of terrorism based on Grossman (1991). Grossman provides the seminal economics paper investigating the integral linkages between civil conflict and the economy. He presents a general equilibrium model that treats insurrection and the suppression of insurrection as economic activities willingly undertaken by the participants. The ruler has to trade off higher taxes not only against the lower tax revenue that comes about when people devote less time to productive activities but also against the added cost of having to
Terrorism: The New Palgrave Dictionary of Economics

The New Palgrave Dictionary of Economics

Without the ability to suppress terrorism, Grossman finds that economies with no conflict equilibria by devoting some resources to soldiering and keeping tax rates low.

With respect to the links between terrorism and the economic environment, Blomberg, Hess and Weerapana (2004a) present a model that describes how one factor – the state of the economy – can lead groups to resort to terrorist attacks. Other authors such as Bernholz (2004) and Wintrobe (2002) have studied the important influences of increased fundamentalism and group solidarity in driving terrorist activity. Still, it is important to note that economic conditions help identify the underlying determinants of these activities. (There is also an existing literature that analyses how economics influences conflict in general. However, most of the analysis to this point has considered the impact on conflicts such as war without considering alternative types of conflict such as terrorism. For example, Hess and Orphanides, 1995; 2001a; 2001b, estimate the probability of conflict for the United States doubles when the economy has recently been in a recession and the president is running for re-election. Abadie and Gardeazabal, 2003, also find a strong relation between the economy and terrorism.) The evidence is best summarized in Blomberg, Hess and Weerapana (2004b) who provide an analysis of the relationship between economic growth phases (for example, expansions and contractions) and transitions into and out of terrorism incidents.

Violence, however, knows no bounds or lack of imagination. As such, it is often challenging to type forms of conflict into discrete, unbending categories. Acknowledging this point, there is a literature analysing the economic impact of terrorism as opposed to other forms of violence. Blomberg, Hess and Orphanides (2004), investigate the impact of various forms of conflict such as terrorism, internal wars and external wars on a country's economic growth. They find that, on average, the incidence of transnational terrorism has a significantly negative effect on growth, albeit one that is considerably smaller and less persistent than that associated with either external wars or internal conflict. They also find that terrorism is associated with a redirection of economic activity away from investment spending and toward government spending.

Other authors have concentrated on analysing one country in particular or on isolating one economic channel through which terrorism harms growth. Eckstein and Tsiddon (2004) provide an analysis of the macroeconomic consequences of terrorism in Israel, and find a large impact of domestic terrorism on economic activity. Using bilateral trade data, Blomberg and Hess (2006) establish that terrorism has a diminishing effect on international trade, and Blomberg and Mody (2006) demonstrate that violence also has a negative impact on foreign direct investment. Glick and Taylor (2004) also provide an analysis of the effect of external conflict on international trade over a longer historical period.

Terrorism data and empirical regularities

To test theories of terrorism as well as to estimate the costs of terrorism, researchers need reliable measures of terrorism. Several competing international data-sets for terrorist incidents have been cataloging attacks since the late 1960s. The dynamics across the major data-sets are roughly similar. In each data-set, the number of events increases during the period 1969 to 1987 (see the discussion in Blomberg and Hess, 2007a; 2007b). The US State Department and ITERATE data-sets estimate a
similar steady increase from approximately 100 to 200 incidents per year up to 500 to 600 incidents per year. The RAND data-set estimates a similar trend, though the levels are smaller (from a base of approximately 100 incidents per year). The difference in the levels of terrorism in these data-sets arises because RAND does not include terrorism from state actor to non-state actor within a country and so systematically underestimates the number of attacks as compared with the other data-sets. These trends demonstrate that the number of terrorist incidents steadily increased and peaked in the mid-to late 1980s. For several years thereafter, the worldwide intensity of transnational violence – violence motivated by international political considerations – fell steadily. In the late 1980s, according to the ITERATE data-set (see Mickolus et al., 2004), approximately one-and-one-half transnational violent events occurred every day. This frequency declined to less than one-half of an event a day by 2000. The decline also indirectly implies that the number of countries affected by a violent event fell over that period. This point has been more seriously addressed in Enders and Sandler (2005), who demonstrate that there has been no increase in violence from terrorism since the Al-Qaeda attacks on the United States on 11 September 2001. They show, if anything, that terrorism has fallen. However, over the time period in question the number of violent episodes may have risen – particularly since 11 September 2001. The average number of deaths per incident was 0.83 during 1968 to 1993. In seven of the following ten years, the number of deaths per incident was higher. Over the entire sample (1968–2003) there has been about one death per incident, and since 2001 the average has been five times that rate. Blomberg and Hess (2006; 2007a; 2007b) demonstrate two additional points. First, the recent drop in terrorism is systematic across regions, governments, income classes, and degrees of openness. Second, the hot spots for terrorism, as measured by incidence per capita, appear to be richer democracies, economies more open to trade and Middle Eastern countries.

Even though there is less systematic data available, terrorism was prominent before the 1960s and has evolved since its inception. In the late 19th and early 20th centuries, terrorists targeted political figures, the most notable examples being the 1881 assassination of Alexander II in Russia and the 1934 assassination of Alexander I of Yugoslavia. Current weapons and computer technology have transformed terrorists into literal artillery weapons causing a large amount of damage with only a few conspirators. Finally, many of these targets are now civilians rather than actual political heads.

### Terrorism, globalization, democratization and development

The changing dynamics of terrorism has led to an emerging set of papers investigating the relationship between globalization, democratization, development and terrorism. At its best, democracy provides a framework that aids the peaceful resolution of political conflicts (see Hess and Orphanides, 2001a, for a discussion of how democracy affects the likelihood of external conflict). It offers access to decision makers and political institutions for citizens, while it also provides checks and balances within competing branches of the government. It also makes political organization cheaper and lowers the costs of political action. In turn, democracies should make illegal activities more expensive than legitimate political activity. In expectation, therefore, there should be less terrorist violence in democracies. Alternatively, the key to the success of any terrorist act is recruitment and organization – both of which are made easier in free societies. Ironically, characteristics of democracies such as civil liberties and freedom of religion, association and movement could actually facilitate terrorist organization building.
Moreover, as terrorists often target innocent civilians, free speech and a free press (hallmarks of democracy) may be good channels for spreading fear. As a consequence, democracies could actually foster terrorist activities.

Is terrorism associated with the positive attributes of a democracy? Eubank and Weinberg (1994; 2001) find that terrorist groups are in fact more frequently hosted by democratic societies. Similarly, Li and Schaub (2004) find more incidents in democratic countries. Still, it may not be democracy that is the true driving force at work here; rather, the process of democratization may be the real culprit. For example, the experience of less democratic or newly democratizing countries such as Afghanistan and Iraq suggests that the transitional period between authoritarianism and democracy is a particularly susceptible one for terrorist activity (see Eubank and Weinberg, 1998). Thus, the linkages between terrorism incidence and the evolution of a country's institutional governance are an important area for further study.

Other evidence on the link between democracy and transnational terrorism is decidedly mixed. Li (2005) attempts to disaggregate the many dimensions of democracy; he finds that voter turnout reduces terrorist incidents, but that constraints on government authority increase incidents. Finally, he finds press freedom raises incidents in a country. Taken as a whole, therefore, the effect of democracy on terrorism is not straightforward.

Globalization also affects the economic environment in which terrorist organizations can operate. If terrorism emerges from an environment of economic deprivation, then globalization, in so far as it enhances economic growth, may offset terrorist tendencies. Alternatively, if globalization increases inequality across countries and groups, then we might expect globalization to lead to more violence. Furthermore, globalization's associated lowered barriers to flows of goods, factors of production (including labour) and finance could make a network of terrorist operations cheaper to operate. Overall, globalization, like democracy, affects the costs, benefits and resources constraints of terrorists in many ways. Learning whether or not globalization is a net contributor to terrorism is therefore an empirical matter. Still, there is ample theory to support either conjecture.

Krug and Reinmoeller (2004) argue that globalization is an important determinant of terrorism. They build a model to explain the internationalization of terrorism as a natural response to a globalizing economy. As countries become more economically integrated and market-oriented, there is no discrimination between what certain terrorist groups might see as bad products and good products or investments. Moreover, the same advances in technology that allow for easy access of goods and services also allow for easy access to military hardware and technology. In the short run, globalization may have the consequence of creating a series of winners and losers. These same losers will find it easier to retaliate in response to their losses, thereby multiplying the effect of globalization on terrorism. (In a pooled cross-section analysis of globalization and transnational terrorism, Li and Schaub, 2004, find that international trade and investment have little effect on the number of terrorist events.)

An alternative view put forth by Crenshaw (2001) is that it is naive to believe that globalization encourages international terrorism; while globalization and terrorism may seem to affect one another, there is something more complicated at work. She argues that the latest wave of terrorism should be seen as a series of civil wars which may be a strategically unified reaction to American power rather than directly to globalization.

In a series of papers, Blomberg and Hess (2006; 2007a) and Blomberg and Rosendorff (2007) are able to...
uncover several important linkages between globalization, democratization, development and terrorism by employing the workhorse model in the international trade literature – the gravity model. Terrorism is defined by the fact that ‘its ramifications transcend national boundaries’ (see Mickolus et al., 2004). Transnational terrorism requires, therefore, a flow of resources across borders, and these papers consider both the source and target countries’ characteristics in determining terrorism. The characteristics of a country that might make it a likely target country may indeed be very different from the characteristics that make a country a likely source of international terrorism. The features of the polity that make a country a terrorist-producer may be different from the political structures, institutions and environment that make a state a terrorist target. The conclusion from these papers is that the advent of democratic institutions, high income and more openness in a source country significantly reduces conflict. However, the advent of these same positive developments in targeted countries actually increases conflict. Ceteris paribus, the impact of being a democracy or participating in the WTO/IMF for a source country decreases the number of terrorist strikes by about two or three per year, which is more than two standard deviations greater than the average number of strikes between any two countries in a given year. Terrorism is a nascent field in economics. Sadly, though realistically, it is also likely to be a growing field in economics. Conflict and the economy are intimately related at the domestic and at the international levels, and across various forms of governance. Moreover, innovations in the strategy of terrorism will continue (see, for example, Berman and Laitin's analysis, 2005, of suicide attacks). Terrorism therefore will remain part of the violence spectrum and affect our economic landscape for years to come.

Article
Hypothesis testing is the customary instrument for analysing the empirical validity of an economic theory. This theory is reduced to a hypothesis which is tested in a statistical model. Hypothesis testing is thus an important tool for conducting statistical inference in economic models. An impressive literature has emerged which discusses tests of economic hypotheses. Instead of providing an incomplete overview of this literature, we provide a somewhat hands on discussion of testing in which we show how an economic theory is tested in a statistical model. We therefore begin with the discussion of the basic results on hypothesis testing and later focus on some recent developments that have improved testing in commonly used economic models. We use a real economic example to illustrate the main findings. When testing an economic hypothesis, we want our test results to hold generally and not to be affected by highly specific assumptions on the statistical model such as, for example, the distribution of the disturbances. Under these general conditions, the finite sample distributions of the involved test statistics are unknown. The realized values of the test statistics are then confronted with critical values that result from the large sample distributions of the statistics under the hypothesis of interest. Since this is currently the common approach to testing, our discussion is conducted solely from the large sample perspective. We illustrate the tests of an economic theory by testing for a unit demand price elasticity for the demand for oranges. We use data on the demand for oranges in the United States during 1910–59. The data results from Nerlove and Waugh (1961) and is also used in Berndt (1991, pp. 417–20). The demand equation is specified as
with \( Q_t \), the traded quantity, \( P_t \), the price of oranges and \( RI_t \), the real disposable income. The other available series are current \((AC_t)\) and past advertisement \((AP_t)\), averaged over the last ten years). We test the hypothesis of a unit demand price elasticity \( H_0: \gamma = -1 \) against the alternative hypothesis \( H_1: \gamma \neq -1 \).

The trinity of tests

Most tests result from one of the three main principles for constructing a test statistic – Wald, likelihood ratio (LR) and Lagrange multiplier (LM) or score – which are often referred to as the trinity of tests (for example, Engle, 1984). When \( p(y; \theta) \) is the joint density of the \( T \times 1 \) data vector \( y \) and we want to test the hypothesis \( H_0: \theta = \theta_0 \) on the \( m \times 1 \) vector of parameters \( \theta \) against the alternative hypothesis \( H_1: \theta \neq \theta_0 \), these three statistics read:

\[
\text{Wald}(\theta_0) = T \left( \frac{\hat{\theta} - \theta_0}{V(\theta)} \right) \quad \text{LR}(\theta_0) = 2 \left[ L(y, \hat{\theta}) - L(y, \theta_0) \right] \quad \text{LM}(\theta_0) = \frac{1}{T} s(y, \theta_0)^T \left( I(\theta_0) \right)^{-1} s(y, \theta_0),
\]

with \( L(y; \theta) \) the logarithm of the likelihood or joint density \( p(y; \theta) \), \( L(y; \theta) = \log(p(y; \theta)) \); \( s(y; \theta) \) is the score, \( s(y, \theta_0) = \frac{\partial}{\partial \theta} L(y, \theta_0) ; \hat{\theta} \) is the maximum likelihood estimator under \( H_1 \) so \( s(y, \hat{\theta}) = 0 \), \( V(\theta) \) is the covariance matrix of \( \hat{\theta} \) and \( I(\theta) \) is the information matrix \( \left( V(\theta) = I(\theta)^{-1} \right) \).

\[
I(\theta) = -E \left[ \frac{1}{T} \frac{\partial^2}{\partial \theta \partial \theta^T} L(y, \theta) \right].
\]

The three statistics provide different measures of the relative distance between \( H_0 \) and \( H_1 \). Under sufficient regularity conditions which ensure the consistency and asymptotic normality of \( \hat{\theta} \), all three statistics converge under \( H_0 \) to the same \( \chi^2(m) \) distributed random variable when the sample size becomes large (for example, Newey and MacFadden, 1994, Th. 9.2). When these regularity conditions hold, usage of a specific statistic is typically a matter of computational ease. The Wald and LM statistics analyse the model only under \( H_1 \) or \( H_0 \) resp. so one could have a preference for either, given the computational effort to analyse the model under \( H_0 \) or \( H_1 \). The LR statistic involves the analysis of the model under \( H_0 \) and \( H_1 \) and is therefore more demanding to compute than the Wald and LM statistics. When one is conducting tests on only one element of \( \theta \), the so-called \( t \)-statistic is often used which equals the square root of the Wald statistic and has a large sample normal distribution under \( H_0 \).

Significance, size and power
When we test $H_0$, we specify a significance level of $100 \times (1 - \alpha)\%$ which sets the probability that we reject $H_0$ while it is true equal to $\alpha$. The critical value associated with this significance level is then such that the probability mass of the large sample distribution of the statistic under $H_0$ above the critical value equals $\alpha$. We then reject $H_0$ with $(1 - \alpha) \times 100\%$ significance when the realized value of the statistic exceeds the $(1 - \alpha) \times 100\%$ critical value.

Another manner to test $H_0$ with $100 \times (1 - \alpha)\%$ significance is by using the $p$-value associated with the realized value of the statistic. The $p$-value equals the probability mass of the large sample distribution of the statistic under $H_0$ that lies above the realized value of the statistic. Hence, we reject $H_0$ with $100 \times (1 - \alpha)\%$ significance when the $p$-value is less than $\alpha$.

Tests of $H_0$: with $\alpha$-significance for a range of values of $\theta_0$ can be used to obtain the $100 \times (1 - \alpha)\%$ confidence set of $\theta$. The $100 \times (1 - \alpha)\%$ confidence set of $\theta$ contains all values of $\theta_0$ for which $H_0: \theta = \theta_0$ is not rejected with $100 \times (1 - \alpha)\%$ significance and therefore contains the true value of $\theta$ with probability $1 - \alpha$.

Besides computational issues there are several other reasons to prefer a specific statistic, especially when it is unclear whether the regularity conditions, which imply the large sample distribution of the statistic under $H_0$, hold. Examples of such other reasons are invariance to transformations of the parameters, observed size of the statistics and discriminatory power.

Especially in models that are nonlinear in the parameters, it is appealing to use a statistic whose specification is invariant to nonlinear transformations of the parameters so it does not depend on the specification of the model. This property is violated by the Wald statistic but satisfied by the LR and LM statistics (for example, Dagenais and Dufour, 1991; Dufour, 1997). Hence it is better to use either the LR or LM statistic in such models.

The specification of the significance level of the test intends to control the Type I error or probability that we reject $H_0$ while it holds. The rejection frequency under $H_0$, to which we refer as the size of the test, should therefore coincide with $\alpha$. Because we use the large sample distribution of the statistic under $H_0$ instead of the unknown finite sample distribution to obtain the critical value of the test, this is, however, not the case. The statistic whose size properties dominate those of the others is then typically preferred. The size properties of the different statistics can often be improved by computing the critical values using the bootstrap instead of the large sample distribution (for example, Horowitz, 2001).

The Type II error of the statistic is the probability of not rejecting $H_0$ while it is false. We thus prefer statistics that minimize the Type II error, or, put differently, maximize the discriminatory power while preserving an adequate size. When the likelihood function is known, the Neymann–Pearson Lemma implies that the LR statistic is the most powerful statistic for testing a point null hypothesis, like $H_0: \theta = \theta_0$, against a point alternative, like $H_1: \theta = \theta_2$. For composite alternatives, like $H_1: \theta \neq \theta_0$, there is typically no statistic that is the most powerful one in all cases.

**Tests in the linear regression model**

To construct test statistics for the linear demand eq. (1), we assume that the disturbances are independently and identically distributed so we can estimate the parameters using least squares:

\[
\log(P_t) = -6.19 - 0.79 \log(Q_t) + 0.92 \log(R|t) + \hat{\varepsilon}_t.
\]

(4)
Testing: The New Palgrave Dictionary of Economics

(The standard errors are reported below the parameter estimates.) To compute the Wald, LR and LM statistics that test for a unit demand price elasticity, we further assume the disturbances to be independently identically normally distributed with mean zero. The specifications of the three tests then read

\[
\text{Wald}(\theta_0) = \frac{\text{RSSR} - \text{USSR}}{\text{USSR}} / T, \quad \text{LR}(\theta_0) = T \log \left( \frac{\text{RSSR}}{\text{USSR}} \right) \quad \text{and} \quad \text{LM}(\theta_0) = \frac{\text{RSSR} - \text{USSR}}{\text{RSSR}} / T,
\]

which test \( H_0 : \theta = \theta_0 \) and where USSR is the unrestricted sum of squared residuals \( \hat{\epsilon}_t \), that is, the residuals under \( H_1 \), and RSSR is the restricted sum of squared residuals, that is, the residuals under \( H_0 \). Under \( H_0 \) and when the disturbances are independently identically distributed with mean zero and a finite fourth order moment all three statistics converge to the same \( \chi^2(1) \) distributed random variable when the sample size gets large.

The expression of the LM statistic in (5) is such that we can compute it as well using an auxiliary regression of the restricted residuals under \( H_0 \) on all explanatory variables. The expression of \( \text{LM}(\theta_0) \) is then such that it equals \( T \) times the \( R^2 \) of this regression.

The values of the statistics that test for a unit demand price elasticity that result from (5) read

\[
\text{Wald}( -1 ) = 3.62 > \text{LR}( -1 ) = 3.50 > \text{LM}( -1 ) = 3.38.
\]

(The value of the Wald statistic in (6) is computed using (5) but could alternatively have been computed using the least squares estimator and standard error that are reported in (4) since \( 3.62 \approx \left( \frac{-0.79 + 1}{0.11} \right)^2 \). All three statistics are smaller than the 95 per cent critical value of 3.84 that results from the large sample distribution of the statistics under \( H_0 \), which is the \( \chi^2(1) \) distribution, so we do not reject the unit demand price elasticity with 95 per cent significance.

The Wald statistic that tests for a unit demand price elasticity exceeds the value of the LR statistic which again exceeds the value of the LM statistic. This result always holds for tests on the parameters of the linear regression model and is not a result of the involved data.

Specification tests

Estimation of the demand eq. (1) by least squares as in (4) presumes that the traded quantity is exogenous since least squares leads to an inconsistent estimator when the traded quantity is endogenous. When the traded quantity is endogenous, we need to use an estimator that remains consistent in that case, like, for example, the two-stage least squares (2SLS) estimator or the limited information maximum likelihood (LIML) estimator (see, for example, Theil, 1953; Hood and Koopmans, 1953).

Exogeneity or endogeneity of the traded quantity lead to different specifications of the statistical model for the demand for oranges. A test for the appropriate specification of the model is the Durbin–Wu–Hausman (DWH) statistic, which tests the difference between two estimators, \( \hat{\theta} \) and \( \tilde{\theta} \), one of which, \( \hat{\theta} \), is efficient and consistent in the model under the null hypothesis but not in the model under the alternative hypothesis, while the other estimator, \( \tilde{\theta} \), is consistent in both
testing: The New Palgrave Dictionary of Economics

models (see Durbin, 1954; Wu, 1973; Hausman, 1978):

\[
DWH(\theta) = T (\bar{\theta} - \hat{\theta})' \left[ V(\bar{\theta}) - V(\hat{\theta}) \right]^{-1} (\bar{\theta} - \hat{\theta}),
\]

with \(V(\bar{\theta})\) and \(V(\hat{\theta})\) the covariance matrices of \(\bar{\theta}\) and \(\hat{\theta}\) and \([…]\)\(^{-}\) the generalized inverse operator. Under sufficient regularity conditions, the DWH statistic converges under \(H_0\) to a \(\chi^2(m)\) distributed random variable with \(m\) the minimum of the number of elements of \(\theta\) and the rank of the matrix \(V(\bar{\theta}) - V(\hat{\theta})\).

Using the current and past advertisement variables as instruments, we computed the DWH statistic to test the null hypothesis of exogeneity of the traded quantity against the alternative hypothesis of endogeneity using both the 2SLS and LIML estimators:

\[
\begin{align*}
DWH_{2SLS}(\theta) &= T (\bar{\theta}_{2SLS} - \hat{\theta}_{LS})' \left[ V(\bar{\theta}_{2SLS}) - V(\hat{\theta}_{LS}) \right]^{-1} (\bar{\theta}_{2SLS} - \hat{\theta}_{LS}) = 4.99, \\
DWH_{LIML}(\theta) &= T (\bar{\theta}_{LIML} - \hat{\theta}_{LS})' \left[ V(\bar{\theta}_{LIML}) - V(\hat{\theta}_{LS}) \right]^{-1} (\bar{\theta}_{LIML} - \hat{\theta}_{LS}) = 4.96.
\end{align*}
\]

Both statistics exceed the 95 per cent critical value of 3.84 of the large sample distribution of the DWH statistic under \(H_0\), which is a \(\chi^2(1)\) distribution. Hence, we reject with 95 per cent significance that the traded quantity is exogenous. This implies that we have to account for the endogeneity of the traded quantity when we test the unit demand price elasticity hypothesis.

Tests in the linear instrumental variables regression model

To accommodate the endogeneity of the traded quantity, we test the demand price elasticity in a linear instrumental variables regression model

\[
y_t = x_t'\beta + w_t'\nu + \epsilon_t x_t = z_t'\pi + w_t'\delta + \nu_t,
\]

where \(y_t\) and \(x_t\) are the endogenous variables, \(w_t\) is a \(k_x \times 1\) vector that contains the included exogenous variables, \(z_t\) is a \(k_y \times 1\) vector that contains the instruments and \(\epsilon_t\) and \(\nu_t\) are the disturbances. The instruments \(z_t\) are uncorrelated
with the structural disturbances $\varepsilon_t$. We assume that the vectors of disturbances $(\varepsilon_t, \nu_t)$ are independently identically distributed. The variables for the demand for oranges are such that

$$\nu_t = \log(P_t), \quad x_t = \log(Q_t), \quad w_t = \begin{pmatrix} 1 \\ \log(R_t) \end{pmatrix} \quad \text{and} \quad z_t = \begin{pmatrix} \log(A_t) \\ \log(AP_t) \end{pmatrix}.$$ 

The structural parameter $\beta$ is typically our parameter of interest and we therefore partial out $w_t$ from the model by replacing all remaining variables with the residuals that result from regressing them on $w_t$:

$$\tilde{\nu}_t = \tilde{x}_t\beta + \varepsilon_t\tilde{x}_t = \tilde{z}_t^\prime\pi + \nu_t, \quad (10)$$

with $\tilde{\nu}_t$, $\tilde{x}_t$ and $\tilde{z}_t$ the residuals that result from regressing $\nu_t$, $x_t$ and $z_t$ resp. on $w_t$.

We want to test a hypothesis on the structural parameter $\beta$, $H_0$: $\beta = \beta_0$, like, for example, that of a unit demand price elasticity. We discuss some statistics that can be used for this purpose most of which belong to the trinity of tests.

**Wald statistics**

Using either the 2SLS or LIML estimator, we can test $H_0$ using a Wald statistic:

$$\text{Wald}_{2SLS}(\beta_0) = T(\hat{\beta}_{2SLS} - \beta_0)^\prime V(\hat{\beta}_{2SLS} - \beta_0)^{-1}(\hat{\beta}_{2SLS} - \beta_0), \quad \text{Wald}_{LIML}(\beta_0) = T(\hat{\beta}_{LIML} - \beta_0)^\prime V(\hat{\beta}_{LIML})^{-1}(\hat{\beta}_{LIML} - \beta_0), \quad (11)$$

with $\hat{\beta}_{2SLS}$ the 2SLS estimator: $\hat{\beta}_{2SLS} = (\hat{n}' \Sigma_{t=1}^T \tilde{z}_t\tilde{x}_t)^{-1}\hat{n}' \Sigma_{t=1}^T \tilde{z}_t\tilde{\nu}_t$ and $\hat{\beta}_{LIML}$ the LIML estimator:

$$\hat{\beta}_{LIML} = \arg\min_{\beta} \frac{\left[ \Sigma_{t=1}^T \tilde{z}_t(\tilde{\nu}_t - \tilde{x}_t\beta) \right]' \left[ \Sigma_{t=1}^T \tilde{z}_t\tilde{z}_t' \right]^{-1} \left[ \Sigma_{t=1}^T \tilde{z}_t(\tilde{\nu}_t - \tilde{x}_t\beta) \right]}{\Sigma_{t=1}^T (\tilde{\nu}_t - \tilde{x}_t\beta)^2 - \left[ \Sigma_{t=1}^T \tilde{z}_t(\tilde{\nu}_t - \tilde{x}_t\beta) \right]' \left[ \Sigma_{t=1}^T \tilde{z}_t\tilde{z}_t' \right]^{-1} \left[ \Sigma_{t=1}^T \tilde{z}_t(\tilde{\nu}_t - \tilde{x}_t\beta) \right]. \quad (12)$$

Both Wald statistics converge under $H_0$ and a number of regularity conditions which rule out zero values of $\pi$ to a $\chi^2(1)$ distributed random variable when the sample size gets large (for example, Newey and MacFadden, 1994). The assumption of a non-zero value of $\pi$ for the large sample distribution implies that finite sample distributions of both Wald statistics depend on the value of $\pi$. The actual size of the Wald statistics can therefore deviate considerably from the assumed Type 1 error which makes these statistics unreliable for usage in practice (for example, Nelson and Startz,
The New Palgrave Dictionary of Economics (1990; Bound, Jaeger and Baker, 1995; Dufour, 1997; Staiger and Stock, 1997). The bootstrap cannot be used to overcome these size distortions (for example, Horowitz, 2001).

Anderson–Rubin statistic

Anderson and Rubin (1949) construct a test for $H_0$ by substituting the equation of $\tilde{x}_t$ into the equation of $\tilde{y}_t$:

$$\tilde{y}_t - \tilde{x}_t \beta_0 = \tilde{z}_t' \phi + u_t,$$

(13)

with $\phi = \pi (\beta - \beta_0)$ and $u_t = \varepsilon_t + \nu_t (\beta - \beta_0)$. Under $H_0$, $\phi$ equals zero and a test for $H_0$ can therefore be conducted using a test for a zero value of $\phi$. Anderson and Rubin (1949) proposed to use the $F$-statistic that tests for a zero value of $\phi$ in (13) for this purpose. This $F$-statistic is commonly referred to as the Anderson–Rubin (AR) statistic.

When the disturbances are independently and identically distributed with finite fourth-order moments, the AR statistic converges under $H_0$ to a $\chi^2(k_2) / k_2$ distributed random variable when the sample size gets large. This large sample distribution of the AR statistic does not depend on the value of $\pi$, which makes the AR statistic a more reliable statistic for practical purposes than the Wald statistics in (11). A disadvantage of the AR statistic is that its large sample distribution is proportional to a $\chi^2$ distribution with a degrees of freedom parameter that equals the number of instruments while we conduct a test on only one parameter. This reduces the discriminatory power of the AR statistic when the number of instruments is large, which is often the case.

LM statistic

When we assume the vector of disturbances $\left( \varepsilon_t, \nu_t \right)$ to be independently identically normally distributed with mean zero, we can construct the likelihood function and therefore also the LM statistic for testing $H_0$ (see Kleibergen, 2002):

$$\text{LM}(\beta_0) = \frac{1}{\sigma_{ee}} \left( \sum_{t=1}^{T} \tilde{z}_t \hat{\varepsilon}_t \right)' \tilde{\pi}(\hat{\beta}_0) \left[ \tilde{\pi}(\hat{\beta}_0)' \left( \sum_{t=1}^{T} \tilde{z}_t \tilde{z}_t' \right) \tilde{\pi}(\hat{\beta}_0) \right]^{-1} \left( \sum_{t=1}^{T} \tilde{z}_t \hat{\varepsilon}_t \right).$$

(14)

with $\hat{\varepsilon}_t = \hat{y}_t - \hat{x}_t \beta_0$,

$$\tilde{\pi}(\hat{\beta}_0) = \left( \sum_{t=1}^{T} \tilde{z}_t \tilde{z}_t' \right)^{-1} \sum_{t=1}^{T} \tilde{z}_t \left[ \hat{\varepsilon}_t - \tilde{\sigma}_{ee} \frac{\tilde{\varepsilon}_t}{\tilde{\sigma}_{ee}} \right], \tilde{\sigma}_{ee} = \frac{1}{T - k_z} \sum_{t=1}^{T} (\hat{y}_t - \hat{x}_t \beta_0)^2, \tilde{\sigma}_{ve} = \frac{1}{T - k_z} \sum_{t=1}^{T} \hat{\varepsilon}_t (\hat{y}_t - \hat{x}_t \beta_0)$

(15)
and where $\tilde{x}_t$ and $\tilde{y}_t$ are the residuals that result from regressing $x_t$ and $y_t$ on $w_t$ and $z_t$. When the disturbances $\{\varepsilon_t\}$ are independently identically distributed and have finite fourth order moments, the LM statistic converges to a $\chi^2(1)$ distributed random variable when the sample size increases. The convergence of the LM statistic does not depend on the value of $\pi$. The large sample distribution of the LM statistic under $H_0$ is therefore typically a rather accurate approximation of the finite sample distribution, and this approximation can even be further improved by using the bootstrap (see Kleibergen, 2004).

**LR statistic**

Under identically independently normal distributed disturbances, Moreira (2003) constructs the likelihood ratio statistic to test $H_0$:

$$LR(\beta_0) = \frac{1}{2} \left[ AR(\beta_0) - r(\beta_0) + \sqrt{(AR(\beta_0) + r(\beta_0))^2 - 4r(\beta_0)(AR(\beta_0) - LM(\beta_0))} \right].$$

(16)

with $AR(\beta_0)k_w$ times the AR statistic that tests $H_0$:

$$AR(\beta_0) = \frac{1}{\sigma_{\varepsilon\varepsilon}} \left( \sum_{t=1}^{T} \tilde{x}_t \tilde{x}_t' \right)^{-1} \left( \sum_{t=1}^{T} \tilde{x}_t \tilde{\varepsilon}_t' \right),$$

(17)

and $r(\beta_0)$ a statistic that tests for a zero value of $\pi$ under $H_0$, so by using $\hat{\pi}(\beta_0)$,

$$r(\beta_0) = \frac{1}{\hat{\sigma}_{\varepsilon\varepsilon}} \hat{\pi}(\beta_0) \left( \sum_{t=1}^{T} \tilde{x}_t \tilde{\varepsilon}_t' \right) \hat{\pi}(\beta_0),$$

(18)

where $\hat{\sigma}_{\varepsilon\varepsilon} = \tilde{\sigma}_{\varepsilon\varepsilon} - \frac{\tilde{\sigma}_{\varepsilon\varepsilon}^2}{\sigma_{\varepsilon\varepsilon}}$ and $\hat{\sigma}_{\varepsilon\varepsilon} = \frac{1}{T-k_w} \sum_{t=1}^{T} \tilde{\varepsilon}_t^2$. Moreira (2003) shows that, when the disturbances are independently identically distributed with finite fourth-order moments, the large sample distribution of $LR(\beta_0)$ under $H_0$ is conditional on the value of $r(\beta_0)$. We thus need to use a different critical value to determine the significance of a realized value of the LR statistic for every value of $r(\beta_0)$. When $r(\beta_0)$ is zero, the large sample distribution of $LR(\beta_0)$ is identical to a $\chi^2(k_w)$ distribution while it equals the $\chi^2(1)$ distribution for large values of $r(\beta_0)$. Besides the
dependence on \( r(\beta_0) \), the large sample distribution of \( LR(\beta_0) \) does not depend on \( \pi \), which makes \( LR(\beta_0) \) a trustworthy statistic for practical purposes. Andrews, Moreira and Stock (2006) show that the LR statistic is the most powerful of those statistics whose large sample distributions do not depend on \( \pi \) and are invariant under transformations of the model.

The unit demand price elasticity

We test for a unit demand price elasticity using each of the above statistics.

\[
\begin{align*}
\text{Wald}_{2SLS}(-1) &= 191 \\
\text{Wald}_{LM}(-1) &= 178 \\
\text{AR}(-1) &= 73.7 \\
\text{LM}(-1) &= 67.3 \\
\text{LR}(-1) &= 69.1.
\end{align*}
\]

The value of \( r(\beta_0) \) is 174, which makes the large sample distribution of \( LR(-1) \) given \( r(\beta_0) \) identical to the large sample distribution of \( LM(-1) \), which is a \( \chi^2(1) \). The large sample distribution of \( AR(-1) \) is a \( \chi^2(2) \) distribution, and the large sample distributions of the Wald statistics are \( \chi^2(1) \) distributions while a non-zero value of \( \pi \) is assumed.

All statistics reject the hypothesis of a unit demand price elasticity with 95 per cent significance. This shows the importance of accounting for the endogeneity of the traded quantity since this hypothesis was not rejected in the linear regression model that assumes the traded quantity to be exogenous. The values of the statistics whose large sample distributions are not influenced by the value of \( \pi \), that is, \( AR(-1), LM(-1) \) and \( LR(-1) \), are all of the same order of magnitude, while the Wald statistics are much larger. This indicates the different behaviour of these statistics and we recommend that these Wald statistics not be used.

More general specifications

We discussed the trinity of tests in a linear model estimated using either least squares or instrumental variables. The Wald, LM and LR statistics extend to a large variety of models which are possibly nonlinear in the parameters and have unknown likelihood functions. The expression of the Wald statistic is such that it can be applied to any estimator which has a normal large sample distribution and for which a consistent estimator of the asymptotic variance exists. The LM test is applicable in any model where the estimators solve a first-order condition. The LR test is based on the difference of an objective function under \( H_0 \) and \( H_1 \), a specification that allows it to accommodate more general statistical models (for example, Engle, 1984; Newey and MacFadden, 1994). In these general settings, such as, for example, the generalized method of moments, the large sample distribution of the Wald statistic is often affected by nuisance parameters while the large sample distributions of the LM and LR statistics remain robust to the value of these nuisance parameters (for example, Kleibergen, 2005). Hence, the LM and LR statistics often provide more reliable tests.

Abstract

The Baring crisis of 1890 is one of the world's most famous financial crises over the last 200 years. The crisis is well known because the Bank of England put together a rescue fund to save the House of Baring. The investment banking firm was in financial trouble because it was the primary debt issuer for Argentina which was experiencing an economic and financial downturn. The Baring crisis is regarded as an early example of a central bank playing the role of a lender of last resort.

Keywords

Argentina; banking; Baring; banking crises; Latin America; lender of last resort

Article

The origins of the Baring crisis of 1890, the most famous financial crisis of the 19th century, can be traced to the world debt crisis of 1873 and ensuing recession, which had large economic effects on Argentina and Latin America. The region did not recover from the downturn until the early 1880s following a resurgence of foreign trade and capital flows from Europe. For Argentina, one of the chief obstacles to economic growth and development was the absence of a strong central government. Historically, the national authority shared power with the provincial governments, and it also faced an internal threat from indigenous people who lived on the pampas. The central government consolidated its power and expanded its borders by driving the indigenous people off the pampas in a series of wars during the late 1870s. With the election of Julio Roca as the country's president, the Indian War hero was able to broker an agreement with the ruling elites of the provinces, which centralized the power of the national government.

One of the primary goals of Roca's government was to employ foreign capital to construct railroads, public works, and to modernize Buenos Ayres (Marichal, 1989). The new leader's first major loan was a railway issue which completed two major trunk lines in the South American country. The construction of a transportation network throughout the country helped consolidate Roca's power as well as stimulate
economic activity by opening up the market for commercial agriculture. Roca also transformed Buenos Aires into the ‘Paris of South America’ by constructing broad avenues, spacious parks, a well-functioning water supply and drainage system, and a modern port. The national and local government carried out a series of state-run infrastructure projects in Latin America (Marichal, 1989; Mitchener and Weidenmier, 2008).

Although the economic policies of the Roca administration stimulated short-run economic activity in Argentina, they posed serious dangers in the long run. The country's expanding debt could only be serviced if the country had sufficient tax revenues. Unfortunately, it would take years before the government would realize significant revenues from commercial activity stimulated by the infrastructure investments (Ford, 1956).

Roca finished his term as Argentina's president in 1886. His brother-in-law Miguel Celman became the country's leader following a fraudulent election. Rather than continuing the policies of his predecessor, Celman reduced the government's role in the administration of the railways. The newly elected president sold the Central Norte and Andino railways, two of the country's most important, to British capitalists. The funds from the sale were supposed to be used to reduce the country's rising debt level. Instead of restoring fiscal discipline, the country began issuing additional debt through state banks even though it stopped borrowing funds to finance railway projects.

From 1886 to 1890, Argentina passed a series of ‘banking reforms’ that fuelled the expansion of credit and paper money issues (Williams, 1920). National and provincial banking authorities ratified a Free Banking Law in 1887 which authorized any banking association to issue notes provided it purchased gold bonds to the full amount of the notes issued. There were several problems with the law. It permitted banks meeting minimum capital requirements to issue paper notes backed by government gold bonds. The bank notes, however, were not redeemable in gold, and since the bonds were new issues, they constituted a new liability on the government's balance sheet. The banks that participated in the note issuance scheme floated loans in Europe to finance the purchase of the domestic gold bonds. This scheme worked as long as foreign investors agreed to purchase the Argentine bonds and as long as additional note issuances were backed 100 per cent by specie. By 1890, Argentine provincial banks had issued more than 30 million pounds of external debt.

Argentina's loose monetary and fiscal policies led to a decline in the country's financial and macroeconomic conditions from the mid-1880s until the outbreak of the Baring crisis in 1890. High-powered money grew at an annual average rate of 18 per cent, inflation averaged 17 per cent, and the paper peso depreciated at an average rate of 19 per cent between 1884 and 1890 (della Paolera and Taylor, 2001). By 1890, nearly 40 per cent of the foreign borrowing was going towards debt service, and 60 per cent of imports were going toward consumption goods.

Weakening economic conditions in Argentina reduced the demand for Argentine securities on the London market. Domestic investors began to dump the country's paper peso. Although the government used specie to defend the exchange rate, the stock of gold at the Banco Nacional had declined to such an extent by December 1889 that the financial institution could no longer carry out this currency operation. Strikes, demonstrations and a failed coup by military leaders ensued in 1889 and 1890. Inflation reduced the real wages of Argentine workers. The country's lax monetary and fiscal policies drained the banking system of specie, provoked a series of banking crises, and ultimately the Baring crisis in 1890. Argentine real GDP declined by more than ten per cent between 1890- and 1891. Last-minute attempts to reform
the country’s poor economic policies failed, and the country entered into a decade long recession. The Argentine crisis potentially had serious implications for global financial markets, especially London. Baring Brothers was the primary investment bank for the South American country. The firm purchased and issued debt for Argentina. The investment bank was heavily involved with the Buenos Aires Water Supply and Drainage Loan, a new debt issue the underwriter failed to sell on the London market (Eichengreen, 1999. The House of Baring secretly notified the Bank of England that it could not service its debt obligations in November 1890. The central bank then pooled financial resources to prevent the beleaguered investment banking firm from causing a larger meltdown on the London market. The Bank of England secured loans from the Bank of France, Russia's central bank, and British financial institutions to help Baring Brothers service its debt obligations and prevent a larger meltdown on the British market. The rescue operation succeeded and prevented a general financial collapse on European markets. Some scholars have argued that the Baring crisis provides one of the earliest examples of a central bank playing the role of a lender-of-last resort in financial markets (Mitchener and Weidenmier, 2008).

Although the Bank of England prevented a financial collapse in Europe, the central bank did little to assist Argentina and Latin America. Argentina experienced a deep recession for several years and did not fully recover from the crisis until the turn of the century. In the absence of macroeconomic data such as GDP, Mitchener and Weidenmier (2008) use interest rates to examine the effects of the Baring crisis on emerging markets. They find that interest rates increased more than 1600 basis points in Latin America while interest rates in other emerging markets were flat. This suggests that the crisis had severe negative macroeconomic effects in Latin America. The evidence suggests that the Baring crisis was largely a regional financial crisis which had few economic effects outside Latin America.

the economy of ancient Greece

Paul Cartledge
From The New Palgrave Dictionary of Economics Online, 2008,
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

There were many ‘economies’ rather than a single ‘economy’ in ancient Greece (a culturally interlinked world, c. 800–300 BCE, stretching across the Mediterranean basin and around the Black Sea). Except in Athens, agriculture (cereals, olives, grapevines, and the raising of small-stock animals – sheep, goats, pigs) predominated over trade and industry as an economic driver. The Greeks did not invent coinage but spread it and embedded it, and although they were thoroughly familiar with the idea of markets and market prices, they did not develop a market economy.

Definitions

‘Ancient Greece’ for the purposes of this entry will be taken to refer to the period from roughly the eighth century BCE to the end of the fourth century BCE: that is, from the rediscovery of literacy by means of the invention of the Greek alphabet, the renewal of intensive trade contacts with the near East, and the beginnings of large-scale permanent overseas emigration and establishment of Mediterranean-wide trade networks, down to the start of the new post-Alexander the Great (d. 323 BCE) ‘Hellenistic’ (mixed Greek-oriental) world.

‘Economy’ is more difficult to specify, or pin down. The word is of Greek derivation but in ancient Greek it meant primarily and literally the management of an individual household (oikos) not the management of a ‘city’ or ‘national’ economy. This led one school of modern interpreters (late 19th-
century German), the so-called ‘primitivists’, to speak of the entire period under consideration here as one of ‘household’ not ‘national’ economy. That is a considerable and highly misleading exaggeration, but it does draw attention to the fact that an ancient Greek city did not have an economy, or practise economics, in anything like a post-Adam Smith, let alone post-Alfred Marshall, sense. Their opponents, the ‘modernists’ or ‘modernizers’, claimed no less excessively that ancient Greece was, economically speaking, pretty much similar to the modern ‘developed’ world (and similar too in its stages of development), except that it operated on an infinitely smaller scale and without the benefits – such as economies of scale – made possible only by the scientific and technological revolutions of early modernity. A sensible compromise was firmly advocated by Moses Finley (1973), who rightly drew attention especially to Greek ideology and terminology; but because he sometimes underestimated the quantity and sophistication of ancient Greek economic activity, he too was (mis)labelled a ‘primitivist’. (The debate is usefully summarized in Scheidel and von Reden, 2002; see esp. Andreau 2002, Cartledge, 2002, Meikle, 2002; also Manning and Morris, 2005.)

A second reason for being chary of the term ‘economy’ is that, after the wave of emigration noted above, there were at any one time between 600 and 300 BCE some 1,000 separate Greek political entities, radically self-differentiated politically but also often very different indeed economically speaking. This is why I have in the past written of ‘the economy (economies) of ancient Greece’ (Cartledge, 2002; cf. Davies, 1998). At one extreme, classical fifth- and fourth-century Athens was as ‘developed’ as any Greek city before Hellenistic Alexandria (founded 332). In the international port of Peiraeus it even had a ‘commercial centre’ separated physically as well as spiritually from the political centre (Garland, 2001), and its total population (civic centre plus surrounding territory) was far larger (c. 250–300,000) and far more diverse ethnically and occupationally than any other Greek city’s. (In size of home territory, however, its c. 2,500 sq km were exceeded by Sparta, c. 8,400, Syracuse, c. 4,000, and Panticapaeum in the Crimea, c. 3,000: Hansen and Nielsen, 2004, pp. 70–3). At the opposite extreme were fundamentally rural settlements, in Arcadia for example, cut off from the sea and long-distance trade, surviving, modestly, on ‘natural’, pastoral as well as agricultural, economy. In between, the modal Greek city had a population of some 2,000–8,000, occupied some 100 sq km, and practised versions of ‘mixed economy’, in which agriculture and stock-raising always predominated over trade and manufacturing industry.

A third problem with doing ancient Greek economic history is that the contemporary ancient data accessible today are resolutely unstatistical. This is partly because the ancient Greeks did not think and so did not audit themselves statistically but also because the nature of their politically overdetermined economies did not generally encourage or lend itself to statistical computation. The figures we get in our sources – for instance, for the impossibly inflated aggregate numbers of slaves in a particular city at any one time – tend therefore to be at best extreme outliers, at worst rhetorical inventions, rarely something reliably identifiable and usable in-between. Hence the regular resort of scholars to ‘proxy data’ – modern data of climate, crop-yields, etc. – making assumptions of continuity and stability as between ancient and modern conditions that are often untestable, but still useful as models or thought-experiments and for setting workable parameters (Manning and Morris, 2005; on this and on all other matters discussed in this entry, see now Scheidel, Morris and Saller, 2007).

The Mediterranean triad: agriculture and trade
The Mediterranean triad of dietary staples – grain, olive oil and wine – was established as such in the Greek sphere during the third millennium BCE (Renfrew, 1972). Not much in the way of improvements in seed-selection, or efficiency in growing or harvesting techniques, is detectable during our period, owing to the likely constraints of Greek soils and microclimates, and the certain constraints of technological backwardness (not even the wheelbarrow was known, apparently).

One huge exception was the massively profitable exploitation after 600 BCE of the black-earth soils of the Ukraine and Crimea (see Panticapaeum, above) for the achieving of – by old Greek standards – huge yields of bread wheat, more nutritious as well as more easily processed than the default Greek grain-crop, barley (up to five times more drought-resistant than wheat on average) (Sallares, 1991). Since the northern shore of the Black Sea cannot grow olives (because of winter frost), there was a considerable uplift in the production of olive oil further south (especially around Athens) for export to these deprived colonial Greeks, in exchange for which came, besides the bread wheat (especially again to Athens: Moreno, 2007), dried fish and slaves.

Olives and their by-products were culturally as well as economically vital, and universally employed – even if not universally manufactured – as unguent, medicament, lubricant, and source of energy as well as food (Foxhall, 2007). This was a standing incentive to extensification. In one small area near Athens, for example, terracing of marginal land is estimated to have extended the cultivated area by some 40 per cent. Regions and cities that experienced sharp population growth, such as Athens in the fifth century, also resorted to intensification, either by reducing the regularity or duration of fallowing, or by intercultivation of grain with olives, or by a combination of the two.

The grapevine flourishes in some soils and aspects more than others. The wine produced around Athens, for example, in sharp contrast to its local olive oil, was thought far less desirable than that produced on the northern Aegean island of Thasos, where legislation was introduced in the fifth century to control the highly lucrative export trade. Other islands that specialized in wine-production for export were Lesbos, Chios and Samos, and each production region generated its own distinctive shape of two-handled, pointed-base, pottery transport vessels (known as amphorae), further distinguished by the liberal application of amphora-stamps – a sort of ancient Greek equivalent of appellation contrôlée. Long-distance, interregional trade in wine, grain and other commodities (especially metals, such as copper from Cyprus or iron from Elba) was sharply marked off institutionally and terminologically from smaller-scale, local wholesale and retail trading (Garnsey, Hopkins and Whittaker, 1983). Long-distance traders were emporoi, literally ‘passengers’ (on ships), and they traded typically in purpose-built, ‘round’, sail-driven merchant vessels to economize on crew and time. But such trade was in Mediterranean weather conditions always risky, not to mention the threat from oar-driven pirate pinnaces and galleys; and from the later fifth century the larger operators were encouraged to take out bottomry or maritime loans – high-risk, high-interest – as a form of insurance, in deals struck with a new breed of commercially minded bankers (Cohen, 1994). The owners of the banks as of the ships would be free, but the bankers and traders might just as likely be slaves as free citizens, and not rarely of non-Greek origin (Reed, 2003).

Labour and manufacture
The ancient Greek world was almost entirely one of human labour, not labour-saving technological devices, and, insofar as production was undertaken beyond the scale of household subsistence (Mattingly and Salmon, 2001), it was a world of manufactories rather than factories. Wind power was of course exploited in navigation, but watermills were a thing of the pretty distant future so far as ancient Greece was concerned. Lifting devices and other forms of ‘engineering’ were most assiduously developed for religious not secular purposes, such as the construction of a temple (Landels, 1978). On the other hand, traditional craft skills in carpentry, metallurgy, ceramics and the weaving of cloth had operated at a high level since the eighth century, even though typically on an individual household or small workshop basis (Burford, 1972). One large exception were the gangs of workers employed in the silver-bearing lead mines belonging to the city of Athens, where possibly as many as 20,000 or even 30,000 may have been employed at any one time in digging, extracting and washing the ore (Lauffer, 1979). But these were not free citizens: they were slaves, performing a task classified as servile, fit only for less-than-human beings.

**Slavery**

Unfreedom is of hoary antiquity, cross-culturally, but it took the ingenuity of the Greeks of the sixth century BCE to transform various kinds of personal dependency into full-blown ownership of the ‘chattel’ slave variety (the kind practised in the American Old South, the Caribbean and Brazil from the 17th to 19th centuries) (Dal Largo and Katsari, 2007). At Athens, for example, all slaves were of the chattel variety, bought on the markets to which they had been brought by traders dealing with the countries of the Black Sea and western Anatolian regions (Scythians and Paphlagonians, for example). But in Sparta, although the same word (*douloi*) was used to describe them, the servile workforce of Helots (‘captives’) was created by enslaving local Greeks and by fair means or foul keeping them locked within a system of hereditary bondage for some four centuries or more (Luraghi and Alcock, 2003). Almost all the 50–100,000 Helots, like the majority of the 100,000 or so slaves at Athens, were somehow engaged in agriculture. Just how economically efficient that system of helotage was cannot be easily determined, but it delivered the goods in the sense that it was the basis of Sparta’s status as a great Greek power for most of those 400 years, and the basis too of Sparta’s extraordinary warrior-communalist lifestyle.

**Money and coinage**

Money has a number of functions and uses, some of which, but not all, can be handily fulfilled by coins (Howgego, 1995). Greeks did not invent the idea of stamping a fixed weight of precious metal (gold, silver, electrum) with a badge and slogan or some other authenticating device, but they did develop this Lydian invention phenomenally, for political as well as economic reasons, and did transmit it to otherwise alien neighbouring cultures such as that of the Persians. The first coins struck, in the first quarter of the sixth century, were of electrum (a gold-silver mix) or silver, and of relatively large denominations, not usable therefore as small change. But by the end of that century sometimes really small fractions were in quite general use, at least in the Aegean, and by the end of the fifth century a move had been made towards a fiduciary coinage of bronze. The Spartans, idiosyncratic as ever, refused
to strike silver coins (until their third-century BCE ‘normalization’), but did operate some sort of ‘currency’ of iron (in the form perhaps of cooking spits). Such monetized spits were used elsewhere than in Sparta too, and offered as dedications to the gods and goddesses in sanctuaries, a nice reminder that the sacred and the profane were close partners in ancient Greece.

Markets

Finally, markets – and the issue of whether, and if so how far, any Greek city developed anything like a market economy: that is, not an economy with markets but an economy centrally defined by price-fixing markets. A famous passage of Aristotle's *Nicomachean Ethics*, written in the 330s, has been read as making the intellectual breakthrough in embryo to a labour theory of value and/or a market theory of price, but it can just as well be read as an exercise in moral philosophy using economic illustrations. Elsewhere, in the *Politics*, Aristotle makes his preference for a ‘free’ Agora unambiguously plain: by ‘free’ he means one where sordid economic transactions were kept to a minimum, or at bay altogether – for example, by barring from the holding of political office any citizen who had traded in a commercial Agora within the past decade, as at Thebes (Austin and Vidal-Naquet, 1977).

There is also objective evidence for a certain conventionality of non-market price-fixing – some commodities turn up in widely different contexts and periods valued at a suspiciously identical exchange price. Likewise, the cost of labour purchased on the market, for instance for large-scale civic construction projects such as temples, seems inelastic to a degree that would be considered irrational in an (economically speaking) free labour-market situation.

Nevertheless there are hints and signs from earlier in the fourth century of an increasing and increasingly generalized marketization of commodity exchange, a process that ‘took off’ exponentially under the conditions of the new world opened up by the middle Eastern conquests of Alexander the Great (334–323). But ‘Hellenistic’ economic globalization (as it were) is another topic, for another essay (see Cartledge, 1997 for an overall outline sketch; in detail, Archibald, Davies and Gabrielsen, 2005; Archibald, Davies, Gabrielsen and Oliver, 2001).

Henri Theil was a highly prolific writer of books and articles in the fields of econometric methods and applied econometrics. His best-known methodological contributions include the method of two-stage least squares, inequality coefficients (for evaluation of forecasting errors), and two measures for income inequality. Most of his other methodological contributions can be found in his Principles of Econometrics (1971). His best-known applied work is on economic forecasting, income inequality, applied demand analysis, and consumption patterns.

Article
Henri Theil was a highly prolific writer of books and articles in the fields of econometrics, statistics and applied economics. The best known of his many contributions are the method of two-stage least squares, two inequality coefficients for the evaluation of forecast errors, and two measures for income inequality based on information theory, along with extensive applied work on stabilization policy, demand systems and consumption patterns.

Theil was born in Amsterdam in 1924. His parents moved first to Gorinchem and later to Utrecht, where he attended the gymnasium and obtained his diploma in 1942. He started as a student of chemistry, physics and mathematics at Utrecht University. There he was exposed to, among other subjects, formal
calculus, which he disliked. In his later life he disdainfully used to call it 'epsilontics'. When he was confronted with the option between a loyalty oath to the German Nazi occupying forces and working in Germany, he decided to go underground, as did the majority of his fellow students. After some time he was caught and sent to a concentration camp, where he was incarcerated for six months. When he became seriously ill with diphtheria, his parents managed to get him out through bribery.

After the war, in 1945 he enrolled as a student at the University of Amsterdam and studied economics. In addition, he attended lectures in mathematical statistics and was a research assistant of Professor Daniel van Dantzig, at that time the most prominent Dutch statistician. As these lectures emphasized foundations rather than applications, Theil taught himself the rest of statistics by studying the two volumes of Kendall (1943; 1946). In 1951 he obtained his Ph.D. and in the same year he married Eleonore Goldschmidt. From 1951 to 1955 he worked at the Central Planning Bureau in The Hague, the main institute of policy analysis in the Netherlands, and one of the important advisers to the Dutch government.

In 1953 Theil was appointed Professor of Econometrics at the Netherlands School of Economics at Rotterdam (now Erasmus University), at first on a part-time basis while he continued his job at the Central Planning Bureau. He spent the academic year 1955–56 as a visitor at the Cowles Commission in Chicago. There he learnt the rule: ‘publish or perish’. In September 1956 he obtained a full-time position in Rotterdam, where he became the first director of the Econometric Institute of the Netherlands School of Economics. This gave him the possibility to appoint research associates and assistant professors to work for him. In the ten years of his period in the Econometric Institute he attracted 27 foreign visitors, most of whom spent a year at the institute, the most prominent ones being A. S. Goldberger, A. Zellner, F. M. Fisher, M. Nerlove and Z. Griliches. In the same year Theil also started a programme in quantitative economics, where matrix algebra and mathematical statistics were prerequisites for his courses in econometric theory.

In 1965 Theil was appointed University Professor at the University of Chicago, one of the ten posts of this type at the university. In 1981 he moved to the University of Florida (at Gainesville), where he accepted the first Eminent Scholar Chair in Florida's State University System (the McKethan–Matherly Chair). He retired in 1994, but thereafter published several articles and in 1996 a book. He died in 2000. During his life he wrote at least 18 books and about 250 published articles. Several books and about half of the articles were co-authored by more than 80 colleagues, most of them his juniors. He also supervised 15 dissertations (for details, see Raj and Koerts, 1992). He could be very generous, but a smooth cooperation with him required either acceptance of his authority or outstanding diplomatic gifts. There were numerous rumours about frictions and conflicts with colleagues and others, but written evidence is usually lacking.

Theil wrote his first well-known paper (1950), a contribution to distribution-free and robust statistics, while he was a research assistant. Consider a set of points \((x_1, y_1), \ldots, (x_n, y_n)\) and consider a pair \((x_i, y_i), (x_j, y_j)\) with \(x_i \neq x_j\). Then the slope of the line through such a pair of points is given by \((y_j - y_i) / (x_j - x_i)\). He proposed the median of all these slopes (for \(x_i < x_j\)) as a distribution-free estimator of the regression line through the \(n\) points. This is an outlier robust estimator in the sense that this median is based on two ‘good’ points (that is, points that are not outliers) provided that the fraction of outliers is less than 0.293. In addition, it is a quite efficient estimator. The method is sometimes called the Kendall–Theil estimator, since Theil's paper made use of a result of M. G. Kendall on rank
correlation. It was extended by Sen (1968) for the case that there are ties among the \( x \) observations. This method is known by the name ‘Theil–Sen estimator’. Finally, Theil's approach was crucially improved by Siegel (1982), who proposed the repeated median estimator. Siegel's first step takes for each \( i \) the median across all \( j \) of the above ratios \((j \neq i)\), and the second step takes the median of all medians obtained in the first step. This estimator does not even break down for a fraction of outliers close to 0.5 (see Rousseeuw and Leroy, 1987, for a more extensive treatment of this subject).

Theil's best known contribution to econometrics, the two-stage least squares (2SLS) method, dates from his period at the Central Planning Bureau. He proposed it in a paper (1953) that was unpublished at the time, but it was soon known at the Cowles Commission at the University of Chicago, in those days the most important centre for econometric theory. In fact, Radner and Bobkowski (1954) of the Cowles Commission wrote a short paper in which they explained 2SLS using Cowles Commission notation. The first published description of 2SLS can be found in Theil's monograph *Economic Forecasts and Policy* (1958), while the original 1953 paper has been reprinted in Raj and Koerts (1992). The problem of systems of simultaneous equations is that most of these equations contain current (that is, non-lagged) endogenous explanatory variables. As a rule, these are not independent of the disturbances of the equation, which leads to inconsistent parameter estimates if (ordinary) least squares is applied. The 2SLS method for estimating such an equation consists of two steps. First, the current endogenous explanatory variables are regressed on the exogenous and lagged endogenous variables of the system. Second, least squares is applied to the original equation where the current explanatory endogenous variables are replaced by the explained parts of the corresponding first stage regressions. The main virtue of the method was that it was a considerable simplification on limited information maximum likelihood, the method proposed four years earlier by Anderson and Rubin (1949). This method requires the computation of eigenvalues of a matrix, a considerable burden at a time when very few universities and other research institutions had computers. (For a more extensive discussion of 2SLS and related methods, see Davidson and MacKinnon, 1993.)

The Dutch Central Planning Bureau published each year a number of forecasts on several important macroeconomic variables. Theil's tasks included the evaluation of these forecasts. One of the criteria he developed for that purpose was the *inequality coefficient*, defined by

\[
U_1 = \frac{\sqrt{\frac{1}{n} \sum (P_t - A_t)^2}}{\sqrt{\frac{1}{n} \sum P_t^2} + \sqrt{\frac{1}{n} \sum A_t^2}},
\]

where \( P_t \) and \( A_t \) denote time series for the predicted and actual changes, respectively, of a certain variable (see Theil, 1958). An attractive property of the formula is that it is positive and does not exceed unity. The zero lower bound corresponds with perfect forecasts, the unit upper bound with the worst possible set of forecasts. Unfortunately this coefficient has a serious drawback. The denominator depends on the chosen forecasting procedure, while when different forecasting procedures are to be compared it is desirable that the denominator is the same. Granger and Newbold (1973) gave a more
formal criticism using a time series model. Several years earlier Theil (1955) had already proposed an alternative formula:

\[
U_2 = \frac{\sqrt{\frac{1}{n} \sum (P_t - A_t)^2}}{\sqrt{\frac{1}{n} \sum A_t^2}},
\]

which is not subject to the above criticisms. It exceptionally takes values greater than unity and it is exactly equal to unity in the case of no change extrapolation \((P_t = 0 \text{ for all } t)\). In (1966) Theil stated why he preferred \(U_2\) to \(U_1\), but he used the same symbol \((U)\) and the same term (inequality coefficient) for both \(U_1\) and \(U_2\) with the unfortunate consequence that if ‘the’ Theil inequality coefficient is cited one does not know whether the author has used \(U_1\) or \(U_2\) unless an explicit definition or reference is given. His criticism on \(U_1\) was not generally noticed, as is demonstrated by the fact that \(U_1\) survives in several places, for instance, in the well-known computer application Eviews.

Theil's most important research projects in his Rotterdam years concerned forecasting, stabilization policy, and information theory. The policy project was quite ambitious. The theory of consumer demand, where a consumer is assumed to maximize his utility function subject to his budget constraint, served as a paradigm. He assumed a government with a quadratic ‘welfare function’ to be maximized subject to the reduced form of a linear (or linearized) macroeconometric model, taking account of the uncertainty caused by the disturbances of the model. This implied linear decision rules for the government. While the theory was already largely developed in his 1958 book, Theil applied the theory in his 1964 book to the US economy in the 1930s and to the Dutch economy in the period 1957–9. After 1964 he left the subject to others.

Theil's book on economics and information theory appeared in 1967 but was entirely written before he left Rotterdam in September 1966. The idea came up in a discussion with Barten and the author in 1962 or 1963 on Barten's first version of the demand system that would later obtain the name ‘Rotterdam model’. Barten (1964) had proposed a system of differenced demand equations. Theil amended this idea, first, by proposing premultiplication by the corresponding current budget shares \(w_i\) (before assuming constant coefficients), and later replaced the current budget shares by the averages of current and lagged budget shares, as was customary in the computation of the Törnqvist approximation to the growth rate of the Divisia quantity index. When commenting on this discussion in Studies in Global Econometrics Theil stated, after having mentioned Barten's research: ‘In 1965 I modified this approach slightly …’ (emphasis added). Not everybody was happy about the Rotterdam model, however. It was criticized at an early stage by McFadden (see Yoshihara, 1969).

When Theil, in exploring the consequences of the assumptions underlying the Rotterdam model, arrived at terms of the type \(\sum w_i \log w_i\), he recognized this as an expression from information theory, and started to study the literature on that subject (see also Raj and Koerts, 1992, Vol. 1, pp. 25–6). Theil proceeded to develop several economic applications of information formulas. The best known is his measure for income inequality.

where \( n \) is the number of subsets in a population, \( x_i \) the population share of subset \( i \) in the total population, and \( y_i \) its income share in total income. The formula has attractive decomposition properties, which explains its popularity among applied researchers. In the same book he also proposed a second measure, which is obtained from the above formula by interchanging the roles of \( y \) and \( x \). In certain situations this is considered to be preferable.

For his lectures in Chicago Theil wrote a new version of his notes on econometric methods, which appeared in 1971 under the title *Principles of Econometrics*. This book was one of the most important reference texts in the field of econometric methods during the 1970s and later. It is also a useful reference to most of his other methodological contributions, such as his work on aggregation, on specification analysis, on the \( k \)-class, on mixed estimation (with A. S. Goldberger), on three-stage least squares (with A. Zellner), on the final form of econometric equation systems (with J. C. G. Boot), on efficient estimation of disturbances, and on several other subjects.

In his Chicago period, Theil also extended his work on statistical decomposition analysis (1972) and on consumer demand systems (1975; 1976). In the early 1970s he wrote three papers containing an economic theory of the second moments of disturbances of behavioural equations, also called rational random behaviour (see his 1975 and 1980 books for summaries and references). This was an ambitious project, which, however, met with little response in the profession.

The demand systems were relatively rich in parameters, with the consequence that asymptotic results were unreliable. Theil organized several Monte Carlo studies (as a rule carried out by his students or associates) in order to get more reliable test results. A survey of this work is given in Theil (1986). In 1978 *Economics Letters*, a new journal, was launched. It specialized in short papers, only lightly refereed and published with minimum delay. Theil very much liked this formula and during the following 20 years he published (with several co-authors) a huge number of papers in the journal on a wide variety of subjects. His principal interest was now in world income inequality and international consumption patterns. For the latter purpose he developed a new type of demand system, later called the ‘Florida model’, and a new estimation method based on information theory. Surveys of most of this research can be found in Theil (1987; 1989; 1996).

Given Theil's enormous productivity, the above survey of his work is necessarily very incomplete. The three volumes edited by Raj and Koerts (1992) contain considerably more information about his work up to 1992. Also of interest is a Festschrift edited by Bewley and Tran Van Hoa (1992) that appeared at about the same time. The interview by Bewley (2000) gives a good impression of Theil as a person and

research worker. In all these publications one can also find more about his life (see also Kloek, 2001; 2002). In his final years he developed a taste for autobiographical writing (see Theil, 1996, pp. 1–6; 1997).

Abstract

Economists and other scientists appraise theories in terms of criteria such as evidential support, predictive accuracy, usefulness, and reliability in research and practice. This entry addresses three general problems concerning theory appraisal. 1. What is it for evidence to be confirmationally relevant to a theory? 2. How can evidential support be measured? 3. On what other criteria should theory appraisal in economics depend? The third question raises special problems, since economic models so often incorporate statements that appear to be false. But answers to general questions concerning confirmation matter to the conduct of economics, too.

Article

There are several reasons why economists and others appraise theories and models. They may want to judge whether theories and models are worthy of study, whether one can rely on them in research and practice, or whether one can judge them to be true or false or predictively adequate. Different purposes may call for different appraisals.

All sciences face three general problems of theory appraisal. 1. What is it for evidence $e$ to confirm, disconfirm, or be evidentially irrelevant to an hypothesis $h$, and how is confirmation possible? 2. How should scientists measure the extent to which $e$ confirms $h$ or how well confirmed $h$ is overall? 3. How does the appraisal of a theory depend on the extent to which it is confirmed, and on what else may theory appraisal depend? The third question raises special problems with respect to economics, because
The conclusions of economics are usually hard to test, whether experimentally or against market data. Economic models incorporate many statements that appear to be false, and the basic principles of economics typically contain, at least implicitly, vague and ineliminable *ceteris paribus* qualifications. These peculiarities are not unique to economics, though their combination and the particular form that questions of theory appraisal take in economics are distinctive.

Answers to general questions concerning confirmation and theory appraisal have immediate implications for the conduct of economics. For example, defenders of real business cycle theory have constructed computational ‘experiments’ in which technology shocks in a calibrated computer model of a simplified economy give rise to simulated business cycles. Are these appropriate methods for testing economic theories? Do the results of these ‘experiments’ justify a positive appraisal of real business cycle theory (Kydland and Prescott, 1996)?

The discussion of confirmation and its measurement, which occupies the next two sections, is quite general, while the discussion of theory appraisal in the final section emphasizes distinctive features of economics.

**Confirmation**

Evidence $e$ confirms an hypothesis $h$ when it provides some support for $h$; $e$ disconfirms $h$ when it provides some evidence against $h$. The theory of confirmation is not concerned with the limiting cases of conclusive proof or refutation. Unlike deductive inferences, in which it is impossible for the premises to be true and the conclusion false, confirmation is a matter of inductive inference, which is fallible. From the two premises, ‘All humans are mortal’ and ‘Bill Gates is human’, one can deduce that Bill Gates is mortal. Though infallible, a deductive inference such as this one is also ‘non-ampliative’ – the conclusion is already implicit in the premises, and drawing the conclusion arguably does not advance our knowledge. To infer that Bill Gates will die from the premises that he is human and that all humans born before 1850 have died is, in contrast, to take a risk. The conclusion goes beyond what is asserted in the premises. The conclusion that *all* humans are mortal obviously goes far beyond any data concerning past births and deaths.

David Hume (1748) issued a serious challenge to the rationality of inductive inferences and to the idea that there is such a thing as confirmation or rational support. As an empiricist, he insisted that all evidence derives from perception and thus can be stated as reports of observations. He then asked what argument employing only observation reports as premises could establish universal generalizations or conclusions concerning phenomena not yet observed. Such arguments could not be deductive, since they are fallible. There was nothing logically impossible about Europeans observing black swans in Australia, even though all swans Europeans previously observed had been white. To get from premises reporting observations to a generalization or a claim about something not yet observed requires as an additional premise or as a rule of inference some principle to the effect that nature is, in the relevant respect, uniform or regular. But Hume points out that we are entitled to rely on such a premise only if it is a logical truth or is itself established by experience. A principle of uniformity is not a logical truth, and it is no easier to establish on the basis of reports of past uniformities than the particular induction we are attempting to justify. Hume draws the extreme sceptical conclusion that humans have no good reason at all to believe the conclusions of inductive inferences, or, in other words, that observational evidence never provides any rational support for any hypotheses. What keeps people out of harm’s way and
enables them to survive is habit. Observing regularities, people cannot help expecting them to persist. Hume confesses that, once he leaves his study, he cannot take his sceptical conclusions seriously. Furthermore, treating confirmation as no more than a matter of conditioned responses to repetition leaves one with few ways to distinguish between sensible uses of evidence on the one hand and prejudice, superstition or even phobia on the other. Hume's problem of induction shows that the notion of justification that is relevant to science and everyday life is piecemeal rather than global. In inductive arguments, scientists can legitimately employ premises that are not observation reports and are hence not beyond questioning. (And, of course, observation reports are fallible, too.) In order to clarify and inform scientific practice, theories of confirmation need to capture the distinction between evidence that supports an hypothesis and evidence that does not, rather than to deny that this distinction exists. In thinking about confirmation, it is helpful to draw three distinctions. First, one may distinguish between ‘incremental’ confirmation – confirmation as a relation between an hypothesis \( h \) and a particular piece of evidence \( e \) – and total or absolute confirmation – as a judgement about how well supported \( h \) is overall or as a relation between \( h \) and the total available evidence. Evidence \( e \) confirms \( h \) incrementally if \( e \) provides (or would provide) some additional support for \( h \), whether or not \( h \) is well confirmed in the sense of total confirmation. Second, confirmation can be thought of either qualitatively or quantitatively. In the total sense, \( h \) is either qualitatively well confirmed or poorly confirmed, while quantitative confirmation theory attempts to quantify how well or poorly confirmed \( h \) is. In the incremental sense, evidence \( e \) may, qualitatively, either confirm, disconfirm, or be evidentially irrelevant to an hypothesis \( h \), while quantitative theory attempts to measure how much \( e \) boosts or diminishes how well supported \( h \) is. Finally, confirmation can be either comparative or non-comparative. Non-comparative confirmation concerns just one hypothesis–evidence pair. In comparative confirmation, on the other hand, one assesses, for example, how well an \( e \) supports an \( h \) relative to how well a different \( e' \) supports the same \( h \) or how well the same \( e \) supports a different \( h' \).

A simple and natural idea is that a general hypothesis of the form ‘All \( Fs \) are \( Gs \)’ is (incrementally) confirmed by ‘positive instances’ – that is, by objects that are both \( F \) and \( G \). A negative instance – an object that is an \( F \) but not a \( G \) – does not merely disconfirm the general hypothesis; negative instances refute universal generalizations. This somewhat misleading asymmetry plays a large role in Karl Popper's insistence that science relies on confirmation rather than verification. For an example of instance confirmation, an increase in a firm's sales following a drop in the price of its product confirms the law of demand. If in addition to instance confirmation one assumes that logically equivalent hypotheses are confirmed by the same evidence, one is immediately faced with a paradoxical conclusion. A white shoe confirms the generalization ‘Everything that is not black is not a raven’, which is logically equivalent to the generalization ‘All ravens are black’. But do reports of white shoes confirm ‘All ravens are black’ (Hempel, 1945)? The most common of the many responses to this paradox rely on a quantitative theory of confirmation and are discussed briefly below. The positive instance criterion was offered as part of a sufficient condition for the confirmation of universal conditionals. Hempel (1945) generalized this criterion to his satisfaction criterion which applies to more complex logical structures for evidence and hypothesis, and which provides explicit definitions of confirmation, disconfirmation, and evidential irrelevance. In defending his satisfaction criterion, Hempel relied on what he regarded as intuitively obvious conditions of adequacy for definitions of confirmation. Besides the equivalence condition mentioned above, the entailment condition covers the limiting case where evidence logically entails an hypothesis: it says that, if \( e \) entails
theory appraisal: The New Palgrave Dictionary of Economics

Hempel also assumed a more controversial special consequence condition, which says that, if $e$ confirms $h$ and $h$ entails $h'$, then $e$ confirms $h'$. The criteria for confirmation discussed above apply when evidence reports and hypotheses are stated in the same language, which Hempel took to be an observational language. What about confirmation of theories, which typically contain theoretical as well as observational vocabulary? Hypothetico-deductivism (HD) or the hypothetico-deductive method is the idea that theories and hypotheses are confirmed by their observational consequences. So, for example, axioms concerning individual preference are confirmed by the same evidence that supports the law of demand, even though that evidence is not an instance of the preference axioms, because that evidence (and the law of demand itself) can be deduced from models which include axioms governing individual preferences. The positive instance and satisfaction criteria are formulations of the idea, roughly, that observations that are logically consistent with a hypothesis confirm the hypothesis, while HD says that deductive consequences of a theory or model confirm the theory or model. Of course, if the prediction fails (if an observational deductive consequence of a theory turns out to be false), then this is supposed to provide disconfirmation of the theory.

The HD method is subject to two serious problems. The first is the problem of irrelevant conjunction or of distributing credit. If an hypothesis $h$ logically implies an observation report $e$, then so does the conjunction, $h \& g$, where $g$ can be any sentence whatsoever. If, as the HD method says, an observation report $e$ confirms any hypothesis that implies $e$, then $e$ confirms $h \& g$. That seems bad enough. Worse still, since $h \& g$ implies $g$, the special consequence condition implies that $e$ confirms $g$, or in other words any sentence whatsoever. A natural response would be to refine the basic HD idea and deny that $e$ confirms $h$ when $h$ entails $e$, unless some further condition is met to the effect that there is no logically weaker hypothesis $h'$ that also entails $e$. But these difficulties are not easily remedied.

The second problem, which is particularly poignant in economics, concerns the distribution of blame. Testable implications can rarely if ever be deduced from scientific theories without additional premises. Deductive logic tells us that, if those testable implications are false, then at least one of the premises from which they follow must be false, but deductive logic alone does not single out which is the culprit. This is the so-called ‘Duhem–Quine problem’ and is discussed later.

Quantitative confirmation: probabilistic approaches

The most influential probabilistic approach to confirmation is called ‘Bayesian confirmation theory’. The basic idea is that evidence $e$ confirms hypothesis $h$ if and only if the conditional probability $p(h \mid e)$ (defined as $p(h \& e)/p(e)$) is greater than the unconditional probability $p(h)$. Disconfirmation is defined by reversing the inequality, and evidential irrelevance is defined by changing the inequality to an equality. The function $p$ measures an agent's 'subjective probability' or degree of belief. Given a set of axioms governing preference, which are stronger than those that must be satisfied in order to attribute ordinal utility functions to agents, one can prove that there exists a ‘cardinal’ utility representation, which is unique up to a positive affine transformation, and which assigns to each lottery a utility equal to the sum of the utilities of its prizes weighted by the agent's subjective probabilities. Such cardinal representation theorems (for example, Harsanyi, 1977, ch. 4) establish that the degrees of belief of agents who satisfy the axioms conform to the axioms of the probability calculus. (Important work in foundations of subjective probability includes Ramsey, 1931; de Finetti, 1937; Savage, 1972; Jeffrey, 1983; and Joyce,
Suppose that \( p(h / e) \), the agent's subjective conditional probability, is equal to what the agent's subjective degree of belief in \( h \) would be if the agent learned that \( e \) is true – that is, in the wake on an observation that \( e \) is true, the agent changes or updates \( p(h) \) to be equal to the current \( p(h / e) \).

On this assumption \( p(h / e) > p(h) \) if and only if the agent's degree of belief in \( h \) would increase if \( e \) were learned. In that case, it is natural to say that, for this agent, \( e \) is positively evidentially relevant to \( h \), even when \( e \) is not in fact learned. So the Bayesian maintains that \( e \) confirms \( h \) if and only if \( p(h / e) > p(h) \), that \( e \) disconfirms \( h \) if and only if the inequality is reversed, and \( e \) is evidentially irrelevant if and only if \( p(h / e) = p(h) \).

People's subjective probabilities will differ, even if they are equally rational, because their background knowledge differs. So, according to the Bayesian approach, confirmation is a relation among three things: evidence, hypothesis and background knowledge. The reason this approach is called ‘Bayesian’ confirmation theory is because of its frequent use of a mathematical theorem discovered by Thomas Bayes (1764), a simple version of which is: \( p(h / e) = p(e / h) p(h) / p(e) \). This expression follows easily from the definition of conditional probability which tells us that \( p(h/e)=p(h&e)/p(e) \) and \( p(e/h)=p(h&e)/p(h) \). Bayes's theorem shows how the quantity of interest, \( p(h / e) \), depends on the so-called ‘prior probability’ – \( p(h) \) – the ‘likelihood’ – \( p(e / h) \) – and the subjective probability of the evidence. When \( p(e) \) is low – that is, when an observation is surprising – then one has much stronger evidence than if the observation was expected.

Bayesian confirmation theory also suggests measures of the degree of evidential support that \( e \) provides for \( h \). The most common measure is the difference measure: \( d(h, e) = p(h / e) - p(h) \), where confirmation, disconfirmation and evidential irrelevance correspond to whether this measure is positive, negative or zero, and degree goes by the magnitude of the difference, but there are other measures, too. One application of the idea of degree of evidential support has been to the ravens paradox, discussed above. Let \( h \) be the hypothesis that all ravens are black; let \( Ra \) symbolize the statement that object \( a \) is a raven; and let \( Ba \) symbolize the statement that \( a \) is black. If \( h \) is probabilistically independent of \( Ra \) (that is, \( p(h / Ra) = p(h) \)), then a positive instance (or report of one), \( Ra&Ba \), of \( h \) confirms \( h \) in the Bayesian sense (that is, \( p(h/Ra&Ba)>p(h) \)) if and only if \( p(Ba / Ra) < 1 \) (that is, if it is not already certain that \( a \) would be black if a raven). Given the same independence assumption, one can prove that a positive instance, \( Ra&Ba \), confirms \( h \) more than a contrapositive instance, \( not-Ba&not-Ra \), does, provided that one's degree of belief that a given raven will be black is less than one's degree of belief that something that isn't black isn't a raven. Since for most people the subjective probability that a particularly non-black thing such as a white shoe is not raven is much higher than the subjective probability that any particular raven is black, black ravens will provide much stronger confirmation of ‘All ravens are black’ than white shoes or pale economists.

Bayesian confirmation theory can also be used to assess Hempel's proposed conditions of adequacy for criteria of confirmation. In particular, Hempel's special consequence condition (unlike the equivalence conditions or the entailment condition) does not follow from the Bayesian definition of confirmation and the axioms of the probability calculus, and by attending to the circumstances in which the special consequence condition can fail, theorists have constructed intuitively compelling examples of an \( h \) entailing an \( h' \), and an \( e \) confirming \( h \) while disconfirming \( h' \). Such examples tell against the special consequence condition and also in favour of Bayesian confirmation theory (for example, Eells, 1982).
One standard objection to Bayesian confirmation theory is that, if \( e \) is already known to be true, then \( p(h \mid e) \) must be the same as \( p(h) \) and, by the Bayesian definition of confirmation, \( e \) cannot confirm \( h \). This is called ‘the problem of old evidence’. One possible Bayesian solution to the problem, suggested by Glymour (1980), would be to say that it is not the already known \( e \) that confirms \( h \), but rather a newly discovered logical or explanatory relation between \( e \) and the particular \( h \). Other solutions have been proposed and various versions of the problem have been distinguished (see Earman, 1992, for discussion). The problem remains one of lively debate.

A second objection to Bayesian confirmation theory is more general and leads to the main contemporary probabilistic alternative. Prior probabilities – the degree of belief agents have in hypotheses in advance of gathering particular evidence – and likelihoods – \( p(e \mid h) \) – play crucial roles in Bayesian confirmation theory. But is it plausible to suppose that these are known? If \( h \) is a newly formulated physical hypothesis, for example, what would justify an assignment of probability to it prior to evidence? One response to the problem is to point to convergence theorems (as in de Finetti, 1937) which show that differences in priors will ‘wash out’ in the long run. But this response is not very satisfactory, since assessments of theories need to be made now, and if initial differences in priors are large enough, the long run must be long indeed.

Those who favour a likelihood approach to the evaluation of evidence – for example, Edwards (1972) and Royall (1997) – believe that there are important contexts in which likelihoods can be known, but that reliance on prior probabilities is rarely justifiable. According to one formulation of the likelihood account, \( e \) confirms \( h \) more than \( e \) confirms \( h' \) if and only if \( p(e \mid h) \) is greater than \( p(e \mid h') \). This is a comparative principle. It doesn't matter that both of these likelihoods may be tiny. The likelihood approach separates the question of which hypothesis it is more justified to believe given all the evidence from the question of which hypothesis is better supported by the particular piece of evidence. There are a variety of different measures of confirmation in terms of likelihoods (see Fitelson, 2001, and Forster and Sober, 2002, for recent discussion and references). Although those who emphasize likelihoods avoid relying on priors, they cannot of course avoid relying on likelihoods, and these too may be hard to know. Although evidence statements are often entailed by the conjunction of the hypothesis under test and a variety of other statements concerning the specific circumstances, measuring apparatus, the absence of interferences and so forth, the conditional probability of the evidence statement conditional on the particular hypothesis may be as hard to nail down as the prior probability.

Inexactness and theory appraisal

The appraisal of theories ought presumably to be strongly influenced by how well confirmed they are both absolutely and in comparison with alternatives. If there is very strong evidence in support of a theory – that is, if a theory is very well confirmed – then the risk of believing it and relying on it both in practice and for the purposes of gaining further knowledge should be small.

But, given how ambitious and wide-reaching the claims of theories often are, it is questionable whether even the best-supported of scientific theories is all that well supported. How could evidence from our little corner of the universe justify conclusions about all bodies and all forces? Furthermore, other features of theories should influence appraisal of them, in addition to how well supported they are. Some theories are more ‘promising’ than others. Some are easier to use or to teach. Some theories are more
Appraising economic theories is particularly challenging because of the limited possibilities for experimentation and because of the limited relevance of market data, which are influenced by many factors from which economic theories abstract. The Duhem–Quine problem is a huge practical problem rather than just a philosophical possibility. Consider, for example, Card and Kreuger's (1995) study of the effect of an increase in minimum wages in New Jersey in 1990, which found, in contradiction to the prediction of simple economic models, that unemployment among unskilled workers did not decline. To carry out this test, they compared employment in fast-food restaurants in New Jersey, where minimum wages increased, and next-door Pennsylvania, where minimum wages did not change. Their results might show, as they maintained, that relatively small changes in the minimum wage do not cause unemployment among unskilled workers. But the results might instead be due to peculiarities of fast-food restaurants, to other changes in the economy or popular culture of New Jersey or Pennsylvania, or to flaws in their data. The problem is ubiquitous: market data bear on economic theories through so many intermediary premises that successes of predictions give economists little reason for confidence in their models, and failures give economists little reason for dissatisfaction with their models. To bridge the gap between even the very best data and economic theories requires a motley assortment of simplifications and \textit{ceteris paribus} clauses, which rarely inspire much confidence. When predictions fail, it is typically more sensible to blame the problem on the simplifications or \textit{ceteris paribus} conditions than on the theory. That means that economists can hang on to their basic principles without much risk of refuting them but also without much prospect of improving them.

If one turns from predictions given by economic models to the propositions out of which the models are constructed, one finds that they rely heavily on premises such as ‘Commodities are infinitely divisible’, ‘All agents have perfect information concerning prices and quantities of all commodities’, or ‘Consumption decisions are taken by a single representative consumer’. No one thinks these claims are true, but many believe that their falsity does not matter. Perhaps they can be regarded as approximations. Perhaps they can be regarded as idealizations. Perhaps they can be regarded as abstracting from details that are, for some purposes, irrelevant. In addition, many of the basic principles or ‘laws’ of economics – claims such as ‘Agents’ preferences are transitive’ or ‘Consumers prefer more commodities to fewer’ – are false, at least if they are construed as universal generalizations. Yet they seem somehow to capture important facts that enable economists to build models that predict and explain important economic phenomena.

The traditional view of theory appraisal in economics receives its best exposition in the works of John Stuart Mill (1843, Book VI). Although an empiricist, Mill thought in terms of causation. Individual causes can be and ought to be studied by observation (if one is fortunate enough to find a domain where no other causal factors are interfering) or experimentally (if one can construct controlled circumstances which differ only with respect to the presence or absence of the particular cause one investigates). Mill’s famous methods of induction guide inferences concerning individual causes (1843, Book III). When one is studying phenomena that are influenced by many causes, like the phenomena that economists study, Mill maintains that direct inductive methods cannot be used. Instead one needs first to determine the laws of the main causes by studying other domains where their action can be isolated, and then one needs to deduce their effect when combined. Mill believes that it is possible to learn the basic
behavioural generalizations governing economic behaviour by means of introspective psychology on the one hand and engineering on the other. Economics then takes the form of exploring the implications of models in which economists combine what they know of the most important causal factors with simplified descriptions of the circumstances to which the model is to be applied. So, for example, economists know that firms generally aim to maximize net revenue and that they have a choice of different production processes which employ relatively more or relatively less unskilled labour. When minimum wage laws increase, wages of unskilled labour increase (unless market rates are already higher than the new minimum wage), and firms will economize on the use of unskilled labour. Employment of unskilled labour will consequently decline. Mill urges in addition that empirical tests such as the Kreuger and Card study be carried out as checks on economists’ deductions and to determine whether they have left out some significant factor. But predictive failures do not show any errors in one's basic principles, which have, in Mill's view, already been conclusively established by the results of introspective observation of the principles separately. The appraisal of basic theory depends on the quasi-experimental study of its individual basic ‘laws’ or principles, and it is largely disconnected from the appraisal of specific models, which depends on whether they serve the particular purposes for which they are constructed.

Although Mill's view that the basic principles of economics are proven truths is unsustainable, he was right to emphasize the difficulty of testing economics against uncontrolled market data and to stress the value of evidence concerning specific principles gathered from everyday experience. As the example of the employment effects of minimum-wage laws illustrates, economists rely on everyday experience to suggest and justify generalizations concerning the behaviour of firms including the flexibility of their employment policies. Causal experience cannot, of course, show how single-minded or relentless firms are in maximizing net returns, or whether this causal factor is one of a small set of factors that is of supreme importance with respect to virtually all economic phenomena. But, given the complexities and ambiguities in empirical studies such as Card and Krueger's, it is not unreasonable to continue to expect increases in unemployment among unskilled workers to result from increases in minimum wages, and it is not unreasonable to hang on to fundamental principles such as profit maximization.

In the second half of the 20th century, many economists became uneasy about espousing a view of theory appraisal that emphasized the extent to which the basic principles of economics were independently confirmed or disconfirmed, often by casual experience. One reason was that empirical work apparently showed that firms do not attempt to maximize profits (Hall and Hitch, 1939; Lester, 1946). Rather than addressing the details of these studies, Milton Friedman (1953) argues famously that such inquiries into the ‘realism’ of the ‘assumptions’ of economics reflected methodological confusion. All that matters is how successfully economic models are at predicting the market price and quantity data that are of interest to economists. Friedman's view appeared to economists to be in better accord with an up-to-date philosophy of science. It was empiricist, and, later on, many saw it as corresponding roughly to Karl Popper's insistence on falsification (Blaug, 1976, p. 149). Given how difficult it is to test economic theory against market data, Friedman's view of theory appraisal in fact served to insulate economics from empirical criticism, which may have been its main appeal.

During the second half of the 20th century methodologists flirted with a number of views of theory appraisal, many of which were constructed with the natural sciences or even mathematics in mind, and none of which has found general favour among economists or economic methodologists. The difficulties of theory appraisal have even led some influential voices to argue for an abandonment of the pursuit of
any normative standards. McCloskey (1985) thus apparently argues that, apart from very unspecific requirements of honesty and open discussion, there are no rules constraining the appraisal economists offer of their theories, while Hands (2001) suggests that the only fruitful questions to ask concerning theory appraisal are questions about the sociological factors that lead communities of scientists to endorse one theory or another.

In our view, in contrast, it is impossible to evade normative questions about how theories and models ought to be appraised. Though these questions have no simple answers, the answers must turn in large part on matters of confirmation. Decisions to rely on particular claims of economics both for theoretical and for practical purposes are weighty indeed, and it would be massively irresponsible to base policy on some economic thesis without asking how well confirmed it is.

Thin markets

Marzena Rostek and Marek Weretka
From The New Palgrave Dictionary of Economics Online, ,
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

A thin market is a market with few buying or selling offers. The concept of market thinness, while
general, is typically used in the context of financial markets. When the number of buying or selling
offers is small, investors' trading positions are large relative to market size. Trading then requires price
concessions and thus exerts an impact on prices. A thin market is characterized by low trading volume,
high volatility and high bid–ask spreads. This article discusses the modelling of thin markets, some
typical phenomena of such markets, and their implications for market design.

Article

A thin market is a market with few buying or selling offers. It is also known as a narrow market. The
signature characteristic of a thin market is traders' price impact. When the number of buying or selling
offers is small, investors' trading positions are large relative to market size. Trading then requires price
concessions and thus exerts an impact on prices. A thin market is characterized by low trading volume,
high volatility, and high bid–ask spreads. The concept of market thinness, while general, is typically
used in the context of financial markets.
Market thinness is a particular source of market illiquidity. Liquidity is broadly defined as the ease of
trading a security. Apart from market power, lack of liquidity can result from asymmetric information,
transaction costs, search and bargaining frictions, imperfect financing ability, limited commitment and
spatial considerations.

Price impact in financial markets
Since transaction-level data became available in the early 1990s, it has been well understood that institutional investors (such as mutual funds, hedge funds, pension funds and investment banks), whose trade on the New York Stock Exchange (NYSE) accounts for more than 70 per cent of daily trading volume, exert a significant impact on prices and take this into account in their trading strategies. The seminal empirical studies include Chan and Lakonishok (1993, 1995), and Keim and Madhavan (1995, 1996, 1998). To mitigate the adverse effects of price impact, large traders do not place their orders at once; rather, they break them up into smaller blocks, which are then placed sequentially. For instance, at the NYSE, only about 20 per cent of the total trading value of all institutional purchases and sales is completed within a single trading day, while more than 50 per cent takes at least four days for execution. If traded at once, a typical institutional package would represent more than 60 per cent of the total trading volume. In financial slang, institutional investors are referred to as elephant traders and institutional trading blocks as iceberg orders. In fact, the trading costs associated with such price impact dominate the explicit costs of trade, such as commission, order processing and brokerage fees. Consequently, extensive resources are devoted to estimating price impact and designing best execution. Such techniques are available to institutional as well as retail investors in the form of software called market impact models.

Modelling thin markets

On the theory side, the presence of market power poses challenges to modelling. In particular, the competitive approach is not suitable for modelling thin markets since it assumes that no individual trader can affect the market price by their buying or selling orders.

A large body of literature has emerged to explain how price impact affects individual portfolio choices of investors and the equilibrium in financial markets. The theoretical mechanisms underlying these models can be grouped into three categories: asymmetric information, inventory effects and nonequilibrium mechanisms. Traditionally, the leading class of models with price impacts is based on asymmetric or private information (e.g. Glosten and Milgrom, 1985; Kyle, 1985, 1989; Easley and O’Hara, 1987; Back, 1992; Foster and Viswanathan, 1996; Holden and Subrahmanyam, 1996). In such models, price impact arises because high sales by an informed trader are interpreted by remaining traders as a signal of low asset value, and hence reduce the asset price.

For many market events that involve anticipated demand or supply shocks, such as preannounced inclusions of new stock into the S&P, the price impact component that derives from asymmetric information can only partially explain the observed magnitudes of price changes. Therefore, an alternative strand of the literature based on inventory effects has emerged. There, because of diversification concerns, risk-averse traders are willing to absorb large, risky orders only at price concessions (Ho and Stoll, 1981; Grossman and Miller, 1988; Vayanos, 2001; Attari, Mello and Ruckes, 2005; Brunnermeier and Pedersen, 2005; Pritsker, 2005; DeMarzo and Urošević, 2006 extended by Urošević, 2005). These papers capture price impact by building Cournot-type models with one or several large investors and a continuum of (infinitesimally) small price-taking traders.

Under Cournot market structure, large investors trade only with small competitive traders. In contrast, it is a stylized fact of financial markets that large investors trade effectively with one another in the sense that an order placed by a large investor is primarily absorbed by (a possibly small group of) other large
traders. Essentially, this is a market structure of bilateral oligopoly, except that all traders can buy and sell. The seminal papers embedding these features are Kyle (1989) and Vayanos (1999). An equilibrium model of symmetric-information market environments in which all buyers and sellers have price impact can be found in Weretka (2006). Rostek and Weretka (2007) study dynamic thin markets and establish implications of market thinness for asset pricing. Rostek and Weretka (2008) examine the implications of market thinness for information aggregation, efficiency and price discovery. Carvajal and Weretka (2007) show that the pricing kernel exists in thin markets.

Finally to study such markets, several nonequilibrium models with price impact have been proposed (e.g. Bertsimas and Lo, 1998; Almgren and Chriss, 2000; Subramanian and Jarrow, 2001; Dubil, 2002; Almgren, 2003; Huberman and Stanzl, 2004; Almgren et al., 2005; Engle and Ferstenberg, 2007). These models assume motivated empirically functional forms of price impact functions, one for every trader, which are then used to analyse market dynamics.

**Thin market phenomena**

Handling large orders through order break-up is but one difference between thin and competitive markets. Market thinness leads to a number of other empirical phenomena that are hard to reconcile with competitive equilibrium asset pricing models, such as CAPM of C-CAPM.

**Pareto inefficiency**

Because of the reduction of buying and selling orders in response to market power, traders do not fully diversify the idiosyncratic risk of their holdings. As a result, allocations are not efficient. This is optimal, since the benefits from diversification need to be balanced against the extra (with respect to the competitive, price-taking, setting) cost of price impact.

**Response to liquidity shocks**

As evidenced by the empirical literature, the exogenous shocks in asset supply, such as inclusions of new stocks into the S&P, weight changes in stock market indices, or forced liquidations, result in price overshooting. Even if the shock is preannounced, on the date of the actual event, the price drops below the new fundamental value to attain that value only in subsequent periods. This phenomenon, often referred to as price overshooting, cannot occur in the competitive model, where prices adjust to the new fundamental value immediately following the shock or its announcement. The overshooting effect is the equilibrium reaction of thin markets to anticipated and unanticipated shocks in asset supply. The overall observed price change can be decomposed into temporary and permanent components. The permanent effect, which occurs upon the announcement, represents the adjustment of the fundamental value that results from the changes in inventory. The effect is amplified by temporary price concessions demanded by liquidity providers to be willing to absorb the shock on the day of its occurrence whether or not the shock is anticipated. An alternative explanation of overshooting involves predatory trading (Brunnermeier and Pedersen, 2005): When a large trader needs to liquidate a portfolio quickly, other investors sell and subsequently buy back the asset. This strategy lowers the price at which they can
Excess volatility and volatility clustering

One of the consequences of price overshooting in thin markets is excess price volatility. That is, the presence of the price impact leads to excess return volatility and changes in volatility unrelated to changes in fundamentals. Since, in addition, the price impact varies over time, periods of high price impact feature high price volatility, thereby inducing volatility clustering.

Limits to arbitrage

Another novel feature of thin markets is the coexistence of anticipated price differentials and limits to arbitrage in equilibrium. According to the competitive theory of asset pricing, whenever there are anticipated price differentials, a trader can make infinite profit by taking unbounded positions. When a market is thin, however, price impact naturally limits the benefits from arbitrage for active traders and also reduces incentives to enter the market. Therefore, unlike in a competitive model, the profits from entering the market are bounded, and even small fixed entry costs may prevent outsiders from arbitraging the price differentials. These entry costs include explicit trading costs, such as transaction costs, but also the cost associated with learning the characteristics of the stocks. Empirically, it may take months for outside capital to bid prices back to their fundamental value (Mitchell, Pedersen and Pulvino, 2007).

Asset valuation

In the presence of price impact, the market value of a large block of shares no longer coincides with the cash value that could be obtained by liquidating the portfolio. To account for the difference, valuation specialists often apply a so-called blockage discount. A typical instance where blockage discounts are applied involves the transfer of a property in a case of divorce. It is in the interest of the divorcees to claim a large price impact (and blockage discount) which implies a large tax discount. The practical approach is based on the implementation shortfall (Perold, 1988), which measures the difference between the closing or arrival price and the final execution price.

Implications for market design

Market thinness has further prompted changes in market design towards automation of the trade execution. To ease competition through the trading cost of price impact, many exchanges have adopted an electronic trading system with posted orders (e.g. Nasdaq, NYSE, Euronext, and the stock exchanges in London, Toronto and Vancouver). In the presence of asymmetric information, market thinness can perversely reduce liquidity under continuous trading. Therefore, several markets have returned to more traditional trading systems.

third world debt

François Bourguignon
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Excessive dependence on foreign savings is a threat. But governments can lead by example by securing fiscal surpluses. As well, appropriate financial sector, tax and other microeconomic policies can help stimulate private domestic savings. Under these conditions, foreign borrowing can be a healthy complement to domestic savings.

Article

Many developing countries have encountered difficulties in managing their foreign debts in the 19th and 20th centuries. A number of crisis episodes are reviewed by Fishlow (1985). Some of them, such as the Baring crisis of 1890, threatened the stability of the international financial system. Others were confined more specifically to a single country with a dispersion of creditors on bonded debt, as was the recent case of the Argentine default of 2002. While there is a long history of ‘Third World’ debt accumulation and subsequent defaults, the frequency of debt crises in developing countries has increased dramatically since the 1982 Mexican debt crisis. The focus of this article is the episodes since the mid-1980s, and the economic literature that emerged to analyse these events.

Much of the attention of the international community on Third World debt during the 1980s and early 1990s was focused on middle-income countries. During the mid- to late 1990s, debt relief for highly indebted poor countries (HIPC) increasingly occupied the attention of policymakers around the world, as debt relief became a cause célèbre for a number of international NGOs. An increasing share of overseas development assistance in the new millennium has been devoted to cancelling the official credits of bilateral and multilateral donors through the Highly Indebted Poor Country ‘HIPC’ Initiative.

Readers who want more detailed accounts should consult the volumes edited by Smith and Cuddington (1985), Sachs (1989) and Husain and Diwan (1989), as well as the books by Cohen (1991) and Cline (1995). On debt relief for low-income countries, a detailed discussion is provided by Birdsall and Williamson (2002), or one can consult the volume edited by Addison, Hansen and Tarp (2004). On recent analyses on the origins of debt crises as well as links to exchange rate policy, the reader is referred to Calvo and Reinhart (2002), Reinhart, Rogoff and Savastano (2003) and Eichengreen, Hausmann and Panizza (2003). Cline (1995, ch. 4) provides a critical review of the theory of sovereign borrowing.

General analytic framework

The neoclassical view of sovereign borrowing by developing countries is straightforward. Developing countries have lower capital stocks and resulting higher returns to capital than the high-income countries. These circumstances provide both borrowers and lenders with the incentive to engage in mutually beneficial debt transactions. The experience with
sovereign defaults over the last two centuries leads to other considerations. Debt contracts across international borders do not fall under a clear legal jurisdiction for enforcement, so the incentives for repayment on the part of the borrower must be understood.

Eaton and Gersovitz (1981) developed a model where developing countries borrow for consumption-smoothing purposes. Under certain circumstances, the desire for continued access to foreign credit for these purposes can be an adequate incentive for borrowers to pay, an incentive that is balanced against the one-off gains from defaulting. Creditors, understanding these incentives, will lend only up to the point at which the marginal costs and benefits of lending are equal. Clearly, this assumes that there is full information about these costs and benefits and coordinated action on the part of the creditors.

Cooper and Sachs (1985) provide another seminal analysis on foreign borrowing where the repayment question is divided into three components, or risks: illiquidity, insolvency and repudiation. The analysis looks at the optimal borrowing path for a debtor nation, taking into account constraints associated with the aforementioned three risks. For example, external solvency is limited by the present discounted value of future trade surpluses. If these surpluses happen to grow at a slower pace than the rate of interest, then the country faces a solvency constraint. The liquidity constraint may arise when, in a given year, the external trade surplus is insufficient to cover debt service, perhaps due to a short-run change in the terms of trade or other external factors. (Later analyses of solvency and liquidity would analyse explicitly an additional constraint: the internal transfer of resources from the domestic private sector to the government debtor. This issue is particularly troublesome in the context of devaluations to improve the trade balance – the external transfer constraint – which lead to a higher domestic currency tax bill that must be raised to effect the internal transfer from agents to the state; see Dornbusch, 1988.) Despite long-run solvency, regulatory issues (for example, limited exposure to a single borrower) or coordination problems among creditors may lead individual banks to refuse to extend loans to cover that debt service. Repudiation risk, similar to the Eaton and Gersovitz concept discussed above, is another reason for creditors to limit loans, even when a negotiated solution to repudiation is anticipated.

Indeed, another critical question from the theoretical literature is the point at which debt relief, or debt forgiveness, becomes mutually beneficial to debtors and creditors. Krugman (1989) provides a simple definition of debt overhang: the expected present value of the resource transfer available to service debt is less than the value of debt. This sounds generally like an insolvency condition, expressed in expected present value terms, and the ‘overhang’ is the degree of excess debt that cannot be repaid under current expected conditions. Incentive problems then arise for overcoming the debt overhang. First of all, the existence of the overhang implies that there is a high marginal tax rate on domestic investment, as much of the return to investment will have to be captured by the sovereign to close the debt overhang. This poses an incentive problem for the sovereign attempting to adjust taxes and exchange rates to increase the capacity to pay: much of the gain from adjustment will accrue to the creditors. Thus, from the debtor’s point of view, there are strong incentives to lobby for a reduction in principal, or a reduction in interest rates, as the only effective means to restore growth and overcome the crisis.

Understanding the dilemma faced by the debtor, creditors may also benefit from debt reduction. At high enough levels of debt, the probability of outright default increases rapidly enough that the expected total repayment to creditors may begin to fall as the overall face value of debt increases. In other words, there is a debt relief Laffer curve (Krugman, 1989), as described in Figure 1. At very low levels of indebtedness, the sovereign is expected to pay in full, and there is no discount on secondary markets. This is represented by the 45 degree line in Figure 1: expected repayment equals the face value of the debt outstanding. As indebtedness levels increase, the probability of eventually facing a repayment problem increases. At point A, expected repayment is now below the face value of debt, and a secondary market discount would appear. However, at this stage it makes sense for creditors to continue lending – or even with ‘defensive’ lending in the face of an external shock – in that an increase in the stock of debt outstanding still leads to an increase in expected repayment. This is no longer the case beyond point C. At point B indebtedness levels have reached the point where additional lending reduces expected repayment. Debt forgiveness, reducing the face value of debt outstanding, would then actually lead to an increase in the expected value of repayment. Yet this raises an issue of coordination among creditors since the value to the collective creditor community of reducing the debt by one dollar is higher than the average price (expected value) which represents the value of that operation to the individual investor (Bulow and Rogoff, 1988). As a result some agreement must be reached among creditors on how to forgive debt, including ‘burden-sharing’ arrangements.

Figure 1
The debt relief Laffer curve
In summary, when debt becomes large enough, the prospects for simply growing out of the problem are dim. ‘Debt overhang’ can tax investment and limit debtors’ incentives to engage in policy reforms to restore solvency, or even limit their incentive to continue to honour their obligations. As secondary market prices fall, the price for purchasing a claim on a debtor deviates greatly from the price a debtor has to pay to retire a claim via regularly scheduled debt service. An alternative is to use international reserves, if available, to purchase debt on the secondary market, thus lowering the cost of retiring the claim. Bulow and Rogoff (1988) point out, however, that the price paid on the secondary market is still too high, in that it represents the average price of debt, and ignores the marginal increase in expected repayments. This analytical framework helps one understand the key issues facing both policy makers and creditors who are trying to realize mutually beneficial exits from a debt crisis. One overriding complication that emerges in a real crisis is uncertainty about the values of the parameters that define whether a country is facing a liquidity or a solvency problem, or if it
is simply unwilling to pay. Krugman (1989) and others have asserted that, in an uncertain world, the distinction between liquidity and solvency is misleading. Liquidity problems arise precisely because there is some reasonable probability that the country is insolvent. The brief recounting below of the history of recent debt crises reveals the difficulty in determining these values in the midst of a crisis. This uncertainty leads to divergent views on the best solution to a particular crisis episode.

This analytical framework continues to be useful. As noted below, the debt crises of the 1990s inspired a broader literature that examines how capital flow reversals, the currency structure of bank or corporate balance sheets and exchange rate policies all interact in causing the debt crises of this later period.

Evolution of external debt: 1980s to the present

Table 1 describes the evolution of the external debt of developing countries over the 1980–2003 period, in constant 2003 dollars. Two noteworthy trends are important for the discussion of the evolution of debt crisis episodes. First of all, we see a shift towards debt owed to ‘public creditors’ – that is, official bilateral and multilateral institutions – during the mid- to late 1980s, as the Baker and Brady Plans responded to the debt crises of the early 1980s. Over the same period, the share owed by the private sector in developing countries declined, as developing country governments assumed the liabilities of the private sector following the crisis. Later, during the early 1990s, we see an acceleration in the growth of the total debt stock, led by a greater role of both lending by private sector creditors and borrowing by private sector borrowers. This is not surprising, given that many developing countries pursued capital account liberalization at the start of the 1990s.

Debt crises of the 1980s

The five paragraphs immediately following have been taken with some modification from Kenen (1992).

Commercial banks and other private institutions did not lend extensively to developing countries in the 1950s and 1960s. The build-up of debt that led to the crisis of the 1980s began in 1974, after the increase in the price of oil which followed the Arab–Israel war in October 1973. Some of the oil-exporting countries ran huge current account surpluses and deposited the proceeds with foreign commercial banks, and many oil-importing countries ran huge deficits. The imbalance was heavily concentrated on the developing countries because the industrial countries moved into recession in 1974–5, reducing their total imports and focusing the global ‘oil deficit’ on the oil-importing developing countries. The economic environment of the 1970s was very conducive to large borrowing. Nominal interest rates were low, and real interest rates were negative. Many developing countries were posting higher growth rates of output and exports than in earlier decades, which held down the ratios of debt to output and of debt-service payments to exports. As noted in the analytical framework above, under these conditions debt accumulation is bound to appear sustainable.

Furthermore, the banks had protected themselves from two of the three risks facing them. First, the deposits of the oil-exporting countries were denominated mainly in US dollars, the
currency in which they were paid for their oil, and most of the banks’ own loans to developing countries were likewise dollar-dominated, so the banks were protected from exchange
rate risks. Second, the interest rates charged on most of the loans were based on the London Inter-Bank Offered Rate (LIBOR), the interest rate paid on most of the deposits, and were
adjusted frequently to maintain the spread over LIBOR, so the banks were protected from interest rate risks.
Yet the way that banks protected themselves from interest rate risk increased their exposure to default risk by linking the debtors’ obligations to very volatile interest rates.
Furthermore, the link to LIBOR, combined with the debtors’ dependence on export earnings from products with cyclically sensitive prices, made it very likely that the debtor
countries would prosper or suffer together, reducing the protection usually afforded by diversification. Finally, the risk of each bank’s exposure to a particular country depended on
the country’s total debt, which depended in turn on the volume of loans made by other banks and on the amount of debt owned by all of the country’s borrowers. In brief, there were
externalities all over the place, but no one was paying attention to them.
The country which set off the crisis was just becoming an oil exporter rather than an oil importer. Mexico had borrowed heavily in the expectation of big oil exports, and much of its
external debt bore floating interest rates. When interest rates rose sharply in the early 1980s, after the tightening of monetary policy in the United States, Mexico's debt-service
payments soared. Together with capital flight, produced by expectations of devaluation, the increase in interest payments depleted Mexico's foreign-exchange reserves, and Mexico
had to suspend those payments in August 1982.
The crisis was caused by a combination of the externalities on the creditor side, discussed above, and lax fiscal policies on the debtor side. In addition, countries with more closed
trade regimes and overvalued exchange rates confronted the greatest difficulties in adjusting to the changes in the external environment.
By 1985, 15 countries were identified as highly indebted and requiring coordinated assistance from the international community, and these 15 were later extended to 17. In terms of
magnitudes, the average debt–export ratio of this group peaked at 384 per cent in 1986 (Cline, 1995).
On the side of the creditors, there were serious concerns about a potential systemic crisis. Exposure rates reached remarkably high levels during the lending boom to developing
countries. Sachs (1989) reports that at the end of 1982 the exposures of nine major banks to developing countries had reached a staggering 289 per cent of bank capital, with much of
this exposure concentrated in several Latin American countries. Prudential regulations on the concentration of exposure to individual borrowers did not avert this problem, since
banks listed individual public agencies or state enterprises within each country as separate borrowers.

Policy response: the Baker and Brady plans

The initial response to the debt distress of the early 1980s was to coordinate efforts for new lending. Creditors largely comprised a group of large international banks. Payment arrears
were viewed as primarily a problem of illiquidity. International economic conditions had turned against a number of heavily indebted emerging markets: sharply rising interest rates,
declining prices for a number of commodities amidst a global economic recession. Coordinated efforts to extend new financing would allow these countries to honour their
obligations until the external situation improved and structural reforms implemented. Projection models (for example, Cline, 1985) suggested that, with feasible policy reforms and
improving external conditions, most debtors could make good use of the new money and emerge as strong solvent sovereigns within a reasonable time period. The IMF would
coordinate new lending.
These coordinated efforts were combined with targets for banks’ and international financial institutions contributions under the 1985 ‘Baker Plan’, named after James Baker, the US
Treasury Secretary of that time. Private banks would provide $20 billion in loans, to be matched by a similar (gross) amount by the multilateral banks (Cline, 1995).
Under the Baker Plan, substantial lending occurred, but less than the original commitments, partially due to the absence of IMF agreements in some defaulting countries. Some of the
new lending was used for buybacks of existing debt, policy conditions were not always met on the recipient side and, in many countries, arrears on new loans began to accumulate.
Meanwhile, by the late 1980s many creditor banks had been able to accumulate provisions against their losses. As a result, debt reduction or forgiveness would not cause the same
degree of stress on the financial system as had been feared during the early years of the crisis. By 1988, a number of banks were used a ‘menu approach’, accepting concessional exit
bonds or contributing to the new lending strategy. Also, by the late 1980s, secondary market prices had declined enough that banks that chose to exit via secondary markets were
accepting large losses. Any coordinated reduction plan that would offer a reduction less than the secondary market discount would be viewed as favourable. A number of countries
did emerge from the period of the ‘new money’ strategy without resorting to debt reduction: South Korea, Indonesia, and Turkey, are several prominent cases. Chile was a notable
example from the Latin American region.
Under the leadership of Nicholas Brady, the new US Secretary of the Treasury, the ‘Brady Plan’ (1989–94) was initiated with a focus on ‘voluntary’ debt reduction; however, still
suggesting a menu of options including rescheduling for those banks/country cases where it might be of interest. The target for debt reduction was $70 billion. US government bonds
were offered as collateral for new bonds used for debt reduction purposes, thus further attracting the creditors. Eventually, about $60 billion of debt was forgiven by 1994. In general,
debt reduction averaged about 30 per cent for private bank debts restructured; however, since official debt was about half the debt outstanding, total debt reduction amounted to about
15 per cent of outstanding debt (Cline, 1995). Renewed economic growth in the early 1990s, accompanied by renewed market access, seemed to indicate that the programme was a
resounding success.
By the end of the Brady Plan period, however, a new round of debt distress had appeared appear in emerging markets. During the late 1980s and early 1990s, many developing countries removed restrictions to capital inflows and liberalized their domestic financial sectors. As noted above, borrowing by the private sector led to the accumulation of debt, as did borrowing from private sector creditors. Another important change that emerged during the 1990s was the shift to bond issues, as opposed to commercial bank loans. This change obviously led to a greater dispersion and variety of creditors.

The new cycle of debt distress and crises again started with Mexico. In March 1994 an initial run on reserves occurred shortly following the assassination of the leading political candidate and a reversal of capital inflows which had been quite strong for a number of years. Mexico had been running large current account deficits during these years, in the context of a crawling band exchange rate policy, and international interest rates were also rising. In the aftermath of this first run on reserves, the central bank expanded domestic credit and it offered long-term bondholders new short-term, dollar-denominated Tesobonos. There was a fear of allowing interest rates to rise due to weaknesses in the banking system (Lustig, 2001). By December, during the last month of the Salinas administration, the government was encountering increasing difficulty in rolling over Tesobonos. An attempted ‘controlled devaluation’ of 15 per cent was followed by a renewed run on reserves. The monetary authorities were left with no option but to allow the currency to float.

Some authors (for example, Dornbusch and Werner, 1994) attribute the Mexican crisis to a traditional problem of an overvalued fixed exchange rate, with persistent current account imbalances and the corresponding accumulation of debt. With the increasing indebtedness, shorter terms and higher interest rates were demanded by the market, further increasing the likelihood of default. Devaluation would also increase indebtedness ratios relative to domestic resources. Others (Calvo and Mendoza, 1996) place greater emphasis on stock imbalances – namely, money balances, short-term debt and gross reserves – and sharp adjustment driven by global capital markets with ‘herding’ behaviour on the part of foreign bondholders. From this point of view, Mexico suffered ‘cruel punishment’ for the ‘petty crime’ of attempting a controlled devaluation to correct a modest balance of payments disequilibrium. This debate again reflected some of the difficulties in determining whether the country was insolvent or merely facing a liquidity problem that could be resolved by some coordination among creditors, as discussed in the theoretical framework above.

Indeed, the ‘punishment’ was heavy. GDP declined by more than six per cent in 1995, real wages declined sharply in the aftermath of the devaluation, and poverty rates increased by about seven or eight percentage points. Half a decade would pass before poverty rates returned to pre-crisis levels.

In early 1995, an international support programme to finance the gap in Mexico’s balance of payments was arranged of the order of some $50 billion in commitments from the IMF and bilateral sources – mainly the United States. The Fund programme of about $18 billion was the largest lending programme in IMF history at that time. The floating of the currency, along with improved trade possibilities due to the implementation of NAFTA, and these official financing flows allowed Mexico to return to growth averaging about 5.5 per cent over the 1996–98 period.

Possibly through contagion from the Mexico crisis, but also for domestic reasons, Argentina suffered a sharp withdrawal of capital and loss of international reserves in early 1995. There, too, an international support package was arranged, and robust growth was restored in 1996.

Mexico's crisis was then followed by several other financial crises in the late 1990s and into the new millennium, all involving either outright default or near default on substantial external liabilities. In East Asia, even South Korea – considered to be virtually a ‘developed’ country – was unable to avoid a substantial crisis based on the accumulation of short-term external liabilities of the private corporate and banking sector rather than government debt. Starting in Thailand, in the summer of 1997 the Asian financial crisis quickly spread by the end of the year to affect heavily Indonesia, Malaysia, Korea and the Philippines. Japan, Taiwan and Singapore also suffered through substantial problems in their financial sectors.

Each country affected by the East Asian crisis had particular circumstances leading up to the crisis; however, the most heavily hit countries had a number of common problems. Fixed exchange rates and either implicit or explicit guarantees by the government motivated private companies and banks to inadequately account for the risk involved in borrowing heavily in foreign currency. (The common features mentioned in this section are drawn from Kawai, Newfarmer and Schmukler, 2001. Goldstein, 1998, also emphasizes a combination of factors, including external imbalance and financial sector fragility due to mismatches.) There were widening current account deficits financed by short-term capital flows. Relatively unregulated financial systems conducted a credit boom with investment in low-return activities, along with substantial currency and maturity mismatches in their balance sheets. Corporations borrowed heavily, leading to exposure to interest and exchange rate shocks. Political uncertainty led to doubts about the continuation of existing exchange rate and other policies.

As in the case of Mexico, economists differ in assigning a direct cause of the crisis. There are those that emphasized fundamentals – along the lines of the common characteristics across countries mentioned above. Others (for example, Radelet and Sachs, 1998) emphasize that the problem was one of illiquidity rather than insolvency, and foreign investor panic led to a withdrawal of the willingness to provide liquidity. Kaminsky and Schmukler (1999) provide empirical evidence to support the view that investors’ reactions to news events – as measured by changes in the stock market – can be characterized as ‘herding behaviour’.

The impact of the crisis was dramatic. The Thai and Indonesian economies shrank by 10.5 and 13.1 per cent respectively, in real terms. The Korean and Malaysian economies shrank by 6.9 and 7.4 per cent, respectively.

In response to the crisis, the IMF was working on numerous fronts to provide financial support to cover debt-servicing needs. Programmes were established in the main countries.
third world debt : The New Palgrave Dictionary of Economics

rate. Countries with fixed exchange rate regimes supported by large capital inflows face the risk of 'sudden stop' (Calvo, Izquierdo and Talvi, 2003) of these inflows, leading to currency. Dollar-denominated liabilities, or even broader dollarization of the domestic financial systems, result in a 'fear to float' (Calvo and Reinhart, 2002) of the nominal exchange policies, and in particular, the exchange rate regime. Vulnerabilities in the financial system, due to lax regulation and supervision, can trigger bank withdrawals, capital flight, and exports and the effectiveness of the debtors’ tax system to secure resources for debt repayment. Clearly export growth is affected by both microeconomic and macroeconomic measures re-established confidence and reversed capital outflows. Argentina, too, was contaminated by the Russian default. Its sovereign debt experienced a sharp rise in spreads, rising to nearly 15 per cent over equivalent US bonds in September 1998. By the end of 1998, bond spreads had declined to below ten per cent; however, the country had slipped into a period of stagnation and eventual recession that lasted through mid-2001. A combination of lingering doubts among investors about the hard currency peg (a quasi-currency board arrangement), national elections in 1999, and falling international commodity prices contributed to the malaise. By mid-2001 confidence had reached a low point, Argentines were pulling (mostly dollarized) deposits out of banks and the central bank was losing reserves at a rapid pace. In the middle of the year, a ‘mega swap’ was conducted to prolong maturities without any reduction in the stock outstanding. This ‘market-based’ approach failed to stem the loss of reserves. New resources of approximately $6 billion by the IMF in August also failed to make a difference. In December, the government declared a freeze on deposits in a last-ditch effort to stem the haemorrhaging. By the end of the month, facing escalating street protests, the president would resign. In early January 2002 an interim president declared unilateral suspension of payments on foreign public debt. The exchange rate would soar from the fixed 1:1 with the dollar (which had dated back to 1991) to over three ARS per dollar. This latest crisis was particularly dramatic. The population had treated the 1:1 fixed exchange rate with the dollar as a national institution. The vast majority of deposits, loans and business contracts were set in dollars. A combination of terms of trade shocks and declining investors’ confidence in politicians’ willingness or ability to sustain the system would be accompanied by a painful, gradual, deflationary adjustment of the real exchange rate leading to the eventual collapse in early 2002. Resolution of the debt default was also particularly problematic. There were many series of bond issues in various international legal jurisdictions and numerous issues that had been passed on by underwriters to the retail level. Relations between the government and multilateral lenders also reached a stand-off, with little or no ‘fresh money’ provided, and brief periods of suspension of payments. For private creditors, the government took a hard-line position: an offer of approximately 25 cents on the dollar, in present value terms – a level lower than the value implied by secondary markets at the time. Some 100 billion dollars were eligible to be exchanged for a menu of bonds, both par and discount and also in either domestic or foreign currency. By the time of the actual transaction international interest rates had declined, so that the final offer presented a present value of just over 30 cents to the dollar of face value, a level close to prevailing secondary market discounts. This transaction represented the sharpest discounts on sovereign debt exchange in history. Just over three-fourths of the defaulted bonds were eventually exchanged, leaving a fairly substantial community of ‘holdouts’. GDP declined by an average of 2.9 per cent per year over the 1999–2001 period. In 2002 the economy shrank by nearly 11 per cent. Headcount poverty rates (national poverty line) more than doubled to around 50 per cent in 2002. Thanks to a robust recovery, GDP in real local currency terms would finally return to 1998 levels in mid-2005. The poverty rate would decline to around just under 40 per cent.

Debt and economic policies: analysis of the crises of the 1990s

As noted in the analytical framework above, indebtedness strategies cannot be viewed in isolation from other economic policies. The ability to pay is determined by the growth of exports and the effectiveness of the debtors’ tax system to secure resources for debt repayment. Clearly export growth is affected by both microeconomic and macroeconomic policies, and in particular, the exchange rate regime. Vulnerabilities in the financial system, due to lax regulation and supervision, can trigger bank withdrawals, capital flight, and exchange rate movements that dramatically shift a country from ‘apparent’ solvency to immediate insolvency. A new nomenclature has developed in the recent literature. Many developing countries commit the ‘original sin’ (Eichengreen, Hausmann and Panizza, 2003) of borrowing in foreign currency. Dollar-denominated liabilities, or even broader dollarization of the domestic financial systems, result in a ‘fear to float’ (Calvo and Reinhart, 2002) the nominal exchange rate. Countries with fixed exchange rate regimes supported by large capital inflows face the risk of ‘sudden stop’ (Calvo, Izquierdo and Talvi, 2003) of these inflows, leading to...
HIPC countries as suffering from ‘debt intolerance’ (Reinhart, Rogoff and Savastano, 2003).

In parallel to these events involving countries borrowing from private markets, there was growing concern that the poor economic performance of many low-income countries was due to excessive indebtedness. A fundamental difference for these countries was that they had virtually no access to private markets for lending: debt stocks had been accumulated with official bilateral and multilateral lenders. There is no rollover risk and the behaviour of private lenders is not an issue. On the other hand, a number of economists in the 1980s began to emphasize debt overhang as a deterrent to growth in heavily indebted poor countries, or ‘HIPC countries’, as they were to come to be known. Others, supported by prominent international NGOs, emphasized that debt service detracted from the resources available for poor countries’ governments to provide basic services for their people.

Debt relief for poor countries dates back to the establishment of the ‘Paris Club’ in the 1950s – the coordinating institution for bilateral creditors to agree on debt relief. Since the early 1980s, however, multilateral efforts to provide debt relief have intensified. Easterly (1999) provides a review of debt relief for poor countries over the previous two decades. The 1977–79 meetings of the United Nations Conference on Trade and Development led to debt write-offs of some $6 billion for 45 low-income countries. In the early and mid-1980s, World Bank reports on Africa increasingly emphasized the debt servicing difficulties of low-income countries. By the late 1980s, debt relief for these countries had entered the agenda of the G7 summits. The summit of 1988 in Toronto established a menu of debt relief terms to be offered to these countries. The multilaterals established special programmes as well: the World Bank’s Special Program of Assistance (SPA) to low-income Africa and the IMF’s Enhanced Structural Adjustment Facility (ESAIF). These facilities would provide fast-disbursing funds to assist in debt repayments.

During the 1990s low-income country debt relief gained further momentum. On the global political front, there was growing support for debt relief – including from religious leaders and high-profile figures in popular culture. The year 2000 marked a symbolic target date for debt relief and ‘Jubilee 2000’ political movements to promote debt relief spread across some 60 countries. According to Jubilee Research, a global petition for debt relief collected 24 million signatures. The ‘Toronto terms’ debt relief mentioned above was followed by a series of expansions of debt relief during international summits in the early 1990s. In 1996, the World Bank and the IMF established the Highly Indebted Poor Country (HIPC) Initiative, and in the same year, the Paris Club of bilateral creditors committed to 80 per cent debt relief in net present value terms (Easterly, 1999). In 1999, the HIPC initiative was ‘enhanced’ to provide faster and broader debt relief and to link debt relief with the elaboration of poverty reduction strategies (as countries were asked to prepare Poverty Reduction Strategy Papers, or PRSPs). These papers would be prepared in collaboration with, and with the support of, the World Bank and IMF. The IMF initiated a new lending facility called the Poverty Reduction and Growth Facility (PRGF) to provide interim financing to the HICPs as they prepared these papers.

The technical criterion for a low-income country to be considered ‘highly indebted’ is either a net present value (NPV) of debt greater than 150 per cent of exports or an NPV of debt greater than 250 per cent of government revenues. HICPs must pass through a process of several steps before receiving debt relief. A ‘Decision Point’ is reached when a country displays a minimum degree of macroeconomic stability, has cleared any arrears in debt service, and has prepared an Interim PRSP. The World Bank and IMF also prepare a debt sustainability analysis at this stage. At the decision point, an initial level of debt relief is granted ‘conditionally’ upon successful passage to the ‘Completion Point’ stage. During the ‘interim’ period between the decision point and completion point, the IMF provides financing under a PRGF and the World Bank may provide policy-based credits through the International Development Association (IDA) as well. If a country has achieved satisfactory performance under the agreed measures of a PRGF and the PRSP has been implemented for at least one year, then the country may reach the Completion Point. At this point, debt relief is granted ‘irrevocably’. Additional debt relief – ‘topping off’ – may also be provided by multilateral and bilateral creditors.

As of mid-March 2005, 27 countries had reached or surpassed the Decision Point, of which 15 had reached the Completion Point, representing a total of approximately $32 billion (in NPV terms at the year of the Decision Point) of debt relief committed by multilateral and bilateral creditors (IDA–IMF, 2005). Another 11 countries were at the pre-Decision Point stage. In NPV terms of 2004, the total expected cost is $58 billion. For the 27 Decision Point (or beyond) countries, debt stocks were reduced by two-thirds (see World Bank, 2007). The HIPC Initiative has generated both supporters and critics. A number of NGOs have complained that the process is too slow and onerous. Easterly (1999) emphasizes that debt relief is likely to be followed by a re-accumulation of debt unless countries change their long-run savings preferences. There have been complaints that the targets are too ‘ad hoc’ and the ‘criteria for debt relief too narrow’ (Addison, Hansen and Tarp, 2004). Others have stated that the programme has generated false expectations in that the real resource transfer involved is limited because these debts would have been ‘rolled over’ indefinitely (Cohen, 2001). On the other hand, there have been proposals to expand debt relief, with deeper relief for current HICPs: broadening the scope to include more low-income countries, safeguarding countries from returning to unsustainable debt levels via a new contingency facility, and shifting the focus of future development assistance from loans to grants and with more multilateral coordination of these aid flows (Birdsall and Williamson, 2002). At the annual meetings of the IMF and World Bank in 2005, donor countries committed to additional debt relief, mostly via covering capital losses to the multilateral institutions if they cancel their own loans to HICPs.
Much of the focus of a new system for international debt flows is on how to make crisis resolution less costly for both debtors and creditors. The IMF proposed a new Sovereign Debt Restructuring Mechanism (SDRM) (Krueger, 2002), that would attempt to capture some of the features of corporate debt restructuring in developed countries. The main features of this proposal were fourfold: (a) ‘majority restructuring’ – a mechanism whereby a qualified majority of bondholders could commit the minority to a restructuring agreement; (b) ‘stay on creditor enforcement’ – a period during which creditors would not be able to pursue litigation to receive payment while attempts are made to reach a majority restructuring agreement; (c) protection of creditor interests – guarantees that debtors will not make payments to ‘non-priority’ creditors and that appropriate policies are pursued by the debtor so as not to reduce asset values (an IMF programme might be the means of supporting the latter); and (d) priority financing – a mechanism to reach agreement on ‘new money’ to facilitate the debt restructuring process, with new money receiving ‘senior status’ relative to old debt.

In principle, the SDRM addresses directly many of the incentive and coordination problems discussed above. To date, little progress has been made in implementing the proposal, with perhaps the exception of the first clause. Collective action clauses allow for a pre-defined majority or super-majority of bondholders to commit to a debt restructured with a distressed debtor. Collective action clauses are already common in many debt contracts issued under British law; however, this spontaneous market response does not address the aggregation issue. The clauses are attached and specified for individual bond issues, and thus they would not assure that all privately held debt could come under a single rule. Some other form of international agreement or institution would be needed to solve the aggregation issue.

Lessons from the crises: domestic debt and fiscal management

A combination of accumulating short-term external debt and heavily managed, or fixed, exchange rates can be fatal, leading to debt distress and subsequent economic strife. Many governments in developing countries are, as of the early 21st century, rebalancing their balance sheets towards debt denominated in domestic currency. By de-linking public debt stocks from the exchange rate, countries are gradually overcoming their ‘fear of floating’ the exchange rate. With more competitive exchange rates, a number of previous defaulters are also running balance of payments surpluses and improving their net foreign asset positions. All of these changes are occurring gradually, leaving them exposed to sudden shocks in the external environment.

Fiscal management remains an issue, however, in many of these countries, and it can limit growth prospects. The shift to borrowing locally crowds out domestic private borrowers, especially in those cases where domestic financial systems are still small following collapses during previous debt crisis episodes. In addition, a number of countries still have domestic financial systems with assets and liabilities denominated in foreign currency: another motivation for ‘fear of floating’.

In the end, an excessive dependence on foreign savings is a threat, as taught to us by the fundamentals of the intertemporal external balance constraints discussed earlier. In fact, many analysts have turned their attention to global imbalances involving the persistent current account deficits of the Unites States as a potential source of future disturbances that could affect those developing countries that are gradually trying to unwind their net external liabilities (see, for example, Goldstein, 2005). Clearly, governments can lead by example by securing fiscal surpluses (Gill and Pinto, 2005, conclude from their review that the first major lesson of the debt crises is ‘that paying attention to the government's intertemporal budget constraint . . . is vital’). As well, appropriate financial sector, tax and other microeconomic policies can help stimulate private domestic savings (Cohen, 1992, concludes that a shift up in the capital stock needs to be accompanied by a level of saving consistent with this larger capital stock in order to sustain growth; he notes that the recipient country must also have an unusual combination: a relatively high endowment of human capital and relatively low physical capital). Under these conditions, foreign borrowing can be a healthy complement to domestic savings.

Appointed as the first Crown Governor of the British territory of Sierra Leone in 1808, Thompson was recalled under suspicion of financial impropriety in 1809. The real explanation for his departure, however, had more to do with the fact that the Sierra Leone Company (which had governed since 1790) found excessively disturbing Thompson's determination to rid the colony of an apprenticeship system whose features, as he saw it, were hardly different from those of slavery. The abuses which Thompson observed had developed, it should be noted, despite the fact that the Sierra Leone Company had been set up by anti-slavery philanthropists, including William Wilberforce and the economist Henry Thornton, with the intention of returning liberated slaves from the Americas to Africa (and, it was hoped, to illustrate the profitability of an African colonial trade not based on slavery).

On his return voyage to England, Thompson was the victim of an act of piracy. His vessel was boarded by the crew of a French corvette, and while its captain entertained Thompson, the British vessel was liberated of its cargo and provisions. Once safely back in England, Thompson applied to the Prime Minister (Lord Liverpool) for another official posting, but ‘in case no other situation should present itself’, he considered the possibility of single-handedly introducing the study of political economy into the University of Cambridge ‘in order to provide a living for myself’ (letter to E.P. Sells, January 1811, cited in Johnson, 1957, p. 70). This idea was not entirely fanciful, since Thompson was a graduate of Queen's College (BA, seventh wrangler, 1802) and a fellow of that college. It transpired, however, that the first regular lectures on the subject at Cambridge were given by George Pryme in 1816, and Thompson instead reactivated his commission in the army (into which service he had switched from the navy in 1806). His command of a defeat at Muscat led to his being court martialled but acquitted (though with a reprimand for ‘rashly undertaking the expedition with so small a detachment’) in 1820. In 1822 Thompson played an active role in the founding the Westminster Review (financed by a £4,000 advance from Bentham), which aimed to provide a radical alternative to the Tory Quarterly Review and
the Whig *Edinburgh Review*. James Mill turned down the offer of its editorship, although he did contribute to its first number (in 1824) for which Thompson himself wrote an article on the ‘Instrument of exchange’. This constituted his first published work on economics. Thompson was sole proprietor of the *Review* from 1829 until 1836 when, on his election to the reformed House of Commons for the seat of Hull (where he had been born on 15 March 1783), he transferred its ownership to William Molesworth.

In 1826 Thompson published the first of his longer tracts on economics, *An Exposition of Fallacies on Rent, Tithes, &c.* Ostensibly an attack on the Ricardian theory of rent (indeed, Thompson retitled its second edition *The True Theory of Rent in Opposition to Mr Ricardo and Others*), John Stuart Mill described it as ‘a striking exemplification of the mistakes of an ingenious, but not thoroughly informed mind’ and claimed that, in fact, Thompson's ‘theory of rent differs from that of Mr Ricardo only in the expression’ (1828, pp. 178–9). However, Mill's claim is open to question. Thompson argued that rent was determined by ‘the limited quantity of land in comparison with the competitors for its produce’ (1826, pp. 8–9) – quite how this could be said to be essentially Ricardo's theory ‘in different words’ is difficult to see. Not only does it fail to distinguish between extensive and intensive rent, but it ignores altogether the effect on the conditions of production of wage goods of restrictions on the importation of corn which is the key to Ricardo's argument. The only observation that needs to be made about Mill's claim is, perhaps, that it may tell us rather more about his own contribution to the decline of Ricardian economics than about Ricardo's theory of rent. That Mill could advance such a claim within five years of Ricardo's death makes it less difficult to understand why many felt that ‘little remained of Ricardo's theory’ by the end of that decade.

In 1827 followed the *Catechism of the Corn Laws* which Mill pronounced ‘one of the most useful works which have appeared in the present controversy’ (1828, p. 186); an interesting judgement given that its opening section was based on the *Exposition*. The *Catechism* presents a list of 120 (later increased to 365) ‘Proteus-like fallacies’ and answers, and has been referred to as ‘the arsenal whence the Anti-Corn Law League drew its best weapons’ (Allibone, 1871). There then followed, during the seven years he owned the *Westminster Review*, better than 100 articles for that periodical on subjects as diverse as the reform of the House of Lords and Catholic emancipation. Most of these were republished in his multi-volume *Exercises, Political and Other* in 1842. Also to be mentioned are his opinions on currency questions (for example, 1848), where he was an opponent of ‘inflationist’ proposals largely on the grounds of the redistribution against workers which he saw as part of the process. In the crisis of 1847, when the Bank Act of 1844 was again the subject of hot debate, Thompson wrote: ‘I hold to my opinion that there will be mischief on the Currency question. I receive more half-mad pamphlets from Birmingham’ (letter to J. Bowring, April 1847, quoted in Johnson, 1957, p. 265). In 1852 he attempted to introduce into Parliament measures which would protect the value of the currency against depreciation due to new gold discoveries, but these were defeated.

There is much more that could be said of Thompson's remarkable career. He was a moral-force, class-alliance chartist (and was invited to participate in writing the draft act of parliament which was to become the People's Charter); he voted consistently with the Radicals when a member of parliament; he constructed, and published, a non-axiomatic system of geometry (Euclid without the axioms); and he invented an enharmonic organ which was exhibited at the Great Exhibition of 1851, where it received an honourable mention. He died at Blackheath on 6 September 1869.

Article

I. Henry Thornton was born in 1760, the youngest son of John Thornton, a London merchant prominent in the Russian trade. All three of John Thornton's sons were important in the business community and all three served as Members of Parliament. The eldest, Samuel, followed his father in the Russian trade, was director of the Bank of England, and its Governor between 1799 and 1801; Robert served as Governor of the East India Company for a time, but business reverses were eventually to lead to his emigration to the United States; and Henry become an extremely successful London banker. He died, probably from consumption, in 1815.

John Thornton had been and early member of the Evangelicals, as those followers of John Wesley who remained within the Church of England were called, and Henry too was among their leaders, the most famous of whom was his second cousin and close friend William Wilberforce. The movement became known as the Clapham Sect largely because their informal headquarters was Thornton's country house, located in that then outlying village. The Evangelical were also known as 'the Party of Saints' and what we would now regard as the conventional piety and respectability of the Victorian middle classes owe much to their influence. Nevertheless, their milieu was not Victorian but Georgian and Regency England, where their insistence that public policy be informed by the same high moral purpose as their private lives was profoundly radical. Their best-known accomplishment was ending Britain's participation in the slave trade in 1809, and in 1833 the abolition of slavery itself in the British Empire; but the role of their Sunday School Movement in promoting popular literacy in Britain, not to mention the influence of their British and Foreign Bible Society on 19th-century missionary activity throughout the world, is also noteworthy.
Henry Thornton was at the centre of all of these activities and many others as organizer, fund-raiser and donor. Before his marriage in 1796 he habitually devoted six-sevenths of his considerable income to charity, and perhaps a quarter thereafter. During his 33 years’ service in Parliament, in addition to his work against the slave trade, he supported such progressive causes as peace with the American colonies, accommodation with France, and Catholic Emancipation. He also devoted considerable time and energy to religious writings and his great-great-grandson E.M. Forster (1951) records that his posthumously published volume of *Family Prayers* was something of a Victorian bestseller which was still earning royalties for his descendants at the end of the 19th century.

Among all of this activity, Henry Thornton found time to study monetary economics. As a prominent banker and Member of Parliament it was natural that he would take a practical interest in such matters, particularly given the financial turbulence associated with the French Wars of 1793–1815 and the suspension of the gold convertibility of Bank of England notes which accompanied them. He gave evidence to the Parliamentary Committees enquiring into the circumstances of the suspension in 1797, and he was an important member of both the Commons Committee which investigated Irish currency problems in 1804 and the famous ‘Bullion Committee’ of 1810. However, he was also and above all a great monetary theorist, and his outstanding treatise, *An Enquiry into the Nature and Effects of the Paper Credit of Great Britain* (1802), gives him a strong claim to be regarded as the most important contributor to monetary economics between David Hume (1752) and Knut Wicksell (1898). Only David Ricardo could seriously be regarded as his rival here.

II. The early 18th century had seen considerable progress in monetary economics, and David Hume's three essays of 1752 are rightly regarded as containing the core of classical monetary theory. They set out the quantity theory doctrine that, other things being equal, the price level varies with the quantity of money, and accompany this with an analysis of the way in which, under a commodity standard, balance of payments mechanisms operate so as to equalize price levels and distribute the precious metals among countries. Although allowing that monetary changes can have short-run effects on real output, they also develop the basic classical postulate that money is neutral in the long run, affecting only prices; and in particular they argue that the rate of interest is not a monetary phenomenon.

Banks are scarcely mentioned in Hume's analysis, and though Adam Smith (1776) paid considerable attention to them, his model was the 18th-century Scottish system. Scottish commercial banks held their reserves in claims upon London, not upon any Scottish central bank, and Scotland was a small, largely price-taking economy. Hence Smith's analysis of the interaction of bank behaviour, the price level and the balance of payments, though remarkably perceptive, was far from complete. It had little to say about the transmission mechanisms at work here and about the role of financial assets other than banknotes in the monetary system. Moreover it had nothing at all to say about central banking.

By the 1790s, the development of the English monetary system had far outstripped the growth of knowledge concerning the principles that underlay its operations, and the financial crisis which culminated in the suspension of February 1797 drew attention to this gap in most dramatic fashion. Thornton's *Paper Credit*, published in 1802 but perhaps begun as early as 1796, not only remedied this deficiency, but brought monetary theory to a level of sophistication that it was not to surpass until the end of the 19th century, as a brief sketch of its contributions will make quite evident.

III. *Paper Credit* begins with a detailed description of the contemporary English monetary system, showing how a rather wide variety of credit instruments had come to circulate as what we would now call money, alongside coin and banknotes, and it argues that the velocities of various components of this
complex ‘circulating medium’ differ among instruments and fluctuate over time. In common with virtually every monetary economist before Irving Fisher (and many thereafter), Thornton regarded velocities of circulation as frequently unstable and he discussed in some detail how the Bank of England should behave, both to minimize the occurrence of monetary instability and to offset its consequences when it arose. Thornton was by no means the only contributor to the ‘Bullionist Controversy’, as the debates of the period are called, to recognize the crucial role and responsibilities of the Bank of England as a central bank, but there were many, not least among the directors of that institution, who refused to do so; and Thornton's exposition of the issues involved represents an important contribution to monetary economics.

No doubt drawing upon his own first-hand observations of the mechanisms at work during the turbulent 1790s, Thornton stressed both the crucial role and the volatility of the public's confidence in the banking system's ability to redeem its liabilities (in terms of Bank of England notes in the case of country and private London banks, and, under convertibility, in terms of specie in the case of the Bank of England). He understood that bank customers, who were confident that they could obtain Bank of England notes or specie when they required it, would not in fact seek such accommodation, and that only those who had doubts about the convertibility of their assets would demand their redemption. Hence he argued that any initial fall in confidence could lead to a self-reinforcing drain of reserves from the system if the Bank of England responded to it by reducing lending and hence cutting down the supply of the very central bank notes that the public were demanding from country and London banks. For Thornton, the right response to such an ‘internal’ (that is, within the country) drain of reserves from the banking system was for the Bank of England to lend freely to all solvent borrowers in order to restore and maintain the public confidence in the system. In short, the by now conventional textbook analysis of the central bank's 'lender of last resort' function found its first full statement in *Paper Credit*.

But Thornton understood well enough that an internal drain was not the only possible source of pressure on reserves. An external drain associated with what we would now call an adverse balance of payments was also a possibility, and here the required remedy might be different. He was clear that, to the extent that the drain stemmed from an uncompetitively high domestic price level, it could only be remedied by monetary contraction, and hence by the central bank scaling down its loans, including those made to the rest of the banking system. In the conventional wisdom of the later 19th century concerning sound central bank practice, an external drain was always appropriately to be met by such measures, but Thornton (unlike Ricardo, who is the true father of that conventional wisdom) was more subtle than this in his analysis.

For him, money wages were sticky and any sudden monetary contraction carried with it the danger of disrupting markets and causing real output and employment to fall, a danger to be avoided if at all possible. Hence when developing the implications for Bank of England policy of his pioneering analysis of what was later to be called ‘the transfer problem’, he advocated that temporary drains of specie abroad, associated with bad harvests or once and for all subsidy payments to allies, be accompanied by as little domestic monetary contraction as seemed to that institution to be prudent. Under arrangements prevailing after 1797, he was even willing to entertain temporary departures of sterling from par with specie in the face of temporary external drains rather than risk the domestic disruption that might accompany monetary contraction. Thornton was thus in *Paper Credit* far from being an advocate of an automatic gold standard, and his views have something in common with those of such later advocates of managed paper currency as Thomas Attwood – not to mention John Maynard Keynes, as certain
commentators, notably Hicks (1967) and Beaugrand (1981) have pointed out.

IV. McCulloch (1845), who confused Henry with his brother Samuel, regarded *Paper Credit* as being too partial to the Bank of England in its arguments, but though it may certainly be regarded as a defence of that institution's behaviour during the early years of the restriction, it is nevertheless a critical defence. Even so, by 1810, Henry Thornton was a prominent member of the Bullion Committee, and had become one of the Bank's sternest critics, advocating, both as a signatory to the Committee's Report (Cannan, 1919) and in two Commons speeches on the Report, that the obligation to redeem its notes in specie be reimposed upon it as soon as possible, a measure which was designed to narrow considerably the scope for discretion left to the Bank when confronted with an external drain.

Thornton's policy stance had changed between 1802 and 1810, but there is no evidence that his underlying analytic views were any different. First and foremost, and despite certain affinities, mentioned above, between his work and that of subsequent advocates of managed paper standards, Henry Thornton was always, as Hicks (1967) has put it, a ‘hard money’ man as far as long-run policy questions were concerned. He regarded the maintenance of the specie value of Bank of England liabilities as the proper overriding end of monetary policy. After 1797 he expected the Bank of England, subject to certain caveats about bad harvests and once and for all transfers, to manage its discounts so as to stabilize the exchange rate and the price of specie. In 1802 he believed that the Bank could be trusted to do so without the check of convertibility, but by 1810 he had changed his mind.

Though the actual conduct of monetary policy, particularly after 1811, shows that, luckily for Britain, they did not always practise what they preached, the directors of the Bank declared themselves firmly committed to the so-called ‘real bills doctrine’ in their evidence to the Bullion Committee, as they did in many other statements. This doctrine distinguishes between ‘real bills’, drawn to finance goods in the process of production and distribution, and ‘fictitious bills’ those which simply represent a debt with no corresponding real asset to back them. It then argues that a banking system in general, and a central bank in particular, which confines its activities to the discount of the former, cannot affect the price level. The quantity of money generated by following such practices will, so it is claimed, vary with the volume of output and adjust itself automatically and passively to the ‘needs of trade’.

Thornton had considered and comprehensively refuted this bundle of fallacies in *Paper Credit*. He had shown that, because there is no necessary relationship between the period for which commercial bills are discounted and the period of time that elapses between the beginning of the production of a particular unit of output and its final consumption, the distinction between ‘real’ and ‘fictitious’ bills was specious. Distinguishing between credit per se, and the role of credit instruments as components of the circulating medium, he had also shown how money, even if created against the security of good quality commercial bills, could influence the price level. Finally, and crucially, he had shown that the demand of manufacturers and merchants for bank credit would vary with the relationship between the banking system's lending rate and the expected rate of profit in such a way that, if the latter were high relative to the former, potentially unlimited monetary expansion and inflation could be generated by a banking system whose central authority took the real bills doctrine as its sole operating guide.

These arguments of Thornton's play a central role in the 1810 *Report* of the Bullion Committee and reflect his influence on that document. The explicit rejection of them by the directors of the Bank of England, not to mention widespread concern about inflation during 1809–10, was a crucial factor in persuading the committee in general, and Thornton in particular as one of its key members, to recommend that the constraint of specie convertibility be reimposed upon the Bank as soon as possible,
a recommendation which was, of course, rejected by Parliament in 1811 along with the rest of the Bullion Report.

V. The reader familiar with the later literature of monetary economics will recognize the essentially Wicksellian (for example, 1898) flavour of Thornton's discussion of the relationship between bank lending policies and inflation. In a parliamentary speech of 1811 on the Bullion Report he elaborated on his earlier analysis by allowing for the influence of inflation expectations on the perceived real interest burden implied by any given nominal bank lending rate. This insight, which plays only an occasional and peripheral role in Wicksell's work, was of course central to the contributions of another great monetary theorist, Irving Fisher (1896). Moreover in his analysis of these matters, Thornton developed a version of what was later to be called the ‘forced saving’ doctrine which played an important role in early 20th-century business cycle theory. In the light of all this, it would be easy to jump to the conclusion that Thornton's work was well known to his successors. However, it was not.

Failing health and a relatively early death removed Henry Thornton from the centre of monetary controversy just as David Ricardo came to the height of his powers and influence. It was Ricardo and not Thornton who was destined to become the recognized authority to whom 19th-century monetary economists working within the classical tradition looked for guidance in matters of monetary theory. As Hutchison (1968) points out, J.S. Mill (1848) was the last important 19th-century author to recognize Thornton's contributions. Thereafter, his name faded from view, and was not even known to Wicksell; it is largely due to the efforts of Jacob Viner (1924; 1937) and particularly Friedrich von Hayek (1939) that his true stature came to be appreciated in the 20th century. Nevertheless, his ideas were well known to his contemporaries, not least to Ricardo, and as transmitted by them, not always without a certain loss of subtlety, they permeate 19th-century classical monetary theory. Thus if Henry Thornton's name was often forgotten by economists, his contributions to the subject were certainly not. For most men, this would be small consolation indeed, but one suspects that so benevolent and self-effacing a man as Henry Thornton might have been content with such an outcome.

Threshold models

Timo Teräsvirta
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article contains a short account of threshold, smooth transition and Markov switching autoregressive models. Neural network models are highlighted as well. Linearity testing, parameter estimation and, more generally, modelling are considered. Forecasting with threshold models receives attention. Suggestions for further reading are supplied.

Keywords

ARIMA models; artificial neural network models; asymmetric behaviour; forecasting; identification; likelihood; linear models; logistic smooth transition regression models; Markov chains; Markov-switching models; maximum likelihood; modelling; purchasing power parity; regression error specification test; smooth transition regression models; switching regression models; threshold autoregressive models; threshold models

Article

The models

Stochastic nonlinear models have been widely used in economic applications. They may arise directly from economic theory. There also exist nonlinear models that have first been suggested by statisticians, engineers and time series analysts and then found application in economics. A broad class of these models, here called threshold models, has the property that the models are either piecewise linear or may be more generally considered as linear models with time-varying parameters. This category of nonlinear models includes switching regression or threshold autoregressive models, smooth transition models, Markov-switching or hidden Markov models. Artificial neural network models may also be included in this class of nonlinear models.

The switching regression (SR) model or, in its univariate form, the threshold autoregressive (TAR)
Threshold models: The New Palgrave Dictionary of Economics

Model, is defined as follows:

$$y_t = \sum_{j=1}^{r} (\alpha_j' z_t + \epsilon_{jt})(\xi_{j-1} < s_t \leq \xi_j)$$

(1)

where $z_t = (w'_t, x'_t)$ is a vector of explanatory variables, $w_t = (1, y_{t-1}, \ldots, y_{t-p})'$ and $x_t = (x_{1t}, \ldots, x_{kt})'$, $s_t$ is an observable switch-variable, usually assumed to be a continuous stationary random variable, $\xi_0, \xi_1, \ldots, \xi_r$ are switch or threshold parameters, $\xi_0 = -\infty$, $\xi_r = M < \infty$, and $I(A)$ is an indicator function: $I(A) = 1$ when event $A$ occurs; zero otherwise. Furthermore, $\alpha_j = (\alpha_{0j}, \alpha_{1j}, \ldots, \alpha_{mj})'$ such that $\alpha_i \neq \alpha_j$ for $i \neq j$, where $m = p + k + 1$, $\epsilon_{jt} = \sigma_j \xi_t$ with $\{\xi_t\} \sim \text{iid}(0, 1)$, and $\sigma_j > 0$, $j = 1, \ldots, r$. It is seen that (1) is a piecewise linear model whose switch-points, however, are generally unknown. The most popular choice in applications is $r=2$, that is, the model has two regimes. If $s_t = t$, eq. (1) is a linear model with $r-1$ breaks and $\alpha_j \neq \alpha_{j+1}$, $j = 1, \ldots, r-1$.

These models have recently become quite popular in econometrics and there is now a substantial literature on how to determine the number of breaks and estimate the break points. For a generalization of the threshold autoregressive regression model to the vector case, see Tsay (1998).

TAR models have been used to characterize asymmetric behaviour in GNP or unemployment rates and to consider the purchasing power parity hypothesis. They have also been applied to modelling interest rate series as well as other financial time series.

One may substitute $l(s_t = j)$ for $I(\xi_{j-1} < s_t \leq \xi_j)$ in (1), where $s_t$ is an unobservable regime indicator with a finite set of values $\{1, \ldots, r\}$. On the assumption that $s_t$ follows a first-order Markov chain, that is, $\Pr\{s_t = j | s_{t-1} = i\} = p_{ij}, i, j = 1, \ldots, r$, (1) becomes a hidden Markov or Markov-switching (MS) model (see Lindgren, 1978). Higher-order Markov chains are possible but rarely used in econometric applications.

Equation (1) with an unobservable regime indicator is not, however, the most frequently applied hidden Markov model in econometrics. Consider the univariate model

$$y_t = \mu s_t + \sum_{j=1}^{p} \alpha_j (y_{t-j} - \mu s_{t-j}) + \epsilon_t$$

(2)
where $s_t$ follows a first-order Markov chain as before, and $\mu_{s_t} = \mu (\theta)$ for $s_t=i$, such that $\mu (\theta) \neq \mu (\theta'), i \neq j$.

The stochastic intercept of this model, $\mu_{s_t} - \sum_{j=1}^{p} \alpha_j \mu_{s_t-j}$, can thus obtain $p+1$ different values, which gives the model the desired flexibility. A comprehensive discussion of MS models can be found in Hamilton (1994, ch. 22). The model (2) has been frequently fitted, for example, to GNP series and interest rates. In the latter case, the model may be used for identifying changes in the monetary policy of the central bank.

SR and Markov-switching models contain a finite number of regimes. There is a class of models called smooth transition regression (STR) models, in which there are two ‘extreme regimes’, and the transition between them is smooth. A basic STR model is defined as follows:

$$Y_t = \Phi ' Z_t + \Psi ' Z_t G(\gamma, c, s_t) + \epsilon_t$$

(3)

where $\Phi = (\phi_0, \phi_1, ..., \phi_m)'$ and $\Psi = (\psi_0, \psi_1, ..., \psi_m)'$ are parameter vectors, $c = (c_1, ..., c_K)'$ is a vector of location parameters, $c_1 \leq ... \leq c_K$, and $\epsilon_t \sim iid(0, \sigma^2)$. The transition function $G(\gamma, c, s_t)$ is a bounded function of $s_t$, continuous everywhere in the parameter space for any value of $s_t$. The logistic transition function has the general form

$$G(\gamma, c, s_t) = \left(1 + \exp \left\{ -\gamma \prod_{k=1}^{K} (s_t - c_k) \right\} \right)^{-1}, \gamma > 0$$

(4)

where $\gamma > 0$ is an identifying restriction. Equation (3) jointly with (4) defines the logistic STR (LSTR) model. The most common choices in practice for $K$ are $K=1$ and $K=2$. For $K=1$, the parameters $\Phi + \Psi G(\gamma, c, s_t)$ change monotonically as a function of $s_t$ from $\Phi$ to $\Phi + \Psi$. For $K=2$, they change symmetrically around the mid-point $(c_1 + c_2)/2$ where this logistic function attains its minimum value.

Slope parameter $\gamma$ controls the slope and $c_1$ and $c_2$ the location of the transition function. When $K=1$ and $\gamma \to \infty$ in (4), the model (3) becomes an SR model with $r=2$.

The LSTR model with $K=1$ (LSTR1 model) is capable of characterizing asymmetric behaviour. As an example, suppose that $s_t$ measures the phase of the business cycle. Then the LSTR1 model can describe processes whose dynamic properties are different in expansions from what they are in recessions, and the transition from one extreme regime to the other is smooth. The same is true for SR and the MS models with the difference that instead of a smooth transition there is an abrupt switch. The LSTR2
model is appropriate whenever the dynamic behaviour of the process is similar at both large and small values of $s_t$ and different in the middle.

Yet another nonlinear model that is worth mentioning because it is related to threshold models is the artificial neural network (ANN) model. The simplest single-equation case is the so-called ‘single hidden-layer’ ANN model. It has the following form

$$y_t = \beta_0' z_t + \sum_{j=1}^{q} \beta_j G(y_j' z_t) + \varepsilon_t$$

where $y_t$ is the output series, $z_t$ is the vector of inputs, and $\beta_0' z_t$ is a linear unit with $\beta_0 = (\beta_{00}, \beta_{01}, \ldots, \beta_{0, q_0 + k})'$. Furthermore, $\beta_j$, $j = 1, \ldots, q$, are parameters, called “connection strengths” in the neural network literature. Function $G(\cdot)$ is a bounded, asymptotically constant function called the ‘squashing function’ and $\gamma_j$, $j = 1, \ldots, q$, are parameter vectors. They form the hidden layer which the name of the model refers to. Typical squashing functions are monotonically increasing ones such as the logistic function and the hyperbolic tangent function. The errors $\varepsilon_t$ are often assumed iid $(0, \sigma^2)$. Many neural network modellers assume $\beta_0 = \beta_0 0$, where $\beta_{00}$ is called the ‘bias’.

A theoretical argument for the use of ANN models is that they are universal approximators. Suppose that $y_t = H(z_t)$, that is, there exists a functional relationship between $y_t$ and $z_t$. Then, under mild regularity conditions for $H$, there is a positive integer $q \leq q_0 < \infty$ such that for an arbitrary $\delta > 0$,

$$|H(z_t) - \sum_{j=1}^{q} \beta_j G(y_j' z_t)| < \delta.$$ 

The importance of this result lies in the fact that $q$ is finite, so that any unknown function $H$ can be approximated arbitrarily accurately by a linear combination of squashing functions $G(y_j' z_t)$. This has been discussed in several papers, including Cybenko (1989), Funahashi (1989) and Hornik, Stinchcombe and White (1989). Neural network models are very generously parameterized and are only locally identified. The log-likelihood typically contains a large amount of local maxima, which makes parameter estimation difficult.

**Testing linearity**

All threshold models nest a linear model but they are not identified when the data are generated from this linear model. For this reason, testing linearity before fitting a threshold model is necessary in order to avoid the estimation of an unidentified model whose parameters cannot be estimated consistently. In this case, linearity testing has to precede any nonlinear estimation.

There exist general misspecification tests that are linearity tests if the specification to be tested is linear; see Bierens (1990) and Stinchcombe and White (1998). There also exist parametric tests that have been
threshold models: The New Palgrave Dictionary of Economics
designed to be tests against an unspecified alternative but are not consistent against deviations from
linearity. The popular Regression Error Specification Test (RESET) of Ramsey (1969) is such a test.
Teräsvirta (1998) and van Dijk, Teräsvirta and Franses (2002) discuss tests against smooth transition
regression models and Hansen (1999) surveys linearity testing against TAR models. Linearity testing in
the Markov-switching framework is considered in Garcia (1998). Some recent econometrics textbooks
discuss linearity tests against various threshold models.

As already mentioned, threshold models nest a linear model and are not identified if linearity holds. For
example, the STR model (3) is not identified if \( \gamma = 0 \) in (4) or \( \psi = 0 \). In the former case, \( \psi \) and \( \epsilon \) are not
identified, and in the latter, the nuisance parameters are \( \gamma \) and \( \epsilon \). Consequently, the standard asymptotic
theory is not applicable in testing linearity. This problem may be solved following Davies (1977). Let \( \gamma \)
be the vector of nuisance parameters. For example, \( \gamma = (\gamma, \epsilon) \) in (3) when the null hypothesis is \( \psi = 0 \).
When \( \gamma \) is known testing linearity is straightforward. Let \( S_T(\gamma) \) be the corresponding test statistic
whose large values are critical and define \( \Gamma = \{ \gamma: \gamma \in \Gamma \} \), the set of admissible values of \( \gamma \). When \( \gamma \) is
unknown, the statistic is not operational because it is a function of \( \gamma \). The problem is solved by defining
another statistic \( S_T = \sup_{\gamma \in \Gamma} S_T(\gamma) \) that is free of nuisance parameters \( \gamma \). The asymptotic distribution
of \( S_T \) under the null hypothesis does not generally have an analytic form, but Davies (1977) gives an
approximation to it that holds under certain conditions, including the assumption that
\( S(\gamma) = \lim_{T \to \infty} S_T(\gamma) \) has a derivative. Other choices of test statistic include the average:

\[
S_T = \text{ave} S_T(\gamma) = \int_{\Gamma} S_T(\gamma) dW(\gamma) \\
(6)
\]

where \( W(\gamma) \) is a weight function defined by the user such that \( \int_{\Gamma} W(\gamma) d\gamma = 1 \), and the exponential

\[
\exp S_T = \ln \left( \int_{\Gamma} \exp \left( \frac{1}{2} S_T(\gamma) \right) dW(\gamma) \right). \\
(7)
\]

Andrews and Ploberger (1994) have recommended these tests and demonstrated their local asymptotic
optimality properties. The statistics (6) and (7) are two special cases in the family of average exponential
tests (for definitions and details, see Andrews and Ploberger, 1994). Hansen (1996) shows how to obtain
asymptotic critical values for these statistics by simulation under rather general conditions. His method
is computationally intensive but useful. It may be pointed out that it works for SR and STR models
where \( s_t \) is observable. For MS models, the situation is more complicated, see Garcia (1998) for
A computationally simpler alternative is to circumvent the identification problem instead of directly solving it. It has been popular in testing linearity against smooth transition models, eq. (3). The idea is to replace the transition function (4) by its Taylor series approximation around the null hypothesis $\gamma = 0$. This transforms the testing problem into one of testing a linear hypothesis in a linear auxiliary regression; see Luukkonen, Saikkonen and Teräsvirta (1988) or Teräsvirta (1998).

**Parameter estimation**

Parameters of threshold models have to be estimated numerically. This is because the objective function to be optimized is not quadratic in parameters, so an analytical solution to the problem does not exist. The easiest models to estimate are the switching regression or threshold autoregressive models. Their parameters are estimated conditionally by ordinary least squares (OLS), given the switch parameters $c_1, \ldots, c_r$, and the combination of $c_1, \ldots, c_r$ yielding the smallest sum of squared residuals gives the estimates of these and the other parameters. For example, when $r = 1$ the OLS estimation is repeated for a set of $c_1$ values such that both regimes contain at least a certain minimum amount of observations, typically 10% or 15% of the total number. Under rather general conditions, including stationarity and ergodicity of the TAR process, the least squares estimators are $\sqrt{T}$-consistent and asymptotically normal. The threshold parameter estimators are super ($T$-) consistent.

Smooth transition models are estimated using standard maximum likelihood. The most efficient numerical method is the Newton–Raphson method that makes use of both the first (the score) and the second (the Hessian) partial derivatives of the log-likelihood function. It has many variants in which the Hessian is replaced by computationally simpler alternatives that either do not require second derivatives, such as the method of scoring or the so-called Berndt–Hall–Hall–Hausman (BHHH) algorithm, or avoid inverting the Hessian altogether. Examples of this include the steepest descent and variable metric methods. Of the latter, the Broyden–Fletcher–Goldfarb–Shanno (BFGS) algorithm can be found in a number of modern software packages.

Hidden Markov models cannot be estimated using standard optimization algorithms because they contain the latent variable $s_t$. Their parameters are typically estimated using the expectation–maximization (EM) algorithm (see Cappé, Moulines and Rydén, 2005, and Hamilton, 1994, ch. 22). Estimation of ANN models using maximum likelihood is often numerically demanding because the likelihood function can contain a large number of local maxima, due to a large number of parameters. This problem has been discussed in Medeiros, Teräsvirta and Rech (2006) and White (2006). Because of this difficulty, the literature on ANN models contains a wide variety of estimation methods of various kinds; see for example Fine (1999) and White (2006).

**Modelling**

Typically, economic theory does not uniquely determine the functional form of a threshold model. This means that the model builder has to select an appropriate model for the problem at hand. In this case, applying a consistent modelling strategy is helpful. The modelling approach of Box and Jenkins (1970)
for the ARIMA class of linear models is a case in point. When it comes to threshold models, modelling strategies consisting of stages of specification, estimation and evaluation have been worked out and applied for TAR or, more generally, SR classes of models as well as STR models. For the former, see Tsay (1989) (univariate models) and Tsay (1998) (multivariate models) and for the latter, Teräsvirta (1998) or Teräsvirta (2004). Medeiros, Teräsvirta and Rech (2006) suggest a similar procedure for ANN models. An essential first stage in all these strategies is testing linearity. If linearity is not rejected, the task of the model builder is considerably simplified.

**Forecasting**

The main purpose of univariate nonlinear models is forecasting. Multivariate models may also be useful for policy analysis. Forecasts are typically conditional means in which the conditioning set consists of a subset of the information available at the time of making the forecast. In nonlinear models such as threshold models, a typical situation is that making forecasts for more than one period ahead requires numerical methods. This is due to the fact that for a random variable $X$, generally $Eg(X) \neq g(EX)$. Equality holds if $g$ is a linear function of $X$.

To illustrate, assume an information set $\mathcal{F}_T$ at time $T$. The optimal one-period mean forecast

$$f^{y}_{T,1} = E\{y_{T+1} | \mathcal{F}_T\},$$

the conditional mean of $y_{T+1}$, given $\mathcal{F}_T$. For example, consider the simple bivariate model

$$y_t = g(x_{t-1}) + \varepsilon_t$$  \hspace{1cm} (8)

where

$$x_t = \beta x_{t-1} + \eta_t$$  \hspace{1cm} (9)

with $|\beta| < 1$, and $\{\eta_t\}$ is a sequence of independent, identically distributed random variables with zero mean. Function $g(\cdot)$ may define an SR, STR or ANN model. The forecast for $y_{T+1}$ equals

$$f^{y}_{T,1} = g(x_T)$$

as $E\{\varepsilon_{T+1} | \mathcal{F}_T\} = 0$. Thus, if one knows the function $g(\cdot)$, one-step forecasts can be obtained with no difficulty.

The optimum two-step forecast is
As $x_{T+1}$ is not usually known at time $T$, it has to be forecast from its autoregressive equation. This gives a one-step OLS forecast $f_{T,1}^x = \beta x_T$. The two-step forecast equals

$$f_{T,2}^y = E\left\{g(x_{T+1})|\mathcal{F}_T\right\}. \tag{10}$$

The exact forecast equals

$$f_{T,G}^y = \int_{-\infty}^{\infty} g(f_{T,1}^x + z) dD(z)$$

where $D(z)$ is the cumulative distribution function of $z$. The integral has to be calculated numerically. It may, however, also be approximated by simulation or by bootstrapping the residuals of the estimated model; see Granger and Teräsvirta (1993) or Teräsvirta (2006a). This alternative becomes even more practical when the forecast horizon exceeds two periods. Yet another alternative is to ignore the error $\eta_{T+1}$, but the “naive” forecast $f_{T,2}^y = g(f_{T,1}^x)$ is biased. In practice, the function $g(\cdot)$ is not known and has to be specified and estimated from the data before forecasting.

One may also obtain the forecast directly as

$$f_{T,2}^y = E(y_{T+2}|\mathcal{F}_T)$$

so that $y_{T+2} = g_2(x_t, y_t) + \xi_t^*$, say, and the function $g_2(\cdot)$ has to be determined and estimated separately, rather than derived from the one-step representation (8). A difficulty with this approach is that the errors will not necessarily be white noise. A separate forecast function is needed for each forecast horizon.

All forecasts from hidden Markov models can be obtained analytically by a sequence of linear
threshold models: The New Palgrave Dictionary of Economics

operations. This is a direct consequence of the fact that the regimes in (1) when \( t \leq c_j \leq t + 1 \) is replaced by \( \{ s_t = j \} \), where \( s_t \) is a latent discrete variable, are linear in parameters. This is discussed for example in Hamilton (1993) or Teräsvirta (2006a).

Experiences from large empirical studies in which macroeconomic variables are forecast with threshold models, are mixed. No model dominates the others, and in several cases nonlinear threshold models do not improve the accuracy of point forecasts compared to linear models. Recent studies of this type include Stock and Watson (1999), Marcellino (2004) and Teräsvirta, van Dijk and Medeiros (2005).

Thünen, Johann Heinrich von (1783–1850)

Jürg Niehans
Edited by Steven N. Durlauf and Lawrence E. Blume

Article

Thünen was born in Canarienhausen (Oldenburg) on 24 June 1783. He died on his estate Tellow (Mecklenburg), near Rostock, on 22 September 1850. His paternal ancestors were farmers; despite the 'von', they did not belong to the aristocracy. After his father's early death, Thünen's mother married a timber merchant. The boy grew up in a small town on the northern seaboard, where he obtained a good, but short, high-school education. As an apprentice he got to know hard manual labour on a farm. There he followed academic studies on all aspects of agronomy, including natural sciences, mathematics and economics, at the agricultural colleges of Gross-Flottbeck and Celle (where he heard Thaer) and at the University of Göttingen (where he read Adam Smith). Nevertheless, Thünen remained essentially a scientifically gifted autodidact. During this period (around 1803), he seems to have conceived the idea of his 'isolated state'. Newly married to the daughter of a respected landowner, Thünen first operated a rented estate. In 1809, with the inheritance from his father, he bought from his brother-in-law the rather run-down estate of Tellow with about 1,200 acres of land. Though his heart was in his intellectual pursuits rather than in practical farming, he succeeded in gradually paying off his initial debt and in raising the value of his property, leaving to his four children a prosperous estate with ample liquid funds. Like Quesnay, who came from a similar background, Thünen made the farm his economic paradigm. With the Physiocrats and Thaer, he belongs to those representatives of the Enlightenment who regarded improvements in agriculture as the key to economic progress. For his estate he kept meticulous accounts, which he used to compute optimal solutions to management problems. He was a model employer with philanthropic, if somewhat paternalistic, ideas on social policy, who established a profit-sharing plan for his employees.

Of Thünen's magnum opus, 'The Isolated State with Respect to Agriculture and Political Economy', the first part, including the analysis of rent, location and resource allocation, appeared in 1826 after more than 20 years of work. The second part, containing the marginal productivity theory of distribution, only appeared in 1850. Additional papers, including important contributions on forestry, were published in 1863 by Thünen's biographer, H. Schumacher. All of this material is united in the third edition of 1875, but Waentig's later edition and also the English translations are limited to Part I and the first (and more important) half of Part II. Additional material was published by Braeuer in his volume of selected works, which also includes a bibliography of Thünen's writings. The literary remains, including unpublished manuscripts, are preserved in the Thünen-Archiv at the University of Rostock. It has been said that Thünen was a prophet with little honour in any country, and even less in his own. This is inaccurate. It is true that he was at first disappointed about the reception of his book. Nevertheless, by 1827 he was an internationally known authority on agriculture, and the first edition was sold out within seven years. Tellow became a mecca for agronomists, attracting visitors from all over Europe. In 1830, Thünen was made a doctor philosophiae honoris causa by the University of Rostock. Politically a progressive liberal, he was elected to the National Assembly in Frankfurt in 1848, but could not attend because of his declining health. In the same year, the town of Teterow, with flags flying and bands playing, made him an honorary burgher. Like Quesnay, he died revered as a sage.

Thünen's scientific achievements are at different levels. In agronomy he made important contributions to the 'statics' of the soil, which are concerned with the steady state where fertility, by suitable crop rotation and fertilization, is maintained at an optimal level. In economics his most fundamental contribution is the method of deriving economic propositions from explicit optimizing models. By 1824 (as Braeuer reports) this had led him to the differential calculus, which he may thus have been the first to apply to economic problems. At a time when German economists liked to criticize Adam Smith for his 'rationalism', Thünen criticized him for his lack of an explicit theory, which he undertook to provide. In mathematical elegance his contribution falls far short of Cournot's, but it exceeds the latter in breadth and depth. It makes Thünen one of the patron saints of modern economics. A more specific contribution is Thünen's theory of rent, location and resource allocation. In terms of modern economics, its elements can be summarized as follows. Suppose rye is sold in a central city at a given market price \( P \). Production takes place on an unlimited plain of uniform fertility. Transportation to the market over \( s \) miles costs \( ts \) per bushel. The producer price, \( p \), therefore, declines with increasing distance according to \( p = P - ts \), as illustrated in the NE quadrant of Figure 1. Output per acre depends on labour per acre...
Thünen, Johann Heinrich von (1783–1850) : The New Palgrave Dictionary of Economics

According to \( q = q(a) \). At each producer price, the manager selects his method of production in such a way that the marginal product of labour, \( q'(a) \), evaluated at the producer price, equals the given (and uniform) wage rate, as described in the NW quadrant. The curve in the SW quadrant expresses the decline in the marginal product of labour as increasingly more labour-intensive methods are applied. The area ‘below’ the marginal product curve is total product. While the rectangle \( q'(a) \) goes to wages, the shaded residual represents land rent. The curve in the SE quadrant, finally, shows labour intensity as a diminishing function of distance.

Figure 1
The solid curve in Figure 2 graphs land rent from rye production as a diminishing function of distance. Similar rent–distance curves can be constructed for other products like vegetables or lumber. They are represented by, respectively, the dotted and the broken curve. At each distance the farmer will plant the product promising the highest rent. This results in Thünen's famous rings. For a given product there may also be rings of different technologies.

Figure 2
In analysing the comparative statics of the ‘isolated state’, Thünen shows that lower transportation costs and more rapidly diminishing returns tend to increase the distance from the city at which a good is produced or a technology is used. It is important to note that Thünen provides not only a theory of location, but also of factor intensities. That the relative efficiency of different technologies depends on market conditions is one of the main propositions he wanted to demonstrate.

The basic model is extended by Thünen in numerous directions. If the required quantities are given, the model determines their market prices. Since the rural workers do not generally pay the given city prices, their money wages will not actually be uniform. Freight costs may not be proportionate to distance. Substitutes and joint products are discussed. To the flows of agricultural products to the market centre, Thünen adds the reverse flows of consumer goods and means of production (like manure) and he pays attention to the unequal quality of the soil. The problem of the spatial distribution of several cities is raised, though not solved. It is finally shown that agricultural protection, by reducing the efficiency of land use, makes both parties worse off and that land taxes do not distort allocation. Despite its richness, Thünen's analysis remains partial in the sense that it does not determine a general spatial equilibrium. His notions about the price mechanism are crude. The long-winded discourse is replete with empirical calculations, relating Thünen's analysis to his account books down to the most minute details.

By applying his optimizing approach to factor inputs, Thünen became one of the originators of the marginal productivity theory of distribution. Using the Ricardian subterfuge of a rentless margin of cultivation, he explains his basic idea in the following words:

Output $p$ is the joint product of labour and capital. How should the share of each factor in the joint product be measured? We measured the effectiveness of capital by the increment in the output per worker due to an increase in the capital he works with. In this context, labour is constant, but capital is a variable magnitude. Suppose
now that this procedure is continued, but in the reverse sense of considering capital as constant and labour as growing. In this case, in a large-scale operation, the effectiveness of labour (the contribution of the worker to output) is recognized from the increment in total output due to the augmentation of workers by one (II, §19).

As in Turgot, the output increments, from both capital and labour, are postulated to decline with an increasing factor input. The profit-maximizing entrepreneur will determine each factor input in such a way that the sales proceeds from the last unit are equal to the given factor price. This implies that at the point of minimum cost the ratio of factor prices is equal to the ratio of what today would be called their marginal products. The word ‘marginal’ does not occur, but the expressions ‘margin’ or ‘limit’ are constantly used. From the laws that govern actual distribution, Thünen, deeply concerned with the ‘social problem’, proceeded to the laws that ought to govern it. This led him to the most controversial of his achievements, his famous ‘natural wage’ formula. In Thünen’s economy, per capita output, \( p \) (measured in rye), depends on capital per worker, \( q \) (measured in terms of the tools a worker can make in a year). Output is divided between the wage, \( w \), and the rental on capital, \( r \), according to \( p(q) = w + rq \). In sharp contrast to later notions, savings are supposed to come out of wages while property income is consumed. Specifically, savings are the excess of wages over some subsistence minimum, \( a \). The economy is growing by the construction of new farms at the rent-less margin of cultivation.

With interest rate \( (p-w)/wq \), the return on savings is

\[
R = \frac{p - w}{wq} (w - a).
\]

Thünen’s ‘natural wage’ maximizes \( R \) on the assumption of fixed \( q \) (and thus \( p \)). By equating \( dR/dw \) to zero, the natural wage is easily determined as the geometric mean of \( p \) and \( a \),

\[
w = \sqrt[p]{pa}.
\]

Thünen’s cumbersome exposition has given rise to many misunderstandings. Some (including Marshall) argued that the correct interest rate would have been \( (p-w)/q \). In this case, the natural wage turns out to be the arithmetic mean \( w = \frac{1}{2}(p + a) \) (as already suggested by Knapp). This criticism would be valid for a one-sector economy in which \( q \) is simply a stock of rye. Actually Thünen (as noted by Samuelson) considers a (rudimentary) two-sector economy in which capital goods are produced by labour only (at constant cost). Thünen is right, therefore, in valuing \( q \) at the wage rate \( w \).

Another objection (raised, among others, by Wicksell and strongly reiterated by Samuelson) concerns the postulated constancy of \( q \). After all, an increase in \( w \) presumably leads to an increase in \( q \) (and thus in \( p \)). Thünen anticipated this objection, for he supplemented his mathematical derivation, both verbally and by numerical examples, with a cogent explanation of how the overall maximum of \( R \) is to be found by searching over different \( q \) (and thus \( p \)). In fact, if output and marginal productivity wages are allowed to adjust to changes in \( q \), the necessary condition for a maximum, as Dorfman (1986) showed, is again Thünen’s square-root formula.

Many have thought Thünen’s natural wage to be inconsistent with his own marginal productivity theory. If wages correspond to the marginal product of labour, how can they at the same time be expected to conform to some particular social ideal? This objection, however, loses its force once it is realized that Thünen (as observed by Dickinson) determined the capital/labour ratio at which the marginal productivity wage happens to be equal to his natural wage.

The fundamental objection to the natural wage formula is that it makes no sense for workers to be interested in the returns on their savings only. What Thünen seems to have been groping for, more than a century before Phelps et al., was a ‘Golden Rule’ of capital accumulation leading to some sort of optimal growth path. (In a one-sector model, the arithmetic variant of the natural wage has indeed such properties; they are analysed in Samuelson, 1986.) He never got it right; in such an optimization problem, the savings parameter, \( a \), can hardly be treated as given. Thünen regarded his formula as important enough to have it engraved on his tombstone in the churchyard of Belitz. It commemorates a brilliant failure.

Part III of the ‘Isolated State’ is concerned with the efficiency of forest management, thereby extending the incomplete treatment in Part I. The detailed analysis of the optimal spacing of trees is of interest mainly to forest engineers. In analysing the optimal rotation period, however, Thünen makes another important contribution to economic theory. He had already pointed out in Part I that the value of a forest should not be measured by the sales value of the timber if the trees are cut today, but rather by the present value of the timber if the trees are cut and sold at the end of the optimal rotation period. In an efficient operation, the latter exceeds the former; if not, the trees should be cut at once. Efficient forest management is thus interpreted as a problem of capital and interest, providing economic theory with one of its most fruitful paradigms.

Thünen’s optimality criterion, in contrast to Wickesell and Fisher, is not the equality of the marginal product of capital and the rate of interest, which, by disregarding the value of land, results in cutting trees too late. As Manz (1986) has shown, Thünen was probably the first to use the correct criterion of maximal land rent, which shortly afterwards was so brilliantly developed by Faustmann. The formula derived in Part III is flawed by incorrect discounting, and the exposition is clumsy. Nevertheless, with respect to substantive content, the capital theory implied in Thünen’s forest model is superior to Böhm-Bawerk’s and it was not surpassed in economic science before Wicksell.

Tiebout hypothesis

Dennis Epple
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Tiebout (1956) argued that efficient local public good provision would emerge as households choose among communities offering different local public goods bundles. This article highlights research linking the Tiebout hypothesis to real-world local political jurisdictions, the first such link having been forged by the pioneering contribution of Oates (1969). Subsequent research has studied voting over tax and expenditure policies within municipalities in a metropolitan area, and sorting of the metropolitan population both within and across those municipalities. This research has provided the foundation for econometric analysis and policy applications.

Article

In his famous paper, Charles Tiebout (1956) argued that there were realistic conditions under which local public goods would be provided efficiently; an efficient allocation would emerge as each household selected the community providing the public good levels most closely aligned to its preferences. This has come to be known as the ‘Tiebout hypothesis’ and the related Tiebout community-choice mechanism has been dubbed ‘voting with your feet’. This article focuses on research linking the Tiebout hypothesis to local political jurisdictions. Oates (1969) gave Tiebout’s hypothesis empirical content. He reasoned that if households selected among communities in the way Tiebout conjectured, ‘capitalization’ should result. That is, *ceteribus paribus*, housing prices should be higher in communities with high levels of public good provision and
lower in communities with high tax rates. Oates tested and found support for these predictions using data for municipalities in New Jersey. His paper led to an explosion of research on capitalization and launched research into a variety of related aspects of the Tiebout hypothesis.

Choice within jurisdictions

Tiebout was largely silent about how communities would settle on their levels of public good provision, though he emphasized parallels with market provision. Study of this market-based approach is largely the domain of the theory of clubs. Another approach, initiated by Barr and Davis (1966), focuses on collective choice within communities. In the terms of Albert Hirschman (1970), Tiebout emphasized ‘exit’ while Barr and Davis emphasized ‘voice’. Much research followed. Bergstrom and Goodman (1973) formalized estimation of demand for local public goods. Romer and Rosenthal (1979) investigated the role of agenda setters. Micro-level estimation of demand for local public goods was undertaken by Bergstrom, Rubinfeld and Shapiro (1982).

Equilibrium among jurisdictions

Not surprisingly, households with higher incomes tend to prefer communities with high levels of local public goods. It is natural to ask whether income stratification can be sustained in equilibrium. Building on the work of Ellickson (1971), Westhoff (1977) proves existence of equilibrium in a model with sorting across communities and voting within communities. Westhoff’s model is extended to incorporate housing markets by Epple, Filimon and Romer (1984), who demonstrate that income-stratified equilibria can be sustained by differentials across communities in the price per unit housing of services. Fernandez and Rogerson (1998) add an important dynamic feature, with community education spending by each generation affecting incomes of the succeeding generation.

While households tend to sort by income across communities, there is much income variation within jurisdictions, even within small neighbourhoods (Hardman and Ioannides, 2004). Several approaches seek to capture this intra-community heterogeneity as an outcome in multi-community equilibrium. One approach emphasizes heterogeneity in preferences as well as incomes. Structural estimation of multi-community equilibrium models embodying such heterogeneity is undertaken by Epple and Sieg (1999) and Epple, Romer and Sieg (2001). This framework is applied to study large-scale policy change by Sieg et al. (2004).

An alternative approach emphasizing heterogeneity and durability of housing is developed by Nechyba (1997). Nechyba has extended and applied this framework to study important policy issues, with particular emphasis on school choice and vouchers (Nechyba, 2000). Structural estimation taking Nechyba’s model as a point of departure is undertaken by Ferreyra (2005) who extends the model to
include heterogeneity in household tastes, including tastes for sectarian and non-sectarian schools. Still another approach, by Bayer, McMillan and Rueben (2004), permits detailed investigation of the way a household's own demographic characteristics affect preferences with respect to the demographic composition of communities and the quality of local public goods. Bayer, Ferreira, and McMillan (2005) apply this framework to estimate household preferences for community composition and to investigate the extent to which sorting within a metropolitan area is driven by preferences for education. Residents of a jurisdiction may affect the public goods provided therein via ‘neighbourhood effects’ and ‘peer effects’. Peer effects are introduced into a multi-jurisdictional model by deBartolome (1990). While research on the Tiebout model emphasizes choice among municipalities in a metropolitan area, there is also population sorting within municipalities, especially central cities. Benabou (1996) and Durlauf (1996) study how peer effects influence such sorting, and the economic consequences of such sorting. Multi-community models increasingly emphasize peer effects (Nechyba, 2000; Eppe and Romano, 2003; Bayer, McMillan and Rueben, 2004; Rothstein, 2006; Sethi and Somanathan, 2004; Ferreyra, 2005).

Equity and efficiency

Local governments impose many restrictions on land use (Fischel, 1985). Hamilton (1975) emphasizes the potential efficiency-enhancing role of zoning. Other research investigates ‘fiscal zoning’, the allegation that jurisdictions use zoning to restrict entry by households who would contribute less in taxes than the cost of public services they would consume. Early contributions are in Mills and Oates (1975). Multi-community models with community residents choosing zoning by majority rule are developed by Fernandez and Rogerson (1997) and Calabrese, Eppe and Romano (2005). Computational results in the latter reveal that zoning can enhance efficiency, but also support critics who argue that fiscal zoning benefits wealthy households at the expense of poorer households. Henderson (1985) emphasizes the role of the private sector in community development. Henderson and Thisse (2001) focus on the role of developers in determining the character of the housing stock in communities. Glaeser and Gyourko (2002) conclude that land use restrictions play a major role in driving up housing prices in some areas of the United States, particularly California and some eastern cities. The essence of the Tiebout hypothesis is that localities provide differing public good bundles to reflect variation within the population in tastes and incomes. Education is arguably the most important locally provided good, and efficiency arguments favouring decentralized provision in Tiebout equilibrium lie in uneasy juxtaposition with equity arguments favouring more centralized provision to increase equality of educational opportunity. US Courts have mandated intervention in many states to achieve greater equality of spending (Evans, Murray and Schwab, 1998). There is growing emphasis in research (Duncombe and Yinger, 1998) and the courts on policies designed to yield greater equality of educational outcomes. There is also increasing emphasis on incentive systems that might stimulate efficient provision of public education (Ladd, 1996) and increasing recognition that interventions intended to achieve greater equity may affect both political support for public education and effectiveness of provision. Oates (2006, p. 42) puts the matter succinctly: ‘There seems to be an inevitable tension here.’ Policies promoting equity need to be designed to harness local incentives for

foreign-trade multiplier; local public finance; public goods; regional development; Tiebout, C. M.; urban economics

Article

Tiebout was born in Norwalk, Connecticut, took his BA from Wesleyan University in 1950, and his Ph. D. from the University of Michigan in 1957. After holding appointments at Northwestern (1954–8) and the University of California at Los Angeles (1958–62), he became professor of economics and business administration at the University of Washington at Seattle in 1962. He died on 16 January 1968. By far his most important work was his ‘Pure Theory of Local Public Expenditure’, which appeared in the October number of the Journal of Political Economy for 1956, from which is derived the so-called Tiebout hypothesis, which is the subject of a separate article in this Dictionary. However, his work on problems in regional and urban economics was more extensive than this one theoretical article on the local provision of public goods might suggest.

For example, in the volume of the Journal of Political Economy that carried his essay on public goods, there also appeared a paper which examined the effects of export growth on the pattern of regional economic development. This analysis represents an attempt to apply a Keynesian model of income determination to regional development. Tiebout argued that exports are only one of a number of sources that act to determine the growth of regional income, and through what appears to be the first application of the foreign-trade multiplier to regional analysis he attempts to reach conclusions as to the relative significance of regional exports vis-à-vis regional demand as a source of income generation. Principal among these is that export-led regional growth is likely to be most effective when the regional base is small.

This paper was followed by work on the construction and use of regional and inter-regional input–output models (1957), which itself produced empirical investigations into the regional distribution of economic activity in the American states of California (1963) and of Washington (1969). The results of these studies were still appearing after Tiebout's early death – especially to be noted in this regard is his inter-
regional input–output model of the linkages between the economies of Washington and California (1970). Add to this his work on the regional impact of the federal government's dispensation of its defence and space budgets (1964), and it becomes fairly clear that to record Tiebout's name solely in regard to his contribution to the pure theory of public goods would be to present a rather one-sided picture of his scientific interests.

time consistency of monetary and fiscal policy

Paul Klein
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Why do even benevolent policymakers frequently break their promises? Kydland and Prescott (1977) discovered that, when outcomes depend on expectations, rational policy choices typically depend on whether (a) the policymaker takes into account the constraint that the expected policy is the actual policy or (b) she takes expectations as given. A government that commits itself to a policy takes this constraint into account, a government that acts at its discretion does not. Since the commitment policy leads to a better outcome, there is the temptation to announce it and then to abandon this policy. This is the time inconsistency problem.

Keywords

asymmetric information; central bank independence; commitment; expectations; Friedman rule; government budget constraint; inflation; inflationary expectations; Markov perfect equilibrium; Phillips curve; public debt; Ramsey equilibrium; rational expectations; reputation; second best; sticky prices; sustainable equilibrium; time consistency of monetary and fiscal policy; time inconsistency

Article

A (possibly time- and state-contingent) strategy is said to be time inconsistent if an agent finds it optimal from the point of view of some initial period 0 but finds it suboptimal in some subsequent period t. Time inconsistency can obviously arise if the government has time-varying preferences because of alternations of government, as shown in Persson and Svensson (1989). However, as Kydland and Prescott (1977) discovered, the time-inconsistency problem is a pervasive feature of environments with a single benevolent policymaker taking decisions over time. This happens even though the policymaker has stable preferences and even in situations where there is no apparent conflict of interest – though the emphasis there should perhaps be on the word ‘apparent’. This means that everyone in the economy can often be made better off if the policymaker gains access to a commitment technology – a mechanism
that forces him or her to keep his or her promises.

As pointed out by Fischer (1980), what these environments have in common is (a) that the Pareto optimal allocation is not implementable, (b) that the behaviour of the private sector depends on its expectations about future government behaviour, and (c) that the government and a typical individual do not share the same preferences. The third of these sounds stronger than it is. It is consistent with the benevolence of the policymaker, that is, that she maximizes the utility of a representative individual. All that it requires is a minimal amount of selfishness on the part of a typical individual – for example, she doesn't internalize the government's budget constraint.

It is important to note that either (a) or (b) on its own is not problematic. If the Pareto optimum can be achieved and I declare a policy at the beginning of time that is consistent with this Pareto optimum, I have no reason to deviate in the future since nothing better is feasible. On the other hand, suppose the Pareto optimum cannot be achieved but current behaviour does not depend on future policy. Then the policymaker will make the right trade-off in each period and the second best will be achieved. However, if both features are present at the same time, then the policy that achieves the second best will typically be time inconsistent: when choosing policy for period $t$, the policymaker faces different incentives in period 0 from the incentives faced in period $t$. In period 0 she rationally takes into account the effects on expectations; in period $t$ it is no longer rational to do that, since expectations in the past are bygones. The temptation to bring the economy closer to the first-best renders the second-best solution time inconsistent, and rational expectations force the economy into a Pareto inferior third-best equilibrium.

The Phillips curve and inflation bias

The central example in Kydland and Prescott (1977) is a central bank setting inflation in an environment with an expectations-augmented Phillips curve. This environment has the feature that inflation surprises lead to deviations of output from its ‘natural’ rate. The authors then assume that a positive inflation surprise is good, since the ‘natural’ rate of output is suboptimal because of various (unspecified) distortions. However, in any rational expectations equilibrium, inflation expectations are fulfilled and output equals its natural rate. If inflation is bad in itself (other things being equal), then the best rational expectations equilibrium features zero expected and actual inflation. This is the second best: the best equilibrium that can be achieved subject to the constraint of rational expectations. The first-best would be for output to be at some ideal level greater than its natural rate but with inflation maintained at zero. However, this ideal outcome is not consistent with rational expectations. Now suppose inflation policy can be revised after expectations are formed. Then the zero-inflation policy that gives rise to the best rational expectations equilibrium is not time consistent: when it is time to set inflation, the central bank would like to set an inflation rate above zero since a small rise in inflation has no first-order effect on the welfare cost of inflation but does have a first-order effect on the welfare cost of output being less than its ideal level. The result, under discretionary monetary policy, is a tendency for inflation to be above its desired level (inflation bias) with no (positive) effect on output or employment.

Overtaxation of capital and liquidity
Another early contribution is that of Fischer (1980), who discussed a situation where a fiscal authority decides on the levels of taxation on labour and capital and of public expenditure. There, the problem is that tomorrow's capital stock depends on today's investment. Meanwhile, today's investment depends on expectations about future capital income taxes. The result is that a government that sets taxes sequentially will typically overtax capital income. Similarly, Calvo (1978) described the time consistency problem in a monetary economy with money in the utility function. He found that, when lump-sum taxation is not available, the Friedman rule of optimal monetary policy is not time consistent; in general, the government wants to expand the money supply to relax the government budget constraint. This is because monetary expansion, like capital taxation, is distortionary only *ex ante*; it is the expectation of monetary expansion (and the consequent inflation) that leads people to economize on liquidity, a socially free resource.

**Relation with game theoretic concepts**

The relationship between time consistency, time inconsistency and various concepts in game theory have been much discussed. A common view, but by no means a consensus, has emerged, asserting that the best way to think about the situation is that the (Ramsey 1927) optimal policy, ‘second best’ or ‘commitment solution’ (these phrases are used interchangeably) is an equilibrium of one game, the time-consistent policy the equilibrium of another. The first game lets the government move before time starts, choosing a time- and state-contingent policy for the indefinite future. Thereafter it does not move again. The second game has the government moving sequentially, setting policy in each period as it arrives. When the policies implied by these equilibria differ, then we say that the Ramsey policy is time inconsistent. On the other hand, any equilibrium of the second game is time-consistent by construction. This view of course leaves open what the correct solution concept is for these various games. Chari and Kehoe (1990) and several successors discuss the appropriate solution concept for the second type of game. From this literature has emerged the concept of ‘sustainable equilibrium’ which roughly corresponds to the sequential equilibrium concept of Kreps and Wilson (1982) but modified to apply to economies with one large agent and many ‘small’ agents. A recent formulation can be found in Phelan and Stacchetti (2001).

**Solving the time inconsistency problem**

The literature on time consistency may usefully be divided into two parts: one attempts to characterize the equilibrium of the sequential-move game, the other tries to solve the time-inconsistency problem by somehow erasing the difference between the Ramsey policy and the time-consistent policy. A celebrated paper in the second category is Lucas and Stokey (1983), which discusses a dynamic monetary economy without capital. A price-taking representative agent chooses labour supply and the government sets labour taxes so as to minimize distortions subject to a government budget constraint. Government expenditure is exogenous. The government can issue state-contingent debt which it is committed to honouring. The main finding of the paper is that, if public debt has a sufficiently rich maturity structure, then the Ramsey optimal policy is time consistent. However, if only one-period state-contingent bonds
are available, then the optimal policy is typically not time consistent. Persson, Persson and Svensson (1987) extend this result to monetary economies, showing how the government can render the optimal policy time consistent by accumulating nominal assets equal to the stock of money so that the outstanding stock of net nominal claims is zero. A minor mistake in that paper was pointed out by Calvo and Obstfeld (1990), but the basic result stands and applies quite generally, as explained in Alvarez, Kehoe and Neumayer (2001). The latter paper establishes a link between the optimality of the Friedman rule (zero nominal interest rates) and the possibility of rendering the Ramsey optimal policy time-consistent: for a wide class of economies they show that the Ramsey optimal policy can be made time-consistent if and only if the Friedman rule is optimal. Domínguez (2007) extends this result further for an economy with capital, showing that, if capital taxes are set one period in advance, then a sufficiently rich maturity structure of public debt is sufficient to render the optimal policy time consistent.

Another sub-literature in this category looks at reputational mechanisms that might render the optimal policy time consistent, or at least bring the time-consistent solution closer to the second-best optimum. In monetary policy, a key early contribution is Barro and Gordon (1983). In an environment with an expectations-augmented Phillips curve, it shows, using the well-known folk theorem from game theory, that the optimal monetary policy in the environment described by Kydland and Prescott (1977) can be sustained as a time-consistent equilibrium provided the policymaker is patient enough. A paper that analyses fiscal policy with a reputational-style approach is Kotlikoff, Persson and Svensson (1988). In this paper it is shown how the optimal tax scheme can be sustained in a two-period overlapping generations environment by threats of moving to the third-best equilibrium if any generation deviates. Yet another set of solutions to the time-consistency problem of monetary policy is found in Rogoff (1985) and Persson and Tabellini (1993). The first, using an idea from industrial organization first published by Vickers (1985), shows that a monetary policymaker will typically be better off delegating monetary policy to a central banker that cares more about low inflation and less about output or employment than he or she does. Rogoff’s result is aptly described as delegation to a ‘conservative central banker’. This delegation improves welfare but does not achieve the second-best optimum. By contrast, the key result in Persson and Tabellini (1993) is that the second best can be achieved by signing a performance contract with the central banker.

Analysing what happens when the time inconsistency problem cannot be solved

The literature on characterizing time-consistent policy also divides into two parts: one focusing on a solution concept (‘sustainable equilibrium’) that is nearly always set-valued and the other on a refinement (‘Markov perfect equilibrium’) that often (but certainly not always) yields a unique equilibrium. The concept of Markov perfect equilibrium, whose purpose is essentially to rule out any reputational mechanisms, is defined in a game-theoretic setting in Maskin and Tirole (2001) and in a macroeconomic setting by, among several others, Klein, Krusell and Ríos-Rull (2006). In the latter paper, the authors find that in the Markov perfect equilibrium labour tends to be under-taxed even in an environment where no other taxes are available and the only other endogenous variable is government spending. That is, a government acting sequentially tends to exaggerate the distortionary effects of taxation. This is in marked contrast to the case of capital and inflation taxes. The reason is that the
current labour income tax encourages labour supply in the previous period, by intertemporal substitution. This effect is ignored by a sequentially moving government that thus neglects a beneficial effect of raising the current labour income tax rate. 

Other papers studying Markov perfect equilibrium in a fiscal policy setting include Klein and Ríos-Rull (2003), who look at time-consistent capital and labour income taxation where capital taxes are set one period in advance and the budget has to balance in each period. The main finding is that a calibrated model can replicate the capital and labour taxes that we observe in, say, the United States, reasonably well. Krusell, Martin and Ríos-Rull (2004) consider public debt policy in an economy without capital and find that for positive initial debt there is a unique equilibrium but infinitely many steady states. For negative initial debt there are infinitely many equilibria, each associated with infinitely many steady states.

On the other hand, Phelan and Stacchetti (2001) study the set of sustainable equilibria in an economy with capital but without public debt. The methods used are similar to those in Abreu, Pearce and Stacchetti (1990). Fernandez-Villaverde and Tsyvinski (2002) consider all the sustainable equilibria in a stochastic environment with capital. They compare the best (from a welfare point of view) in that class with the Markov perfect equilibrium and the Ramsey equilibrium. Also, a literature is emerging on time-consistent policy under asymmetric information. Recent contributions include Sleet (2003) and Sleet and Yeltekin (2004).

A new departure in the study of time consistency of monetary policy is the consideration of the role of sticky prices. This introduces a new channel through which time inconsistency may arise: when prices are sticky and firms are bound to produce whatever is demanded at the given price, a surprise monetary expansion raises output. This is typically ex post welfare-improving in an economy suffering from some distortion, typically monopolistic rather than perfect competition. Important contributions include Albanesi, Chari and Christiano (2003a), who show that without commitment the economy can get stuck in an ‘expectation trap’ in the following sense. There are multiple, Pareto-ranked, equilibria. In the lower-ranked equilibria, the private sector expects high inflation. The measures the private sector takes to protect itself from high inflation create incentives for the policymaker to accommodate these expectations. On the other hand, in Albanesi, Chari and Christiano (2003b) the same authors show that optimal monetary policy is time consistent – and the Markov perfect equilibrium unique – in a wide class of models.

**Article**

Time preference is the insight that people prefer ‘present goods’ (goods available for use at present) to ‘future goods’ (present expectations of goods becoming available at some date in the future), and that the social rate of time preference, the result of the interactions of individual time preference schedules, will determine and be equal to the pure rate of interest in a society. The economy is pervaded by a time market for present as against future goods, not only in the market for loans (in which creditors trade present money for the right to receive money in the future), but also as a ‘natural rate’ in all processes of production. For capitalists pay out present money to buy or rent land, capital goods, and raw materials, and to hire labour (as well as buying labour outright in a system of slavery), thereby purchasing expectations of future revenue from the eventual sales of product. Long-run profit rates and rates of return on capital are therefore forms of interest rate. As businessmen seek to gain profits and avoid losses, the economy will tend toward a general equilibrium, in which all interest rates and rates of return will be equal, and hence there will be no pure entrepreneurial profits or losses.

In centuries of wrestling with the vexed question of the justification of interest, the Catholic scholastic philosophers arrived at highly sophisticated explanations and justifications of return on capital, including risk and the opportunity cost of profit forgone. But they had extreme difficulty with the interest on a riskless loan, and hence denounced all such interest as sinful and usurious.

Some of the later scholastics, however, in their more favourable view of usury, began to approach a time preference explanation of interest. During a comprehensive demolition of the standard arguments for the prohibition of usury in his *Treatise on Contracts* (1499), Conrad Summenhart (1465–1511), theologian at the University of Tübingen, used time preference to justify the purchase of a discounted debt, even if
the debt be newly created. When someone pays $100 for the right to obtain $110 at a future date, the buyer (lender) doesn't profit usuriously from the loan because both he and the seller (borrower) value the future $110 as being worth $100 at the present time (Noonan, 1957).

A half-century later, the distinguished Dominican canon lawyer and monetary theorist at the University of Salamanca, Martin de Azpilcueta Navarrus (1493–1586) clearly set forth the concept of time preference, but failed to apply it to a defence of usury. In his Commentary on Usury (1556), Azpilcueta pointed out that a present good, such as money, will naturally be worth more on the market than future goods, that is, claims to money in the future. As Azpilcueta put it:

> a claim on something is worth less than the thing itself, and...it is plain that that which is not usable for a year is less valuable than something of the same quality which is usable at once. (Gordon, 1975, p. 215)

At about the same time, the Italian humanist and politician Gian Francesco Lottini da Volterra, in his handbook of advice to princes, Avvedimenti civili (1574), discovered time preference. Unfortunately, Lottini also inaugurated the tradition of moralistically deploring time preference as an overestimation of a present that can be grasped immediately by the senses (Kauder, 1965, pp. 19–22).

Two centuries later, the Neapolitan abbé, Ferdinando Galiani (1728–87), revived the rudiments of time-preference in his Della Moneta (1751) (Monroe, 1924). Galiani pointed out that just as the exchange rate of two currencies equates the value of a present and a spatially distant money, so the rate of interest equates present with future, or temporally distant, money. What is being equated is not physical properties, but subjective values in the minds of individuals.

These scattered hints scarcely prepare one for the remarkable development of a full-scale time preference theory of interest by the French statesman, Anne Robert Jacques Turgot (1727–81), who, in a relatively few hastily written contributions, anticipated almost completely the later Austrian theory of capital and interest (Turgot, 1977). In the course of a paper defending usury, Turgot asked: why are borrowers willing to pay an interest premium for the use of money? The focus should not be on the amount of metal repaid but on the usefulness of the money to the lender and borrower. In particular, Turgot compares the ‘difference in usefulness which exists at the date of borrowing between a sum currently owned and an equal sum which is to be received at a distant date’, and notes the well-known motto, ‘a bird in the hand is better than two in the bush’. Since the sum of money owned now ‘is preferable to the assurance of receiving a similar sum in one or several years’ time’, returning the same principal means that the lender ‘gives the money and receives only an assurance’. Therefore, interest compensates for this difference in value by a sum proportionate to the length of the delay. Turgot added that what must be compared in a loan transaction is not the value of money lent with the value repaid, but rather the ‘value of the promise of a sum of money compared to the value of money available now’ (Turgot, 1977, pp. 158–9).

In addition, Turgot was apparently the first to arrive at the concept of capitalization, a corollary to time preference, which holds that the present capital value of any durable good will tend to equal the sum of its expected annual rents, or returns, discounted by the market rate of time preference, or rate of interest. Turgot also pioneered in analysing the relation between the quantity of money and interest rates. If an increased supply of money goes to low time-preference people, then the increased proportion of savings
to consumption lowers time preference and hence interest rates fall while prices rise. But if an increased quantity goes into the hands of high time-preference people, the opposite would happen and interest rates would rise along with prices. Generally, over recent centuries, he noted, the spirit of thrift has been growing in Europe and hence time preference rates and interest rates have tended to fall.

One of the notable injustices in the historiography of economic thought was Böhm-Bawerk's brusque dismissal in 1884 of Turgot's anticipation of his own time-preference theory of interest as merely a ‘land fructification theory’ (Böhm-Bawerk, vol. 1, 1884–9). Partly this dismissal stemmed from Böhm's methodology of clearing the ground for his own positive theory of interest by demolishing, and hence sometimes doing injustice to, his own forerunners (Wicksell, 1911, p. 177). The unfairness is particularly glaring in the case of Turgot, because we now know that in 1876, only eight years before the publication of his history of theories of interest, Böhm-Bawerk wrote a glowing tribute to Turgot's theory of interest in an as yet unpublished paper in Karl Knies's seminar at the University of Heidelberg (Turgot, 1977, pp. xxix–xxx).

In the course of his demolition of the Ricardo–James Mill labour theory of value on behalf of a subjective utility theory, Samuel Bailey (1825) clearly set forth the concept of time preference. Rebutting Mill's statement that time, as a ‘mere abstract word’, could not add to value, Bailey declared that ‘we generally prefer a present pleasure or enjoyment to a distant one’, and therefore prefer present goods to waiting for goods to arrive in the future. Bailey, however, did not go on to apply his insight to interest.

In the mid-1830s, the Irish economist Samuel Mountifort Longfield worked out the later Austrian theory of capital as performing the service for workers of supplying money at present instead of waiting for the future when the product will be sold. In turn the capitalist receives from the workers a time discount from their productivity. As Longfield put it, the capitalist

pays the wages immediately, and in return receives the value of [the worker's] labour,... [which] is greater than the wages of that labour. The difference is the profit made by the capitalist for his advances••••as it were, the discount which the labourer pays for prompt payment. (Longfield, 1971)

The ‘pre-Austrian’ time analysis of capital and interest was most fully worked out, in the same year 1834, by the Scottish and Canadian eccentric John Rae (1786–1872). In the course of attempting an anti-Smithian defence of the protective tariff, Rae, in his Some New Principles on the Subject of Political Economy (1834), developed the Böhm-Bawerkian time analysis of capital, pointing out that investment lengthens the time involved in the processes of production. Rae noted that the capitalist must weigh the greater productivity of longer production processes against waiting for them to come to fruition. Capitalists will sacrifice present money for a greater return in the future, the difference – the interest return – reflecting the social rate of time preference. Rae saw that people's time preference rates reflect their cultural and psychological willingness to take a shorter or longer view of the future. His moral preferences were clearly with the low time-preference thrifty as against the high time-preference people who suffer from a ‘defect of the imagination’. Rae's analysis had little impact on economics until resurrected at the turn of the 20th century, whereupon it was generously hailed in the later editions of Böhm-Bawerk's history of interest theories (Böhm-Bawerk, vol. 1, 1959).
Time preference, as a concept and as a foundation for the explanation of interest, has been an outstanding feature of the Austrian School of economics. Its founder, Carl Menger (1840–1921), enunciated the concept of time preference in 1871, pointing out that satisfying the immediate needs of life and health are necessarily prerequisites for satisfying more remote future needs. In addition, Menger declared, ‘all experience teaches that we humans consider a present pleasure, or one expected in the near future, more important than one of the same intensity which is not expected to occur until some more distant time’ (Wicksell, 1924, p. 195; Menger, 1871, pp. 153–4). But Menger never extended time preference from his value theory to a theory of interest; and when his follower Böhm-Bawerk did so, he peevishly deleted this discussion from the second edition of his *Principles of Economics* (Wicksell, 1924, pp. 195–6).

Böhm-Bawerk's *Capital and Interest* (1884) is the *locus classicus* of the time preference theory of interest. In his first, historical volume, he demolished all other theories, in particular the productivity theory of interest; but five years later, in his *Positive Theory of Capital* (1889), Böhm brought back the productivity theory in an attempt to combine it with a time preference explanation of interest (Böhm-Bawerk, vols 1 and 2, 1959). In his ‘three grounds’ for the explanation of interest, time preference constituted two, and the greater productivity of longer processes of production the third, Böhm ironically placing greatest importance upon the third ground. Influenced strongly by Böhm-Bawerk, Irving Fisher increasingly took the same path of stressing the marginal productivity of capital as the main determinant of interest (Fisher, 1907; 1930).

With the work of Böhm-Bawerk and Fisher, the modern theory of interest was set squarely on the path of placing time preference in a subordinate role in the explanation of interest, determining only the rate of consumer loans and the supply of consumer savings, while the alleged productivity of capital determines the more important demand for loans and for savings. Hence, modern interest theory fails to integrate interest on consumer loans and producers’ returns into a coherent explanation.

In contrast, Frank A. Fetter, building on Böhm-Bawerk, completely discarded productivity as an explanation of interest and constructed an integrated theory of value and distribution in which interest is determined solely by time preference, while marginal productivity determines the ‘rental prices’ of the factors of production (Fetter, 1915; 1977). In his outstanding critique of Böhm-Bawerk, Fetter pointed out a fundamental error of the third ground in trying to explain the return on capital as ‘present goods’ earning a return for their productivity in the future; instead, capital goods are *future* goods, since they are only valuable in the expectation of being used to produce goods that will be sold to the consumer at a future date (Fetter, 1902). One way of seeing the fallacy of a productivity explanation of interest is to look at the typical practice of any current microeconomics text: after explaining marginal productivity as determining the demand curve for factors with wage rates on the y-axis, the textbook airily shifts to interest rates on the y-axis to illustrate the marginal productivity determination of interest. But the analog on the y-axis should not be interest, which is a ratio and not a price, but rather the *rental price* (price per unit time) of a capital good. Thus, interest remains totally unexplained. In short, as Fetter pointed out, marginal productivity determines rental prices, and time preference determines the rate of interest, while the capital value of a factor of production is the expected sum of future rents from a durable factor discounted by the rate of time preference or interest.

The leading economist adopting Fetter's pure time preference view of interest was Ludwig von Mises, in his *Human Action* (Mises, 1949). Mises amended the theory in two important ways. First, he rid the...
concept of its moralistic tone, which had been continued by Böhm-Bawerk, implicitly criticizing people for ‘under’-estimating the future. Mises made clear that a positive time preference rate is an essential attribute of human nature. Secondly, and as a corollary, whereas Fetter believed that people could have either positive or negative rates of time preference, Mises demonstrated that a positive rate is deducible from the fact of human action, since by the very nature of a goal or an end people wish to achieve that goal as soon as possible.

The analysis of economic time series is central to a wide range of applications, including business cycle measurement, financial risk management, policy analysis based on structural dynamic econometric models, and forecasting. This article provides an overview of the problems of specification, estimation and inference in linear stationary and ergodic time series models as well as non-stationary models, the prediction of future values of a time series and the extraction of its underlying components. Particular attention is devoted to recent advances in multiple time series modelling, the pitfalls and opportunities of working with highly persistent data, and models of nonlinear dependence.
Any series of observations ordered along a single dimension, such as time, may be thought of as a time series. The emphasis in time series analysis is on studying the dependence among observations at different points in time. What distinguishes time series analysis from general multivariate analysis is precisely the temporal order imposed on the observations. Many economic variables, such as GNP and its components, price indices, sales, and stock returns are observed over time. In addition to being interested in the contemporaneous relationships among such variables, we are often concerned with relationships between their current and past values, that is, relationships over time.

The study of time series of, for example, astronomical observations predates recorded history. Early writers on economic subjects occasionally made explicit reference to astronomy as the source of their ideas. For example, Cournot (1838) stressed that, as in astronomy, it is necessary to recognize the secular variations which are independent of the periodic variations. Similarly, Jevons (1884) remarked that his study of short-term fluctuations used the methods of astronomy and meteorology. During the 19th century interest in, and analysis of, social and economic time series evolved into a new field of study independent of developments in astronomy and meteorology (see Nerlove, Grether and Carvalho, 1979, pp. 1–21, for a historical survey).

Harmonic analysis is one of the earliest methods of analysing time series thought to exhibit some form of periodicity. In this type of analysis, the time series, or some simple transformation of it, is assumed to be the result of the superposition of sine and cosine waves of different frequencies. However, since summing a finite number of such strictly periodic functions always results in a perfectly periodic series, which is seldom observed in practice, one usually allows for an additive stochastic component, sometimes called ‘noise’. Thus, an observer must confront the problem of searching for ‘hidden periodicities’ in the data, that is, the unknown frequencies and amplitudes of sinusoidal fluctuations hidden amidst noise. An early method for this purpose is periodogram analysis, suggested by Stokes (1879) and used by Schuster (1898) to analyse sunspot data and later by others, principally William Beveridge (1921; 1922), to analyse economic time series.

Spectral analysis is a modernized version of periodogram analysis modified to take account of the stochastic nature of the entire time series, not just the noise component. If it is assumed that economic time series are fully stochastic, it follows that the older periodogram technique is inappropriate and that considerable difficulties in the interpretation of the periodograms of economic series may be encountered.

At the time when harmonic analysis proved to be inadequate for the analysis of economic and social time series, another way of characterizing such series was suggested by the Russian statistician and economist, Eugen Slutsky (1927), and by the British statistician, G.U. Yule (1921; 1926; 1927). Slutsky and Yule showed that, if we begin with a series of purely random numbers and then take sums or differences, weighted or unweighted, of such numbers, the new series so produced has many of the apparent cyclic properties that were thought at the time to characterize economic and other time series. Such sums or differences of purely random numbers and sums or differences of the resulting series form the basis for the class of autoregressive moving-average (ARMA) processes which are used for modelling many kinds of time series. ARMA models are examples of time domain representations of time series. Although the latter may look very different from spectral representations of time series, there is a one-to-one mapping between time domain analysis and spectral analysis. Which approach is preferred in practice is a matter only of convenience. The choice is often determined by the transparency
with which a given question can be answered. The remainder of this article explores these two complementary approaches to the analysis of economic time series.

1 Basic theory

1.1 Stationarity and ergodicity of time series processes

Consider a random variable $x_t$ where $t \in N$, the set of integers; the infinite vector $\{x_t, t \in N\}$ is called a discrete time series. Let $M$ denote a subset of $T$ consecutive elements of $N$. The distribution of the finite dimensional vector $\{x_t, t \in M\}$ is a well-defined multivariate distribution function, $F_M(\cdot)$. The time series $\{x_t, t \in N\}$ is said to be strictly stationary if, for any finite subset $M$ of $N$ and any integer $\tau$, the distribution function of $\{x_t, t \in M + \tau\}$ is the same as the distribution function of $\{x_t, t \in M\}$. In other words, the joint distribution function of the finite vector of observations on $x_t$ is invariant with respect to the origin from which time is measured. All the unconditional moments of the distribution function, if they exist, are independent of the index $t$; in particular,

$$E(x_t) = \mu$$

$$\gamma(\tau) = E[(x_t - \mu)(x_{t+\tau} - \mu)],$$

where $\gamma(\tau)$ is the autocovariance function and depends only on the difference in indices, $\tau$. Time-series processes for which (1) holds, but which are not necessarily strictly stationary according to the definition above, are said to be weakly stationary, covariance stationary, or stationary to the second order. Time-series processes for which $F_M(\cdot)$ is multivariate normal for any subset $M$ of $N$ are called Gaussian processes. For Gaussian processes covariance stationarity implies strict stationarity.

In practice, we usually observe only one realization of a finite subset of the time series of interest, corresponding to one of the many possible draws of length $T$ from $F_M(\cdot)$. The question is whether the moments of $x_t$ may be inferred from one such realization; for example, from the time averages of sums (or sums of products) of the observed values of a time series. If the process is what is known as ergodic, time averages of functions of the observations on the time series at $T$ time points converge in mean square to the corresponding population expectations of $x_t$ across alternative draws, as $T \to \infty$ (Priestley, 1981, pp. 340–3; Doob, 1953, p. 465). It is possible for a process to be stationary, yet not ergodic.

Consider, for example, the process $x_t^{(i)} = \eta_t^{(i)} + \varepsilon_t$ where $x_t^{(i)}$ denotes the $i$th draw for observation $x_t$ from the universe of all possible draws for $x_t$. Suppose that $\eta_t^{(i)} \sim N(0, \lambda^2)$ is the mean of the $i$th draw and that $\varepsilon_t \sim N(0, \sigma^2)$ is independent of $\eta_t^{(i)}$. This process is clearly stationary in that the probability limit of the ensemble average is zero, yet the time average $\sum_{t=1}^{T} x_t^{(i)} / T = \eta_t^{(i)} + \sum_{t=1}^{T} \varepsilon_t / T$ converges
1.2 The Wold decomposition and general linear processes

Let \( \{ \varepsilon_t \} \) be one element of a time series of serially uncorrelated, identically distributed random variables with zero mean and variance \( \sigma^2 \). Then the infinite, one-sided moving average (MA) process

\[
x_t = \sum_{j=0}^{\infty} b_j \varepsilon_{t-j},
\]

(2)

where \( b_0 = 1 \) and \( \sum_{j=0}^{\infty} b_j^2 < \infty \), is also a well-defined stationary process with mean 0 and variance \( \sigma^2 \sum_{j=0}^{\infty} b_j^2 \). Processes of this form and, more generally, processes based on an infinite two-sided MA of the same form are called linear processes, are always ergodic, and play a key role in time series analysis (Hannan, 1970).

The importance of the process (2) is underscored by the Wold decomposition theorem (Wold, 1938), which states that any weakly stationary process may be decomposed into two mutually uncorrelated component processes, one an infinite one-sided MA of the form (2) and the other a so-called linearly deterministic process, future values of which can be predicted exactly by some linear function of past observations. The linearly deterministic component is non-ergodic.

2 Linear processes in time and frequency domains

2.1 Autocovariance and autocovariance generating functions

The autocovariance function of a stationary process, defined in (1) above, or its matrix generalization for vector processes, provides the basic representation of time dependence for weakly stationary processes. For the stationary process defined in (2), it is

\[
\gamma(\tau) = \sigma^2 \sum_{j=0}^{\infty} b_j b_{j+\tau}.
\]

(3)
Let $z$ denote a complex scalar. Then the autocovariance generating transform is defined as

$$g(z) = \sum_{-\infty}^{\infty} \gamma(\tau)z^{\tau}$$

(4)

in whatever region of the complex plane the series on the right-hand side converges. If the series $\{x_t\}$ is covariance stationary, convergence will occur in an annulus about the unit circle. The autocovariance generating transform for the one-sided MA process defined in (2) is

$$g(z) = \sigma^2 B(z)B^{-1}(z^{-1})$$

(5)

where

$$B(z) = \sum_{k=0}^{\infty} b_kz^k.$$ 

If $B(z)$ has no zeros on the unit circle, the process defined in (2) is invertible and also has an infinite-order autoregressive (AR) representation as

$$A(L)x_t = \varepsilon_t$$

(6)

where $L$ is the lag operator such that $L^j x_t = x_{t-j}$ and $A(L) = a_0 + a_1L + a_2L^2 + \ldots$. 

So-called ARMA processes have an autocovariance generating transform which is a rational function of $z$. If the ARMA process is both stationary and invertible, $g(z)$ may be written as
where $|\beta_k|, |\alpha_j| < 1 \ \forall \ j, k$. Then the corresponding ARMA model is

$$Q(L)x_t = P(L)\varepsilon_t,$$

where

$$Q(L) = \prod_{j=1}^{\infty} (1 - \alpha_j L) \text{and } P(L) = \prod_{k=1}^{\infty} (1 - \beta_k L).$$

2.2 Spectral density functions

If the value of $z$ lies on the complex unit circle, it follows that $z = e^{-i\lambda}$, where $i = \sqrt{-1}$ and $-\pi \leq \lambda \leq \pi$. Substituting for $z$ in the autocovariance generating transform (5) and dividing by $2\pi$, we obtain the spectral density function of a linearly non-deterministic stationary process \( \{x_t\} \) in terms of the frequency $\lambda$:

$$f(\lambda) = \frac{1}{2\pi} g(e^{i\lambda}) = \frac{\sigma^2}{2\pi} \mathcal{B}(e^{i\lambda})\mathcal{B}(e^{-i\lambda}) = \frac{1}{2\pi} \sum_{-\infty}^{\infty} \gamma(\tau)e^{-i\lambda\tau}, \quad -\pi \leq \lambda < \pi.$$

Thus, the spectral density function is the Fourier transform of the autocovariance function. It can be shown that for a process with absolutely summable autocovariances the spectral density function exists and can be used to compute all of the autocovariances, so the same time series can be characterized equivalently in terms of the autocovariance function in the time-domain or in terms of the spectral density function in the frequency domain.

$$G(z) = \frac{P(z)P(z^{-1})}{Q(z)Q(z^{-1})} = \sigma^2 \frac{\prod_{k=1}^{m} (1 - \beta_k z)(1 - \beta_k z^{-1})}{\prod_{j=1}^{n} (1 - \alpha_j z)(1 - \alpha_j z^{-1})}$$

(7)
The spectral density function for a linearly non-deterministic, stationary, real-valued time series is a real-valued, non-negative function, symmetric about the origin, defined in the interval \([-\pi, \pi]\):

\[
f(\lambda) = \frac{1}{2\pi} \left[ \gamma(0) + 2 \sum_{\tau=1}^{\infty} \gamma(\tau) \cos \lambda \tau \right].
\]  

Moreover,

\[
E(x_t - \mu)^2 = \int_{-\pi}^{\pi} f(\lambda) \, d\lambda,
\]

so that the spectral density function is a frequency-band decomposition of the variance of \(\{x_t\}\).

When the process generating \(\{x_t\}\) is merely stationary, that is, when \(\{x_t\}\) may have a linearly deterministic component, the spectral density function is

\[
f(\lambda) = \int_{-\pi}^{\pi} e^{i\lambda \tau} \, dF(\lambda),
\]

where \(F(\lambda)\) is a distribution function (Doob, 1953, p. 488). Note that deterministic seasonal effects, for example, may cause a jump in the spectral distribution function.

The autocovariance function, its generating transform and the spectral distribution function all have natural generalizations to the multivariate case, in which \(\{x_t\}\) can be thought of as a vector of time-series processes.

The estimation and analysis of spectral density and distribution functions play an important role in all forms of time-series analysis. More detailed treatments are Doob (1953), Fishman (1969), Koopmans (1974), Fuller (1976), Nerlove, Grether and Carvalho (1979, ch. 3) and Priestley (1981).

2.3 Unobserved components (UC) models

In the statistical literature dealing with the analysis of economic time series it is common practice to
classify the types of movements that characterize a time series as trend, cyclical, seasonal, and irregular components. The idea that a time series may best be viewed as being composed of several unobserved components is by no means universal, but it plays a fundamental role in many applications, for example, the choice of methods for seasonal adjustment. Nerlove, Grether and Carvalho (1979, ch. 1) review the history of the idea of unobserved components in economics from its origin early in the 19th century. In the 1960s, Nerlove (1964; 1965; 1967) and Granger (1966) suggested that the typical spectral shape of many economic time series could be accounted for by the superposition of two or more independent components with specified properties. There are basically two approaches to the formulation of UC models: Theil and Wage (1964) and Nerlove and Wage (1964), Nerlove (1967) and Grether and Nerlove (1970) choose the form of components in such a way as to replicate the typical spectral shape of the series which represents their superposition. For example, let $T_t$, $C_t$, $S_t$, and $I_t$ represent the trend, cyclical, seasonal, and irregular of a monthly time series; then the observed series can be represented as

$$y_t = T_t + C_t + S_t + I_t,$$

where

$$T_t = a_0 + a_1 t + a_2 t^2 + \ldots + a_p t^p,$$

$$C_t = \frac{1 + \beta_1 L + \beta_2 L^2}{(1 - \alpha_1 L)(1 - \alpha_2 L)} \varepsilon_{1t},$$

$$S_t = \frac{1 + \beta_3 L + \beta_4 L^2}{1 - \gamma L} \varepsilon_{2t},$$

$$I_t = \varepsilon_{3t},$$

and $\varepsilon_{1t}$, $\varepsilon_{2t}$, and $\varepsilon_{3t}$ are i.i.d. normal variables with variances $\sigma_{11}$, $\sigma_{22}$, and $\sigma_{33}$, respectively. This approach has been carried forward by Harvey (1984), Harvey and Peters (1990) and Harvey and Todd (1984).

An alternative approach is to derive the components of the UC model from a well-fitting ARMA model (obtained after suitably transforming the data), given sufficient a priori identifying restrictions on the spectral properties of the components. See Box, Hillmer and Tiao (1978), Pierce (1978; 1979), Burman (1980), Hillmer and Tiao (1982), Hillmer, Bell and Tiao (1983), Bell and Hillmer (1984), Burridge and Wallis (1985), and Maravall (1981; 1984). The basis of this procedure is the fact that every stationary
UC model, or the stationary part of every UC model, has an equivalent ARMA form, the so-called canonical form of the UC model (Nerlove and Wage, 1964; Nerlove, Grether and Carvalho, 1979, ch. 4).

3 Specification, estimation, inference and prediction

3.1 Autocovariance and spectral density functions

Suppose we have a finite number of observations of a realization of the process generating the time series, say $x_1, \ldots, x_T$. For expository purposes it is assumed that all deterministic components of $x_t$ have been removed. If $\mu$ is unknown, this may be accomplished by subtracting the sample mean of the time series observations from the data prior to the analysis. For a zero mean series $x_t$ there are basically two ways of estimating $\gamma(\tau)$ defined in (1): the first is the biased estimator

$$c(\tau) = \frac{1}{T} \sum_{t=1}^{T-|\tau|} x_t x_{t+\tau}, \quad \tau = 0, \pm 1, \ldots, \pm M, \quad M \leq (T-1).$$

(14)

The second is the unbiased estimator

$$\tilde{c}(\tau) = \frac{1}{T-|\tau|} \sum_{t=1}^{T-|\tau|} x_t x_{t+\tau}, \quad \tau = 0, \pm 1, \ldots, \pm M, \quad M \leq T-1.$$

(15)

Although $c(\tau)$ is biased in finite samples, it is asymptotically unbiased. The key difference between $c(\tau)$ and $\tilde{c}(\tau)$ is that $c(\tau)$ is a positive definite function of $\tau$ whereas $\tilde{c}(\tau)$ is not (Parzen, 1961, p. 981). The variance and covariances of the estimated autocovariances are derived, inter alia, by Hannan (1960), and Anderson (1971). As $T \to \infty$, both tend to zero, as the estimates are asymptotically uncorrelated and consistent. However,

$$E[(c(\tau) - Ec(\tau))^2] / E[c(\tau)] \to \infty \quad \text{as} \quad \tau / T \to 1.$$

(16)
This property accounts for the failure of the estimated autocorrelation function

\[ r(\tau) = c(\tau) / c(0) \]  

(17)
to damp down as \( \tau \to \infty \), as it should for a stationary, linearly non-deterministic process (Hannan, 1960, p. 43).

A ‘natural’ estimator of the spectral density function is obtained by replacing \( Y(\tau) \) in (10) by \( c(\tau) \) or \( \hat{\tau}(\tau) \). The resulting estimator is proportional, at each frequency, to a sample quantity called the periodogram:

\[ l_T(\lambda) = (2 / T) \left| \sum_{1}^{T} e^{i \lambda t} x_t \right|^2 \]  

(18)

usually evaluated at the equi-spaced frequencies

\[ \lambda = 2 k \pi / T, \quad k = 1, 2, ..., [T / 2] \]  

(19)
in the interval \([0, \pi]\). Although, for a stationary, nonlinearly deterministic process, the periodogram ordinates are asymptotically unbiased estimates of the spectral densities at the corresponding frequencies, they are not consistent estimates; moreover, the correlation between adjacent periodogram ordinates tends to zero with increasing sample size. The result is that the periodogram presents a jagged appearance which is increasingly difficult to interpret as more data become available.

In order to obtain consistent estimates of the spectral density function at specific frequencies, it is common practice to weight the periodogram ordinates over the frequency range or to form weighted averages of the autocovariances at different lags. There is a substantial literature on the subject. The weights are called a ‘spectral window’. Essentially the idea is to reduce the variance of the estimate of an average spectral density around a particular frequency by averaging periodogram ordinates which are asymptotically unbiased and independently distributed estimates of the corresponding ordinates of the spectral density function. Related weights can also be applied to the estimated autocovariances which are substituted in (10); this weighting system is called a ‘lag window’.

Naturally the sampling properties of the spectral estimates depend on the nature of the ‘window’ used to
obtain consistency (see Priestley, 1981, pp. 432–94 for further discussion). Regardless of the choice of window, the ‘bandwidth’ used in constructing the window must decrease at a suitable rate as the sample size grows. In the spectral window approach, this means that the window width must decrease at a slower rate than the sample size. In the lag window approach, this means that the number of included autocovariances must increase at a slower rate than the sample size.

3.2 ARMA models

The autocovariance function and the spectral density function for a time series represent nonparametric approaches to describing the data. An alternative approach is to specify and estimate a parametric ARMA model for $x_t$. This approach involves choosing the orders of the polynomials $P$ and $Q$ in (7) and (8) and perhaps also specifying that one or more coefficients are zero or placing other restrictions on $P$ and $Q$. The problem then becomes one of estimating the parameters of the model.

Despite the poor statistical properties of the estimated autocovariance function and a related function called the partial autocorrelation function, these are sometimes used to specify the orders of the polynomials $P$ and $Q$. An alternative approach is to select the model that minimizes the value of information-theoretic criteria of the form

$$
\text{IC}(i) = \log(\hat{\sigma}_i^2) + k_i c_T,
$$

(20)

where $k_i$ refers to the number of estimated parameters in the candidate models $i = 1, \ldots, M$, and $\hat{\sigma}_i^2$ to the corresponding maximum likelihood estimate of the residual variance. Such criteria incorporate a trade-off between the fit of a model and its degree of parsimony. That trade-off depends on the penalty term $c_T$ (Akaike, 1970; 1974; Schwarz, 1978). There is no universally accepted choice for $c_T$. For $c_T = \frac{2}{T}$ expression (20) reduces to the Akaike information criterion (AIC), for example, and for $c_T = \ln(T)/T$ to the Schwarz information criterion (SIC). The asymptotic properties of alternative criteria will depend on the objective of the user and the class of models considered.

Given the orders of the AR and MA components, a variety of maximum likelihood or approximate maximum likelihood methods are available to estimate the model parameters. Newbold (1974) shows that, if $x_t$ is characterized by (8) with $\xi_t \sim NID(0, \sigma^2)$, then the exact likelihood function for the parameters of $P(\cdot)$ and $Q(\cdot)$ is such that the maximum likelihood estimates of the parameters and the least-squares (LS) estimates (in general highly nonlinear) are asymptotically identical. Only in the case of a pure AR model are the estimates linear conditional on the initial observations. Several approximations have been discussed (Box and Jenkins, 1970; Granger and Newbold, 1977; Nerlove, Grether and Carvalho, 1979, pp. 121–5).

Exact maximum likelihood estimation of ARMA models has been discussed by, inter alia, Newbold
time series analysis: The New Palgrave Dictionary of Economics
(1974), Anderson (1977), Ansley (1979), and Harvey (1981). Following Schweppe (1965), Harvey suggests the use of the Kalman filter to obtain the value of the exact-likelihood function, which may be maximized by numerical methods. The Kalman filter approach is easily adapted to the estimation of UC models in the time domain.

An alternative to exact or approximate maximum-likelihood estimation in the time domain was suggested by Hannan (1969). Estimates may be obtained by maximizing an approximate likelihood function based on the asymptotic distribution of the periodogram ordinates defined in (18). These are asymptotically independently distributed (Brillinger, 1975, p. 95), and the random variables $2 \ln(f(\lambda)) / f(\lambda)$ have an asymptotic $\chi^2$ distribution with two degrees of freedom (Koopmans, 1974, pp. 260–5). This means that the asymptotic distribution of the observations, $\{x_1, \ldots, x_T\}$ is proportional to

$$\prod_{j=0}^{[T/2]} \left[ 1 / f(\lambda_j) \right] \exp\left[ -l(\lambda_j) / f(\lambda_j) \right]$$

(21)

where $\lambda_j = 2j \pi / T$, $j = 0, \ldots, [T/2]$, are the equi-spaced frequencies in the interval $[0, \pi]$ at which the periodogram is evaluated (Nerlove, Grether and Carvalho, 1979, pp. 132–6). Since the true spectral density $f(\lambda)$ depends on the parameters characterizing the process, this asymptotic distribution may be interpreted as a likelihood function. Frequency domain methods, as these are called, may easily be applied in the case of UC models.

Whether approximate or exact maximum-likelihood estimation methods are employed, inference may be based on the usual criteria related to the likelihood function. Unfortunately, serious difficulties may be encountered in applying the asymptotic theory, since the small sample distribution of the maximum likelihood estimator may differ greatly from the limiting distribution in important cases (Sargan and Bhargava, 1983; Anderson and Takemura, 1986).

### 3.3 Prediction and extraction

The problem of prediction is essentially the estimation of an unknown future value of the time series itself; the problem of extraction, best viewed in the context of UC models described in section 2.3, is to estimate the value of one of the unobserved components at a particular point in time, not necessarily in the future. Problems of trend extraction and seasonal adjustment may be viewed in this way (Grether and Nerlove, 1970). How the prediction (or extraction) problem is approached depends on whether we are assumed to have an infinite past history and, if not, whether the parameters of the process generating the time series are assumed to be known. In practice, of course, an infinite past history is never available, but a very long history is nearly equivalent if the process is stationary or can be transformed to stationarity. It is common, as well, to restrict attention to linear predictors, which involves no loss of
generality if the processes considered are Gaussian and little loss if merely linear. To devise a theory of optimal prediction or extraction requires some criterion by which to measure the accuracy of a particular candidate. The most common choice is the minimum mean-square error (MMSE) criterion, which is also the conditional expectation of the unknown quantity. For a discussion of alternative loss functions see Granger (1969) and Christoffersen and Diebold (1996; 1997).

The theory of optimal prediction and extraction due to Kolmogorov (1941) and Wiener (1949) and elaborated by Whittle (1963) for discrete processes assumes a possibly infinite past history and known parameters. As a special case of the Wiener–Kolmogorov theory for non-deterministic, stationary processes, consider the linear process defined by (2). Since the $\xi_t$ are i.i.d. with zero mean and variance $\sigma^2$, it is apparent that the conditional expectation of $\hat{x}_{t+}^v$, given all innovations from the infinite past to $t$, is

$$\hat{x}_{t+}^v = b_v \xi_t + b_{v+1} \xi_{t+1} + \ldots$$

(22)

Of course, even if the parameters $b_j$, $j = 0, 1, \ldots$, are assumed to be known, the series \{\xi_t\} is not directly observable. The $\xi_t$'s are sometimes called the innovations of the process, since it is easy to show that $\xi_t = x_{t+1} - \hat{x}_{t+1}$ is the one-step ahead prediction error. If the process is invertible, it has the autoregressive representation (6) and so can be expressed solely in terms of the, generally infinite-order, autoregression

$$\hat{x}_{t+}^v = D(L) x_t$$

(23)

where the generating transform of the coefficients of $D$ is

$$D(z) = \frac{1}{B(z)} \left[ B(z) \frac{1}{z^v} \right]_+.$$

The operator $[ \cdot ]_+$ eliminates terms involving negative powers of $z$.

The problem of extraction is best viewed in the context of multiple time series; in general we wish to 'predict' one time series \{y_t\} from another related series \{x_t\}. It is not necessary that the series \{y_t\}
actually be observed as long as its relationship to an observed series \( \{x_t\} \) can be described (Nerlove, Grether and Carvalho, 1979, ch. 5).

The Kalman filter approach to prediction and extraction (Kalman, 1960) is both more special and more general than the Wiener–Kolmogorov theory: attention is restricted to finite-dimensional parameter spaces and linear processes, but these processes need not be stationary. The parameters may vary with time, and we do not require an infinite past. This approach represents a powerful tool of practical time-series analysis and may be easily extended to multiple time series. A full discussion, however, requires a discussion of ‘state-space representation’ of time series processes and is beyond the scope of this entry (Harvey, 1989)

### 4 Multipleteimeseries analysis

A general treatment of multiple time series analysis is contained in Hannan (1970). The two-variable case will serve to illustrate the matter. Two stationary time series \( \{x_t\} \) and \( \{y_t\} \) are said to be jointly stationary if their joint distribution function does not depend on the origin from which time is measured. Joint stationarity implies, but is not in general implied by, weak or covariance joint stationarity; that is, \( \text{cov}(x_t, y_s) \) is a function of \( s - t \) only. In this case the cross-covariance function is

\[
Y_{yx}(\tau) = \mathbb{E}[y_t - \mu_y] [x_{t-\tau} - \mu_x],
\]

(24)

where \( \mu_x = \mathbb{E}x_t \) and \( \mu_y = \mathbb{E}y_t \). Note that \( Y_{yx}(\tau) \) and \( Y_{xy}(\tau) \) are, in general, different. The cross-covariance generating function is defined as

\[
g_{yx}(z) = \sum_{-\infty}^{\infty} Y_{yx}(\tau) z^\tau
\]

(25)

in that region of the complex plane in which the right-hand side of (25) converges. For two jointly stationary series this occurs in an annulus containing the unit circle. In this case, the cross-spectral density function is defined as

\[
f_{yx}(\lambda) = \frac{1}{2\pi} g_{yx}(e^{i\lambda}).
\]

(26)
Since $\gamma_{yx}(\tau)$ and $\gamma_{xy}(\tau)$ are not equal, the cross-spectral density function is complex valued and can be decomposed into a real part (the co-spectral density) and a complex part (the quadrature spectral density):

$$f_{yx}(\lambda) = \epsilon_{yx}(\lambda) + iq_{yx}(\lambda).$$  \hspace{1cm} (27)

In polar form, the cross-spectral density may be written as

$$f_{yx}(\lambda) = \alpha_{yx}(\lambda) \exp \{ i \varphi_{yx}(\lambda) \},$$  \hspace{1cm} (28)

where $\alpha_{yx}(\lambda) = \left[ \epsilon_{yx}^2(\lambda) + q_{yx}^2(\lambda) \right]^{1/2}$ is called the amplitude or gain, and where $\varphi_{yx}(\lambda) = \arctan \left\{ -q_{yx}(\lambda) / \epsilon_{yx}(\lambda) \right\}$ is called the phase. Another useful magnitude is the coherence between the two series, defined as

$$\rho_{yx}(\lambda) = \frac{\mid f_{yx}(\lambda) \mid^2}{f_{xx}(\lambda) f_{yy}(\lambda)},$$  \hspace{1cm} (29)

which measures the squared correlation between $y$ and $x$ at a frequency $\lambda$. Clearly, $\rho_{yx}(\lambda) = \rho_{xy}(\lambda)$. Estimation of cross-spectral density functions and related quantities is discussed in Priestley (1981, pp. 692–712).

Often it is convenient to impose additional parametric structure in modelling multiple time series. The workhorse multiple time series model in econometrics has been the covariance-stationary $K$-dimensional vector autoregressive model, which may be viewed as a natural generalization of the univariate AR model discussed earlier:

$$A(L) x_t = \varepsilon_t$$
where $A(L) = I_k - A_1 L - \ldots - A_p L^p$. Here each variable in $x_t$ is regressed on its own lags as well as lags of all other variables in $x_t$ up to some pre-specified lag order $p$. This vector autoregression (VAR) can also be viewed as an approximation to a general linear process $x_t$, and may be estimated by LS. Similarly, the formulation of ARMA and UC models discussed earlier may be extended to the multivariate case by interpreting the polynomials in the lag operator as matrix polynomials and by replacing the scalar random variables by vectors. Although these vector ARMA and UC models bear a superficial resemblance to the corresponding univariate ones, their structure is, in fact, much more complicated and gives rise to difficult identification problems. In the univariate case, we can formulate simple conditions under which a given covariance function identifies a unique ARMA or UC model, but in the multivariate case these conditions are no longer sufficient. Hannan (1970; 1971) gives a complete treatment. State-space methods have also been employed to study the structure of multivariate ARMA models (Hannan, 1976; and, especially, 1979).

5 Unit roots, co-integration and long memory

Standard tools for time series analysis have been developed for processes that are covariance stationary or have been suitably transformed to achieve covariance stationarity by removing (or explicitly modelling) deterministic trends, structural breaks, and seasonal effects. The presence of a unit root in the autoregressive lag order polynomial of an ARMA process also violates the assumption of stationarity. Processes with a unit root are also called integrated of order one (or I(1) for short) because they become covariance-stationary only upon being differenced once. In general, I($d$) processes must be differenced $d$ times to render the process covariance-stationary. The presence of unit roots has important implications for estimation and inference. When the scalar process $x_t$ is I(1) the variance of $x_t$ will be unbounded, model innovations will have permanent effects on the level of $x_t$, the autocorrelation function does not die out, and $x_t$ will not revert to a long-run mean. Moreover, coefficients of I(1) regressors will have nonstandard asymptotic distributions, invalidating standard tools of inference.

The simplest example of an autoregressive integrated moving-average (ARIMA) process is the random walk process: $x_t = x_{t-1} + \varepsilon_t$. The potential pitfalls of regression analysis with I(1) data are best illustrated by the problem of regressing one independent random walk on another. In that case, it can be shown that $R^2$ and $\hat{\beta}$ will be random and that the usual $t$-statistic will diverge, giving rise to seemingly significant correlations between variables that are unrelated by construction. This spurious regression problem was first discussed by Yule (1926), further illustrated by Granger and Newbold (1974), and formally analyzed by Phillips (1986) and Phillips and Durlauf (1986). Similar problems arise in deterministically detrending I(1) series (Nelson and Kang, 1981; Durlauf and Phillips, 1988). Unbalanced regressions, that is, regressions in which the regressand is not of the same order of integration as the regressor, may also result in spurious inference. An exception to this rule is inference.
on coefficients of mean zero $I(0)$ variables in regressions that include a constant term (Sims, Stock and Watson, 1991).

The standard response to dealing with $I(1)$ data is to difference the data prior to the analysis. There is one important exception to this rule. There are situations in which several variables are individually $I(1)$, but share a common unit root component. In that case, a linear combination of these variables will be $I(0)$:

$$\begin{align*}
    c' x_t &= u_t + l(0), \ c \neq 0
\end{align*}$$

(31)

where $x_t$ denotes a $K$-dimensional vector of $I(1)$ variables and $c$ is a $(K \times 1)$ parameter vector. In other words, these variables share a common stochastic trend. This phenomenon is known as co-integration (Granger, 1981; Engle and Granger, 1987) and $c$ is known as the co-integrating vector. Clearly, $c$ is not unique. It is common to normalize one element of $c$ to unity. The LS estimator of $c$ in (31) is consistent, but corrections for omitted dynamics are recommended (Stock and Watson, 1993; Phillips and Hansen, 1990). Co-integrating relationships have been used extensively in modelling long-run equilibrium relationships in economic data (Engle and Granger, 1991).

Variables that are co-integrated are linked by an error correction mechanism that prevents the integrated variables from drifting apart without bound. Specifically, by the Granger representation theorem of Engle and Granger (1987), under some regularity conditions, any $K$-dimensional vector of co-integrated variables $x_t$ can be represented as a vector error correction (VEC) model of the form:

$$\begin{align*}
    \Delta x_t &= \sum_{i=1}^{\rho-1} \Gamma^i \Delta x_{t-i} - \Pi x_{t-\rho} \\
\end{align*}$$

(32)

where $\Gamma^i, \ i = 1, \ldots, \rho - 1,$ and $\Pi \equiv BC$ are conformable coefficient matrices and $\Delta$ denotes the first-difference operator. Model (32) allows for up to $r$ co-integrating relationships where $r$ is the rank of $\Pi$. For $r = 0$, the error correction term in model (32) drops out and the model reduces to a difference-stationary VAR. For $r = K$, all variables are $I(0)$ and model (32) is equivalent to a stationary VAR in levels. Otherwise, there are $0 < r < K$ common trends. If the $(r \times K)$ matrix of co-integrating vectors, $C$, is known, the model in (32) reduces to
\[ \Delta x_t = \sum_{i=1}^{p-1} \Gamma_i \Delta x_{t-i} - B z_{t-p} \]

where \( z_{t-p} = C x_{t-p} \), and the model may be estimated by LS; if only the rank \( r \) is known, the VEC model in (32) is commonly estimated by full information maximum likelihood methods (Johansen, 1995).

Starting with Nelson and Plosser (1982), a large literature has dealt with the problem of statistically discriminating between \( I(1) \) and \( I(0) \) models for economic data. Notwithstanding these efforts, it has remained difficult to detect reliably the existence of a unit root (or of co-integration). The problem is that in small samples highly persistent, yet stationary processes are observationally equivalent to exact unit root processes. It may seem that not much could hinge on this distinction then, but it can be shown that \( I(1) \) and \( I(0) \) specifications that fit the data about equally well may have very different statistical properties and economic implications (Rudebusch, 1993).

For processes with roots near unity in many cases neither the traditional asymptotic theory for \( I(0) \) processes nor the alternative asymptotic theory for exact \( I(1) \) processes will provide a good small-sample approximation to the distribution of estimators and test statistics. An alternative approach is to model the dominant root, \( \rho \), of the autoregressive lag order polynomial as \textit{local-to-unity} in the sense that \( \rho = 1 - \epsilon / T, \ \epsilon > 0 \). This asymptotic thought experiment gives rise to an alternative asymptotic approximation that in many cases provides a better small-sample approximation than imposing the order of integration or relying on unit root pretests (Stock, 1991; Elliott, 1998).

Stationary ARMA processes are ‘short memory’ processes in that their autocorrelation function dies out quickly. For large \( \tau \), ARMA autocorrelations decay approximately geometrically, that is, \( \rho(\tau) \approx r^\tau \), where \( r \) is a constant such that \( |r| < 1 \). In many applied contexts including volatility dynamics in asset returns, there is evidence that the autocorrelation function dies out much more slowly. This observation has motivated the development of the class of \textit{fractionally integrated} ARMA (ARFIMA) models:

\[ Q(L)(1 - L)^d x_t = p(L) \epsilon_t \]

(33)

where \( d \) is a real number, as opposed to an integer (Baillie, 1996). Stationarity and invertibility require \(|d| < 0.5\), which can always be achieved by taking a suitable number of differences. The autocorrelation function of an ARFIMA process decays at a hyperbolic rate. For large \( \tau \), we have \( \rho(\tau) \approx \tau^{2d-1} \), where \( \epsilon < 1 / 2 \) and \( d \neq 0 \). Such ‘long memory’ models may be estimated by the two-step procedure of Geweke and Porter-Hudak (1983) or by maximum likelihood (Sowell, 1992; Baillie, Bollerslev and Mikkelsen, 1996). A detailed discussion including extensions to the notion of fractional co-integration is
provided by Baillie (1996). Long memory may arise, for example, from infrequent stochastic regime changes (Diebold and Inoue, 2001) or from the aggregation of economic data (Granger, 1980; Chambers, 1998). Perhaps the most successful application of long-memory processes in economics has been work on modelling the volatility of asset prices and powers of asset returns, yielding new insights into the behaviour of markets and the pricing of financial risk.

6 Nonlinear time series models

The behaviour of many economic time series appears to change distinctly at irregular intervals, consistent with economic models that suggest the existence of floors and ceilings, buffer stocks and regime switches in the data. This observation has given rise to a large literature dealing with nonlinear time series models. Nonlinear time series models still have a Wold representation with linearly unpredictable innovations, but these innovations are nevertheless dependent over time. This has important implications for forecasting and for the dynamic properties of the model. For example, the effects of innovations in nonlinear models will depend on the path of the time series and the size of the innovation, and may be asymmetric.

6.1 Nonlinear dynamics in the conditional mean

The increasing importance of nonlinear time series models in econometrics is best illustrated by two examples: hidden Markov chain models and smooth transition regression models of the conditional mean.

The idea of hidden Markov chains first attracted attention in econometrics in the context of regime switching models (Hamilton, 1989). The original motivation was that many economic time series appear to follow a different process during recession phases of the business cycle than during economic expansions. This type of regime-switching behaviour may be modelled in terms of an unobserved discrete-valued state variable (for example, 1 for a recession and 0 for an expansion) that is driven by a Markov chain. The transition from one state to another is governed by a matrix of transition probabilities that may be estimated from past data. The essence of this method thus is that the future will in some sense be like the past. A simple example of this idea is the regime-switching AR(1) model:

\[ x_t = \begin{cases} 1_{s_t} x_{t-1} + \varepsilon_t, & \varepsilon_t \sim \text{NID}(0, \sigma^2) \\ \end{cases} \]

(34)

where the regime \( s_t \) is the outcome of an unobserved two-state Markov chain with \( s_t \) independent of \( \varepsilon_t \) for all \( t \) and \( \tau \). In this model, the time-varying slope parameter will take on different values depending on the state \( s \). Once the model has been estimated by maximum likelihood methods, it is possible to infer how likely a given regime is to have generated the observed data at date \( t \). An excellent review of the literature on hidden Markov models is provided by Cappé, Moulines and Ryden (2005); for a general
The idea of smooth transition regression models is based on the observation that many economic variables are sluggish and will not move until some state variable exceeds a certain threshold. For example, price arbitrage in markets will only set in once the expected profit of a trade exceeds the transaction cost. This observation has led to the development of models with fixed thresholds that depend on some observable state variable. Smooth transition models allow for the possibility that this transition occurs not all of a sudden at a fixed threshold but gradually, as one would expect in time series data that have been aggregated across many market participants. A simple example is the smooth-transition AR(1) model:

\[ x_t = \Phi(z_{t-1}, \ldots, z_{t-d}, \Gamma) x_{t-1} + \varepsilon_t \quad \varepsilon_t \sim NID(0, \sigma^2) \]  

where \( \Phi( \cdot ) \) denotes the transition function, \( z_t \) is a zero mean state variable denoting the current deviation of \( x_t \) from a (possibly time-varying) equilibrium level and \( \Gamma \) is the vector of transition parameters. Common choices for the transition function are the logistic or the exponential function. For example, we may specify \( \Phi( \cdot ) = (\exp\{\gamma(z_{t-1})^2\}) \) with \( \gamma < 0 \). If \( z_{t-1} = 0 \), \( \Phi( \cdot ) = 1 \) and the model in (35) reduces to a random walk model; otherwise, \( \Phi( \cdot ) < 1 \) and the model in (35) reduces to a stationary AR(1). The degree of mean reversion is increasing in the deviation from equilibrium. For further discussion see Granger and Teräsvirta (1993).

### 6.2 Nonlinear dynamics in the conditional variance

While the preceding examples focused on nonlinear dynamics in the conditional mean, nonlinearities may also arise in higher moments. The leading example is the conditional variance. Many economic and financial time series are characterized by volatility clustering. Often interest centres on predicting these volatility dynamics rather than the conditional mean. The basic idea of modelling and forecasting volatility was set out in Engle's (1982) path-breaking paper on autoregressive conditional heteroskedasticity (ARCH). Subsequently, Bollerslev (1986) introduced the class of generalized autoregressive conditionally heteroskedastic (GARCH). Consider a decomposition of \( x_t \) into the one-step ahead conditional mean, \( \mu_{t|t-1} \equiv E(x_t|\Omega_{t-1}) \), and conditional variance, \( \sigma_{t|t-1}^2 \equiv Var(x_t|\Omega_{t-1}) \), where \( \Omega_{t-1} \) denotes the information set at \( t-1 \):

\[ x_t = \mu_{t|t-1} + \sigma_{t|t-1} \nu_t \quad \nu_t \sim NID(0, 1) \]
The leading example of a GARCH model of the conditional variance is the GARCH(1,1) model, which is defined by the recursive relationship

\[
\sigma^2_{t-1} = \omega + \alpha \varepsilon^2_{t-1} + \beta \sigma^2_{t-1} t-2
\]

(37)

where \(\varepsilon_t \equiv \sigma_{t|t-1} \nu_t\) and the parameter restrictions \(\omega > 0, \ \alpha \geq 0, \ \beta \geq 0\) ensure that the conditional variance remains positive for all realizations of \(\nu_t\). The standard estimation method is maximum likelihood. The basic GARCH(1,1) model may be extended to include higher-order lags, to allow the distribution of \(\nu_t\) to have fat tails, to allow for asymmetries in the volatility dynamics, to permit the conditional variance to affect the conditional mean, and to allow volatility shocks to have permanent effects or volatility to have long memory. It may also be extended to the multivariate case.

It follows directly from the formulation of the GARCH(1,1) model that the optimal, in the MMSE sense, one-step-ahead forecast equals \(\sigma^2_{t+1}\). Similar expressions for longer horizons may be obtained by recursive updating. There is a direct link from the arrival of news to volatility measures and from volatility forecasts to risk assessments. These and alternative volatility models and the uses of volatility forecasts are surveyed in Andersen et al. (2006). For a comparison of GARCH models with the related and complementary class of stochastic volatility models, see Andersen, Bollerslev and Diebold (2006) and Shephard (2005).

### 7 Applications

Time series analytic methods have many applications in economics. Here we consider five: (1) analysis of the cyclic properties of economic time series, (2) description of seasonality and seasonal adjustment, (3) forecasting, (4) dynamic econometric modelling, and (5) structural vector autoregressions.

#### 7.1 Analysis of the cyclic properties of economic time series

Suppose that the time series \(\{x_t\}\) is a linearly non-deterministic stationary series and that the series \(\{\nu_t\}\) is formed from \(\{x_t\}\) by the linear operator

\[
\nu_t = \sum_{j=m}^{n} w_j x_{t-j}, \quad \sum_{m}^{n} w_j^2 < \infty .
\]

(38)
Such an operator is called a time-invariant linear filter. Analysis of the properties of such filters plays an important role in time series analysis since many methods of trend estimation or removal and seasonal adjustment may be represented or approximated by such filters. An interesting example that illustrates the potential pitfalls of using such filters is provided by Adelman (1965), who showed that the 20-year long swings in various economic series found by Kuznets (1961) may well have been the result of the trend filtering operations used in preliminary processing of the data. For a fuller treatment see Nerlove, Grether and Carvalho (1979, pp. 53–7).

Since the 1980s, there has been increased interest in the use of nonlinear filters for extracting the business cycle component of macroeconomic time series. Examples include the band-pass filter (Christiano and Fitzgerald, 2003) and the Hodrick–Prescott (HP) filter (Hodrick and Prescott, 1997; Ravn and Uhlig, 2002). The latter approach postulates that \( Y_t = T_t + c_t \) where \( T_t \) denotes the trend component and \( c_t \) the deviation from trend or ‘cyclical’ component of the time series \( y_t \). The trend component is chosen to minimize the loss function:

\[
\sum_{t=1}^{T} c_t^2 + \lambda \sum_{t=1}^{T} \left[ (T_{t+1} - T_t) - (T_t - T_{t-1}) \right]^2
\]

(39)

where \( c_t = Y_t - T_t \) and \( \lambda \) is a pre-specified parameter that depends on the frequency of the observations. The trade-off in this optimization problem is between the degree to which the trend component fits the data and the smoothness of the trend.

7.2 Description of seasonality and seasonal adjustment

Many economic time series exhibit fluctuations which are periodic within a year or a fraction thereof. The proper treatment of such seasonality, whether stochastic or deterministic, is the subject of a large literature, summarized rather selectively in Nerlove, Grether and Carvalho (1979, ch. 1). More recent treatments can be found in Hylleberg (1992), Franses (1996) and Ghysels and Osborn (2001).

Seasonality may be modelled and its presence detected using spectral analysis (Nerlove, 1964) or using time domain methods. Deterministic seasonality, in the form of model parameters that vary deterministically with the season, offers no great conceptual problems but many practical ones. Stochastic seasonality is often modelled in the form of seasonal unit roots. In that case, seasonal differencing of the data removes the unit root component. Multiple time series may exhibit seasonal co-integration. Sometimes it is convenient to specify stochastic seasonality in the form of an UC model (Grether and Nerlove, 1970). Appropriate UC models may be determined directly or by fitting an ARIMA model and deriving a related UC model by imposing sufficient a priori restrictions (Hillmer and Tiao, 1982; Bell and Hillmer, 1984).
7.3 Forecasting

One of the simplest forecasting procedures for time series is exponential smoothing based on the relationship

\[
\hat{X}_{t+1|k} = (1 - \theta) x_t + \theta \hat{X}_{t|k-1}
\]

(40)

where \(x_t\) is the observed series and \(\hat{X}_{t|k}\) is the forecast of the series at time \(j\) made on the basis of information available up to time \(k\). Muth (1960) showed that (40) provides an MMSE forecast if the model generating the time series is \(\epsilon_t\). Holt (1957) and Winters (1960) generalized the exponential smoothing approach to models containing more complex trend and seasonal components. Further generalization and proofs of optimality are contained in Theil and Wage (1964) and Nerlove and Wage (1964).

Perhaps the most popular approach to forecasting time series is based on ARIMA models of time series processes (Box and Jenkins, 1970). The developments discussed in the preceding paragraph led to the development of UC models, which give rise to restricted ARIMA model forms (Nerlove, Grether and Carvalho, 1979). State-space representations of these models permit the application of the Kalman filter to both estimation and forecasting. Harvey (1984) presents a unified synthesis of the various methods.

More recently, the focus has shifted from traditional forecasting methods towards methods that exploit the increased availability of a large number of potential predictors. Consider the problem of forecasting \(X_{t+h}\) based on its own current and past values as well as those of \(N\) additional variables, \(x_t\). Of particular interest is the case in which the number of predictors, \(N\), exceeds the number of time series observations, \(T\). In that case, principal components analysis provides a convenient way of extracting a low-dimensional vector of common factors from the original data-set \(x_t\) (Stock and Watson, 2002a; 2002b). Forecasts that incorporate estimated common factors have proved successful in many cases in reducing forecast errors relative to traditional time series forecasting methods. Boivin and Ng (2005) provide a systematic comparison of alternative factor model forecasts. Another promising forecasting method is Bayesian model averaging across alternative forecasting models (Raftery, Madigan and Hoeting, 1997). The latter method builds on the literature on forecast combinations (Bates and Granger, 1969).

7.4 Dynamic econometric modelling

There is a close connection between multivariate time-series models and the structural, reduced and final forms of dynamic econometric models; the standard simultaneous-equations model (SEM) is a specific and restricted case.
Suppose that a vector of observed variables $y_t$ may be subdivided into two classes of variables, ‘exogenous’, $\{x_t\}$, and endogenous, $\{z_t\}$. A dynamic, multivariate simultaneous linear system may be written.

\[
\begin{bmatrix}
\Psi_{11}(L) & \Psi_{12}(L) \\
0 & \Psi_{22}(L)
\end{bmatrix}
\begin{bmatrix}
z_t \\
x_t
\end{bmatrix} =
\begin{bmatrix}
\Theta_{11}(L) & 0 \\
0 & \Theta_{22}(L)
\end{bmatrix}
\begin{bmatrix}
\varepsilon_{1t} \\
\varepsilon_{2t}
\end{bmatrix}
\]

(41)

where $\Psi_{ij}(\cdot)$ and $\Theta_{ij}(\cdot)$, $i, j = 1, 2$ are matrix polynomials in the lag operator $L$. Such systems are known as vector ARMAX models and conditions for their identification are given by Hatanaka (1975). The reduced form of the system is obtained by expressing $z_t$ as a function of lagged endogenous and current and lagged exogenous variables. The final form is then obtained by eliminating the lagged endogenous variables (see Zellner and Palm, 1974; Wallis, 1977).

7.5 Structural vector autoregressions

An important special case of the dynamic SEM is the structural vector autoregressive model in which all variables are presumed endogenous, the lag structure is unrestricted up to some order $p$, and identification of the structural form is achieved by imposing restrictions on the correlation structure of the structural innovations (Sims, 1980). The most common form of the structural VAR($p$) model imposes restrictions on the contemporaneous interaction of structural innovations. Consider the structural form for a $K$-dimensional vector $\{x_t\}$, $t = 1, \ldots, T$:

\[
B_0 x_t = \sum_{i=1}^{p} B_i x_{t-i} + \eta_t
\]

(42)

where $\eta_t \sim (0, \Sigma_{\eta})$ denotes the $(K \times 1)$ vector of serially uncorrelated structural innovations (or shocks) and $B_i$, $i = 0, \ldots, p$, the $(K \times K)$ coefficient matrices. Without loss of generality, let $\Sigma_{\eta} = I$. The corresponding reduced form is

\[
x_t = \sum_{i=1}^{p} B_0^{-1} B_i x_{t-i} + B_0^{-1} \eta_t = \sum_{i=1}^{p} A_i x_{t-i} + \varepsilon_t
\]

(43)
where $\varepsilon_t \sim (0, \Sigma)$. Since $\varepsilon_t = B_0^{-1} \eta_t$, it follows that $\Sigma \varepsilon = B_0^{-1} B_0^{-1}'$. Given a consistent estimate of the reduced form parameters $A_{i\cdot} \ i = 1, \ldots, p,$ and $\Sigma \varepsilon$, the elements of $B_0^{-1}$ will be exactly identified after imposing $K(K-1)/2$ restrictions on the parameters of $B_0^{-1}$ that reflect the presumed structure of the economy. Given estimates of $B_0^{-1}$ and $A_{i\cdot} \ i = 1, \ldots, p,$ estimates of the remaining structural parameters may be recovered from $B_i = B_0 A_{i\cdot}$.

In practice, the number of restrictions that can be economically motivated may be smaller or larger than $K(K-1)/2$. Alternative estimation strategies that remain valid in the over-identified case include the generalized method of moments (Bernanke, 1986) and maximum likelihood (Sims, 1986). An instrumental variable interpretation of VAR estimation is discussed in Shapiro and Watson (1988). Semi-structural VAR models that are only partially identified have been proposed by Bernanke and Mihov (1998).

Alternative identification strategies may involve putting restrictions on the long-run behaviour of economic variables (Blanchard and Quah, 1989; King et al., 1991) or on the sign and/or shape of the impulse responses (Faust, 1998). Other possibilities include identification via heteroskedasticity (Rigobon, 2003) or the use of high-frequency data (Faust, Swanson and Wright, 2004).

The estimates of the structural VAR form may be used to compute the dynamic responses of the endogenous variables to a given structural shock, variance decompositions that measure the average contribution of each structural shock to the overall variability of the data, and historical decompositions of the path of $x_t$ based on the contribution of each structural shock.

8 Conclusions

The literature on time series analysis has made considerable strides since the 1980s. The advances have been conceptual, theoretical and methodological. The increased availability of inexpensive personal computers in particular has revolutionized the implementation of time series techniques by shifting the emphasis from closed-form analytic solutions towards numerical and simulation methods. The ongoing improvements in information technology, broadly defined to include not only processing speed but also data collection and storage capabilities, are likely to transform the field even further. For example, the increased availability of large cross-sections of time series data, the introduction of ultra high-frequency data, the electronic collection of micro-level time series data (such as web-based data or scanner data), and the increased availability of data in real time all are creating new applications and spurring interest in the development of new methods of time series analysis. These developments already have brought together the fields of empirical finance and time series econometrics, resulting in the emergence of the new and fertile field of financial econometrics. As the use of time series methods becomes more widespread in applied fields, there will be increasing interest in the development of methods that can be adapted to the specific objectives of the end user. Another question of growing importance is how to deal with rapidly evolving economic environments in the form of structural breaks and other model...
instabilities. Finally, the improvement of structural time series models for macroeconomic policy analysis will remain a central task if time series analysis is to retain its importance for economic policymaking.

Time use

Duncan Ironmonger
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Time is a finite, irreplaceable resource, and unlike money is equally distributed. Statistics of time use and money use can be combined, giving two-dimensional pictures of individual economic behaviour and the national economy. A framework for the microeconomics of time use and household production was established in the 1960s. In coming decades, a macroeconomics of time use and household production will arise. Within a production, consumption and investment framework, this will employ continuous national time accounts and satellite accounts of the household economy. Consequently the household's true economic role and its powerful interactions with the market will be revealed.

Article

Time is a finite, irreplaceable resource available to every man, woman and child in equal amounts of 168 hours per week over the course of life. Time use refers to the allocation of time to alternative uses such as sleep, leisure or work.
Time is perhaps the most fundamental scarce resource; unlike money income or wealth, it is equally
distributed; and how well or wastefully it is used largely determines the progress, achievement and well-being of individuals, families, communities and societies.

One way to assess progress and well-being is to measure aggregate changes in the uses of time rather than, or in addition to, the usual monetary statistics of national income and expenditure. National time accounts are more comprehensive than money accounts as they simultaneously measure the productive time spent in both the market and the household, as well as the time spent in consumption of outputs from both.

The advent of radio astronomy in 1957, using a wider spectrum than that provided by the visible light frequencies, opened up new views of the astronomical universe. Similarly, official statistical organizations are beginning to provide new views of the economic and social universe by observing the world through a ‘time frequency’ rather than the more visible ‘money frequency’.

Researching time use and human behaviour

Time use economics is the scientific study of human behaviour concerning the allocation of time between alternative uses (cf. Robbins, 1932, p. 16).

Time use can be usefully considered under the three comprehensive categories of production, consumption and investment. These accord with the theoretical framework of macroeconomics. Time use data show how individuals and households allocate their time between production (paid work and unpaid work), consumption (meals, television, social interaction and recreation) and human capital formation and maintenance (education, self-care and sleep).

Margaret Reid provided the well-known ‘third person’ test for separating production from consumption: ‘If an activity is of such character that it might be delegated to a paid worker, then that activity shall be deemed productive’ (Reid, 1934, p. 11).

To facilitate analysis, macroeconomics makes a further distinction between resources for immediate use – consumption – and those for use over a longer time period – investment. Accordingly, time spent learning a skill or gaining knowledge in education is clearly investment in human capital. Similarly, time spent in sleep and self-care can be regarded as a necessary daily investment to maintain functioning minds and bodies.

When people spend time, in economic terms they are effectively allocating time between market production, household production, consumption and investment. Modelling of household time-allocation decisions goes beyond understanding the simple work-leisure trade-off. It provides knowledge of the detailed interactions between production, consumption and investment activities. It also provides a framework for the analysis of the derived demands for market commodities implicit in household production and consumption.

Becker (1965) offers a theoretical framework for the microeconomics of time use by including the cost
of time on the same footing as the cost of market goods and by assuming households ‘combine time and market goods to produce more basic commodities that directly enter their utility functions’ (1965, p. 494). This neoclassical approach to a theory has been criticized on many grounds, summarized recently by Folbre (2004).

While neoclassical micro-theory provides a useful framework for a *microeconomics of household production and consumption*, it completely disregards the full macroeconomic magnitude of household production. In most developed countries more labour is required for household production than for market production (Goldschmidt-Clermont and Pagnossin-Aligisakis, 1995). Indeed, if the unpaid time spent in caring for children is fully measured, including the ‘parallel’ or ‘secondary’ time when other activities are simultaneously undertaken, total work in household production is considerably greater than market work (Ironmonger, 2004).

Existing official labour statistics are misleading indicators of total work as they ignore labour inputs to household production. They measure only that time spent on activities within the production boundary of the System of National Accounts (SNA). A broader definition of work includes unpaid work outside the SNA boundary but within the general production boundary. This non-SNA work is employment in household production – the provision of meals, clean clothes, accommodation, care and transport by households for themselves or other households without remuneration (Ironmonger, 2001).

Time use economics is much more than the microeconomics of choice. It includes the study of the large non-monetary economy where households combine time, *their own capital* and intermediate inputs from the market to produce services that compete with market services. Including the use of household capital, the *Gross Household Product (GHP)* of the household economy is comparable to the *Gross Market Product (GMP)* of the market (Ironmonger, 1996a).

Time use data will provide the raw materials for a new *macroeconomics of the household economy*. A principal objective of the recent Eurostat and United States initiatives to collect more time use data has been not only to value unpaid work but to produce satellite accounts giving monetary valuations of the household economy (Varjonen et al., 1999). To be effective as a new set of tools for macroeconomic modelling of the household economy, these accounts and the national time accounts will need to be a continuous time series of annual or even quarterly data covering a run of years.

Considering its enormous magnitude, the performance and rate of growth of the household economy deserve as much attention as that given to the market economy. Macroeconomic modelling of the household economy could help explain the rate of change of household production, the impact of changes in household technology on productivity, and the effects of monetary and fiscal policies on GHP and its broad components.

Modelling of the total economic system – especially the dynamic interactions between the market and household economies – will be greatly improved by using a continuous record of time use taking account of changing economic, social and technological factors. Booms and slumps affect the mix between paid and unpaid work in the market and household economies; new products and technologies can quickly affect the relative productivity of these sectors, and tax policies can alter the relative attractiveness of paid work, unpaid work and leisure.

Using national time accounts and satellite accounts of household production, a macroeconomic model of the household economy could be constructed and linked with a macroeconomic model of the market (Ironmonger, 1994; 1996b). Such a comprehensive model could investigate the cyclical and long-run
relationships between market and household production. One hypothesis worth verification is that the two spheres of production vary in a counter-cyclical pattern (Ironmonger, 1989). If this is so, the amplitude of the fluctuation of Gross Economic Product (GEP, the sum of GHP and GMP) will be less than either component.

Measuring time use

The accurate scientific measurement of how people use time began with independent surveys in a number of countries, particularly in the USSR and the United States in the 1920s. A major advance was made in 1965 when Alexander Szalai directed internationally comparable, diary-based surveys in 12 countries under the sponsorship of UNESCO and the International Social Science Council (Szalai, 1972). Subsequent official measurement of time use included Norway at ten-year intervals from 1971, the Netherlands at five-year intervals from 1975, Canada in 1981, 1986, 1992 and 1998, and Australia in 1987, 1992 and 1997. Several developing countries – for example, India in 1998–9 and South Africa in 2001 – have now conducted official time use surveys.

This development in scientific measurement culminated in the harmonized surveys across some 20 European countries in 1998–2003. They used what is regarded as the most valid technique to measure time use – a diary recording the chronology of various time uses over one or more days from a representative sample of the population. The European surveys collected one weekday and one weekend day from people aged ten upwards; the Indian surveyed one day from age six upwards. Although the 1965 surveys were in one city in one month of the year, the subsequent official surveys cover the whole population, urban and rural, and all seasons of the year.

Research on time use by universities, government agencies and private business has been greatly facilitated by access to the unit record files of individual diary days. The Multinational Time Use Study (MTUS) contains a growing collection of these files covering 78 surveys in 27 countries, including the original 12 from the 1965 cross-national time budget study. The ‘World’ files of MTUS are a particularly rich resource for international comparison, as data have been made as comparable as possible by providing common categories of time use and standard definitions of demographic and household variables.

In addition to the diary-based surveys of time use, some official statistical organizations make estimates, on a continuous basis, of time used in the market economy. For example, in Australia, since 1966, the monthly household survey of employment and unemployment also provides estimates of average hours of market work. In this survey the interviewer's question is: 'How many hours did you work last week in (all) your job(s)?' This is a ‘stylized’ question subject to biases that differ from the diary-based method. Each method – detailed diary or stylized question – has its own bias against ‘reality’.

With the inauguration of the American Time Use Survey (ATUS) in January 2003, the Bureau of Labor Statistics and the US Census Bureau took a giant stride in the scientific measurement of time use. In the world's first continuous survey, diary data on time use are collected each month from a representative sample of adults aged 15 or more years.

This groundbreaking response to fill the biggest single gap in the Federal Statistical System of the United States was 12 years in development. It traces its origin to 1991 when a bill introduced in the 102nd Congress called for the Bureau of Labor Statistics to ‘conduct time-use surveys of unremunerated
work performed in the United States and to calculate the monetary value of such work’ (Horrigan and Herz, 2004).

Table 1 shows the Time Resources and Time Use Account for the United States of America for 2003 derived from the first results of ATUS and arranged according to the macroeconomic categories of production, consumption and investment. Estimates of the time use of children under 15 based on other surveys have been included to complete the table.

* ATUS provides estimates of secondary child care, but restricted to times when respondents are awake and children are not in bed. If these estimates are used, this figure would increase by about 19 per cent to 7,600 million hours per week if, without double-counting other household work, the hours spent in caring for children younger than 13 years as a secondary activity is included. Most of his extra time occurred simultaneously with consumption activity but some overlapped with market work, education and self-care.

As the way children spend time is a critical issue for many research and policy purposes, time use data should be extended to include children. An innovative feature of the new longitudinal study of Australian children is a time-use diary where parents record details of what their child did in two 24-hour periods (Australian Institute of Family Studies, 2005).

Conclusion

The development of national time accounts and satellite accounts of the household economy should be an interactive process between researchers, model builders, policymakers and official statisticians. The national money income and expenditure accounts developed this way.

At the beginning of the 21st century statistical measurements are starting to provide the raw materials for a *macroeconomics of the household economy*. New continuous time use observations will provide regular national time accounts and satellite accounts of household production.

The new data will enable the building of more relevant economy-wide models to explore the continuing interactions between the household and the formal market and public sectors of the economic system. The true macroeconomic role of the household will become clear, not only as the place for consumption and leisure but as the largest user of labour time in economic production. The new household-based models should provide better understanding of issues of work and leisure, and produce policies conducive to a more equitable and satisfactory allocation of time.

Article

The Keynesian economist Mabel Timlin was the first tenured woman among Canadian economists, the first woman elected president of the Canadian Political Science Association (which then covered all social sciences, including economics), the first woman outside the natural sciences elected a Fellow of the Royal Society of Canada (1951), and one of the first ten women to serve on the executive committee of the American Economic Association (1958–60), despite becoming an assistant professor only in her 50th year, after a long career as an academic secretary. She was born in Forest Junction, Wisconsin, on 6 December 1891, and, after studying at the Milwaukee State Normal School, taught in Wisconsin and rural Saskatchewan. She became a secretary at the University of Saskatchewan in 1921, while studying for a BA there. At first Timlin intended to study economics, but after seeing the Department of Economics and Political Science at Saskatchewan she decided (probably correctly) that she could learn more economics on her own. She took a BA with great distinction in English in 1929, and then directed the university’s correspondence courses in economics. Mabel Timlin became an instructor in economics at the University of Saskatchewan in 1935, after completing graduate course work in economics at the University of Washington during summers and a six-month leave. Her doctoral dissertation at the University of Washington, supervised by the much younger Raymond Mikesell, was accepted in 1940 and published as Keynesian Economics (1942). In 1941, Timlin became an assistant professor of economics at the University of Saskatchewan (associate professor 1946, full professor 1950) and a member of the executive committee of the Canadian Political Science Association (Vice-President 1953–5, President 1959–60).

Keynesian Economics did more than introduce Keynesian theory into Canadian academic life. Timlin offered one of the early general equilibrium interpretations of John Maynard Keynes’s General Theory, and was particularly noteworthy in treating it as a system of shifting equilibrium, presented with

innovative diagrams on which she collaborated with the eminent geometer H.S.M. Coxeter. Timlin began work on Keynesian Economics in 1935, before Keynes published his General Theory: Benjamin Higgins had come to Saskatoon from the London School of Economics in 1935 for a one-year appointment, carrying a copy of the summary of Keynes's Cambridge lectures that Robert Bryce had presented in Friedrich Hayek’s LSE seminar.

Beyond her work on Keynes, Timlin also expounded international developments in welfare economics and general equilibrium analysis to a Canadian audience more used to historical and institutional economics than to formal theory (for example, Timlin, 1946). Timlin (1953) sharply criticized the Bank of Canada for failing to follow Keynesian countercyclical stabilization policies during the Korean War inflation. Much of her later work (for example, Timlin, 1951; 1958; 1960) concerned immigration policy, emphasizing the economic benefits of freer immigration.

Mabel Timlin never married. Generations of former students were her extended family. She remained active as a scholar long after her official retirement in 1959, publishing a major report on the social sciences in Canada in 1968. She remained devoted to the University of Saskatchewan despite job offers from such institutions as the University of Toronto, and died in Saskatoon on 19 September 1976.

Tinbergen, Jan (1903– 1994)

Peter A. Cornelisse and Herman K. van Dijk
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Jan Tinbergen was the first Nobel Laureate in economics in 1969. This article presents a brief survey of his many contributions to economics, in particular to macroeconometric modelling, business cycle analysis, economic policymaking, development economics, income distribution, international economic integration and the optimal regime. It further emphasizes his desire to contribute to the solution of urgent socio-economic problems and his passion for a more humane world.

Article

Jan Tinbergen was born in The Hague, The Netherlands, on 12 April 1903, the first of five children in an intellectually stimulating family with a love of foreign languages. Eventually two of the children would win a Nobel Prize: Jan in economics (in 1969) and Niko, an ethologist, in physiology or medicine (in 1973).

Jan Tinbergen enrolled as a student of mathematical physics at Leiden University in 1921, where he obtained his doctorate in 1929. By that time he had already decided to switch to economics.
to 1928 Tinbergen worked as a conscientious objector to national military service, first in a convict prison and later, and of greater import to his subsequent career, at the Central Bureau of Statistics. He continued to work there until 1945. In 1933 he became extraordinary professor of statistics, mathematical economics and econometrics at the Netherlands School of Economics in Rotterdam. As a result of his quantitative approach to the study of economic dynamics, he was invited to the League of Nations in Geneva during the period 1936–8 in order to carry out statistical tests of business cycles theories. In 1945, at the end of the Second World War, Tinbergen was appointed as the first director of the Central Planning Bureau at The Hague. He held this position until 1955, when he became full professor of mathematical economics and development planning at the Netherlands School of Economics, later Erasmus University, Rotterdam. Throughout the 1960s and a part of the 1970s he acted as adviser to various international organizations and to governments of a considerable number of less-developed countries. He was elected chairman of the United Nations Committee on Development Planning in 1965 and held this position until 1972. In 1969 he was awarded, together with Ragnar Frisch, the first Nobel Prize in Economics. After his retirement as full professor in 1973 he held the Cleveringa Chair in Leiden for two years. He continued to be involved in various research projects at old age. Jan Tinbergen died on 9 June 1994.

**Personal motivation**

Already at an early age Tinbergen was profoundly impressed by the horrors of the Great War – subsequently numbered as the First World War – partly because of the fate of the Austrian refugee children his parents had lodged. Later, in Leiden as a student, when he was invited by his postman to join him on his rounds, he was appalled by the conditions of poverty in which the local population lived. Wishing to contribute to the struggle against such social evils, he decided to become an economist. This decision was characteristic of Tinbergen and his attitude towards economic science in his later life: his scientific contributions would always be inspired by the desire to tackle the social problems he observed. Paul Ehrenfest, professor of theoretical physics and Tinbergen's mentor in Leiden, was not unsympathetic towards the switch from physics to economics. Having made important contributions to statistical mechanics together with his wife Tatyana Afanasyeva, he called Tinbergen's attention to the possibilities that a mathematical representation of economic problems would offer. The dissertation on minimum problems in physics and economics that Tinbergen defended in 1929 bridged the two disciplines.

**Econometric modelling and business cycle research**

In 1969 Tinbergen was awarded, together with R. Frisch, the first Nobel Prize in Economics ‘for having developed and applied dynamic models for the analysis of economic processes’, as the Nobel Prize committee described it. The desire to combat the socio-economic consequences of the Great Depression of the 1930s was Tinbergen's most important motivation for studying business cycles. In his inaugural address as extraordinary professor in 1933 he summarized his project as ‘statistics and mathematics in the service of business cycle research’. His approach contrasted with previous approaches to business cycle research.
After a 19th-century undertaking by Juglar (1862) ascribing the recurrent business crises in Europe and North America to credit crises, and Jevons's (1884) study pointing to agricultural production cycles connected with sunspot numbers, several research projects in the early 20th century were devoted to the construction of so-called business cycle barometers. The purpose was to measure economic fluctuations through a particular index (or set of indices) with the aim of giving warning signals for turning points that would lead to a depression. An example was the Harvard Index of Business Conditions, informally known as the Harvard Barometer, constructed by a team led by Persons (1919). Another well-known descriptive approach to the business cycle during this period had been initiated by Mitchell (1913). His work was followed by that of Yule (1927) and Slutzky (1927), who suggested that the cumulative effect of random shocks could be the cause of cyclical patterns in economic variables. Frisch (1933), co-recipient of the 1969 Nobel Prize, applied these ideas introducing econometric models in which impulse propagation mechanisms led to business cycles.

However useful it could be as a starting point, Tinbergen criticized descriptive analysis as being too vague for use in policy preparation, and started a quantitatively oriented research programme to explore the possible economic causes of the periodic upswings and downswings in economic activity. In an earlier theoretical study Aftalion (1927) had argued that lags in an economic model could generate cyclical variation in economic activity. Following up this argument, Tinbergen specified a first simple case using a system of difference equations to express lagged responses of supply to price changes in a market for a single good. He noted that the systematic fluctuations that could arise in such a system had been observed in an empirical study of the pork market by the German economist Hanau (1928), a phenomenon that became known as the ‘cobweb model’ (Tinbergen, 1979, presents additional relevant literature).

Tinbergen subsequently generalized the specification of dynamic equations with lagged adjustment processes to macroeconomic settings, arguing that fluctuations in components of national product, such as investment and consumption expenditures, would lead to business cycle fluctuations in general economic activity. In 1936 he published the first applied macroeconometric model (for the Netherlands). It was a dynamic model, consisting of 22 equations in 31 variables. Employing what we now see as basic statistical techniques like correlation and regression analysis, it was meant to be used for the analysis of the particularly pressing unemployment problem. The specification of consumption and employment in this model anticipated elements of Keynes's theory (1936). This modelling exercise resulted in a strong policy recommendation in favour of a devaluation of the Dutch guilder to tackle unemployment. But its importance for the economics profession was far more profound: for the first time the economic-policy debate had been based on empirically tested, quantitative economic analysis and not on rather informally stated economic theory, the so-called verbal approach. Thus, according to Solow (2004, p. 159), Tinbergen's work during this period ‘was a major force in the transformation of economics from a discursive discipline into a model-building discipline’.

In 1936 Haberler had published a survey of theories on business cycles for the League of Nations. As a follow-up, and in reaction to the dynamic model for the Netherlands Tinbergen had published in that year, the same institution invited him to examine statistically which factors could be considered to contribute most to macroeconomic fluctuations. This project resulted in his two-volume book Statistical Testing of Business Cycles Theories (1939). The first volume contained a description of the
methodology applied, while the second volume presented a dynamic macroeconometric model for the United States with the aim of studying business cycles in that country after the First World War. This model was not only considerably larger than the one for The Netherlands; as imports and exports were much less important for the United States, it also allowed a relatively undisturbed view of internal dynamic mechanisms. Subsequently, the US model was much refined and enlarged by Klein (1950) and Duesenberry et al. (1965). Tinbergen presented his views on the dynamics of business cycles and on objectives and instruments of business-cycle policy for a wider audience in Tinbergen (1943) and Tinbergen and Polak (1950).

Discussion with Keynes

The formulation of some relations in Tinbergen's 1936 model showed some resemblance to Keynes's theory. Nevertheless, in an article in the *Economic Journal* of 1939, Keynes was remarkably sceptical of Tinbergen's work. Keynes labelled Tinbergen's method of estimating the parameters of an econometric model and computing quantitative policy scenarios as 'statistical alchemy', arguing that this approach ‘… is a means of giving quantitative precision to what, in qualitative terms, we know already as the result of a complete theoretical analysis’ (Keynes, 1939, p. 560). Their widely diverging views on the relevance of quantitative economic analysis were also illustrated by Keynes's reaction to Tinbergen's estimate of the price elasticity of demand for exports. When, in 1919, Keynes had strongly criticized the excessive war indemnity payments enforced upon Germany after the First World War, his argument had depended critically on the value of this elasticity. Tinbergen empirically found this value to be minus 2, precisely the value that Keynes had assumed a priori in his study. When informed about this Keynes replied: 'How nice that you found the correct figure' (Kol and de Wolff, 1993, p. 8.)

Keynes's critical attitude towards macroeconometric modelling and analysis originated from his view that the underlying economic theory should be complete in the sense that it should include all relevant variables and set out in detail its causal and dynamic structure. Econometrics could be used only for measuring the relations ('curve fitting' was the term used); it could not refute economic hypotheses or evaluate economic models. Tinbergen, on the other hand, argued that economic theories cannot be complete. Econometric research could be useful for scrutinizing elements of economic theories and for examining whether one theory describes reality better than another. Further, it could provide the numerical values of the coefficients in dynamic models that determine the cyclical and stability properties of a model, and, by applying a testing procedure of trial and error, it could yield suggestions for an improved specification of dynamic lags.

In this controversy Tinbergen's approach soon gained the upper hand as increasing numbers of economists, especially in the United States, noted its practical results in terms of model construction and verification, including forecasting. However, Keynes's comments on the role of expectations and uncertainty in macroeconometrics and on specification and simultaneous equation biases remained relevant. Haavelmo (1943) advocated the use of probability theory in bridging the gap between theory and data in business cycle analysis. Later these issues would become the subject of intensive debate and research.

Theory and practice of economic policy
In 1945 Tinbergen was appointed director of the newly established Central Planning Bureau (CPB), an institution occupied with forecasting the effects of economic policy and advising the government on related matters (tasks which are more adequately captured by its present-day English name: Netherlands Bureau for Economic Policy Analysis). In the aftermath of the Second World War work at the CPB concentrated on the nation's pressing macroeconomic problems: a depleted capital stock, severe inflationary pressure, low levels of employment and an extreme shortage of foreign exchange. In the economics discipline macroeconometric modelling had rapidly become accepted as a useful tool with the publication of such studies as by Klein (1950), Leontief (1950) and Klein and Goldberger (1955). But Tinbergen, having gained experience with the practice of policy preparation, felt the need for a systematic discussion of the logic of economic policy and of the use of models for policy purposes. It led to several monographs on the theory of economic policy (1952; 1956). He distinguished, among other things, between reforms (changes in the foundations of society), qualitative policy (changes in the structure of economic and social organization) and quantitative policy (changes in the instruments of economic policy). The latter could help to avoid the shortcomings of the traditional approach by offering a systematic policy where trial and error had been practised, by taking account of interdependence between instruments and by providing a quantitative indication of effects. Further, building on earlier work by Frisch distinguishing between various types of variables in relation to their role in policy models, Tinbergen demonstrated the connection between the analytical, or explanatory version and the policy, or normative version of economic models. In the analytical version, the policy targets were explained by other endogenous variables and by exogenous variables, which included the policy instruments. In the policy version the position of targets and instruments would be reversed (targets becoming exogenous and instruments endogenous variables) such that, in a well-behaved linear system, a solution requires only equality of the numbers of targets and instruments. This conclusion, which became known as the ‘Tinbergen rule’, brought an end to the popular misconception of a one-to-one correspondence between targets and instruments.

**Development economics**

In reaction to his experiences during a trip to India in 1951, Tinbergen left the Central Planning Bureau in 1955 and moved to the field of development economics, more specifically the planning of the socioeconomic development of low-income countries. Much earlier he had published a mathematical-statistical study of the theory of long-term economic growth (1942), but this had related only to industrialized countries. In the model technological progress had explicitly been included and the statistical tests (with data for Great Britain, France, Germany and the United States from the decades before the First World War) already suggested that capital and labour growth could explain only a relatively small portion of the growth of production. Characteristically, Tinbergen applied a quantitative, systematic policy approach to the development problem. This approach, which became known as ‘planning-in-stages’, distinguished macro, middle and micro stages, dealing with policy problems of private and public decision makers at the national, sectoral and project level, respectively (1967). In view of the difficult transportation conditions and the scarcity of skilled labour in developing countries, he subsequently added spatial and educational dimensions to the backbone of the planning-in-stages approach. He greatly simplified the calculation procedure for
project evaluation by devising the semi-input-output method. This method was based on the notion that only the indirect effects emanating from sectors producing non-tradable (national) goods needed to be incorporated. At a time when computer capacity was still very limited, such a simplification was most useful. However, consistency between the micro stage and the other two levels was achieved only with the advent of computable general equilibrium models.

Tinbergen acted as adviser on matters related to economic development to the governments of Egypt, Turkey, Venezuela, Surinam, Indonesia and Pakistan, and he wrote studies for international organizations such as UNESCO and the OECD. As Chairman of the UN Committee on Development Planning from 1965 to 1972, he was involved with, among other things, the preparation of the UN Second Development Decade (1971–80).

**Income distribution**

Tinbergen revisited the field of income distribution after his retirement as full professor (1972a; 1975). His approach, then as much as before, was inspired to a considerable extent by the positional-exchange criterion that had emerged from discussions in his student days with Paul Ehrenfest. According to this criterion a distribution of welfare could be considered fair when no one would wish to take another person's position. It was, for example, expressed in the individual welfare function Tinbergen proposed, which depended negatively on the difference (positive or negative) between the level of schooling required for a job and the actual schooling obtained by the person on this job. The notion that an income distribution is the outcome of a confrontation of demand and supply factors was another characteristic element of his approach. Thus, the development of a country's income distribution would be governed to a large extent by the process of technological innovation (a demand factor) and the rise of educational attainment levels (a supply factor). On the basis of material from the United States and The Netherlands from 1900 onwards, he found that this ‘race’ was mostly won by the rise in education, which resulted in more equitable distributions.

In his contributions to the field of income distribution – which concentrated on the remuneration of labour categories – he aimed to examine the effect of some unorthodox propositions. One such proposition was to consider the applicability of a capability tax which, as a lump sum tax, would be preferable to the familiar income tax. (Remarkably, this proposal ran counter to his finding that tax changes have a very slight impact on primary incomes, such that tax shifting would hardly be a problem.) Further, and true to his conviction that scientific progress and practical applications depend on quantitative tests of hypotheses, he treated welfare as measurable on the assumption that further progress in this area would be feasible. Assuming that workers move freely from one job to another so utility would be equalized, he derived an empirical relation expressing the connection between wage income on the one hand and attained schooling and the difference between attained and required schooling on the other. He then used this relation to compute an optimal or just distribution of income, tentatively relating to the situation in The Netherlands in the early 1960s. It would require very considerable shifts in income as compared with the actual situation.

**International economic integration**

Tinbergen's earliest work on international economic relations was still connected with national
Tinbergen, Jan (1903–1994) : The New Palgrave Dictionary of Economics

policymaking. Thus, his estimates of price elasticities of trade packages were meant to examine the effectiveness of a devaluation policy, where he emphasized the need to use long-term rather than short-term elasticities. His gravitation model (1962, Appendix VI) was a Newtonian approach to the explanation of bilateral trade flows which appeared to depend positively on the GNPs of the trade partners and negatively on the shipping distance separating them. It could be used to identify, among other things, the magnitude of potential trade lost to higher-than-average trade barriers, which impeded the efficient international division of labour he advocated in a number of studies written in the 1960s. Tinbergen (1954) applauded the international economic integration movement as it could remove trade barriers (which he dubbed negative economic integration) and could even result in new institutions for coordinated and centralized policymaking (positive economic integration). But he attached particular importance to the fact that economic integration would effectively reduce the probability of armed conflicts. From historical processes in Europe he derived a ‘velocity of integration’ which he hoped would remain positive until full integration at the regional and indeed the world level were achieved (1991a).

The optimal regime

His lifelong concern for (inter)national policymaking and, in that context, his special concern for the underdog resulted in a number of publications on the optimal economic order. In a deviation from his usual approach, Tinbergen emphasized in his Nobel Prize acceptance speech (1969) that the problem here consisted not of establishing the right mix of values of economic variables but of finding the proper set of institutions regarding the size and content of the public sector, the extent and content of (de)centralization of socio-economic decision making and therefore also of market regulation. He developed his ideas on the optimal order within a welfare-economic framework concerned with identifying the conditions that must be fulfilled to achieve maximum social welfare subject to the restrictions, such as production technologies, that apply in human society (1972b). In such a setting it would be useful to select the social welfare function at the beginning so as to limit the ethical possibilities in the subsequent analysis. The activities of the institutions would be described by a number of behaviour equations, the total of which should coincide with the conditions for optimal welfare. Tinbergen argued against rigidities, privileges, monopolies and insider-determined remunerations that bore no relation to marginal productivities, but he also rejected excessively generous social security systems that invited rent seeking. In Tinbergen's view the interests of developing countries deserved separate attention in discussions on the optimal economic order. No country would accept within its borders an income inequality between groups of rich and poor citizens as could be found between rich and poor countries in the world. Not only must obstacles to exports from developing countries be removed; it would also be necessary to support these countries’ development efforts by providing technical and financial aid. Tinbergen urged replacing the arbitrary UN target for international aid of 0.7 per cent of GNP of rich countries by the volume of aid that would be required for a harmonization of incomes within a predetermined number of years. He coordinated a study (1977) for the Club of Rome offering views on the international order, development aid, food production, the international division of labour, energy sources and raw materials, technological development, the environment and the arms race, among other things.

With the help of the theory of the optimal regime Tinbergen further sought to rid the confrontation between the Communist East and the Capitalist West of the dogmatic character that dominated world
politics before the fall of Communism in 1989. Horrified by the prospect of nuclear warfare, he devoted a large part of his later years to a plea for a rational debate on the pros and cons of both systems and for a stronger role of a reformed United Nations taking decisions that would incorporate international external effects (1990).

In conclusion

Tinbergen's contribution to the economics discipline lies in his pioneering work in a number of different economic fields. He would not consider himself an expert even in these areas, would gladly admit that others who had come in after him had meanwhile gained a better understanding, and would move on to another area where another pressing social problem needed to be addressed. In his own words (1991b), ‘solving the most urgent problems first’ is what moved him most in his intellectual agenda.

He had little patience with studies lacking applicability to practical problems, and was not much impressed by scientific elegance for its own sake. His work discipline, punctuality and efficiency were exemplary. For an appointment, students and assistants he supervised would get seven minutes on the watch he would keep nearby. Still, Tinbergen also gave innumerable lectures for organizations and social action groups even of humble status.

His intense desire for a more humane world led him to put great trust in the benevolence and effectiveness of governments and international organizations, realizing that policies to overcome social problems would nearly always require the participation of public institutions. The latter's serious shortcomings in terms of management and governance were just another problem to be solved. He nursed a strong hope that people would behave more sensibly over time and learn to avoid the terrible conflicts that had caused so much suffering and devastation in the 20th century. It was for all these characteristics that Samuelson (2004, p. 153) described Tinbergen as ‘a humanist saint’. Naturally, during his long life Tinbergen was often deeply disappointed. Still, his optimism never left him, if only because, as he said at an advanced age: ‘I cannot afford to be pessimistic’.

Gerhard Tintner was born in Nuremberg, Germany, of Austrian parents, and educated in Vienna, completing his doctorate in economics, statistics and law at the University of Vienna in 1929. Tintner was much ahead of his time in important respects. First, he made early and significant contributions toward the development of a theory of behaviour under uncertainty (Tintner, 1941a; 1941b; 1942a; 1942b; 1942c). Second, he consistently stressed the need for a broad view of probability in the behavioural sciences and economics (Tintner, 1960; 1968). His seminal article ‘Foundations of Probability and Statistical Inference’ (1949) started from Carnap's view of probability as degree of confirmation and raised issues some of which are now being debated in current reformulations of econometric methodology (Harper and Hooker, 1976; Koch and Spizzichino, 1982). Third, he firmly believed that the tools of modern disciplines such as cybernetics and system theory should be adapted and used to gain insight into individual and social behaviour, which is the basis of all applied economic models (Tintner and Sengupta, 1972).

Tintner's first book (1935) was written as part of the programme of the Austrian Institute for Trade Cycle Research. In it Tintner applied Anderson's (1927) variate difference method to some 300 series of commodity prices from 1845 to 1914. Under certain assumptions, this method eliminated (most of) the random component from each series, leaving the systematic component for further study; Tintner (1940) presented a more complete statement of the method.

By 1935, Tintner had become enthusiastic about the work of the American mathematicians G.C. Evans (1922; 1924; 1930) and C.F. Roos (1925; 1934), who were applying calculus of variations to theoretical problems in economic dynamics. It appears that Tintner hoped to make a major breakthrough by extending the Evans–Roos approach. From 1936 to 1942 he published a series of brilliant articles (1936;

1937; 1938a; 1938b; 1939; 1941a; 1941b; 1942a; 1942b; 1942c) on such topics as maximization of utility over time, the theoretical derivation of dynamic demand curves, and the pure theory of production under technological risk and uncertainty; his last article of this type was ‘A Note on Welfare Economics’ (1946). Apparently these articles attracted little attention under the disturbed conditions of the time and were not consulted by the young economists who applied similar methods in the 1950s and 1960s to the theory of economic growth and uncertainty. Tintner's work on dynamic economic theory deserves a thorough reappraisal.

The early literature on linear programming dealt exclusively with the deterministic case. Tintner (1955) and Charnes and Cooper (1959) were the first to develop theories and methods for dealing with the various stochastic cases in which inputs, outputs, technical coefficients and/or constraints are subject to random disturbances. Tintner's development of an active approach to stochastic programming (as opposed to a passive approach) pointed the way to current research on self-tuning control combining both estimation and regulation (Sengupta, 1985). Tintner's students and others also made important contributions to stochastic programming; by the late 1970s its literature included several hundred articles and a number of books – see, for example, Kolbin (1977), Tintner and Sengupta (1972), van Moeseke (1965), and Sengupta (1972; 1982).

A selected bibliography of Tintner's publications through 1967 is included in Fox, Sengupta and Narasimham (1969). Tintner spent the bulk of his career at Iowa State University (1937–62) and the University of Southern California (1963–73). From 1973 until shortly before his death (in Vienna, 13 November 1983) he was professor of econometrics at the Technische Universität in Vienna and Honorary Professor at the University of Vienna. His textbooks (Tintner 1952; 1953) had considerable influence on the teaching of econometrics and he also published important articles on multivariate analysis, time series analysis and homogeneous systems in mathematical economics.

Titmuss, Richard Morris (1907–1973)

Philippe Fontaine
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Arrow, K.; social policy; blood procurement; Buchanan, J.; ethics and economics; Friedman, M.; gifts; Hayek, F.; Institute of Economic Affairs; invisible hand; Olson, M.; socialism; Solow, R.; Titmuss, R.

A professor of social administration at the London School of Economics (LSE) from 1950 to his death, Richard Titmuss has often been depicted as an inept critic of economics. With *The Gift Relationship* (1970), however, he managed to attract the attention of leading economists. Robert Solow (1971) and Kenneth Arrow (1972), for instance, took pains to write lengthy review articles of what they and a number of their prominent peers, such as James Buchanan and Milton Friedman, regarded as a highly significant book. In a subject which has a solid tradition of confining ethical matters to its periphery and which has frequently resisted ideas emanating from other social sciences, it is paradoxical that a book of strong ethical inspiration and uncertain disciplinary origins attracted so much interest. One way out this paradox is perhaps to note that, starting with Mancur Olson's *The Logic of Collective Action* (1965), and accompanying the economic difficulties of the late 1960s, economists began to question the power of the invisible hand of the market in bringing about social cohesion. By the early 1970s the time was ripe for reconsidering the virtues of alternative coordinating mechanisms.

The context played a role in the reception of *The Gift Relationship*, but it was above all its subject that made the difference. Long before the book was published in early 1971, Titmuss (1959; 1963; 1968) had been a major figure in the debate over the welfare state, and in this capacity had criticized economists for their incomplete notion of what holds a society together and the unfortunate policy prescriptions they derived from it. With his new essay, however, he presented his own conception of social cohesion and social policy by contrasting the British system of blood procurement and distribution, based on free giving, to the partly commercialized US system. Metaphorically, the gift of blood illustrated the consolidation of the social bond, while its sale stood for social collapse. In other words, Titmuss pointed to the dangers of society's increasing commercialization.

The son of a small farmer and his wife of less humble origins, Titmuss lacked formal schooling beyond
the age of 14, and when he joined the Eugenics Society in 1937 it was hardly expected he would end up in academe. Yet, after participating in several of the society's research projects, including those of the Population Investigation Committee, then headed by Alexander Carr-Saunders, Director of the LSE, he made a name for himself in academic circles. Subsequently, the historian Keith Hancock approached him to work as historian of the Cabinet office, as a result of which Titmuss produced the monumental Problems of Social Policy (1950). Not only did the book secure him the chair in Social Administration at the LSE but it also illustrated the importance of the experience of the Second World War in shaping his 'vision of good conduct as generalised obligation' (see Reisman, 2004). Based on values of solidarity and social duty, this vision may well have been suitable to describe the wartime and immediate post-war British society. From the mid-1960s, however, it became clear that it was incomplete, as was the vision of those economists who regarded the market as the main, if not exclusive, coordinating mechanism in society.

It is these economists’ ideas and the applications suggested by their allies at the Institute of Economic Affairs (IEA), the London-based think tank inspired by Hayek, that Titmuss fought from the late 1960s to 1973 (see Fontaine, 2002). He was of the opinion that ‘social growth’ was more important than its economic counterpart, and that a ‘socialist’ social policy – not the invisible hand of the market – was essential to social cohesion. These two ideas were intimately connected. Titmuss used the former to show that the economists’ social indicators were inadequate: the economy could grow economically and still regress socially because negative externalities supplanted positive ones. Likewise, ‘socialist’ social policies stimulated ethical behaviour, which generated positive externalities and averted negative externalities, whereas ‘private’ social policies, as envisaged by the IEA, favoured commercialism, which neglected positive externalities and underestimated negative externalities.

While Titmuss's criticism that economists relied too much on the invisible hand of the market may have actually applied only to a few of them (Solow, 1971), his thesis that too much commercialism undermines the social bond concerned them all. Most economists remained unconvinced, but, faced with Titmuss's emphasis on the role of the gift in so unusual a setting as impersonal interactions, where they typically saw selfishness as reigning supreme, the economists were forced to contemplate the possibility that 'a world of giving may actually increase efficiency in the operation of the economic system' (Arrow, 1972, p. 351).

Tobin, James (1918–2002)

Donald D. Hester
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

James Tobin was a brilliant economist and the leading proponent of Keynesian economics in the second half of the 20th century. He greatly advanced understanding of financial institutions and monetary theory and policy. He stressed the importance of asset holdings and wealth on consumer spending. He also argued that ‘q’, the ratio of a firm's market value to the replacement value of its assets, was an important determinant of its investment decisions. He made major contributions to econometric methods, international economics, the theory of growth and business cycles, and policies designed to improve the welfare of minorities and the poor.

Article
James Tobin was a major contributor to economic science and macroeconomic analysis who received the Nobel Memorial Prize in Economic Science in 1981 for ‘his analysis of financial markets and their relations to expenditure decisions, employment, production, and prices’. He received a BA in 1939, an MA in 1940, and a Ph.D. in 1947 from Harvard University. (Between 1941 and 1945 Tobin was an officer on a destroyer in the US Navy.) He made many early penetrating theoretical and empirical explorations of the underpinnings of Keynes's *General Theory of Employment, Interest, and Money* (1936). Throughout his long career he was a vigorous participant in the design of fiscal and monetary policies and in actively promoting their implementation. He was on the faculty of Yale University from 1950, and from 1957 until his death he held a prestigious Sterling professorship there.

He published a large number of influential papers in professional journals and other places, and his impact on economics can only be hinted at in this unavoidably incomplete article. Buiter (2003) has published a much longer but still incomplete survey of Tobin's work, which consists of about 500 articles over a period of 60 years. Many of his papers are accessible in a series of volumes of his collected works (1971; 1975; 1982; 1996a) in addition to their original places of publication.

Apart from his dissertation, his earliest empirical evaluations of the Keynesian approach (1947; 1951), were influential informal studies that respectively examined the interest elasticity of the demand for money and the underpinnings of the consumption function. The latter showed that evidence for Duesenberry's (1949) ‘relative income hypothesis’ was not persuasive when compared with a wealth-augmented variation of Keynes's absolute income hypothesis, when individuals were broken down into savers and dissavers and variations in the cost of living were taken into account. The importance of wealth and portfolio composition on behaviour would be a major theme in Tobin's work in subsequent decades.

Perhaps his most important applied econometrics article (1950) examined the demand for food in the United States. It refined techniques that had been used in his dissertation, which analysed the consumption function. By combining estimates of income elasticities obtained from cross-sectional budget data with price elasticities estimated from time series, Tobin attempted to avoid the problem of multicollinearity that often arises when one uses time series data exclusively. He focused on food rather than aggregate consumption in this paper in order to avoid problems associated with purchases of durable goods. This paper has stood the test of time remarkably well and was celebrated in a special issue of the *Journal of Applied Econometrics* (1997).

Shortly after finishing this paper, Tobin (1952a) and Tobin and H. S. Houthakker, (1951; 1952) completed an elegant series of papers on the theory of rationing and its implications for econometric analysis.

### Household balance sheets and spending

Upon arriving at Yale, Tobin developed a distinctive empirical approach to household spending and portfolio behaviour that was foreshadowed by an illuminating survey article, ‘Asset Holdings and Spending Decisions’ (1952b). He critically reviewed attempts to include money, liquid assets, and government debt holdings by households as predictors of consumption in both macroeconomic and microeconomic studies. He argued that such asset holdings are best viewed as part of a dynamic optimization process; people accumulate liquid assets in preparation for executing spending
programmes. Liquid assets cannot sensibly be interpreted as exogenous determinants of consumption. An early empirical study (1957) analysed the relation between consumer holdings of debt, liquid assets and durable goods and decisions to acquire more of each of them. He reported that high levels of debt discouraged acquisition of more debt and durable goods, and in an illuminating diagram suggested that individuals with different attributes tend to have different desired mixtures of debt and liquid assets, which can be interpreted as target levels of ‘portfolio balance’. A second empirical study, coauthored with H. W. Watts (1960) extended this portfolio balance approach to broad collections of assets and liabilities.

Tobin made a very important econometric methods contribution that was a consequence of his work with household assets. He noted that many household assets took on zero values until a certain threshold was crossed. Linear regressions attempting to represent relations, say, between a household's income and the value of its car would be severely misspecified if some observations in a sample had no car. In (1958a) he developed an ingenious probit-regression technique (subsequently named ‘tobit’ by A. S. Goldberger), which allowed maximum likelihood techniques to be used to obtain consistent estimates of such relationships. The technique continues to be widely used.

A dynamic aggregative model and the effects of money on economic growth

Portfolio balance assumed a central role in a very innovative model (1955) where Tobin managed to combine endogenous economic fluctuations and economic growth. This paper, which Tobin viewed as his favourite (see Breit and Spencer, 1986, p. 128), is Keynesian in that money wages may be inflexible and may lead to unemployed labour. An important innovation in the model was a linear homogeneous production function that allowed for substitution between capital and labour, as in the nearly contemporaneous economic growth models of Solow (1956) and Swan (1956). However, its major new contribution was the formal introduction of portfolio balance and money. Changes in money are equal to the government deficit in this model. Wealth consists of physical capital and the real money supply. Momentary price equilibrium exists when the price level allows wealth holders to be satisfied with the mix of capital and real money holdings in their portfolios. Because investors are assumed to be risk averse, portfolio equilibrium does not require that the negative expected rate of change of price equals the expected marginal productivity of capital. Depending upon price expectations, monetary expansion may affect the rate of capital formation positively or negatively. The paper briefly explores how technical progress relates to price changes and growth.

Introducing inflexible money wage rates leads to a variety of results that include inflation, deflation, secular economic growth or stagnation, and economic cycles, which can be seen when two summary relations describing labour market balance and portfolio balance are examined. Recovery from cyclical slumps may occur if extreme conditions cause money wage rates to become flexible or if capital depreciates sufficiently.

In this model and in its specializations to economic growth (1965b; 1968), money and government debt are indistinguishable. In an important unpublished manuscript dating from 1958, which eventually was published in 1998, Tobin addressed this distinction and presented an elegant analysis of how monetary policy worked through banks and how changes in the composition of government debt affected capital and growth. In Tobin (1961) and in his contribution to the Commission on Money and Credit (1963a), Tobin drew on this manuscript to analyse debt and monetary policies and their relation to the return on
capital. The reasons for the long delay in publication of the manuscript are unclear, but surely part of the explanation was that Tobin was a member of the Kennedy administration's Council of Economic Advisors for 18 months beginning in January 1961.

The demand for money

Tobin published two papers that were narrowly focused on the demand for money (1956; 1958b). The first was an inventory theoretic model of the transactions demand for money that had close antecedents in Allais (1947) and Baumol (1952). These three papers cast doubt on the constancy of the income velocity of money, Y/M, by arguing that an individual's income elasticity of demand for money is likely to be about 0.5 and the interest rate elasticity about – 0.5. As the theory predicted, the post-war income velocity of money in the United States rose as per capita income and interest rates rose.

The second paper was a path-breaking effort that proposed a novel explanation for the portfolio demand for money. It was written at about the time Markowitz was writing his monograph (1959) on portfolio selection at Yale, but had a very different orientation. For simplicity Tobin assumed cash had a riskless rate of return. He introduced uncertainty about the rate of return on a second asset, and explored how an investor should split his portfolio between cash and the risky asset over a single planning period. His goal was to eliminate an unsatisfactory assumption about interest rate expectations of investors that underlay Keynes's exposition of liquidity preference. He assumed either that investors’ utility functions were quadratic or that the distribution of the risky rate of return was normal, and derived the optimal mixture of the risky asset and cash. Although his discussion was not error-free, as was pointed out by Borch (1969) and Feldstein (1969), it provided a foundation from which a large literature in finance developed. Initially Tobin assumed the second asset was a consol, in the spirit of Keynes's discussion. Then he showed that the second asset could be a linear combination of a set of risky assets and that investors’ portfolio problem could often be reduced to a mixture of that combination and cash. He was the first to recognize ‘two fund’ separation, which would play a major role in the theory of finance.

Financial intermediation and policy

Tobin's unpublished manuscript included a discussion of commercial banks and their role in the transmission of monetary policy, topics that he extensively developed in the 1960s. An early unpublished paper (1959) examined how financial intermediaries in general responded to monetary controls; it would be extensively revised and appear with the same title in a rigorous discussion of monetary policy, coauthored with William Brainard (1963). Tobin and Brainard argued that a monetary policy action's effect can be measured with the required rate of return on real capital; restrictive (easing) monetary policy will raise (lower) this rate. They assumed that all assets and liabilities are gross substitutes. Thus, for assets an increase in the rate of return on one asset increases the demand for it and does not increase the demand for any other asset, and analogously for liabilities. They analysed how a monetary policy-induced change in currency affects the required rate of return in regimes with controlled and uncontrolled intermediaries, where controls consist of reserve requirements and interest rate ceilings on deposit liabilities. The controls may strengthen the efficacy of monetary policy, but it works when they are absent. Tobin (1963b) provided an accessible intuitive discussion of the responses
of banks and other intermediaries to monetary policy actions.

Tobin (1969) presented a general equilibrium interpretation of the overall approach and emphasized the importance of ‘q’, the ratio of the market value of a firm to the replacement value of its assets, a central focus of his approach to monetary policy and a prominent variable in subsequent empirical studies of the investment decision. Intuitively, when q is greater (less) than unity, stockholders gain (lose) when a firm undertakes net new investment. *Ceteris paribus*, a high real rate of interest (and thus restrictive monetary policy) is likely to reduce market values and thus discourage new investment. Tobin and Brainard (1977) reported a very ambitious attempt to measure average q using panel data and introduced the important distinction between marginal and average q, a topic that was subsequently thoroughly developed by Hayashi (1982). While acknowledging that q was an endogenous variable partly determined by animal spirits and investor expectations, they argued that an estimate of q for firms should be included among the variables guiding monetary policy.

Tobin and Brainard (1968) reported simulation experiments using a hypothetical model that illustrated the central role of q and the importance of taking into account cross equation restrictions. Drawing on well-known arguments from the theory of consumer demand, they suggested that empirical models of financial markets often were misspecified because investigators ignored adding-up constraints on parameters across equations on interest rate, income and lagged variables. They argued that such requirements were especially important in dynamic specifications, where often the only lag in an asset demand equation was the asset's value in a previous period; in principle, all lagged asset variables in a well-specified portfolio adjustment model must appear in each asset demand equation. Implicitly, these two Tobin and Brainard articles indicate the enormous sensitivity of models to arbitrary accounting conventions and the unavoidable errors in variables that such conventions lead to.

**Monetary theory and policy**

Beginning with his review (1965a) of Friedman and Schwartz's *Monetary History of the United States*, Tobin increasingly assumed the role of defending the Keynesian approach to macroeconomics against an emerging monetarist formulation that was led by Milton Friedman. Tobin had been a major contributor to the highly successful policies of the Kennedy and Johnson administration policies of the early 1960s, but was very critical of the latter's financing of the Vietnamese war (1981, pp. 357, 360). As the decade wore on, the Keynesian approach came increasingly under attack. For example, Milton Friedman's presidential address (1968) to the American Economic Association, which had been preceded by Phelps (1967) with the same idea, questioned the existence of a stationary Phillips curve. Friedman argued that workers would increasingly seek redress from inflation if unemployment were below the non-accelerating inflationary rate of unemployment (NAIRU, where the price-inflation Phillips curve crosses the abscissa). If a non-stationary Phillips curve led to accelerating rates of inflation, prices would no longer be sticky as the Keynesian approach assumed. Friedman's alternative approach argued that money demand was a function of permanent income and that empirical support for the monetarist model came from the fact that in time series money led income, which suggested that money was a causal element. Tobin and Swan (1969) reported empirical relations between permanent income and money that did not support the monetarist model. Tobin (1970) reported simple theoretical models that illustrated that one could not infer from lead–lag relationships in time series of money and income whether a model was
fundamentally Keynesian or monetarist. Space limitations prevent a full and fair exposition of the debate, which continued with varying levels of intensity for many years; see, for example, Tobin (1993b; 1995).

The controversies led to ambitious efforts to see whether fiscal and monetary policy effects in the static IS–LM model were likely to carry over in a dynamic long-run framework. Tobin and Buiter (1976) and Tobin (1979) examined this question formally using elegant techniques and were not able to conclude in general that the effects of policy were either transitory or long-lasting in models with a stationary state. They were able to describe some model specifications with predictable effects in the long run and discussed their intuitive plausibility. Tobin and Buiter (1980) examined the same issue in the context of a growth model, with similarly inconclusive results. All the same, these papers are valuable examples of how to analyse such questions.

Tobin provided a relatively complete statement of his views on the theory of macroeconomic policy in his three Yrjö Jahnsson lectures and a related Paish Lecture given in England that appear in Tobin (1980). His first Jahnsson lecture considered how price level changes affected economic activity, focusing on the Pigou effect, the Keynes effect, and Fisher's debt-deflation hypothesis. He believed that the Fisher hypothesis won over the Pigou effect in the short and medium run. He denied that Keynes had demonstrated an underemployment equilibrium, but accepted the IS–LM model as a reasonable guide to policy in the short run.

His second Jahnsson lecture attacked both Friedman's views about a shifting Phillips curve that are discussed above and Lucas's (1972) rational expectations hypothesis. He argued that the latter was more radical than Friedman's discussion because it denied even the short-run efficacy of monetary policy. Tobin explained that, while everyone agrees that expectations are important, expectations are highly diverse in an economy and based on different information sets; therefore, they are not likely to be unbiased. Further, he denied the Lucas contention that labour and product markets are always being cleared at existing wages and prices, and criticized as ad hoc Lucas's specification ‘about the information available to buyers and sellers’ (Tobin, 1980, p. 42).

His third Jahnsson lecture addressed an obvious deficiency of the short-run IS–LM model, namely, that the capital stock and other measures of wealth are assumed to be constant even though investment is occurring and debt is being issued. He sketched out a model that integrates flow-of-funds accounts with variables in the IS–LM model, which derived from his papers with Buiter. An especially ambitious attempt at constructing such a model is reported in Backus, Brainard, Smith and Tobin (1980).

The Paish lecture examined the plausibility of Ricardian equivalence – the idea that there is no difference resulting from decisions to finance an increase in government spending by printing money and/or raising taxes, and/or issuing government debt. Robert Barro (1974) had resurrected and developed this thesis, which denies that government deficits have an effect because households take into account the fact that increased issues of debt would require an increase in future taxes, which would be needed to service and retire the debt. While the Barro argument might be true in a simple hypothetical world where household dynasties are infinitely lived and each household in a generation behaves so as to fully take into account effects on its counterparts in other generations, Tobin argued that demographic events like no heirs, generational myopia, and financial conditions such as liquidity constraints, possibly resulting from imperfect capital markets, and wealth and other distorting taxes invalidated it.
As a visiting professor at the University of Nairobi in the 1972–3 academic year, Tobin wrote two instructive papers that use the linear activity analysis model. The first (1974a) examined a model with two technologies, traditional and modern (more productive), where unemployment was possible in an economy with a constant saving rate and where capital in each of the technologies had possibly different depreciation rates. Depending upon parameter values, he showed that it could be optimal to invest capital in the traditional rather than the modern technology, in both the short and the long runs. In (1974b) he studied the effects of expulsion of alien residents and expropriation of their assets. Depending upon the compensation, if any, for expropriating the assets of the former residents, the linear model yielded predictions about how remaining citizens would fare. Tobin did not analyse the ethical justification, if any, for expulsion and expropriation, but nevertheless provided a very insightful discussion about who might gain and lose in situations where expropriation occurred.

William Nordhaus and Tobin in a very ambitious paper entitled ‘Is Growth Obsolete?’ (1972) proposed a primitive measure of economic welfare (MEW) for the United States. They argued that the national income accounts measure production and are not appropriate for analysing welfare, for several reasons. The accounts do not measure the flow of services from the stock of durable goods or the value of human capital acquired through education and training, nor do they account for the depletion of minerals, environmental degradation, and the disamenities of urbanization. The national income accounts include all consumer and government expenditures. Nordhaus and Tobin viewed many of these as ‘instrumental’ expenditures that are regrettably necessary for welfare. Examples include commuting costs, police services, national defence and sanitation. They subtracted such expenditures from their measure, which is expressed on a per capita basis, and made an imputation for the flow of leisure. The authors argued that technical progress and capital formation have more than compensated for the depletion of natural resources so far and are guardedly optimistic that this will continue. However, they stated that the effects of pollutants on melting polar ice caps warrant a higher priority in research and that pollution is a problem because it is not priced to reflect social costs. While the possibility of catastrophic global disturbances cannot be excluded, their conclusion was that growth is not obsolete.

International economics

Tobin and Braga de Macedo (1980) modified the standard paradigm of Mundell (1961) and Fleming (1962) of how monetary policy works in a floating exchange rate system by introducing the exchange rate in asset demand functions and assuming that all assets are gross substitutes. There are three assets – cash, foreign holdings and bonds – because bonds and capital are conventionally assumed to be perfect substitutes. In the case of a small open economy they showed that with these modifications fiscal policy affects the economy's level of real income, although the effect cannot be signed without information about some parameters in this variation of a standard IS–LM model. This contrasts with the Mundell and Fleming models where fiscal policy is impotent in a pure floating exchange rate system. The authors then expanded the small open-economy model to have four assets, by assuming that bonds and capital are not perfect substitutes. They continued to assume that all assets are gross substitutes and employed a discrete time specification to analyse some of the consequences of asset accumulation. This second model describes a single period, but beginning-of-period stocks and within-period flows yield complex effects that unfortunately cannot be summarized adequately in the present article. However, it
is usually the case that fiscal policy again has non-zero effects in a flexible exchange regime. They also examined fiscal policy in a two-country, flexible-exchange world, where neither is small and in each country bonds and capital are perfect substitutes. The rich analytical framework of this paper is applied insightfully in Tobin (1993a) and partly underlies a simulation exercise by Tobin and Brainard (1992). Tobin (1978) argued that countries should impose a tax on purchases of financial instruments denominated in another country's currency in order to allow some autonomy in setting domestic stabilization policies. This controversial ‘Tobin tax’ proposal to throw sand into the gears of international finance first appeared in Tobin (1974c, pp. 88–92), achieved wide approval outside the United States, and was analysed in ul Haq, Kaul and Grunberg (1996).

Overview and summary

As stated at the outset, one cannot do justice to Tobin's extraordinary career in a short article. However, before closing, it is important to acknowledge his extensive contributions to public debate on policy that appear in Tobin (1966; 1996b), and especially on welfare and inequality that are reprinted in part in Tobin (1982, pp. 497–624). He was a forceful advocate of the negative income tax, reducing inequality, and improving the economic condition of minorities in the United States, especially during the turbulent 1960s and 1970s.

Abstract

Tobin's q is the ratio of the market value of a firm to the replacement cost of its assets, a statistic that depends on the firm's profitability and financial markets’ required rate of return. Although there are a variety of measurement issues, including the distinction between marginal and average q, Tobin's q can be used to predict investment spending or to control for a firm's current and future profitability in empirical studies of corporate structure and behaviour.

Article

A standard tenet of corporate finance is that the retention of earnings to finance expansion raises a stock's price if the rate of return on these investments, $\rho$, is larger than shareholders’ required return on their stock, $R$. For example, an investment that costs $1$ million is worth more than $1$ million to stockholders if $\rho > R$. This principle suggests that whether a firm's stock sells for a premium or a discount relative to the cost of its assets depends on $\rho$ versus $R$ and, further, that a firm's investment decisions ought to depend on a comparison of $\rho$ with $R$.

The shareholders’ required return is determined in financial markets by shareholders pricing stock to yield an anticipated return that is competitive with comparable investments they might make. This determination of required returns is one of the primary ways in which financial markets affect real economic activity. When interest rates fall, required stock returns decline, making it more likely that $\rho > R$, so that the profits from prospective investments are sufficient to make these investments attractive for firms that care about their shareholders.
But where do firms (or economic forecasters) see these shareholder required returns? It is straightforward to calculate the yield to maturity on a bond by determining the discount rate that equates the present value of the promised cash flow to the market price. There are no comparable calculations for stocks because the cash flow to investors is unknown. An ingenious alternative, proposed by James Tobin (Brainard and Tobin, 1968; Tobin, 1969), is to look at stock prices. Specifically, Tobin argues that we should look at how financial markets value a firm relative to the replacement cost of the firm's assets:

\[ q = \frac{\text{market value}}{\text{replacement cost}} \]

The numerator and denominator of Tobin's q can be aggregate market value and replacement cost or, equivalently, price per share and assets per share. If a firm has debts, these can be included in the numerator.

What determines q?

How can assets be valued in financial markets at other than their replacement cost? Assets are of value to shareholders only to the extent that they generate profits. It matters not at all that a factory cost $1 billion to build if it doesn't make a cent of profits. For a factory to be worth what it costs shareholders, it must earn the shareholder's required rate of return.

For a simple example, suppose that a hamburger chain has no debt and pays out all earnings as dividends. Assume also that a new restaurant costs $1 million to build and is expected to earn a constant 20 per cent profit (\( \rho = 0.20 \)), $200,000 a year for ever. The value that financial markets place on the $200,000 annual cash flow depends on how highly hamburger earnings are valued. If Treasury bonds yield five per cent, perhaps stock in risky hamburger restaurants is priced to yield ten per cent (\( R = 0.10 \)). Because the anticipated dividends are a constant $200,000, the market value of the restaurant is

\[ V = \frac{200,000}{0.10} = 2,000,000 \]

Valued at $2 million, the $200,000 annual dividend provides stockholders their requisite ten per cent return.

In this case, the market value of the restaurant is twice its construction cost: \( q=2 \). Stockholders welcome this investment, because the use of $1 million in potential dividends to build the restaurant provides $2 million in market value. The underlying reason is that the restaurant's 20 per cent profit rate is larger than the market's ten per cent required rate of return.

If, on the other hand, shareholders' required rate of return is 25 per cent, then
Now $q = 0.8$ and the construction of the restaurant will be to the detriment of shareholders. Because the restaurant earns only 20 per cent on its cost, the stock must be valued at less than the asset's cost in order to provide shareholders their 25 per cent required return.

**Implications for investment decisions**

A connection between business investment spending and market value relative to cost was pointed out many years ago by John Maynard Keynes (1936, p. 151):

> [T]he daily revaluations of the Stock Exchange, though they are primarily made to facilitate transfers of old investments between one individual and another, inevitably exert a decisive influence on the rate of current investment. For there is no sense in building up a new enterprise at a cost greater than that at which a similar existing enterprise can be purchased; whilst there is an inducement to spend on a new project what may seem an extravagant sum, if it can be floated on the stock exchange at an immediate profit.

Similarly, Tobin argues that a firm should invest in new buildings and equipment if the stock market will value the project at more than its cost (that is, if the project's $q$ is greater than 1). If the market value is larger than the cost, shareholders prefer that the firm make this investment rather than distribute its cost as dividends, gladly giving up a dollar of dividends in exchange for a two-dollar increase in the value of their stock. Put more plainly, the appropriate question a firm should ask is whether, if it were to sell shares in its new venture, it could raise enough money to cover the project's cost. It can if the value of Tobin's $q$ is larger than 1, but not otherwise. Thus Tobin's $q$ provides a barometer of the incentives for business investment.

Similarly, the firm should compare the price it can get for selling its existing assets with the value that financial markets place on these assets. If the market value is less than the sale price ($q<1$), the firm is worth more dead than alive, and it should sell off its assets and distribute the proceeds either through dividends or share repurchases. A low market value relative to replacement cost may also motivate takeover bids, since an outside group may profit by purchasing enough stock to gain control of a company and then liquidating its assets.

**Marginal and average $q$**

Why don't firms immediately exploit any differences between market value and replacement costs, thereby causing $q$ to return to 1 instantaneously? Three, sometimes related, explanations involve convex
adjustment costs, monopoly rents and heterogeneous capital (Lucas and Prescott, 1971; Mussa, 1977; Smith, 1981; Hayashi, 1982; Abel, 1983; Erickson and Whited, 2000; Gomes, 2001). A consideration of these issues requires a distinction between average q, the aggregate market value and replacement cost of a firm's assets, and marginal q, the change in a firm's market value resulting from a specific investment relative to the cost of that investment.

An observed average q that is greater than 1 might accurately reflect a company's substantial profits, but further investment may be restrained by convex adjustment costs that cause the marginal q for a large expansion to be less than 1. It might be prohibitively expensive for a hamburger chain to triple its size in a year. A related strand of literature (summarized by Hubbard, 1998) investigates how investment by financially constrained firms may be less sensitive to q and more sensitive to the firm's cash flow. Similarly, a firm might earn monopoly rents that cause average q to exceed 1, but have a marginal q that is less than 1 because new investments would erode these rents. A hamburger restaurant with a patented secret formula might not want to open a competing restaurant next door that would lure away customers. The grower of an exotic fruit may not want to flood the market with produce that could only be sold by lowering prices.

Finally, prospective ventures might be quite different from the firm's existing operations, with different rates of return and with risks that command different required returns. A tobacco company acquires a snack food company; a yogurt maker enters the bottled water market; a software company enters the video game market. In each case, marginal q might be quite different from average q.

A further complication is that observed market values presumably take into account not only existing assets but also future investments anticipated by the market. Suppose, for example, that a firm currently has assets with a replacement cost and market value that both equal $100 million and is planning to make an investment that will cost $20 million and have a market value of $30 million. Average q for the firm's current assets is 1 and marginal q for this investment is 1.5. If the stock market takes into account this projected investment, the current market value is increased by $10 million (discounted somewhat to the extent the value added will occur in the future and if there is uncertainty about whether the investment will be made). Thus observed average q reflects both the profitability of the current capital stock and the perceived profitability of the firm's future opportunities, overstating the former and understating the latter.

Estimates of q

The book value reported by firms is a rough proxy, a starting point, for estimating the replacement cost of a firm's assets. Accounting conventions value assets at historical cost, with no adjustments for subsequent cost increases, and depreciate assets according to accounting conventions rather than true economic depreciation. Inflation can cause book values to understate the replacement cost of assets (think of real estate); technological progress can cause the reverse (think of computers). The market value of a firm's equity is commonly estimated by multiplying the market price of a firm's stock by the number of shares outstanding; data on the market value of a firm's preferred stock and debt are not so easily obtained because databases generally record the book values reported by firms in their balance sheets.

A variety of often complex procedures have been employed to estimate the market value of a firm's
debts and the replacement cost of its assets (Brainard, Shoven and Weiss, 1980; Lindenberg and Ross, 1981; Lewellen and Badrinath, 1997; Lee and Tompkins, 1999), while other authors argue that more readily available book values provide sufficiently accurate approximations (Chung and Pruitt, 1994; Perfect and Wiles, 1994).

Because of these measurement errors, when $q$ is used as an explanatory variable in a regression model, least squares estimates of the coefficient of $q$ will be biased towards zero and estimates of the coefficients of other explanatory variables may be biased towards zero or away from zero. For example, in a model that uses a firm's $q$ and current cash flow to predict investment spending, the coefficient of $q$ will be biased downward (towards zero) and the coefficient of cash flow may be biased upward. Erickson and Whited (2000) propose sophisticated estimators to deal with measurement error and obtain relatively large estimates of the relationship between $q$ and investment.

Another issue is whether we should use the market's valuation or the firm's internal valuation of prospective investments, since the firm may have better information about the projected cash flows and speculative stock market noise can cause market prices to wander from fundamental values (Morck, Shleifer and Vishny, 1990; Blanchard, Rhee and Summers, 1993). Several authors have proposed creative ways of estimating marginal $q$ from information available to managers (Abel and Blanchard, 1986; Gilchrist and Himmelberg, 1995) or from stock analysts' earnings forecasts (Cummins, Hasset and Oliner, 2006; Bond and Cummins, 2000). Gentry and Mayer (2006) apply the $q$ model to real estate investment trusts (REITs) and find that the use of appraised value in place of accounting-based replacement cost increases the estimated empirical relationship between REIT investment and $q$.

Uses of $q$

Empirical studies using Tobin's $q$ initially focused on either explaining $q$ (Lindenberg and Ross, 1981; Salinger, 1984) or using $q$ to predict investment spending (von Furstenberg, 1977; Summers, 1981; Hayashi, 1982), but have since broadened to include many issues in corporate finance that hold investment opportunities constant. For example, if we want to use cross-section data to see whether dividend policy affects the value of a firm, we need to control for each firm's profitability. Thus $q$ has been used in studies of the effects of managerial equity ownership (Morck, Shleifer and Vishny, 1988; McConnell and Servaes, 1990), the size of a company's board of directors (Yermack, 1996), corporate diversification (Berger and Ofek, 1995; Rajan, Servaes and Zingales, 2000); and dividend changes (Lang and Litzenberger, 1989; Denis, Denis and Sarin, 1994). For similar reasons, Tobin's $q$ has been used to hold investment opportunities constant while investigating the determinants of capital structure (Titman and Wessels, 1988), leveraged buyouts (Opler and Titman, 1993), and takeovers (Lang, Stulz and Walkling, 1989; Servaes, 1991).

Tobin's $q$ will no doubt be used in many other empirical studies of corporate structure and behaviour because it circumvents the unresolved issue of how to estimate shareholders' risk-adjusted required return by looking directly at observable market prices, which incorporate both the cash flow expectations of investors and the required returns they use to discount this anticipated cash flow.

Tobit model

Jean-Marc Robin

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Tobit models are used to model variables subject to exogenous censoring. For example, duration data cannot be observed longer than the survey period; hours of work cannot be observed negative although an individual might be better off consuming more leisure time than is available. This article reviews a list of econometric techniques to estimate Tobit models. Maximum likelihood, Heckman's two-stage estimator, and Powell's trimmed least squares are successively addressed.

Keywords

censored regression model; endogenous regressors; heteroskedasticity; labour supply; maximum likelihood; non-normal errors; ordinary least squares; probit model; Tobit model; trimmed least squares; two-stage estimation

Article

The Tobit model, or censored regression model, is useful to learn about the conditional distribution of a variable $y^*$ given a vector of regressors $x$, when $y^*$ is observed only if it is above or below some known threshold (censoring). In the original model of Tobin (1958), for example, the dependent variable was expenditures on durables, and values below zero are not observed.

Censoring models state that the observed dependent variable $y$ follows from the latent variable $y^*$ as

$$ y = \max\{y^*, 0\}, $$

where we have assumed a censoring of the form $y^*>0$ without loss of generality because, for any given top or bottom threshold $a$, it is always possible to change $y^*$ into $\pm(y^*-a)$.

Censoring may either be a property of the sample or a property of the population. For example, top-coding of earnings in the Current Population Survey (CPS) generates censoring in a way that is independent of individual decisions. In contradistinction, the zero purchases of Tobin's households are individual decisions. This type of censoring is usually modelled as a corner solution of a decision-theoretic model. For example, the labour supply model predicts that the number of hours worked by a person is equal to the interior solution of the consumption-and-leisure utility maximization problem, if it is greater than zero; it is zero otherwise. (See Pudney, 1989, for a survey of the economics and econometrics of corner solutions.)
The relationship between the latent variable $y^*$ and regressors $x$ is assumed linear:

$$ y^* = x^T \beta + u, $$

where $\beta$ is a vector of parameters, $x^T \beta$ denotes the scalar product of $x$ and $\beta$ ($T$ is the transpose operator), and $u$ is a residual component with cumulative distribution function (cdf) $F$ conditional on $x$. We assume that the distribution of $u$ given $x$, that is $F$, is continuous. It hence has a density $f = F'$.

The Tobit model corresponds to the particular case of $F(u) = \Phi \left( \frac{u}{\sigma} \right)$, where $\Phi$ denotes the cdf of the standard normal distribution $N(0,1)$, and $\sigma^2$ is the variance of $u$ (that is $u \sim N(0, \sigma^2)$).

The distribution of $y$ given $x$

Let $G(y|x)$ denote the cdf of the observation $y$ given $x$. The distribution of $y$ is not continuous. It has a mass point at 0. The probability mass at 0 is

$$ G(0|x) = \Pr\{y = 0|x\} = \Pr\{y^* \leq 0|x\} = \Pr\{u \leq -x^T \beta|x\} = F(-x^T \beta). $$

Notice that $F(-x^T \beta) = 1 - F(x^T \beta)$ if $u$ has a symmetric distribution.

Any positive observation $y>0$ is necessarily such that $y=x^T \beta + u$. Therefore, the cdf of the observed outcome at $y>0$ given $x$ is equal to the cdf of $u$ at $y-x^T \beta$:

$$ G(y|x) = F(y-x^T \beta), \ \forall y > 0. $$

The density of any observation $y>0$ given $x$ is

$$ g(y|x) = \frac{\partial G(y|x)}{\partial y} = f(y-x^T \beta). $$

Notice that, since 0 is a mass point of the distribution of $y$, its density at 0 can be defined as

$$ g(0|x) = G(0|x) - G(0^-|x) = G(0|x), $$
where \( G(0^- | x) = \lim_{y \to 0^-} G(y | x) = 0 \). (The probability density function, pdf, of a distribution or random variable is defined relative to a particular measure. Continuous variables admit a density with respect to the Lebesgue measure. Discrete distributions admit a density with respect to the counting measure. One can also define a density function for mixed discrete-continuous distributions with respect to mixtures of the Lebesgue measure and the counting measure.)

In the case of the Tobit model, \( f(u) = \frac{1}{\sigma} \phi \left( \frac{u}{\sigma} \right) \), where \( \Phi(v) = \frac{1}{\sqrt{2\pi}} e^{-\frac{v^2}{2}} \) is the density of the standard normal distribution. So,

\[
g(0|x) = G(0|x) = F(-x^T \beta) = \Phi \left( \frac{x^T \beta}{\sigma} \right), \quad g(y|x) = f(y-x^T \beta) = \frac{1}{\sigma} \phi \left( \frac{y-x^T \beta}{\sigma} \right), \quad \forall y > 0.
\]

Moments of \( y \) given \( x \)

Two conditional moments of \( y \) are of particular interest: \( E(y|x) \) and \( E(y | x, y > 0) \). First, notice that

\[
y = \max \left\{ y^*, 0 \right\} \geq y^*
\]

implies that

\[
E[y|x] \geq E[y^* | x]
\]

and

\[
E[y | x, y > 0] = \frac{E[y|x]}{Pr(y > 0 | x)} \geq E[y|x].
\]

So both \( E(y|x) \) and \( E(y | x, y > 0) \) overestimate the first moment of the variable of interest, that is \( E(y^* | x) \). Specifically,

\[
E[y|x] = E[\max \{ y^*, 0 \} | x] = E[\max \{ x^T \beta + u, 0 \} | x] = \int_{-x^T \beta}^{+\infty} (x^T \beta + u) f(u) du = x^T \beta (1 - F(-x^T \beta)) + \int_{-x^T \beta}^{+\infty} u f(u) du
\]

and
In the particular case of the Tobit model, $\phi'(v) = -v\phi(v)$. It thus follows that $\lambda(v) = \frac{\phi(v)}{\Phi(v)}$. Notice that $\frac{\phi}{\Phi}$ is the inverse Mills ratio of the standard normal distribution.

**Ordinary least squares**

Let $\{(y_i, x_i), i = 1, ..., N\}$ be an i.i.d. random sample of observations. Regressing $y_i$ on $x_i$ for the uncensored observations $i$ such that $y_i > 0$ does not yield a consistent estimator of $\beta$ because of the omitted variable $\lambda(x_i^T\beta)$ which is correlated with the regressors $x_i$.

For the Tobit model, a two-stage estimation procedure can be devised.

1. First, estimate a Probit model for $d_i \equiv 1\{y_i > 0\} (=1$ if $y_i > 0$ and $=0$ otherwise):

$$Pr\left\{d_i = 1|x_i\right\} = \Phi(x_i^Tc),$$

with $c = \frac{\beta}{\sigma}$. Let $\hat{c}$ be the Probit estimator of $c$.

2. Regress $y_i$ on $x_i$ and the inverse Mills ratio $\frac{\phi(x_i^T\frac{c}{\sigma})}{\Phi(x_i^T\frac{c}{\sigma})}$ by OLS. This yields a consistent estimator of $\beta$ and $\sigma$.

Two remarks are in order. First, as any multi-stage estimation procedure, the OLS estimator of the second stage has $\frac{\phi(x_i^T\frac{c}{\sigma})}{\Phi(x_i^T\frac{c}{\sigma})}$ instead of $\frac{\phi(x_i^T\frac{c}{\sigma})}{\Phi(x_i^T\frac{c}{\sigma})}$. The measurement error $\frac{\phi(x_i^T\frac{c}{\sigma})}{\Phi(x_i^T\frac{c}{\sigma})}$ tends to 0 when $N$ tends to infinity. So the OLS estimator of $(\beta, \sigma)$ is asymptotically unbiased and consistent. However, its asymptotic variance has to be corrected for the statistical error on parameter $c$.

Second, the first stage requires knowing the entire distribution of $u_i$. It is therefore not clear why one would want to use this two-stage procedure instead of maximum likelihood (ML), which is efficient.

**Maximum likelihood**
The likelihood of one observation \( y_i \) conditional on \( x_i \) is \( g(y_i | x_i) \). The conditional sample log-likelihood is then

\[
L_N = \sum_{i=1}^{N} \ln g(y_i | x_i) = \sum_{i=1}^{N} \left\{ d_i \ln f(y_i - x_i^T \beta) + (1 - d_i) \ln F(-x_i^T \beta) \right\}.
\]

Under standard regularity conditions, the values of \( \beta \) and any other parameters of \( F \) that maximize the log-likelihood \( L_N \) are root-\( N \) consistent and asymptotically normal and efficient.

For the Tobit model, we obtain

\[
L_N = \sum_{i=1}^{N} (1 - d_i) \ln \left( 1 - \Phi \left( \frac{x_i^T \beta}{\sigma} \right) \right) - N \ln \sigma - \frac{1}{2 \sigma^2} \sum_{i=1}^{N} d_i (y_i - x_i^T \beta)^2
\]

where \( N^+ = \sum_{i=1}^{N} (1 - d_i) \) is the number of uncensored observations.

It is useful to change \((\beta, \sigma)\) into \((c, s) = (\frac{\beta}{\sigma}, \frac{1}{\sigma})\) because

\[
L_N = \sum_{i=1}^{N} (1 - d_i) \ln (1 - \Phi(x_i^T c)) + N \ln s - \frac{1}{2} \sum_{i=1}^{N} d_i (s y_i - x_i^T c)^2
\]

is strictly concave with respect to \((c, s)\). Maximizing \( L_N \) with respect to \((c, s)\) is easy and fast using standard gradient algorithms. One can then use the delta method to recover an estimate of the asymptotic variance of \( (\hat{\beta}, \hat{\sigma}) = (\frac{c}{s}, \frac{1}{s}) \). Consistency of ML obviously rests on the model being well specified. Non-normal errors and heteroskedasticity (when homoskedastic, normal errors are assumed) lead to inconsistent estimates.

**Trimmed least squares**

Powell’s (1986) symmetrically trimmed least squares is a simple consistent estimator that is consistent under the assumption that the distribution of \( u_i \) is symmetric. It can yet be non-normal or heteroskedastic.

The idea is to replace \( y_i \) by \( 2 x_i^T \beta \) when \( y_i \geq 2 x_i^T \beta \), if \( x_i^T \beta > 0 \), and drop all observations such that \( x_i^T \beta \leq 0 \) from the sample, as no symmetric trimming is possible in this case. In effect, let

\[
\tilde{y_i} = \min \{ y_i, 2 x_i^T \beta \} = x_i^T \beta + \delta_i
\]
where

\[ g_i = \begin{cases} 
- x_i^T \beta & \text{if} \ u_i \leq - x_i^T \beta \\
 u_i & \text{if} \ - x_i^T \beta < u_i \leq x_i^T \beta \\
x_i^T \beta & \text{if} \ x_i^T \beta < u_i 
\end{cases} \]

As \( u_i \) has a symmetric distribution conditional on \( x_i \), then so does \( g_i \). Hence,

\[ \mathbb{E}[y_i|x_i] = x_i^T \beta. \]

The trimmed least squares estimator is obtained by iterating the following sequential procedure until convergence. Start with an initial value \( \beta_0 \) for \( \beta \). For example, regress \( y_i \) on \( x_i \) on the uncensored sample. If, at iteration \( p \), one has obtained a value \( \beta_p \) for \( \beta \), then compute \( \beta_{p+1} \) by regressing \( y_i(\beta_p) = \min \{ v_h, 2 x_i^T \beta_p \} \) on \( x_i \) using the sample of observations \( i \) such that \( x_i^T \beta_p > 0 \).

**Endogenous regressors**

In the standard labour supply model, the observed dependent variable \( y_i \) is the actual number of hours worked by individual \( i \), and the latent variable \( y_i^* \) is the interior solution to a utility maximization problem. This interior solution depends on the individual's wage, \( w_i \), and other variables \( x_i \) such as non-labour income or education and age:

\[ y_i^* = x_i^T \beta + \alpha w_i + u_i \]

The residual \( u_i \) captures unobserved heterogeneity factors influencing the trade-off between consumption and leisure. It is usually understood that wages \( w_i \) and unobserved taste shifters \( u_i \) are correlated across individuals: \( \text{Cov}(w_i, u_i) \neq 0 \).

Suppose that \( w_i \) and \( x_i \) are both observed when \( y_i = 0 \). The following simple control-function procedure can apply to solve the endogeneity problem. Suppose that there exists a vector \( z_i \) of instruments such that

\[ w_i = z_i^T \gamma + v_i \]

with \( \text{Cov}(z_i, y_i) = 0 \). Suppose also that...
with \( \varepsilon_i \) normal \( N(0, \sigma^2) \) conditional on \( x_i, z_i \) and \( v_i \). This will be the case in particular if \( u_i \) and \( v_i \) are jointly normal conditional on \( x_i \) and \( z_i \).

Then, the following two-stage procedure produces consistent estimators of \( \beta, \alpha \) and \( \rho \).

1. Regress \( w_i \) on \( z_i \) by OLS and compute residuals \( \hat{V}_i \).
2. Estimate the Tobit model assuming normally distributed, by ML or other appropriate method.

\[
v_i = \max \left\{ x_i^T \beta + \alpha w_i + \rho \hat{V}_i + \eta_i, 0 \right\},
\]

assuming \( \eta_i = \varepsilon_i - \rho (\hat{V}_i - v_i) \) normally distributed, by ML or other appropriate method.

One can test for the exogeneity of \( w_i \) by testing for \( \rho = 0 \) with a standard \( t \)-test. If the null hypothesis is rejected, then this two-stage procedure yields consistent estimates, but correct asymptotic standard errors, accounting for the approximation of \( v_i \) by \( \hat{V}_i \), require a specific calculation.

Finally, if \( w_i \) is not observed when \( y_i = 0 \), which is the case for wages of not employed individuals, this procedure does not work. Heckman (1974) assumed joint normality of \( (u_i, v_i) \) and applied maximum likelihood to \( (y_i, w_i), i = 1, \ldots, N \), conditional on exogenous variables.

Tocqueville, Alexis Charles Henri Clérel de (1805–1859)

J. Goodwin
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

civil society; democracy; equality of conditions; individualism; liberty; Physiocracy; Tocqueville, A. C. H. C. de

Article

Alexis de Tocqueville was born at Verneuil, in Normandy, France, on 29 July 1805. In 1831 he journeyed to the United States with his friend Gustave de Beaumont to study the American penal system. He then wrote *Democracy in America*, the first volume of which appeared in 1835, the second in 1840. Tocqueville was a member of the French Chamber of Deputies and served briefly as Minister of Foreign Affairs in the republic established after the Revolution of 1848. The events of this period are recounted in his *Recollections* (1893). Tocqueville was among those arrested during the *coup d'état* of Louis Napoleon on 2 December 1851, and he subsequently retired from public life. Tocqueville devoted his last years to a major study of the French Revolution, although he completed only the first volume before his death. This appeared as *The Old Régime and the French Revolution* in 1856. He died at Cannes on 16 April 1859.

Tocqueville was interested in the political, cultural, and, to a lesser extent, economic consequences of ‘democracy’, by which he meant not representative government or political arrangements of any sort, but ‘equality of conditions’. (John Stuart Mill would argue that Tocqueville had confounded the effects of ‘democracy’ with the tendencies of modern commercial society.) By equality of conditions, Tocqueville meant neither the absence of classes nor mere equality of opportunity, but something like rough social equality, including, especially, the absence of the legally prescribed hierarchy of social groups characteristic of ‘aristocratic’ societies.

Tocqueville's major intellectual, not to say political, preoccupation was discovering how ‘liberty’ might be preserved under democratic conditions. By ‘liberty’ Tocqueville meant above all the local control and administration of a community's common affairs by a politically engaged and civic-minded populace. He was thus a strong critic of both the administrative centralization of the state and the narrow, self-interested ‘individualism’ of bourgeois society. This explains Tocqueville's appeal to those on both the
Tocqueville's search for the institutional and ideological supports of liberty under democratic conditions was the ulterior purpose of his journey to the United States, a country which had managed to combine democracy and liberty. In *Democracy in America*, Tocqueville analysed a number of factors which he believed helped to maintain political liberty in the United States, including administrative decentralization, the profusion of voluntary associations, and what he termed ‘self-interest properly understood’, that is, a disposition to devote part of one's time and wealth to the good of the community. *The Old Régime and the French Revolution*, by contrast, explored the failure of France's revolutionary transition to democracy to produce a stable liberal regime; this Tocqueville attributed principally to the immense administrative centralization of the pre-revolutionary period and the consequent degradation of French political culture.

Tocqueville's reflections on economic matters are few. In fact, he once ‘confessed’ to Nassau Senior that he ‘was insufficiently informed on this important portion of human science’. In *The Old Régime*, however, Tocqueville did not hesitate to criticize the Physiocrats, whom he believed perhaps best represented the abstract and utopian type of intellectual nourished by the illiberal environment of pre-revolutionary France. Tocqueville thought that the Physiocrats lacked any concern for political, as opposed to economic, liberty, offering only the ‘intellectual panacea’ of universal education. They were for abolishing all hierarchies, all class distinctions, all differences or rank, and the nation was to be composed of individuals almost exactly alike and unconditionally equal. In this undiscriminated mass was to reside, theoretically, the sovereign power; yet it was to be carefully deprived of any means of controlling or even supervising the activities of its own government.

Tocqueville's reflections on economic matters in *Democracy in America* comprise only a few pages of that voluminous work. Tocqueville argued that rents tend to rise and the terms of leases to shorten in democracies owing to the dissolution of the close, customary relationship between landlord and tenant and its replacement by the impersonal contract. He also thought that democratic conditions made it easier for workmen to combine and pressure their employers for higher wages; he thus argued that ‘a slow, progressive rise in wages is one of the general laws characteristic of democratic societies’. At the same time, Tocqueville feared that the very richest industrialists could wait out strikes and force permanently lower wages on their workers. In fact, Tocqueville believed that a dangerous business or industrial ‘aristocracy’ might arise within the womb of democratic society. However, this potential aristocracy was not to be greatly feared, Tocqueville thought, since industrialists seldom look beyond their own interests and share no common traditions or corporate spirit; still, Tocqueville warned, ‘if ever again permanent inequality of conditions and aristocracy make their way into the world, it will have been by that door that they entered’.

Tooke, Thomas (1774– 1858)

Massimo Pivetti

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Bank Charter Act (1844); Bank of England; Banking School; convertibility; cost of production; Currency School; endogenous money; free trade movement; Political Economy Club; price level; rate of interest; Tooke, T.; Torrens, R.; Wicksell, J. G. K.

Article

Thomas Tooke, the leading member of the Banking School, was born at St Petersburg in 1774, the eldest son of William Tooke, historian of Russia and man of letters, at that time chaplain to the English church at St Petersburg. Not a professional scientist but an active man of business of comfortable social standing, Thomas was successively a partner in the London firms of Stephen Thornton & Co. and Astell, Tooke & Thornton, Russian merchants, and was governor of the Royal Exchange Corporation and chairman of the St Katharine's Dock Company. In 1802 he married Priscilla Combe, by whom he had three sons.

As an early supporter of the free trade movement, he drew up the Merchants’ Petition of the City of London, which contained the statement of the principles of free trade and was presented to the House of Commons in May 1820. He gave evidence on monetary questions before several parliamentary committees, from the Resumption Committees of 1819 to the Committees on Bank Acts in the 1850s. Tooke was elected Fellow of the Royal Society in March 1821; shortly afterwards, with Ricardo, Malthus, James Mill and others, he founded the Political Economy Club and took a prominent part in its discussions until very late in his life. He died in London on 26 February 1858. A few days later, in a letter to Engels, Marx wrote: ‘Friend Thomas Tooke has died, and with him the last English economist of any value’ (Letter of 5 March 1858, in Marx and Engels, 1983, p. 284).

Tooke's writings may be divided into two groups, two phases of his work which it is useful to distinguish for a better appraisal of his contribution. The first phase consists essentially in a systematic attempt to collect and analyse as much historical material and statistical information as possible, connected with price changes in England from 1793 onwards: a thorough observation of facts, aimed at understanding the determinants of fluctuations in the domestic price level. This phase is represented by...
his writings from 1823 to 1838 – from Tooke's first pamphlet *Thoughts and Details on the High and Low Prices of the Thirty Years from 1793 to 1822* to the first two volumes of his *History of Prices*, that is to say, with his *Considerations on the State of the Currency* (1826) and the two Letters to Lord Grenville (1829) in between. In the second group of writings, Tooke finally brings into focus and elaborates a few significant general principles which he gradually became certain could be derived from his observation of facts; moreover, he fully perceives the conflict between those principles and the prevailing notions, and copes with the arguments of his critics. This second phase of Tooke's work covers the writings from Volume 3 of the *History* (1840) to Volumes 5 and 6 (1857, a year before Tooke's death) and comprises his *Inquiry into the Currency Principle* (1844) – the most representative and outstanding piece, together with Volume 4 of the *History* (1848), of Tooke's voluminous work.

The main result emerging from Tooke's observation of facts in the first group of writings can be summarized as follows: the great fluctuations of prices that occurred in the 45 years following 1792 must be attributed to circumstances affecting the conditions of supply of commodities, rather than to the alterations in the system of the currency – the latter being represented by the suspension of convertibility from 1793 and its resumption after 1819 (by the Resumption Act of 1819). The prevailing view was that the value of the currency had been depreciated by the suspension, and enhanced by the contraction in the amount of circulating medium that the resumption of convertibility was alleged to have brought about. According to Tooke, ‘the most extensive induction of facts’ made it apparent that the phenomena of high prices from 1792 to 1819 and of the comparatively low prices after 1819, did not originate in the variations in the quantity of money (independently of whether the latter proceeded from the alterations in the system of the currency or from any other cause). The great fluctuations of prices originated instead from alterations in the cost of production and from other ‘accidents’ affecting supply: the character of the seasons (more unfavourable on the average from 1793 to 1818 than from 1818 to 1837); marked variations in the cost of imported commodities, as well as in the existence and removal of various obstacles (revolutions, wars) from the several sources of foreign supply; significant improvements in machinery and sciences generally, all tending to reduce the cost of production of numerous commodities (or to provide cheaper substitutes). In Volume 2 of the *History*, the rate of interest is listed for the first time amongst the causes of the high and of the low prices in the period under consideration – ‘a higher rate of interest constituting an increased cost of production’ and ‘a reduction of the general rate of interest’ leading ‘to reproduction at a diminished cost’ (1838, pp. 847 and 849). As we shall see, this is in our view the crucial point upon which hinge those aspects of Tooke's contribution that are most relevant for the modern scholar of capitalism.

The connection between money and prices occupies the centre of the stage in the second group of Tooke's writings: ‘the prepossession or prejudice’, as he puts it, that the quantity of money must have a direct influence on the prices of commodities. By ‘money’ must be understood, Tooke insists in pointing out to the supporters of the Currency Theory, not only coin and paper money (banknotes), but also cheques, bills of exchange, settlements and whatever form of paper credit which may come to be a component part of the circulating medium, performing the functions of money in daily transactions. By 1844 he was fully convinced

that the prices of commodities do not depend upon the quantity of money indicated by the amount of bank notes, nor upon the amount of the whole of the circulating medium; but that, on the contrary, the amount of the circulating medium is the consequence of prices.
Tooke's evidence for this conclusion was ultimately the fact that the banks, including the Bank of England, did not appear to have the power to add to the quantity of money in circulation – unless other independent circumstances, such as an extension of trade and a rise in prices, were ‘coincidently’ in progress (1844, p. 66); nor did the banks appear to have the power to diminish the total amount of the circulation. Banks may withhold loans and discounts, and may refuse any longer to issue their own notes, but those loans, discounts and notes will be replaced in due course, Tooke argues, ‘by other expedients calculated to answer the same purpose’ (1844, p. 122). Only compulsory paper money issued directly by a government in payment for goods and services (like the French assignats) constitutes a fresh source of demand, so that alterations in its quantity act directly as an originating cause on prices (see 1844, pp. 68–78; 1848, pp. 183–97).

The power of the banks to expand and contract the quantity of the circulating medium at pleasure, was taken for granted by the Currency School and by most writers. It was a challenging task, for Tooke and the Banking School, to convince those writers of the lack of such a power, and, in consequence, of the fact that such alterations in the quantity of money as do actually occur are the effect of increased transactions and prices, and not the cause of them. Tooke has the great merit of having succeeded in bringing into focus the heart of the matter: the question of the effects of changes in the rate of interest on the inducement to purchase commodities. ‘Abundance of money’ – that is, a high disposition on the part of the banks to make advances in the way of loan or discount – results in the first place in a high price of securities and a low rate of interest; thus the power of the banks to add to the amount of the circulating medium, and hence to act as an originating cause on trade and prices, will ultimately depend on whether a low rate of interest supplies the stimulus to purchase commodities. Tooke points out that actual experience does not validate the notion that the facility of borrowing at a low rate of interest, not only confers the power of purchasing commodities, but also affords the motive and inducement to do it. ‘The error’, he says, ‘is in supposing the disposition or will to be co-extensive with the power’ (1844, p. 79).

No relation of cause and effect between variations in the rate of interest and variations in the demand for commodities can be inferred from trustworthy evidence (compare 1857, vol. 5, p. 345). The questions of the connection between money and prices and between the rate of interest and the price level are thus clearly seen as two sides of the same coin. Arguing against the dominant opinion that a low rate of interest raises prices and that a high rate depresses them, Tooke actually maintained that a persistent reduction in the rate of interest constitutes a reduction in the cost of production, which could not fail, by the competition of the producers, to bring about a fall of prices (compare 1844, p. 81). He went so far as to state that it is difficult to find evidence of facts more in contrast with the influence ascribed to a low rate of interest in raising prices and vice versa: ‘The theory is not only not true, but the reverse of the truth’ (1844, p. 84).

It is important to notice that Tooke's conception of the relation between the rate of interest and the price level, and the connected notion of ‘endogenous money’ (as we would now call his view of the relation between money and prices), are in no way contingent upon the particular currency system of his day, with the relevant part played in it by precious metals. Rather, it is the denial of any power on the part of the banks to regulate at will the amount of the circulating medium, together with the emphasis on the circumstances affecting supply, that provide Tooke with the basis for his criticism of the idea that every influx or efflux of the precious metals must cause a rise and fall of prices, independently of
circumstances connected with the cost of production of commodities. On that same basis he opposes the prevailing view that the discovery of a gold mine within the premises of the Bank of England – Ricardo's famous assumption in his first pamphlet (1811) – would necessarily raise the prices of commodities. And he argues that for an increased production of gold to be associated with a permanent rise in the prices of commodities, measured in gold, the increased production must be the consequence either of the discovery of more fertile mines, or of improved methods of working the existing ones (1848, pp. 199 ff.; 1857, vol. 6, pp. 413–4).

Monetary policy questions, naturally, permeate all of Tooke's writings. The chief place amongst them is occupied by the Bank Charter Act of 1844 and the controversies that both preceded and followed its implementation – controversies centred upon the idea of a separation of the business of the note issue from the banking business of the Bank of England. This idea, opposed by Tooke, was given statutory effect by the Act, and brought about in due time many of the shortcomings that had been foreseen by Tooke (for an extensive critical account of Tooke's views on banking policy, see Gregory, 1928; 1929, vol. 1).

On several policy issues that are still relevant today, the modern orthodox scholar of monetary questions and central banking policy is likely to find himself more in agreement with Tooke's views than with those of the supporters of the Currency School. This hardly applies, however, to those views of Tooke's which are more strictly connected with his conception of the relation between money and prices, and of the influence of the rate of interest on the price level. As an important example of one such view, one may refer to Tooke's contention that, as the Bank of England and the banks collectively cannot arbitrarily change the amount of the circulating medium, nor operate through that medium on the prices of commodities, the only 'infallible means' they have to influence foreign exchanges – 'so as to arrest a drain, or to resist an excessive influx' – is by a forcible operation on securities: a great advance in the rate of interest on the one hand, or a great reduction of it in the other. Now, the articulated line of argument laid down by Tooke in discussing the power of the central bank to influence foreign exchanges (cf. 1844, pp. 123–4), appears on the whole no less alien from today's quantity of money approach to problems of general prices than it was in Tooke's day.

Besides Marx (see above, and also 1857–8; 1859), Tooke's most outstanding contemporaries who praised his work and ideas were Malthus (1823) and J.S. Mill (1844; 1852, ch. 24, pp. 203–4). (Malthus's appreciation, however, must not be overrated: he tends to understand Tooke's early contribution merely as a confirmation of his own views on value against those of Ricardo – namely, 'that everything must be attributed to supply and demand’, rather than simply to ‘labour and the costs of production’; 1823, p. 218.) The most strenuous opponent of Tooke's ideas and policy recommendations was Robert Torrens (1840; 1844; 1848). This author's criticisms grew increasingly severe as Tooke's work advanced with the development of more general principles from the empirical analyses. By 1844, Tooke's thesis that the prices of commodities do not depend upon the quantity of money is referred to and criticized as ‘the most astonishing of the many astonishing fallacies’ (Torrens, 1844, p. 43). Torrens's criticisms are extensively dealt with by Tooke in Volume 4 of the History of Prices (1848), and by Fullarton (1844) and Wilson (1847).

If Torrens was the most outstanding critic of Tooke amongst classical economists, Knut Wicksell, the father of 20th-century monetary theory, has been his most outstanding critic since the inception of marginalism. Wicksell's conceptions ultimately constitute the main reference-point of this century's (not
Tooke, Thomas (1774–1858) : The New Palgrave Dictionary of Economics

so large) literature in which Tooke's work and ideas are somehow taken into consideration, starting from Gregory's *Introduction to the History of Prices* (1928). In fact, we can look today at Tooke and Wicksell as the chief exponents of two alternative ways of reasoning about the connection between money and prices. Wicksell's criticisms of Tooke's view are somewhat vitiated by their being mostly based upon the interest elasticity of the demand for loan capital, as postulated by the marginalist theory (see 1898, ch. 7; 1906, pp. 175–208). There is, however, one important criticism which does not reflect Wicksell's tendency to superimpose upon Tooke's view his own theory. He criticizes Tooke's reasoning about the effect of the rate of interest on the cost of production and commodities prices, as entailing that every persistent move in either direction would cause a progressive divergence of both interest and prices from their initial levels: a persistent reduction in the rate of interest

would lead to a reduction … in the demand for loans by business people, money would flow into the banks and would cause a further reduction of interest rates, and so on, until the rate fell to nil – In other words, the money rate of interest would be in a state of unstable equilibrium. (Wicksell, 1906, p. 187)

This conclusion actually follows, not from Tooke's view of the influence of the rate of interest on prices, but from his conception of the rate of interest as a magnitude ‘entirely governed by the supply of and demand for monied capital’, on which the central bank can exercise only a temporary influence (1826, sect. I; 1857, pp. 556–7; see also Newmarch, 1857, pp. 66–72).

Not to have acknowledged that the monetary authorities do have the power of determining the rate of interest – albeit a power exercised under a wide range of constraints – constitutes, in our opinion, the main shortcoming of Thomas Tooke and the Banking School.

Article

Torrens, if not in the top rank of the classical economists, or in the class for example of Ricardo, Senior or John Stuart Mill, certainly was of the second rank and the equal of, or even above, James Mill or McCulloch in terms of originality, theoretical reasoning and the range of economic topics that he considered. His work was almost completely neglected in the years after his death in 1864 and his re-emergence to his rightful place as an important member of the Classical School was initially due to Seligman in his famous article ‘On Some Neglected British Economists’ (1903) and later to the definitive study by Lionel Robbins (1958). In recent years Torrens has also come to the fore again because of the debates surrounding the Sraffa interpretation of Ricardo.

Robert Torrens was a most prolific writer and produced a vast quantity of books and pamphlets on all sorts of economic matters for over 50 years. His first publication appeared in 1808 (The Economists Refuted) and his last in 1858 (Lord Overstone on Metal and Paper Currency). He managed all of this against the background of an extremely busy life that included several different careers. He was a professional soldier – a colonel in the Marines – and was decorated for gallantry at the battle of Anholt. Subsequently he became the proprietor of the Globe newspaper, a Member of Parliament, the planning genius behind the colonization and development of New South Wales, a founder member of the Political Economy Club and many other things besides. He even found time to write two never-read novels, the Hermit of Killarney and Coelobia in Search of Husband, both of which contain hefty chunks of economic discourse.

His specific contributions to economics may be dealt with under the general headings of
Torrens's main contributions to microeconomics concerned the Ricardian system. He objected to the search for an absolute, invariant measure of value and also tried to replace the labour quantity theory of value with a capital theory of value – where relative commodity values are determined by relative capital inputs. He did not however fully realize that his definition of capital combining wages and materials was different from Ricardo's which was really only wages.

On the other hand, and somewhat inconsistently, it is now clear (see Langer, 1982; de Vivo, 1985) that Torrens fully understood the corn-ratio theory of profits that Sraffa ascribed to Ricardo, and that he (Torrens) derived this from Ricardo. He also saw, following Ricardo that given the agricultural rate of profit, the price of manufactured goods relative to corn, was given. All of this is clearly spelt out in the second edition of An Essay on the External Corn Trade (1820) and must therefore lead one to doubt Hollander's argument (1979) that Ricardo did not mean the corn-ratio theory of profit and the key role of the agriculture sector in his analysis to be taken too seriously.

In the first edition (1815) of the Essay Torrens has a clear statement of the principle of comparative advantage well before its more popularly ascribed origins in Ricardo's Principles (1819). He makes a clear distinction between absolute and comparative advantage and indeed he actually hints at this distinction in his earlier Economist Refuted (1808).

In the field of money and banking Torrens is best known for his championing of the Currency School in their debate with the Banking School. Essentially the currency principle was that a mixed currency, that is, a currency consisting of notes and coins, should be regulated so that movements in it were the same as under a purely metallic currency. Unlike the bullionists, however, the Currency School did not believe that convertibility alone would achieve the conformability of a mixed currency to a metallic one. To this end, Torrens may claim to have been the originator of the plan, activated in the Bank Charter Act of 1844, to separate the issue and banking department of the Bank of England. This he did in his Letter to Lord Melbourne (1837) and he later vigorously defined the legislation in his Principles and Practical Operation of Sir Robert Peel's Bill of 1844 (1848).

Students of Torrens find an inconsistency with this aspect of his monetary thinking and his earlier espousing of the anti-bullionist position; in particular his Essay on Money and Paper Currency (1812) is a strong plea for a paper currency without convertibility and relying on the real bills doctrine to prevent excess issue. The reasons for abandoning this extreme anti-bullionist position and his switch to the Ricardian line are explained in his On the Means of Establishing a Cheap, Secure and Uniform Currency (1828).

Torrens's main contribution to the theory of commercial policy was to suggest a modification of the general classical case for free trade. He pointed out, and was amongst the first to do so, that a country might alter its terms of trade in its favour by use of an import tariff. In a series of letters to Lord John Russell (published in 1844 as The Budget) he argued the case for what he termed ‘reciprocity’, that is, if some countries had tariffs unilateral free trade was a mistaken policy and in these cases reciprocal tariffs should be adopted. Against the change that he was abandoning the central classical (Ricardian) belief in free trade, Torrens replied that he was just applying the logic of the Ricardian analysis.

Finally, Torrens had a significant influence on the theory and practice of colonization. Along with most of the later classical economists he rejected the Smithian view that colonies were of no economic benefit to the colonial power. Much of the later classical case for colonies was based on the view that colonies would provide profitable investment outlets to offset a declining rate of profit at home. Torrens used this
argument in some of his later writings but his main argument was that colonies were an ideal solution to the Malthusian overpopulation problem. In this view he was undoubtedly influenced by his interpretation of the causes of Irish poverty – a country incidentally where Torrens was born and in general its problems had a profound effect on his thinking. In terms of colonization policy Torrens, like Wakefield, was opposed to the movement of labour on to free land on the grounds that this would lead to a dispersed population and land holdings of suboptimal size. He advocated systematic colonization with the price of land set sufficiently high that large units of capital would have to be amassed before the immigrant labourers became independent farmers.

Total factor productivity (TFP) is the portion of output not explained by the amount of inputs used in production. As such, its level is determined by how efficiently and intensely the inputs are utilized in production.

TFP growth is usually measured by the Solow residual since Solow (1957). Let $\gamma$ denote the growth rate of aggregate output, $\kappa$ the growth rate of aggregate capital, $\lambda$ the growth rate of aggregate labour, and alpha the capital share. The Solow residual is then defined as $\gamma - \alpha \cdot \kappa - (1 - \alpha) \cdot \lambda$. The Solow residual accurately measures TFP growth if (a) the production function is Cobb–Douglas, (b) there is perfect competition in factor markets, and (c) the growth rates of output and the inputs are measured accurately.

TFP plays a critical role on economic fluctuations, economic growth and cross-country per capita income differences. At business cycle frequencies, TFP is strongly correlated with output and hours worked. Based on this observation, Kydland and Prescott (1982) initiated the real business cycle (RBC) literature. In the standard business cycle model, shocks to TFP are propagated by pro-cyclical labour supply and investment, thereby generating fluctuations in output and labour productivity at business cycle frequencies with an amplitude that resembles the US data. Subsequent work has introduced pro-
cyclical fluctuations in measured TFP by incorporating unmeasured labour hoarding and/or capacity utilization in the standard framework (see, for example, Burnside, Eichenbaum and Rebelo, 1995; Basu, 1996; King and Rebelo, 1999). In this way, TFP fluctuations can be driven by shocks to aggregate demand in addition to the standard interpretation that attributes them to aggregate supply shocks. As shown in the landmark article by Robert Solow (1956), long-run growth in income per capita in an economy with an aggregate neoclassical production function must be driven by growth in TFP. For over 30 years, the conceptual difficulty when trying to endogenize TFP growth was how to pay for the fixed costs of innovation in a perfectly competitive economy with constant returns to scale in capital and labour. In this context, all output is exhausted by paying capital and labour their marginal products; therefore, no resources are left to pay for the innovation costs. Romer (1990) and Aghion and Howitt (1992) solved this problem by granting the innovator monopolistic rights over his innovation, which are sustainable through the patent system. In this way, innovators can recoup the initial fixed costs of innovation through the profit margin they make from commercializing their patent. By linking the TFP growth rate to innovation, endogenous growth models shed light on the determinants of TFP growth. R&D subsidies and an abundance of skilled labour reduce the marginal cost of conducting R&D and increase the rate of innovation development and, therefore, the TFP growth rate. Expanding markets increase the innovators’ revenues, leading to more innovation and higher TFP growth. Solow (1956) also demonstrated that cross-country differences in technology may generate important cross-country differences in income per capita. Klenow and Rodriguez-Clare (1997) and Hall and Jones (1999) have confirmed that most of the gap in income per capita between rich and poor countries is associated with large cross-country differences in TFP. Cross-country differences in TFP can be due to differences in the physical technology used by countries or in the efficiency with which technologies are used. To explore the relative importance of these factors, it is necessary to have data on direct measures of technology. Comin, Hobijn and Rovito (2006) put together direct measures of technology adoption for approximately 75 different technologies and show that the cross-country differences in technology are approximately four times larger than cross-country differences in income per capita. Further, technology is positively correlated to income per capita. Thus, cross-country variation in TFP is, to a large extent, determined by the cross-country variation in physical technology.

**Likely future directions**

**Economic fluctuations**

Recognizing that a large portion of TFP growth is caused by endogenous innovation decisions has significant implications for the business cycle. This is likely to be an important research topic. Comin and Gertler (2006) show that low-persistence, non-technological shocks generate pro-cyclical fluctuations in the market value of innovations. Agents arbitrage these innovation opportunities and generate a pro-cyclical rate of innovation development and, hence, of TFP growth. The model-induced fluctuations in TFP are as large and persistent as in the data. More important, by linking a component of TFP to innovation activity, TFP becomes a mechanism that propagates low-persistence shocks, thus
Total factor productivity: The New Palgrave Dictionary of Economics

increasing its persistence, rather than a source of disturbances as in standard RBC models. This same logic can be extended to other processes that determine the endogenous level of technology, such as endogenous technology adoption processes, which are more relevant in developing economies. This may be an important ingredient to understanding high and medium-term fluctuations in developing economies.

Long-run growth

A significant fraction of innovations are not patented. For some, this is because they are not embodied in any new good or are not a recipe for a new chemical process and, therefore, are not patentable. Others are not patented because innovators simply decide not to apply for a patent. Three important areas of research are to understand (a) how important patents are for innovation activity, (b) the determinants of non-patentable innovations and (c) how they interact with the patentable R&D type of innovations that fit the properties of the Romer (1990) and Aghion and Howitt (1992) models.

Two papers have argued that patents are not necessary for the innovators to recoup the innovation costs. Innovators in Hellwig and Irmen (2001) can obtain rents to cover innovation costs despite being perfectly competitive because they face an increasing marginal cost of producing the intermediate goods that embody their innovations. Boldrin and Levine (2000) model innovation in perfectly competitive settings. In their model, to copy an innovation it is necessary to purchase one unit of the good that embodies it. Hence, the innovator is the monopolist of the first unit produced, and the revenues he extracts from selling it may cover the innovation costs, making up for a lack of patent protection.

Comin and Mulani (2006) model the development of disembodied innovations such as managerial and organizational techniques, personnel, accounting and work practices, and financial innovations. These are very different from embodied innovations in that the rents extracted by the innovators are not associated with selling the innovation per se. This has some interesting implications. First, the revenues accrued by the innovator–producer originate from the increased efficiency in producing his good or service with the innovation. If the innovator–producer has some monopolistic power in the market for his good or service, the increased efficiency from using the innovation in production yields an increase in profits that may cover the innovating costs. Second, since the innovator–producer's gain from innovating comes from the increased efficiency of production, the marginal private value of developing disembodied innovations is increasing in the value of the firm. This has important cross-sectional and time-series implications. In the cross-section, firms with higher values (resulting from larger sizes or ability to charge higher markups) have more incentives to develop disembodied innovations. In the time series, shocks that reduce the value of the firm reduce its incentives to develop disembodied innovations. One such shock may be an increase in the probability that a competitor steals the market. If the occurrence of this shock requires the development of a new patentable product, the model implies the possibility of an aggregate trade-off between investments in developing disembodied innovations and embodied innovations. A complete understanding of the determinants of these different types of innovation may be critical for explaining secular TFP dynamics.

Development
Understanding the determinants of technology adoption is key to explaining cross-country variation in TFP. On the theory side, an increasing number of theories link the adoption of technologies to the role of institutions (Acemoglu, Antras and Helpman, 2007), financial markets (Alfaro et al., 2006; Aghion, Comin and Howitt, 2006), endowments (Caselli and Coleman, 2006) and policies (Holmes and Schmitz, 2001). The challenge is to bring these theories to the data and assess their empirical relevance. The new country-level data on measures of micro technologies must be an important input towards this goal.

Tournaments

Tor Eriksson
From The New Palgrave Dictionary of Economics Online, , 2009
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Tournament theory is a theory of promotion-based incentives which also contributes to the understanding of firms' wage structures and individual earnings. In tournaments wage-rank differentials act as an incentive scheme when firms cannot directly observe employees' effort. Empirical evidence is mainly from sports and lab experiments while there are fewer studies of businesses and organizations.

Keywords

pay; promotions; raises; relative performance; wage structures

Article

A significant proportion of employees work together with other workers, some of whom are performing the same tasks. Moreover, for many jobs it is difficult to observe individual performance. Under such conditions relative performance schemes are frequently used a mechanism for motivating employees. These can take the form of competition for promotions or schemes that award tenure when performance exceeds a certain standard. Because of the similarity of these reward schemes to those found in professional sports competitions, scholars have named them tournaments. Tournament theory aims at explaining promotions and raises associated with them. As a considerable share of pay increases occurs through job (title) changes, the theory complements other explanations of individual earnings differentials. Tournament models also contribute to our understanding of firms' wage structures and differences therein.

The basic model

The basic tournament model developed in Lazear and Rosen (1981) has risk-neutral agents, a firm with two identical contestants (employees), operating in a competitive industry. The employee's utility is a function of her net income, that is, the difference between income from work and the cost of effort.
Output is the sum of the two employees' effort and two stochastic disturbances: a common and an individual-specific component. The firm does not directly observe the employees' efforts. The payment scheme is fixed in advance and has a winner's and a loser's prize to the better and poorer performer of the contestants, respectively. The prizes are independent of levels as well as of differences in employees' performance. The worker's problem is to choose her optimal level of effort taking into account the firm's compensation scheme. In other words she maximises her expected utility, which depends on the probability of winning the two prizes and her cost of effort.

As the contestants are assumed to be identical ex ante, the probability of winning is 0.5 and they choose the same equilibrium level of effort, which depends on two factors. The first is the difference between the winner's and the loser's prize. A larger prize spread induces employees to compete harder for earning the promotion and hence to exert more effort. Second, the more important individual-specific random components in output are, the less effort the contestants will provide.

The firm also needs to set wage levels high enough to attract workers to participate in the tournament. The solution is that the firm chooses a wage spread that induces employees to put forth effort up to the point where the marginal cost of effort equals the marginal benefit of it to the firm. Thus, the tournament compensation scheme is efficient and brings about first-best level of effort. Luck also affects the firm's decision. To maintain a given level of effort, an increase in the random component in output has to be offset by an increase in the wage spread.

Extensions and predictions

The Lazear-Rosen article contained analyses where some of the assumptions of the basic tournament model were relaxed, and this line of research continued in a series of articles (Green and Stokey, 1983; Nalebuff and Stiglitz, 1983; O'Keefe, Viscusi and Zeckhauser, 1984) which offered several extensions; see also the survey by McLaughlin (1988). These papers examined a number of additional variations on tournaments such as winning by a gap, rewards depending on distance from the loser's performance and multiple prizes. Empirically, these are of rather limited interest and have not been followed up in the recent literature.

Assumptions that turned out to affect equilibrium outcomes qualitatively were risk-neutrality, only two contestants, homogeneous agents and the one-stage tournament. The key result from relaxing the assumption of risk-neutrality is that the optimal level of effort is lower than the first-best level as risk-averse contestants want income insurance. Thus, risk aversion narrows the wage spread which yields lower effort. Does the size of the tournament matter? Intuitively, the larger the number of contestants, the lower the expected probability of winning, so in order to induce same level of effort, the firm has to widen the wage spread. Consequently, the spread increases in tournament size. With risk-averse agents this result is fragile (McLaughlin, 1988), but for relevant tournament ranges the spread is plausibly increasing.

Allowance for heterogeneous contestants has been modelled by assuming that ability differentials equal differences in marginal cost of effort. Two information structures for heterogeneity in ability been studied: (i) agents know their own but not their contestant's ability, and (ii) full knowledge. In both cases mixing high and low ability agents gives rise to inefficiency; in (i) because of no sorting and in (ii) because the tournament is not attractive to low performers. In the asymmetric information case, more
knowledge (such as entry credentials) is needed. Alternatively a larger pay spread can induce self-sorting. In the full knowledge case, segregating low and high performers also leads to inefficiency (in both leagues). Handicaps may overcome some of the problems: typically at the expense of efficiency, however.

In many firms there are usually several rounds of promotion competitions over workers' careers. Rosen (1986) analyses the multistage tournament, more precisely a sequential, elimination tournament like in professional tennis. In this setting promoted employees earn not only a raise but also the expected value of continued competition. With a constant spread, effort would decline through rounds (as the tournament shrinks in size) and would be lowest at the top. Rosen shows that in order to keep effort unchanged, the wage spread has to grow linearly with rank, and will make a jump at the top to compensate for the absence of further competition. An implication of the analysis is that the firm uses a convex pay-rank schedule as a means for providing incentives to all its employees.

A key prediction of tournament theory is that increased wage spread yields higher effort and output. However, the participation constraint puts an upper bound on the optimal wage spread. When cooperation among employees is important, or when jobs are strongly interdependent, relative performance games may give rise to too strong incentives for uncooperative behaviour. Extending the basic model to allow for employees to behave strategically against their rivals shows that sabotaging behaviour lowers equilibrium effort (Lazear, 1989). Thus, firms might also compress their internal wage structures on efficiency grounds. Another form of strategic employee behaviour that can lower effort is collusion among employees. This (and sabotaging) is more likely when there are few contestants. Mitigating harmful effects by increasing the tournament size is costly. As the contestant pool grows, it becomes more heterogeneous giving rise to increased inefficiency. Tournament models also predict that firms will favour insiders over outsiders (Chan, 1996).

Several papers compare (the efficiency of) tournaments with other individual incentive pay schemes, in particular piece rates. The question that has not been addressed much is why do (especially larger) firms use tournament structures? The principal advantage of tournaments is that contestants are insulated from common risks. Thus, tournaments are predicted to be more common in risky environments. The other main advantage is that it is less costly to measure relative than absolute performance. A third, but less well understood, possibility is that promotions also can serve other functions, notably sorting of employees.

**Empirical tests**

Tournament theory yields quite a number of testable predictions. These have been tested on data from sports, laboratory experiments and businesses. The studies examine whether observed empirical patterns are consistent with tournament models, but none has to my knowledge tested tournaments against the other theoretical explanation for promotions: promotions as signals (Waldman, 1984).

Following Ehrenberg and Bognanno's (1990) study of the effects of prize structures on professional golfers’ performance, a large empirical sports literature has built up, providing in the main evidence in support of several of tournament theory's predictions. Sports data are rich and of high quality, but to what extent the results are generalizable to firms remains an open question.

Almost from the beginning tournaments have been studied by means of lab experiments that allow
researchers to control for a host of parameters while examining a number of treatments, and also to compare with other incentive schemes. Beginning with Bull et al. (1987), several experimental studies have confirmed the predictions about the impact of wage spread on performance but have found a high variance in subjects' effort. In general many of the other predictions like those concerning tournament size, number of rounds and degree of uncertainty have been supported by the laboratory evidence. Again, generalizability to businesses is an issue. Some key concepts like cost of effort or attitudes to risk are very difficult to observe outside the lab. However, as has been shown in some recent experiments, endogenous sorting can have profound effects on results. Generalizing from the lab to the upper echelons of organizations can in particular be associated with external validity problems.

Evidence outside sports and the lab is rather scarce. The evidence that exists is often based on data from a single firm, specific industries or firms' managerial personnel. Many studies have tested the prediction that a larger wage spread increases employees' effort and hence firm performance. The hypothesis finds support in many, but not all, studies. Another implication that has been tested is the convexity of firms' wage structures. These results are, however, consistent not only with tournament theory but also with other theories. A problem in testing tournaments is that there are potential alternative explanations for individual predictions. Thus, a positive relation between pay spread and firm performance, and convex within-firm wage structures, are also consistent with convex returns to ability due to magnification effects (in hierarchies bosses' decisions matter more) and with the promotions-as-signals hypothesis.

More direct tests concern the hypotheses of a positive relation between number of contestants and the magnitude of the raise from promotion, and that tournament organizations favour insiders. One way to arrive at more convincing evidence is to test several hypotheses on the same data set. Only a few studies (e.g. Eriksson, 1999; Knoeber and Thurman, 1994) have done this. A number of single-firm studies have documented more facts about wage and promotion dynamics within firms. Although one should be cautious in treating them as stylized facts, a fruitful avenue for further research on tournaments is to extend tournament models to account for patterns observed in these studies.

Townshend, Hugh (1890–1974)

Victoria Chick

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

liquidity preference; loanable funds; Townshend, H.; Walras's Law

Article

Townshend is an anomaly amongst economists, for he owes his reputation almost entirely to one brilliant article. He took a First in mathematics at Cambridge in 1912 and stayed on to prepare for the civil service examinations under Keynes's supervision. He served with the Post Office, where his duties included economic forecasting.

His correspondence with Keynes over the just-published General Theory (Keynes, 1979) reveals both the extent of Townshend's intellectual grasp of that complex and difficult book and something, whether derived from his studies with Keynes or innate in his temperament, which allowed him to accept aspects of The General Theory which others resisted. These qualities bore fruit in the famous 12-page article, published as a note in the Economic Journal (1937a). This note takes issue with Hicks's attempt, in his review of the General Theory (Hicks, 1936; Keynes, 1936), to transform the theory of liquidity preference into a mirror image of loanable funds theory by Walras's Law. Townshend saw that this was an attempt to retain the link between prices and the flow concepts of cost and demand. In contrast, he argued, it was in the nature of Keynes's liquidity preference theory that expectations of the future could change the value of assets overnight and be reflected in market prices of those assets even in the absence of actual trading. Thus current prices could be determined by subjective as well as objective factors and future prices were indeterminate.

Townshend's achievement was to 'follow liquidity preference theory where it led: to the destruction of determinate price' (Shackle, 1967). Keynes had left this implicit. Townshend's restatement required the courage to go against established modes of thought: whether by temperament or because they are imbued with outdated conceptions of science, most economists are determinists. Townshend's stock can only rise as the methodological change that has occurred in science becomes known across the divide between science and the arts.

Townshend also wrote four book reviews for the Economic Journal (1937b; 1938; 1939; 1940).
show a breadth of conception and keenness of intellect from which one wishes economics had benefited more.

Toynbee, Arnold (1852–1883)

A. Kadish

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

economic history; Industrial Revolution; liberalism; New Liberalism; Toynbee, A.

Article

Arnold Toynbee, best known for his lectures on the Industrial Revolution (published posthumously in May 1884), was during the late 1870s and early 1880s a major influence on the shape and direction of the interest at Oxford in socio-economic questions and their history. Born in London on 23 August 1852, Arnold Toynbee was the fourth child and second son of Dr Joseph Toynbee, FRS, a philanthropist and a successful aural surgeon. Initial plans for his education at Rugby were first delayed by an accident at the age of 13 or 14 which resulted in severe concussion and, in the long run, in recurring migraines, impeding prolonged mental exertion. These plans were finally shelved for financial reasons following Joseph Toynbee's death in a laboratory accident. After two unprofitable years in a military preparatory school, and some classes at King's College London, Toynbee's education was reduced to long periods of solitary reading. He developed an independent if unsystematic bent, coupled with overconfidence in his capability to master on his own any subject which might catch his attention.

Having come into a modest inheritance from his father's estate at the age of 21, Toynbee entered Pembroke College, Oxford, in January 1873 with the intention of reading for Greats. He shortly afterwards migrated to Balliol, which he found socially and intellectually more attractive. For health reasons he eventually settled for a Pass degree, obtained in 1878. However, he had impressed the college sufficiently to be offered a tutorship in charge of the candidates for the Indian civil service. In 1881 he was appointed Senior Bursar, and at the time of his death was about to be elected Fellow. Toynbee had meanwhile become involved in a number of public causes, all of which may be seen as related to efforts to revive liberalism as a radical-reformist movement. These included Church reform aimed at the democratization of Church of England government on the parish level, adult education through the cooperative movement, rural reform, Irish land reform, and municipal politics. In 1883 he stood, unsuccessfully, as a liberal candidate for one of the north ward seats on the Oxford City Council.

(represented by T.H. Green until his death in 1882) and Toynbee may well have contemplated the possibility of a political career. His academic interests reflect his search for a scientifically reasoned programme for comprehensive reform, while his inquiries were greatly influenced by a fear of the consequences of rising working-class radicalism.

The Industrial Revolution lectures, delivered in 1881–2, offered a liberal interpretation of industrialization and its political, social and economic consequences as an alternative to both socialist and laissez-faire views of industrial society. Despite their ideological bias and fragmentary form they constituted an important departure in English economic history. They demonstrated the usefulness of an historical approach to the study of industrial society, thereby suggesting an alternative to economic theory, which at the time was increasingly regarded as either morally or ideologically unacceptable or as inapplicable to current conditions. Hence Toynbee directly contributed to the Oxford inclination towards an empirical and historical approach to the study of socio-economic questions. In addition, Toynbee outlined the possibility of an historical and, thereby, a relativist consideration of economic theories, seen as reflecting historical circumstances in which they were formed and, while of a limited general application, of considerable interest to the historian. Finally, and perhaps most importantly, the Industrial Revolution lectures suggested an autonomous approach to the study of economic history, based on its own type of primary sources, in which economic circumstances were not placed in causal subservience to political developments (as in the work of W. Cunningham). Toynbee's approach was ideologically and philosophically acceptable to the next generation of economic historians. It was not materialistic yet it tended to regard economic change in terms of general impersonal trends rather than attributing it to the conscious action of narrow interest groups (as in the work of J.E.T. Rogers).

Following an attempt to convince a hostile London audience of the futility of land nationalization and the desirability and attainability of liberal alternatives, Toynbee suffered a nervous breakdown. While convalescing he contracted meningitis and died at the age of 30, widely hailed as a martyr to the cause of social harmony and to the type of reformism which became known as New Liberalism. His reputation and martyrdom contributed to the popularity of the university settlements, beginning with Toynbee Hall, and a general interest at Oxford and Cambridge in social and economic reform. His importance as an economic historian, however, emerged only with the development of the study some years after his death.

Tozer, John Edward (1806–1877)

G. Campanelli
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
fixed capital; mathematics and economics; Tozer, J. E.; Whewell, W.

Article

Tozer was born at Woolwich in 1806 and died in London in 1877. He was privately educated and at the age of 26 was admitted as a ‘Pensioner’ of Caius College, Cambridge. He immediately showed his ability in mathematics by carrying off the first prize in 1833 and 1834. In the four years after his graduation in 1836, Tozer wrote two essays on mathematical economics, the first on ‘Machinery’ (1838), and the second on ‘Landlords’ (1840). However, soon after the publication of these two papers he abandoned economics and went into law, in which he achieved distinction. Later he went into university administration.

Tozer's two papers on economics represent a systematic application of mathematical reasoning to political economy. In that period Whewell, at Trinity College, Cambridge, was trying to introduce mathematical analysis into economics and Tozer adopted his method. Like Whewell, Tozer believed that mathematics, because it turned economics into a ‘science’ characterized by a series of propositions leading to ‘axiomatic truths’, was not only appropriate but necessary to the subject (Tozer, 1838, pp. 1–2).

Of the two essays on economics, that on ‘Machinery’ is by far the more interesting. In this paper, Tozer wants to provide a mathematical basis for the idea that the employment of machinery always increases the wealth of community. His final conclusion is that the capitalist is ‘not only … unable to secure his own advantage at the expense of any other class, he cannot even prevent a general participation in the benefit’ (Tozer, 1838, p. 10).

However, the most original feature of this paper is Tozer's mathematical treatment of the problem of machinery. In particular the calculation of the annuity and the algebraic formulation of the construction period of machinery can undoubtedly be regarded as a sophisticated contribution to the fixed-capital debate of that time.

tradable and non-tradable commodities

A.D. Woodland
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The distinction between internationally tradable and non-tradable commodities lies at the heart of the reason for the development of the theory of international trade as an area of economics distinct from the general theory of value. The existence of non-tradable commodities as well as tradable commodities implies that some markets are domestic while others are international. Connections between the prices of these two sets of commodities have been the subject of the famous factor-price equalization and Stolper–Samuelson theorems. Non-tradable goods play a prominent role in the analysis of many problems, such as tariff reform, exchange rates and international transfers.

Article

The distinction between internationally tradable and non-tradable commodities lies at the heart of the reason for the development of the theory of international trade as an area of economics distinct from the general theory of value. If the theory of value approach were adopted, nations would simply be a collection of production and consumption units, each with its own monetary and political system. The international trade literature has, however, imposed the assumption that certain classes of commodities are non-tradable. Accordingly, there exist purely domestic markets as well as international markets, and this is arguably the most important distinguishing feature of the international trade literature. The early classical economists made a clear distinction between products which were assumed to be
Tradable and non-tradable commodities: The New Palgrave Dictionary of Economics

Internationally tradable, and factors of production such as land, labour and capital, which were assumed to be non-tradable internationally but perfectly mobile within each nation. This distinction, which is central to the writings of such eminent classical theorists as Ricardo, Torrens, J.S. Mill and Bastable, was carried on by early 20th-century writers such as Taussig (1927), Yntema (1932), Ohlin (1933), Haberler (1936) and Mosak (1944). The modern literature, initiated perhaps by Samuelson (1953), has continued with the same basic model structure.

The traditional international trade model, therefore, contains non-tradable commodities. However, they are in the form of non-producible factors of production rather than products, and this provides important structure to the traditional model. Moreover, and perhaps more importantly, further structure is typically imposed by assuming that the non-tradable factors are in fixed supply. As a result, consumer preferences do not play a role in the market for non-tradable commodities. It therefore follows that the traditional model of trade encompasses non-tradable commodities in a very special way.

A more general, and more useful, way to deal with non-tradable commodities is to define a set of commodities that are non-tradable, and allow this set to include products as well as factors. While the existence and importance of non-tradable commodities in the form of products was recognized as early as, for example, Ohlin (1933, ch. 8), Haberler (1936, pp. 34–5) and Taussig (1927, ch. 5), it was not until much later that non-tradable products were explicitly incorporated into international trade models. For earlier surveys of this literature, see McDougall (1970) and Woodland (1982, ch. 8).

There is the fundamental question of why certain commodities are not traded internationally. Some may be non-traded because of their intrinsic nature; they are simply not transportable. Others may be transportable and hence tradable but are not traded because it is unprofitable to do so due to the costs of transportation or other expenses such as tariffs. Finally, products may be tradable, but trade in them may be illegal – an extreme form of trade quota.

While it has long been recognized that there is a difference between a commodity being tradable and being traded, and that the difference arises as a result of the profitability of trade, few models actually deal with non-traded commodities in this way. Rather, it is typically assumed that transport costs are zero for some commodities (tradable) and infinite, or, at least, sufficiently large for others (non-tradable) so as to preclude their trade. Exceptions do exist. Hadley and Kemp (1966) and Woodland (1968) explicitly model transportation and thus endogenize the division into traded and non-traded commodities. Xu (2003), using a continuum of goods with transport costs and tariffs, has the boundary between traded and non-traded goods endogenous. Melitz (2003) models a continuum of firms with different levels of productivity producing a continuum of varieties in which only the more productive firms export, the remainder producing varieties only for the domestic market.

**Relationships between domestic and international markets**

The existence of non-tradable commodities as well as tradable commodities implies that some markets are domestic while others are international. However, this does not mean that the domestic markets operate in isolation from international markets. On the contrary, the prices of domestic (non-tradable) commodities will be influenced by activities in the international markets. Though of less apparent interest, the reverse is also true: the prices of internationally traded commodities are influenced by activities in domestic markets. The various national markets for non-tradable commodities are, of
course, connected only indirectly via the international markets for tradable commodities.

Let $p = (p_t, p_n)$ denote the partition of the price vector for a nation into tradable and non-tradable commodities, and let $\lambda(p) = (\lambda_t(p), \lambda_n(p))$ denote the vector of excess supply functions correspondingly partitioned. If the foreign nation's functions and variables are distinguished by an *, the perfectly competitive equilibrium conditions for internationally tradable commodities and the non-tradable commodities of the home and foreign nations may be written as

$$\lambda_t(p_t, p_n) + \lambda_t^*(p_t, p_n^*) = 0$$

$$\lambda_n(p_t, p_n) = 0$$

$$\lambda_n^*(p_t, p_n^*) = 0.$$  

Under reasonable regularity conditions the market equilibrium conditions for the domestic commodities in the home nation, (2), may be solved for $p_n$ as a function of $p_t$ as $p_n = \lambda_n(p_t)$. Similarly, (3) may be solved as $p_n^* = \lambda_n^*(p_t)$. Thus, the equilibrium conditions for domestic commodities provide the connection between the prices of tradable commodities and the prices of domestic or non-tradable commodities. An elegantly simple analysis of the connection between the markets for tradable and non-tradable commodities is provided by Jones (1974).

A significant amount of the international trade literature has been devoted to the relationship between prices of tradable and non-tradable commodities. Within the context of factors being the only non-tradable commodities, there are several famous propositions that emerge. The Stolper–Samuelson (1941) theorem indicates, within a two-product, two-factor model, that if the relative price of one product increases then one factor price will increase proportionately more and the other factor price will fall. The factor whose price increases, and whose real income therefore increases, is the one used relatively intensively by the product whose price increases. Jones (2006) provides a historical perspective on this
The factor-price equalization theorem provides conditions under which the factor-price vectors, here $p_n$ and $\bar{p}_n$, are the same in the two nations despite differences in factor endowments. The sufficient conditions are that each nation should have the same production technology and that their endowment vectors be sufficiently close so that each nation is diversified and produces the same set of traded goods (Samuelson, 1953; McKenzie, 1955; Dixit and Norman, 1980). Recent contributions include Blackorby, Schworm and Venables (1993) and Chakrabarti (2006), who provide necessary and sufficiency conditions.

The role of non-tradable commodities

The reason non-tradable commodities complicate the analysis of many problems in international trade theory is that, whenever there is a disturbance to equilibrium, there will be an effect on the markets for non-tradable goods. The price of non-tradable goods will have to adjust to restore equilibrium. This adjustment of prices will, in general, affect the variable of interest and may yield different qualitative results than are obtained from a model without non-tradable commodities (factors or products). Much of the literature is concerned with the question of how the introduction of non-tradable products affects results obtained from models with only tradable products. However, some recent literature has gone the other way, enquiring whether trade in one or more factors alters results obtained on the assumption that all factors are non-tradable.

As an example of the role that non-tradable products can play, consider an increase in the international price for a small open economy's import good. If there are just two traded products, a single consumer, and all non-tradable commodities are factors in fixed supply, then it is well known that the quantity of imports will fall. The introduction of a third product that is produced and consumed but not traded internationally can upset this result if there are sufficient complementarities in production or consumption. The rise in the price of the imported product causes imports to change directly, and indirectly via the consequent change in the price of the non-tradable product. At the initial price of the non-tradable good, the import price increase induces higher home production and lower demand since the income effect is unambiguously negative. This direct effect implies lower imports, just as when non-tradable commodities don't exist. However, if imports and the non-tradable good are net complements, an excess supply of the non-tradable good ensues from the import price increase (ruling out inferiority). Its price then falls to clear the domestic market. This fall in price causes a reduction in the net supplies of both the imported and the non-tradable goods since they are net complements. If this indirect reduction in the net supply of the importable good is sufficiently strong to outweigh the direct positive effect of the increase in its price, the quantity of imports will rise. Thus arises the paradoxical case where an increase in the price of the imported product causes the level of imports to rise. This case occurs because of the assumed net complementarity between the imported and non-tradable products. It is noteworthy that many of the difficulties that occur when non-tradable products are included in a model arise in the consumption sector. In the example of the previous paragraph, if there is a fixed demand for the non-tradable product the indirect income effect vanishes and so the quantity of imports falls in response to a rise in their price. Alternatively, one can ensure this result by assuming that the non-tradable and imported products are net substitutes.

For some problems the existence of non-tradable commodities has no substantial influence upon the
formal solution. The prices of non-tradable products can be eliminated from the equilibrium conditions by first solving for their prices in terms of the prices for tradable goods, and then substituting into the excess supply functions for tradable goods. This yields the excess supply functions expressed in terms of tradable goods’ prices, and the equilibrium conditions reduce to

\[ \ddot{X}(p_t) = X_t(p_t, P_n(p_t)) = 0. \]

These resulting ‘reduced form’ excess supply functions can then be used directly to analyse various problems. For example, the usual stability conditions for international equilibrium can be applied to the reduced form excess supply functions on the assumption that domestic markets clear instantly. The problem of the effect of a transfer of income upon the terms of trade can be similarly handled. For details on the reduced form approach to non-tradable goods see Dixit and Norman (1980, pp. 89–92) and Woodland (1982, pp. 172–3, 218–22). Those that prefer to deal with the structural form include Komiya (1967), McDougall (1970) and Jones (1974).

**Situations where the role of non-tradable commodities is prominent**

For other problems, or where interest centres on the variables in the structural model relating to non-traded goods, the existence of non-tradable commodities has to be explicitly taken into account. Some specific instances are as follows:

1. In the case of shadow pricing of commodities for the purpose of evaluating the welfare effects of a public project in the presence of tariffs, the existence of non-tradable commodities provides special complications. While tradable commodities should be evaluated using world prices, the appropriate shadow prices for non-tradable commodities depend in a complex way upon technology and taste conditions (Warr, 1982; Dinwiddy and Teal, 1987).

2. Several analyses of technological advances in the production of a traded product upon the output levels of other traded goods, and upon the real exchange rate, have focused attention upon the role played by non-tradable commodities. In general, the effect of the ‘boom’ upon the other tradable good’s production is ambiguous, stemming partly from the adjustments in the market for non-tradable commodities. For details, see Corden and Neary (1982) and references therein.

3. The effect of the introduction of non-tradable products upon the Stolper–Samuelson, Rybczynski and factor-price equalization theorems was thoroughly analysed by Ethier (1972). In the case of the Stolper–Samuelson theorem, a change in the relative price of the non-tradable products induces a change in the price of the non-tradable product. This has a further effect upon factor prices. The question of whether a particular factor gains in real income depends upon the directions of these price changes, and can be answered only from knowledge of the technology and preferences. In the case of the factor-price equalization theorem, Mainwaring (1978)
demonstrates that non-traded goods may result in the non-equalization of national interest rates, while Deardorff and Courant (1990) argue that non-traded goods reduce the likelihood of factor-price equalization by reducing the size of the diversification cone.

4. The ‘purchasing power parity’ theory of exchange rates states that the relative value of currencies equals the relative purchasing power of each currency in its domestic markets. Clearly, the existence of non-tradable commodities with different prices across countries will cause the purchasing power of each currency to be different independently of the value of the exchange rate.

5. The responses to currency devaluation are also potentially affected by the existence of non-tradable products. An example of such an analysis is Dornbusch (1973), who concludes that his basic results hold up when a non-tradable product is introduced into the model. Neary (1980) models sticky prices in domestic labour and product markets and shows that short-run policy (for example, devaluation) responses are affected. More generally, non-traded goods affect macroeconomic variables in dynamic models. They explain persistent deviations from purchasing power parity and interest rate differentials (Backus and Smith, 1993) and affect the responses to an oil price shock (Marion, 1984), while productivity shocks in traded and non-traded goods sectors have different effects (Murphy, 1986).

6. The welfare implications of tariff reform depend upon the existence of non-tradable products. Following early work by McDougall (1970) and Dornbusch (1974) on the role of non-traded goods for tariff reform, Hatta (1977) and Fukushima (1979) have shown that the policy of reduction of the highest rate of import duty to the next highest is welfare improving if non-tradable and tradable products are net substitutes. If they are sufficiently complementary, the policy may reduce welfare. Non-traded goods are incorporated, and play important roles, in the analyses by Diewert, Turunen-Red and Woodland (1989; 1991) of tariff reform and in the trade restrictiveness index of Anderson, Bannister and Neary (1995). Xu (2003) shows that increased wage inequality can arise from the shifting boundary between traded and non-traded goods as a result of a tariff reform.

7. The effect of a transfer of income from abroad upon the welfare of a small open economy is affected by adjustments in the non-traded goods markets and may lead to the transfer paradox whereby the recipient’s welfare declines, as shown by Yano and Nugent (1999). Schweinberger (2002) emphasizes the role of complementarities between non-traded and traded goods in this context.

9. Davis and Weinstein (2001) show that, while the Heckscher–Ohlin–Vanek model is empirically rejected, a model that accounts for non-traded goods is consistent with the data for trade by ten OECD countries.

Concluding comments

It is somewhat surprising that non-tradable products (as opposed to factors) have only relatively recently
attracted explicit attention in the literature, given that most economic activity is in the markets for domestic products. Perhaps more future studies will introduce non-tradable products automatically, except where a reduced form analysis is applicable, and give more attention to the endogeneity of the division of commodities into traded and non-traded groupings. Globalization, whereby the costs of undertaking international trade are being reduced by technological improvements in transport and communications and trade policy liberalization, will continue to change the boundary between traded and non-traded commodities. The trend towards more outsourcing of services and intermediate inputs from foreign countries provides a clear example.

Trade liberalization is one of the most common policy prescriptions offered to initiate the process of poverty eradication in poor countries. Since the 1980s, our understanding of the link between trade and poverty in developing countries has been increasingly informed by empirical evidence. One part of the literature considers dynamic effects of trade on poverty via growth, while other parts emphasize the more static relationship between trade and poverty through changes in relative prices of goods and wages of the less educated. Growth is potentially the most important channel through which trade might affect poverty. The usual argument goes as follows: trade promotes growth and growth leads to lower poverty. While many economists believe that these dynamic effects provide an important channel towards poverty reduction, the link between trade and poverty via growth has been empirically elusive. Many cross-country studies on trade and growth, perhaps best exemplified by Frankel and Romer (1999), find a positive association.
between trade and growth. But others, most notably Rodriguez and Rodrik (2001), have questioned the robustness of these findings and whether the positive association is indicative of good domestic policies and institutions in countries with economically sound trade policy. Growth could lower poverty by expanding employment and earnings opportunities of the poor, but growth could also bypass the poor (see Ravallion, 2001). Two influential empirical studies by Dollar and Kraay (2002; 2004) conclude that growth is good for the poor by showing that average incomes of the poor move in tandem with average national incomes, and that trade via growth is good for the poor by showing that countries with bigger tariff cuts on average observed greater declines in poverty. Yet these findings remain a topic of heated academic debate, outlined in Deaton (2005) and Ravallion (2001).

Much of the academic debate on trade and poverty has focused on the static relationship between trade and poverty through changes in relative prices and wages of less educated workers. The stylized version of the Hecksher–Ohlin model predicts that trade should benefit the poor in a less developed country that is relatively well endowed with less educated labour and has a comparative advantage in unskilled labour-intensive goods. According to the Stolper–Samuelson theorem, trade liberalization will increase the return to the factor of production that is relatively abundant in a country and decrease the return to the scarce factor. Consequently, trade liberalization should reduce inequality between educated and less educated workers and lift the poor out of poverty in developing countries. In an influential project on trade and employment in developing countries, Krueger (1983) used this insight to argue in favour of outward-oriented trade regimes over import-substitution strategies adopted by many poor countries at that time.

Many developing countries liberalized trade during the 1980s and 1990s. As detailed micro-surveys of workers, households, and firms became more readily available, the researchers began to empirically examine the consequences of these reforms. Motivated by the academic debate on whether trade with poor countries in part contributed towards growing wage inequality in the OECD countries during the 1980s, these studies initially focused on the consequences of trade for wage inequality between more and less educated workers rather than for poverty. As reviewed in Wood (1999) and Goldberg and Pavcnik (2007), trade reforms were associated with increases (rather than the expected decreases) in inequality. Studies reviewed in Goldberg and Pavcnik (2007) concluded that the increases in the relative earnings of educated workers in poor countries could have been in part caused by an increase in the relative demand for educated workers in the aftermath of trade reforms due to trade-induced skill-biased technological change, outsourcing, or the higher skill intensity of exporting firms relative to non-exporters. But the studies remained silent on how trade reforms affected those at the bottom of the income distribution through economy-wide changes in the absolute demand for less skilled workers and through other channels ranging from consumption, industry wages, and unemployment to compliance with labour market standards. Only recently have studies focused on these issues.

Porto (2006) embeds heterogeneous households in a general equilibrium model of trade, where trade-induced relative price changes influence household welfare through changes in labour income (via the usual Hecksher–Ohlin mechanisms) and consumption. He explicitly accounts for the fact that households at the bottom of the welfare distribution are relatively less endowed with educated labour and spend a higher share of their household budget on basic items such as food than richer households. The model, combined with the estimates of key parameters from micro surveys, is used to simulate the effects of Mercosur-induced changes in prices on welfare and poverty in Argentina. Although poor
Argentine households were worse off after Mercosur because they tended to consume a relatively high share of the now more expensive unskilled-labour-intensive goods, these negative consumption effects were substantially smaller than the trade-induced increases in labour income of less educated workers. A series of papers in the Globalization and Poverty project organized by Harrison (2007) consider the link between trade and poverty in a setting where labour is not perfectly mobile across industries and/or regions within a country. These studies examine whether individuals living in areas or industries that were more exposed to trade experienced smaller or bigger changes in poverty than less exposed areas or industries. The Ricardo–Viner model with industry-specific labour would predict that industry tariff cuts are associated with declines in relative industry wages. Since tariff declines in many developing countries were concentrated in sectors with lower wages and higher shares of unskilled workers before the reforms, this channel could in the short run increase poverty in areas with a higher pre-reform concentration of protected industries relative to the national trend. A study by Topalova (2007) shows that individuals living in rural Indian districts, where pre-reform employment was heavily concentrated in industries that experienced larger declines in tariffs, suffered increases in poverty relative to the national trade of declining poverty during the 1990s. Topalova conjectures that these individuals fare relatively worse because immobility, in part stemming from inflexible labour regulations, precludes them from reallocating from sectors that have been hit hardest by declines in tariffs toward sectors or areas that benefit from export expansion. A related study by Hanson (2007) finds that the poor living in Mexican states with higher concentration of export-oriented industries and inflows of foreign direct investment (FDI) fared better during the 1990s than the poor in areas with lower export and FDI exposure.

Overall, the studies of trade and poverty based on micro evidence suggest that there is substantial heterogeneity in how trade affects the poor within developing countries. Future work on trade and poverty needs to further examine barriers that inhibit the less educated from moving away from industries, areas, or firms that have been hit hardest by tariffs cuts to industries and firms benefiting from new exporting opportunities.

An important component of the policy debate on the effect of trade on the world's poor is the link between trade and child labour. Many are concerned that, because less developed countries are assumed to specialize in exports of low-skill products, high-income countries foster child labour in low-income countries by raising the demand for the products intensive in unskilled labour. In fact, as discussed in Edmonds and Pavcnik (2005a), the link between trade and child labour is far more complicated and depends on how trade affects family incomes and poverty, the availability of substitutes or complements for the child's work, the returns to education, and consumption prices in addition to how trade affects the demand for child labour. Empirically, the association between trade and living standards seems to be the dominant factor in how trade affects child labour. Cross-country evidence in Edmonds and Pavcnik (2006) provides no support for the claim that trade perpetuates high levels of child labour in poor countries via the demand channel. Similarly, Edmonds and Pavcnik (2005b) show that child labour declined in Vietnam following the rice market liberalization that relaxed rice export quota and improved the standard of living of many net-rice producing households, even though the employment opportunities in the rice sector increased. There are many reasons for a connection between child labour and family incomes or poverty. Ranjan (2001) in particular emphasizes the relaxation of credit constraints as important for understanding why growing trade might be associated with declining child
labour despite rising demand for unskilled labour. In this vein, Edmonds, Pavcnik and Topalova (2007) argue that, in the Indian context, the child's economic contribution to the household through the avoidance of schooling costs is important in understanding the interconnections among trade policy changes, child labour and schooling.

Trade costs refer to the additional costs paid potentially by the final consumer of a good or service beyond the price at which a producer sells a good. In international trade, such costs may include the transport cost from origin to destination, taxes (or tariffs) imposed by importing nations’ governments, the costs of infrastructure to facilitate trade, the costs of communications, and foreign exchange costs.

Article
‘Trade costs’ refer to the costs above and beyond the ‘mill price’ that the final consumer of a good (or service) pays. If a product is sold by producer \( i \) to consumer \( j \) at (mill) price \( p_i \) (in dollars), the consumer pays \( p_i + T_{ij} \), where \( T_{ij} \) denotes the ‘trade costs’ (also in dollars). Such costs may cover the opportunity costs of resources, but some trade costs are just rent seeking barriers. International trade provides a fertile ground for studying the various types and economic effects of trade costs. International trade flows travel across large distances and empirical estimates of the costs of transporting goods between two economic centres are available. However, such flows also face less obvious trade costs. A broad interpretation of trade costs includes – beyond transport costs – information-gathering costs for a consumer to locate a foreign producer, financial and legal costs of negotiating contracts, policy-related barriers, and costs of final distribution in the importing country. As discussed in Anderson and van Wincoop (2004), the total trade costs associated with exporting a good from producer \( i \) to consumer \( j \) may be an average ad valorem add on of 170 per cent to the (mill) price of a good. In this article, we discuss some of the different types of international trade costs (subsets of which form national and local...
Trade costs: The New Palgrave Dictionary of Economics

... (trade costs), and how such costs can influence the volume of trade between two nations and the relative prices of nations’ goods.

Except for economic size, trade costs are probably the most important factor determining the volume of trade between a pair of countries (see Anderson, 1979; Bergstrand, 1985; and Anderson and van Wincoop, 2003). Trade costs play a critical role in understanding outsourcing, the factor content of trade, the field of economic geography, foreign direct investment and foreign affiliate sales of multinational enterprises, and the proliferation of regional trade agreements in the post-war period. Obstfeld and Rogoff (2000) argue that trade costs in goods markets provide the critical common element that also explains at least six major puzzles in international macroeconomics.

The trade cost that comes immediately to mind is the cost of transporting a good from producer i to consumer j. EXW (‘ex works’) refers to the price of a good at the point of origin; mill price is a synonym for the ex works price (‘mill’ refers to where the good was produced). FOB (‘free on board’) refers to the price of a good delivered to and put ‘on board’ an overseas vessel. CIF (‘cost, insurance, freight’) refers to the price of a good to a named overseas port, including insurance costs. Empirical researchers have used both FOB export data and CIF import data but prefer the latter because import data measured at customs points is more accurate.

A common measure of international transport costs is consequently the difference between the CIF and FOB values of a trade flow. The International Monetary Fund (IMF) provides data on average ‘CIF/FOB factors’ [100 × (CIF value–FOB value)/FOB value] for countries. Baier and Bergstrand (2001) report that average CIF/FOB factors for 16 Organisation for Economic Co-operation and Development (OECD) countries in 1958 and 1988 were 8.2 per cent and 4.3 per cent, respectively. David Hummels (2001) finds that freight rates vary dramatically across countries with average transport costs ranging from 3.8 per cent of EXW price $p_i$ for the United States to 13.3 per cent for land-locked Paraguay in 1994, varying even more across commodities within countries. Hummels (1999) finds evidence that inflation-adjusted tramp shipping rates have declined between 40 and 70 per cent from 1950 to 1995, but also finds evidence suggesting ocean shipping rates have not declined. It is common to express transport costs on an ad valorem (or rate) basis. Hence, the price faced by consumer j for producer i’s product, $p_{ij}$, can be expressed as $p_{ij} = p_i (1 + tc_{ij})$ where $tc_{ij}$ is the (CIF – FOB)/FOB factor (for example, 0.04).

Another important trade cost is that associated with policy-related barriers imposed by national (or perhaps sub-national) governments. The trade cost most often envisioned here is a ‘tariff’, a tax imposed at customs points on imported goods. Specific tariffs are expressed in an amount of the home currency per unit imported good; $T_{ij}$ used earlier denoted a specific trade cost. Ad valorem tariffs are expressed as a fraction of the value of the good; hence, an ad valorem tariff of $ta_{ij}$ would cause the imported price of producer i’s product for consumer j to be $p_{ij} = p_i (1 + ta_{ij})$ when the tariff is imposed on the FOB value and $p_{ij} = p_i (1 + tc_{ij})(1 + ta_{ij})$ when the tariff is imposed on the CIF value. Other entries in this dictionary address tariffs in more detail.

Transport costs and tariff barriers are arguably the easiest trade costs to measure directly. Because of difficulty in measuring other types of trade costs directly, empirical economists have turned to indirect methods to estimate trade costs. Indirect methods fall into two basic categories: inferring trade costs from differences in trade volumes between pairs of countries and inferring trade costs from differences in prices between pairs of countries.
International trade economists have long used and increasingly applied the ‘gravity equation’ to explain empirically international trade flows (see Feenstra, 2004, ch. 5; gravity equation). The gravity equation typically explains bilateral trade flows between country pairs using cross-sectional or panel data on pairs’ gross domestic products (GDPs), bilateral distances between country pairs’ economic centres, and several other variables representing bilateral trade costs to infer the effects of such costs on members’ trade. Distance has long been a central variable explaining trade volumes, and typically has been interpreted as a measure of transport costs. However, the effect of distance probably measures more than transport costs, such as information costs. For instance, empirical work explaining bilateral foreign direct investment (FDI) flows also finds that distance has an economically significant effect on deterring such flows, even though theory suggests that measures of trade costs and FDI costs should have opposite effects on each others’ flows (see Markusen, 2002). Portes and Rey (2005) find empirically that distance also has a significant negative effect on portfolio flows, for which the transaction cost should be minimal. Other sources of trade costs (which consume resources) include infrastructure, communication and foreign exchange costs. Limao and Venables (2001) find that infrastructure has a significant effect on trade volumes, with a decline in the level of infrastructure investment from the median level to the 75th percentile equivalent to a 2,166-mile (3,466-km) increase in sea distance travelled. Tang (2006), using various measures of information technology, finds that communication costs have a significant effect on the volume of trade. Economists have long thought that exchange rate variability and its associated uncertainty should impose a significant trade cost and deterrent to trade. However, a survey of studies reveals that the trade-volume effects are probably small (see Cote, 1994).

With the use of the gravity equation in international trade, indirect estimates of the trade costs associated with national trade policies have proliferated. While a few empirical studies have looked at the effects of tariff rates explicitly on trade flows, the vast bulk have measured the presence or absence of (typically regional) economic integration agreements and currency unions on trade between country pairs. Many earlier studies using standard gravity equations found surprisingly small estimated effects on trade of arguably important trade agreements such as the Treaty of Rome (see Frankel, 1997). However, more recent studies incorporating modern theoretical foundations for the gravity equation and econometric techniques suggest that such small estimates are probably due to a bias introduced by self-selection of countries into such agreements (see Baier and Bergstrand, 2004; 2007). By contrast, work by Rose (2000) indicates that a currency union may have a very strong impact on trade between country pairs. Estimates of trade costs have also been inferred indirectly using discrepancies in prices between countries. Engel and Rogers (1996) demonstrated that price variability of similar goods between US and Canadian cities is much greater than that between equidistant cities in the same country. Engel and Rogers (2001) showed that a ‘real barriers’ effect owing to incomplete market integration is present, but also that some dispersion could be explained by exchange rate variability and sticky price behaviour. Parsley and Wei (2001) showed that distance, unit-shipping costs, and exchange rate variability all contribute to dispersion of relative tradable goods prices across 96 cities in Japan and the United States. However, Crucini, Telmer and Zachariadis (2005) used price data from European cities to show that goods markets – at least, those in Europe – may be much more integrated than earlier work showed.

The dynamics of capitalist economies are characterized by two facts: sustained growth of production and employment and wide oscillations of these magnitudes and the level of prices as well. This oscillatory behaviour of economic activity as a whole is indeed the subject of trade cycle theory. The use of the word ‘cycle’, besides pointing to alternation of ups and downs, also suggests the idea that oscillations are somewhat regular.

Concerning the occurrence and regularity of the cycle there exist two entirely different positions. According to one line of thought, it is possible to explain it exogenously. The economic system by itself would not display any tendency to fluctuate regularly but for the influence of external cyclical impulses such as the alternation of seasons. A more sophisticated version of this principle recognizes that external impulses do not even have to be cyclical in order to induce regular fluctuations of the system. This approach, which is very old and recurrent among economists, reflects an essentially pessimistic view about their ability to explain a prominent feature of modern economies.

The opposite opinion holds that the generation and the persistence of cycles are totally or mainly endogenous to the economic system. This is an idea rather difficult to argue cogently. One can fairly easily represent a dynamic system characterized by a succession of expansions and contractions. It is a much harder task to define rigorously a system whose oscillations persist indefinitely, independent of
external impulses, with amplitude and frequency determined solely by the structural parameters. Only recently has the economics profession acquired the necessary mathematical tools to solve this problem satisfactorily.

A possible third alternative – which possesses some elements of the other two – is to postulate that oscillations are normally damped and would therefore eventually die out, were they not continually revived by erratic shocks that resupply the system with the energy needed to sustain the cyclical motion. We shall return to this idea later since its discussion merges into that of some recent developments in economic dynamics.

The very existence of specific (and measurable) cycles of different lengths has been the object of heated discussions among economists. Joseph Schumpeter, the author of a monumental historical investigation on business cycles (1939), detected three main types of cycles. The shortest ones, named after the economist Joseph Kitchin, would last approximately three years. The intermediate ones (the Juglar cycles) would comprise three Kitchins and last approximately ten years. Finally, the ‘long waves’ (Kondratieff) would reflect major technological innovations and extend over 50–60 years. Subsequent empirical research failed to find conclusive evidence of the actual existence of such regularities in the ups and downs of capitalist economies. And yet the recession of the 1970s has prompted a renewed interest in Schumpeter's work and one hears economists speak once again of the Kondratieff cycle.

Two considerations are here in point. First of all, the (courageous) formulations of hypotheses concerning the exact shape and duration of cycles and the subsequent discussions thereof provided fresh evidence as well as new and better tools of analysis, which greatly improved our knowledge of the subject, even when those hypotheses were eventually discarded. Secondly, since the 1930s economic agents’ improved understanding of fluctuations, and the vastly increased public intervention to counteract their most negative consequences, have certainly modified both the economic mechanisms that produce those fluctuations and people's expectations about them. On this point too we shall have to return.

The discussion of long waves naturally leads one to consider trend in relation to cycle. Indeed the rising phase of a very long cycle may not be distinguishable over a certain period of time from sustained growth. The presence of a trend itself raises a number of problems. First of all, we would like to understand the economic forces that determine it. In most analyses of growth and cycle one assumes that trend is determined mainly by such long-run factors as population growth and technical progress. The latter, however, are usually represented by given functions of time, which is tantamount to admitting that we do not know much about them.

On the other hand, the causal relation may well run in the opposite direction: that is to say, in an economy characterized by sustained expansion, both population growth and productivity might be stimulated by general prosperity, the latter being determined by other factors. In most economic systems there obviously exist ‘hereditary factors’ owing to which the ‘long run’ is resolved into a chain of ‘short run’ events. For instance, technical progress – at least that of the ‘learning by doing’ type – depends on the cumulative levels of production (or investment) over a more or less distant past. Moreover, both productivity and desired consumption display important ‘ratchet effects’, that is, they move more easily upwards than downwards. All these considerations suggest a dependence of trend on the cyclical path actually followed by the economy. However, a rigorous analysis of the process through which this influence is exerted is still lacking.
There also exists an inverse causal relation running from trend to cycle; that is, the characteristics of a cycle, in particular its amplitude and duration, are markedly different according whether the economy is in a phase of stagnation or prosperity. Unfortunately, the question of the relation between cycle and trend remains to this day one of the many obscure points of economic theory. Most models tend to overcome this difficulty by assuming that short run (cycle) and long run (trend) may be dealt with separately and then re-combined in a ‘cyclical growth model’. This procedure, however, requires rather formidable (and usually hidden) hypotheses; in particular, the relevant dynamic equations of the model must be linear, so that one may apply the principle of superposition of solutions of a dynamic model. The different authors’ explanations of the trade cycle are better investigated in the wider context of their economic theories as a whole and nothing close to a comprehensive survey may be attempted here. We shall only try to put the contemporary discussions into a historical perspective, without which it would be difficult to understand what the various theories state and why.

Broadly speaking, we can identify three main phases in the development of cycle theory. The first phase – the classical one – comprises the works of economists who wrote in the 18th century and in the first half of the 19th century. These writers did not provide a true scientific explanation of the cycle, but addressed certain basic questions whose understanding would prove essential to subsequent developments. In particular, classical economists debated the question of the stability of economic systems with a view to establishing whether capitalist economies possess an inherent tendency to equilibrium, that is, whether they are able to generate and maintain prices and quantities consistent with one another as well as with the structural parameters of the system. This problem, formulated by Adam Smith in terms of the ‘invisible hand’, was discussed in the first half of the 19th century mainly in relation to the possibility (or probability) of general crises of overproduction. In this context, Say (1803), Ricardo (1817) and James Mill (1821) shared the opinion that production always creates its own demand and no general overproduction is therefore possible. Lauderdale (1804), Sismondi (1819) and especially Malthus (1820) dissented and pointed out that accumulation (saving) is not simply a redistribution of expenditure between consumption and investment goods. If incentive to invest is lacking or too weak, saving may well result in a general lack of expenditure and a consequent decline of production and employment.

The idea that capitalist economies have an intrinsic tendency to disequilibrium was also argued, in a very different context and with different overtones, by Karl Marx. Marx never produced a rigorous explanation of the cycle but his ideas provided inspiration to contemporary writers, in particular Kalecki and Goodwin. Marx, too, opposed the so-called Say's Law and pointed out that in a market economy, where purchases and sales are disjoint operations connected by the intermediation of money, discrepancies between demand and supply are always possible, not only in each individual sector but also in the economy as a whole. In Volume 1 of Das Kapital (1867), Marx came close to formulating a self-consistent model of the cycle. Accumulation of capital, Marx argues, by reducing the rate of unemployment (the ‘reserve industrial army’), pushes up wages (down profits), thus discouraging further investment. The ensuing recession brings about higher unemployment, leading to lower wages (higher profits) and therefore re-establishing the profitability of accumulation. This cyclical mechanism would be reformulated rigorously one century later by Richard Goodwin (1967) and others, to provide a ‘classical theory of the cycle’ based on the interaction of capital accumulation and distribution of
income. A second phase in the theory of the cycle, which we can locate between 1850 and 1930, may be termed ‘modern’ and among its forerunners we shall mention Juglar (1862), Jevons (1884) and Tugan-Baranowsky (1901). In this phase the cycle as such became an object of specific investigation. Economists then attempted to define hypotheses and construct theories to explain the ‘true and fundamental’ causes of economic fluctuations.

Broadly speaking, we can distinguish three main ‘explanations’ of the cycle, namely: (i) a monetary theory; (ii) an overinvestment theory, in its turn subdivided into a monetary and a real variation; (iii) an underconsumption theory. We shall briefly present the main ideas of the leading exponents of each group of theories. Separate consideration will be given to Keynes’s contribution, which marks a watershed between modern and contemporary cycle theories.

The monetary theory of the trade cycle has been most forcefully argued by Ralph Hawtrey (1919). According to this author, the rising phase of the cycle is caused by credit expansion, realized mainly through a reduction of the rate of interest. This induces inventory accumulation by dealers, whose increased demand in turn stimulates producers’ expenditure. The rise in demand for investment and consumption goods brings about a undesired reduction of the inventory–sales ratio to which dealers respond with further accumulation. A self-sustaining expansionary process ensues – possibly reinforced by secondary speculative waves – and will continue as long as monetary expansion goes on. However, Hawtrey argues, insofar as the monetary system is constrained by a link between global liquidity and a real asset whose quantity is limited, monetary expansion must come to an end. Monetary flows, moreover, tend to generate fluctuations of real variables, owing to the lagged response of the demand for money to changes in income. Thus, in the ascending phase of the cycle, demand for money does not grow pari passu with expenditure and consumers’ income. Consequently the banking system experiences net monetary inflows, which permit it to pursue an expansionary policy. However, as soon as demand for money catches up with income, banks’ liquidity deteriorates, forcing them sooner or later to increase the rate of interest and squeeze credit. This initiates a downwards cumulative process. In a recession the lagged response of the demand for money will again act as a brake, slowing down the decline of the real output and employment. Eventually excess liquidity will reappear, the rate of interest will be reduced and the cycle will start anew.

The overinvestment theory of the cycle in its monetary version is perhaps best represented by Hayek's so-called ‘concertina effect’, as described in his book *Prices and Production* (1931). Two ideas here play a crucial role. The first one is a typically neo-Austrian proposition stating that capital intensity (assumed to be unambiguously measurable) is an inverse function of the rate of interest. The second idea is based on the distinction between voluntary and forced saving. An increase in voluntary saving is accompanied by a reduction in the rate of interest and by an increase in capital intensity. While these adjustments take place, the system remains in equilibrium and no fluctuations arise. On the contrary, when saving is forced by an excessive credit expansion, investment is no longer constrained by ex ante saving. Owing to the unduly low rate of interest, the production process becomes too ‘indirect’ that is, there will be an excessive development of those stages of production which are more removed from the final, consumption stage.

In sum, according to Hayek's theory, the structure of demand and in particular the distribution between investment and consumption goods is determined by the propensity to save, whereas the structure of production is a function of the rate of interest. In equilibrium the rate of interest is fixed so as to make those two structures consistent. Excess credit causes an overproduction of capital goods, which must
eventually manifest itself through increased profitability in the consumption good sector and corresponding losses in the investment sector. The latter will therefore experience a crisis that will turn the boom into a recession.

It is interesting to observe that in both Hawtrey's and Hayek's theories the culprit for the recession is the banking system, which keeps the rate of interest too low during expansion. However, for Hayek this leads to an undue ‘lengthening’ of the production process, bound to be reversed when the supply of money ceases to grow at an excessive rate. For Hawtrey, a low rate of interest provokes an excessive rise in global demand vis-à-vis the available stock of money.

A real version of the overinvestment theory of the cycle was put forward by Wicksell (1907) and Schumpeter, whose ideas on this subject are best summarized in the already quoted treatise (1939). These authors shared the view that growth and cycle are intrinsically related, and the main theoretical problem in this context is to explain why economic expansion does not take place smoothly, ‘as trees grow’, but why it occurs in leaps and bounds. Wicksell and Schumpeter also agreed that the oscillatory behaviour of capitalist economies is related to the process of innovation through which the employment of limited quantities of primary factors (labour and land) results in increasingly greater amounts of consumption and investment goods. Essentially the trade cycle depends on the fact that innovations, that is, the introduction of new techniques, new products and new markets, are not distributed uniformly in time, but take place in a discontinuous manner, in groups or ‘swarms’.

Schumpeter especially emphasized the role of entrepreneurial activity in the generation of business cycles. Since innovation implies a break of routine, it cannot occur smoothly but requires a minimum critical amount of energy to overcome inertia. Such energy is provided by exceptional individuals who possess the courage, strength and imagination necessary to ‘do things differently’. Once these few pioneers have opened the way, many others will follow to share in the extra-defeating process, made available by innovation. This is a self-defeating process, though. Insofar as the new methods products have been absorbed by the market, prices and profits will fall, terminating the boom and reversing the direction of the cycle. Secondary waves many amplify the oscillations, bringing about overoptimistic booms followed by severe slumps.

For Schumpeter and Wicksell alike, however, not everything about recession is bad, provided the worst consequences of deep depressions can be avoided. Recession is indeed a phase of adjustment during which innovations are ‘digested’ and leads the economy to an intrinsically superior stage. Recession, so to speak, realizes what the boom had promised: a permanently increased flow of commodities, reduced costs, entrepreneurial profits transformed into higher incomes of the other social classes. Schumpeter insisted upon the Darwinian function of (normal) recessions, during which ‘lame ducks’ are eliminated and only the stronger and more efficient survive. Similar arguments would be employed in the 1980s on both sides of the Atlantic Ocean to justify severe anti-inflationary policies.

The best-known exponent of underconsumption theories of the cycle was undoubtedly Hobson (1922). His theory of investment did not differ much from that of Wicksell and Schumpeter and he shared their view that investment opportunities are basically determined by the needs of development, which are in turn governed by technical changes and population growth.

According to Hobson, though, depressions are caused by insufficient expenditure, which in capitalist economies arises from a skew distribution of income. Increases in income are accompanied by more than proportional increases in saving, leading to overinvestment first and overproduction later. Hobson did not believe in the efficacy of the traditional remedies to overproduction, namely a reduction in the
rate of interest and in the level of prices. As concerns the former, he was of the opinion that saving responded little, if at all, to changes in the interest rate. On the other hand, changes in prices are too sluggish to counteract undesired changes in real variables. Instead, actual economies eliminate excess saving in the most inefficient and painful way, that is, through depression and unemployment. Hobson's arguments are clear anticipation of certain Keynesian ideas which would become very popular a few decades later.

It may be noticed that both the overinvestment and the underconsumption theories locate the origin of the crises in a 'vertical' imbalance between the investment and consumption sectors, an idea which had already been discussed by Marx, Rosa Luxemburg and Tugan-Baranowsky. Those theories differ from one another concerning which of the two sectors is overexpanded, the investment sector according to the former, the consumption sector to the latter. Both of them, moreover, could be comprised under the more general label of overcapitalization theories, but the one (underconsumption) argues that there are too many capital goods (and consequently too many consumption goods) vis-à-vis global demand, the other (overinvestment) maintains that there is excess accumulation vis-à-vis saving. It follows that policy recommendations suggested by the supporters of these theories conflict: a reduction of consumption according to overinvestment; a redistribution of income leading to greater consumption according to underconsumption theory.

Keynes's own theory of the cycle – as distinguished from Keynesian theories – constitutes a *trait d'union* between the modern and the contemporary phase. Even if all the elements necessary to build a true model of the cycle exist in Keynes's work, this task was left to his followers. We shall describe here the essence of Keynes's argument as it appears in the *General Theory* (1936).

At an abstract level, Keynes was fully aware that cyclical motion must result from alternations in the relative strength of expansive and contractive forces, to wit that the cycle must be nonlinear. The changes in the balance between expansive and contractive forces may take place smoothly or abruptly, the latter case being more frequently in a boom, the former in a slump. These ideas would be further developed by younger economists inspired by Keynes, in particular by Kaldor and Goodwin. For Keynes the trade cycle is a complex mechanism but its most important manifestations are the fluctuations of the marginal efficiency of capital, which is determined by psychological as well as economic considerations, and primarily depends on abundance or scarcity of capital goods, their cost and expectations about their future returns. Most often a recession is precipitated by a turnaround of expectations, which, to Keynes, is a much more decisive factor than the increase in the rate of interest sometimes associated with it.

In the last part of the boom, entrepreneurs' optimism offsets all the other unfavourable circumstances: excess capital goods, increasing costs and a high rate of interest. Estimates of future returns to assets are distorted and exaggerated by ignorance, speculation, and vested interests of financial intermediaries and asset-owners. When finally the overoptimistic forecasts are falsified by facts, there follow excessive and even catastrophic readjustments. The increase in liquidity preference that usually accompanies the decrease in the marginal efficiency of capital aggravates the situation and nullifies the effects of expansive monetary measures.

At this point, Keynes contrasts his own theory with that based on overinvestment and observes that the latter is an ambiguous term. If overinvestment means that capital goods in general are so abundant that no investment project can be found whose expected return could justify the cost, then, according to Keynes, this is a rare occurrence even at the peak of a boom. Instead – Keynes continues – investment is
excessive either in the sense that actual returns are lower than those on the expectations of which the
decision to invest has been taken, or in the sense that severe unemployment makes investment
superfluous. It follows that in a recession the right remedy is to reduce, not to increase, the rate of
interest.

On the other hand, Keynes thought that the essential propositions of the underconsumption theory were
substantially correct. Under capitalist rules of the game, the volume of investment is not controlled, let
alone planned, and depends on the vagaries of the marginal efficiency of capital, with a rate of interest
systematically kept above a conventional minimum. In this situation, in order to maintain high rates of
employment it may well be necessary to stimulate consumption. Keynes's only criticism of the
underconsumption theory is its neglect of the possibility of stimulating investment directly. But this –
according to Keynes – is a matter of expediency rather than theory.

The modern phase of the cycle theory was characterized by a rich theoretical investigation which led to a
deeper understanding of the dynamics of capitalist economies. It did not result, however, in the
production of true models, that is, sets of rigorously formulated propositions containing the (necessary
and) sufficient conditions to represent in idealized form the cyclical behaviour of the economy. The
‘contemporary’ phase of cycle theory – from the 1930s onwards – does not consist so much in the search
for new explanations of the ‘enigma of the cycle’ (Wicksell, 1907) as in the attempt to analyse in a
rigorous manner concepts and ideas put forward by earlier writers in an intuitive form.

The foundations of the mathematical theory of the trade cycle were laid down mostly in the 1930s, and
the early works in this field (Frisch, 1933; Tinbergen, 1959: Kalecki, 1935; 1943; and Samuelson, 1939)
were characterized by a distinctly Keynesian flavour. Keynes's own writings – and of course even more
so the world crisis – had convinced a growing number of economists that the free functioning of the
market was more likely to lead to an oscillatory behaviour of income, employment and prices, than to
full employment equilibrium.

Multiplier–accelerator theory, in different versions and with different refinements, rapidly became
predominant in the decades immediately before and after the Second World War.

In the 1960s, however, the economics profession's attention turned away from the problem of the cycle.
Several reasons contributed to this change, but four of them seem to stand out as crucial.

First of all, economic events after the Second World War seemed to suggest that business cycles had
become obsolete. After a phase of settlement following the turmoil of the war, the world economy (or at
least that of the major industrialized countries) seemed to have entered an epoch of sustained growth
without (or with only minor) fluctuations. Economists, and especially the younger ones, were quick to
respond to the current social and political mood.

Secondly, the prevailing models of the cycle, those of Keynesian inspiration, suffered from a major
drawback. The solution of such models consists of fluctuations, perfectly regular in the sense that a
certain periodic orbit, once established, repeats itself over and over again.

In such a situation, economic agents would sooner or later notice the periodic character of the dynamics
of the system and learn to calculate the amplitude and frequency of the cycles. This in turn would lead to
a revision of their expectations. The behavioural hypotheses of the model – on which the cyclical motion
of the system depends – would no longer be tenable and the model itself would have to be reformulated.

Incidentally, this criticism of the deterministic models of the cycle is perhaps the most important
element of truth in the theory of rational expectations.

Thirdly, historical data on the main economic variables do not confirm the periodic regularity predicted
Finally, and partly in response to the theoretical difficulties mentioned above, there has recently been a
revival of what we would call the ‘static prejudice’ in economics, whose most explicit expression is
perhaps ‘equilibrium business cycle theory’. In a nutshell, this theory describes the working of the
economy by means of a model whose deterministic part is characterized by a unique, stable equilibrium.
A stochastic part is added to it which depends on imperfect information of economic agents, whose
decisions are therefore mistaken. With rational expectations these errors are ‘white noise’, that is, they
are normally distributed above and below the optimal (equilibrium) values. The resulting fluctuations
of the system are non-periodic but bounded and their amplitude and frequency can be estimated
statistically. This approach is reminiscent of certain early ideas first developed in the 1920s and 1930s
by Slutsky (1937), Hotelling (1927), Yule (1927), Frisch (1933) and later by Kalecki (1954), to explain
the persistence of the cycle. However – as Hicks commented long ago (1950) – when the random factors
‘explain’ a substantial part of the deviations of a system from its equilibrium position, the proposed
theory amounts to a confession of ignorance.

Mentioning a ‘static prejudice’ in economics raises a few methodological questions, discussion of which
is perhaps the best way to introduce the recent developments in the theory of the cycle (and, more
generally in economic dynamics) and to conclude this essay.

In spite of the great practical importance of the problems discussed and the high intellectual quality of
the results obtained, cycle theory has generally been regarded as an interesting but as a whole marginal
branch of economics, whose exponents as such rarely managed to hold centre stage in professional
debates.

The great theoretical systems developed in the 18th and 19th centuries, for example, those of Ricardo
and of Walras, were more suited to the explanation of interdependence of economic variables, rather
than their evolution in time. This problem is better formulated by means of a system of algebraic
equations, whose solution (not necessarily unique) is a set of values of the variables – typically prices of
commodities and quantities produced – which is consistent with the postulated relationships and the
exogenously fixed parameters. The equations themselves define certain equilibrium conditions, for
example, equality of demand and supply, or uniformity of the rate of profits. Uniqueness and stability of
equilibrium are deemed to be desirable properties of the model, in a descriptive as well as in normative
sense. Indeed only stable systems are observable. Multiple equilibria, on the other hand, are not
satisfactory for two reasons. First of all, in the general case they are alternatively stable and unstable;
secondly, the multiplicity of equilibria introduces a certain amount of relativism as far as their optimality
properties are concerned.

Discussion of stability must bring (and historically has brought) dynamic considerations into the picture.
Early writers provided intuitive, but not very cogent stories arguing that the system ‘tended to’ or
‘gravitated towards the natural or equilibrium values and prices’. Walras took a step forward, providing
a principle (Walras's Law) which shows that, under the postulated maximizing behaviour, disequilibria
of notional demands and supplies cannot be entirely haphazardous, but must take place according to
certain rules (that is, the value of total excess demand must be equal to zero). This led to rather
optimistic considerations as far as stability of competitive equilibrium was concerned, but was a far cry
from a rigorous statement of the problem.

A deeper understanding of the intricacies of non-equilibrium behaviour of dynamical systems and more
powerful mathematical techniques were required. Fundamental progress along this line was made in the
interwar period (Hicks, 1939) and more so during and after the Second World War, when certain necessary mathematical results became available to economists. (The list of important contributions is too long to be quoted exhaustively here: we shall only mention Samuelson, 1941; 1942; Metzler, 1945; Morishima, 1952; Arrow and Hurwicz, 1958.)

The conclusions were rather dismaying though, since a rigorous analysis showed that sufficient stability conditions entailed the most heroic assumptions on the specifications of the system. Economists’ overwhelming preoccupation with equilibrium explains their neglect of cycle theory. Indeed cycle theory must by definition concern itself with off-equilibrium states of the system.

Empirical observation suggests that the economy is not normally in equilibrium, but fluctuates without ever coming to rest or, if we except relatively rare historical occurrences, without ‘exploding’. Is this restlessness only the result of random external shocks, or is it a structural characteristic of the system, owing to the operation of endogenous mechanisms? In dealing with this problem the cycle theorist is naturally led to posing typically dynamic questions such as ‘what are economic agents’ reactions to non-equilibrium, and therefore unsatisfactory situations?’; or, more generally, ‘what laws of motion govern the system, starting from a given, generally off-equilibrium state?’

An exact formulation of this problem required an even more sophisticated analytical apparatus than was the case with static theory. Its natural mathematical set-up is a system of differential (or difference) equations, whose solution is a set of functions of time which, given the initial conditions, describes, so to speak, the history of the variables under consideration. The fact that the relevant part of theory of differential equations became available to economists at a rather late date is perhaps a further explanation of their preference for static rather than dynamic problems.

In discussing the problem of fluctuations, economists must soon run up against the question of linearity. Most systems, as described by economists’ models, are linear; that is, the coefficients that appear in those models do not depend on the variables or their derivatives with respect to time. The crucial importance of this assumption can be appreciated by considering how it affects the analysis of stability. From the point of view of linear analysis, equilibrium is either stable or unstable. A disturbance is therefore followed by a return to rest in the former case, or by an indefinite increase in the magnitude of the deviation in the latter. But this is a very rough description of the behaviour of an economic system.

Linear analysis, by its very nature, completely disregards the effect of the size of disturbances. Indeed an economy may be stable with respect to small deviations from equilibrium, but not so when those deviations are large. On the other hand, an economy may be locally unstable, in the sense that it does not show any tendency to return to its equilibrium position when subjected to small shocks, but it may possess self-correcting mechanisms which only operate far from equilibrium. In either case, the conclusions reached by means of a linearization around the equilibrium point would be misleading.

The linear approximation is unsatisfactory not only because it provides a simplified and therefore distorted picture of reality. A much more fundamental shortcoming is that there exist certain phenomena (economic or otherwise) which cannot be idealized at all by means of linear models. In particular, it is well known that a system of linear differential (or difference) equations, if structurally stable, cannot describe sustained oscillations, that is, oscillations that do not expire or explode.

The discovery that certain basic questions of economic dynamics, in particular persistent cycles, could not be tackled effectively by means of linear models led an increasing number of economists to make use of nonlinear methods of analysis. In so doing, they experienced what Poincaré – to whom modern dynamic analysis owes more than to anybody else – had described several decades earlier. The study of
the cycle had proved precious to the analyst, all the more so since it constituted a first necessary step into the mysterious and hitherto inaccessible realm of non-equilibrium dynamics.

At that point the phrase ‘cycle theory’ became an elliptical expression designating not a particular problem, but economic dynamics as a whole or, more appropriately, a method for investigating dynamic processes in economics. But from the analysis of fluctuations economists have obtained much more than a number of new methods and mathematical tools. The most aware of them have undergone a true cultural revolution that Frisch already in the early 1930s (1933) thought would be as important to economics as the transition from classical to quantum mechanics had been to physics. Equilibrium states, stable and unstable and even limit cycles have now been revealed as rather special configurations in a much more complex and morphologically rich theoretical universe. As soon as the linearity assumption has been dropped, even a simple model may exhibit a very complicated behaviour. The objection may be raised that this is very nice, but what does it have to do with real systems, in our case real economies? On the contrary, recent developments in dynamic theory have finally provided economists with tools of analysis such that theoretical results are, at least qualitatively, comparable with empirical observations. Take, for example, so-called chaotic behaviour. This characterizes a large class of dynamic models, economic or otherwise and, in common parlance, describes irregular fluctuations of a type that has so far been exclusively associated with random (and therefore essentially unexplained) disturbances. After all, what could be more realistic than irregular but bounded fluctuations of income, employment and prices, and what more unrealistic than a stable unique equilibrium point?

Clearly cycle theory and, more generally, economic dynamics is in a state of transition. To produce theoretically meaningful and socially relevant models of real systems, economists must fulfill two main requirements:

1. (i) to define mechanisms of adjustment that realistically describe economic agents’ behaviour in disequilibrium;
2. (ii) to employ techniques of analysis suitable to study the dynamic systems resulting from the operation of those mechanisms.

Recent developments have contributed substantially to solve some of the problems in (i). Instead, off-equilibrium behaviour of economic agents remains to this day a rather fuzzy area of economic investigation.

Abstract

This area of research tries, through the introduction of politics in economic models, to explain the existence and the extent of anti-trade bias in trade policy. The two main approaches, namely, the median-voter approach and the special-interest approach are surveyed. Certain applications of these approaches to policy issues, such as trade agreements, the issue of reciprocity versus unilateralism in trade policy, regionalism versus multilateralism, hysteresis in trade policy and the choice of policy instruments, are discussed. Finally, the empirical literature on the political economy of trade policy is surveyed. The new literature that employs a more ‘structural’ approach is emphasized.

Article

While economists clearly understand the benefits of free trade, they have always found it difficult to explain departures from it in the real world. Most of these departures are in the direction of limiting the volume of trade. In trying to explain the existence and the extent of this anti-trade bias in trade policy,
trade economists have introduced politics in their economic models. Parts of this political-economy literature have also tried to explain why policy instruments that are more efficient than trade policy and can achieve the same political and economic objectives are not often used. An important empirical contribution of the political-economy literature has been to uncover the main determinants of cross-country and cross-industry variations in protection.

Modelling approaches

Median-voter approach

Political economy models of trade are of two main types. One of them adopts the majority voting approach. Such models are called ‘median voter’ models in the literature. Preferences are assumed to be ‘single peaked’ and conditions are imposed such that the most preferred policy of each individual is monotonic in a certain characteristic. Then, with other individual characteristics held constant across the population, the tariff chosen under two-candidate electoral competition is the median voter's most preferred tariff. The median voter here is the median individual in the economy when ranked according to the characteristic under consideration. Mayer (1984) applies this median-voter principle to the Heckscher–Ohlin and specific-factors trade models. In the Heckscher–Ohlin case, the political economy equilibrium tariff is the most-preferred tariff of the median individual in the economy-wide ranking of the ratio of capital to labour ownership. If this median individual's capital to labour ratio is less than the economy’s overall capital to labour ratio – that is, if the asset distribution in the economy is unequal – the equilibrium trade policy is different from free trade and is one that redistributes income from capital to labour – pro-trade in a labour-abundant economy and anti-trade in a capital-abundant economy.

Special-interest politics

The other type of political economy model in the trade literature focuses on ‘special-interest’ politics. The first papers to model lobbying explicitly in the trade arena were by Findlay and Wellisz (1982) and Feenstra and Bhagwati (1982). The Findlay–Wellisz model is a two-sector model in which production in each sector is carried out using a factor of production specific to that sector – land for food production and capital for manufactures – and an economy-wide general factor, namely, labour. Both types of specific factor owners are fully organized politically and they lobby against each other. This simple model shows the existence of an equilibrium tariff determined through the Nash interaction between the two opposing groups. The government is modelled very indirectly through a tariff formation function which is increasing in the amount of labour devoted to lobbying by the import-competing specific factor and decreasing in labour used in lobbying by the specific-factor owners in the export sector. While only labour is used as an input in lobbying in the Findlay–Wellisz model, both capital and labour are used as inputs into lobbying in the Feenstra–Bhagwati model. However, only one sector is assumed to be politically active in the model. Unlike in the Findlay–Wellisz model, the government in the Feenstra–Bhagwati model is not a monolithic entity but has a two-layered structure. While one layer is a clearing house for lobbies, the other cares about social welfare. The tariff is determined through an interaction between the two layers.
Another approach to modelling ‘special-interest’ trade politics is the ‘political support function’ approach pioneered by Hillman (1989). (Some of the classification terminology here is borrowed from Rodrik, 1995, to which the interested reader is referred for a detailed typology of political-economy models. See also Helpman, 2002, for an analytical survey within a unified framework.) Under such an approach, the government's objective function, also called the political support function, incorporates its preferential treatment of each organized industry as well as the cost of protecting this industry given by the excess burden on society. Van Long and Vousden (1991) use a specific form of Hillman's political support function which is linear in the welfare levels of different types of specific-factor owners, with different weights being assigned to different factors.

Magee, Brock and Young (1989) explicitly model electoral competition. They use a two-sector, two-factor Heckscher–Ohlin set-up with two political parties – one pro-trade and another pro-protection – and two lobbies – one representing capital and the other labour. Lobbies contribute to their respective favoured political parties to maximize their chances of winning elections. Policy platforms here are chosen prior to decisions on campaign contributions.

The special-interest approach has evolved from the simple Findlay–Wellisz ‘tariff-formation function’ approach to the state-of-the-art Grossman and Helpman (1994) ‘political-contributions’ model. The latter is path-breaking for several reasons. First, it is multi-sectoral. Second, it provides micro-foundations for the behaviour of organized lobbies and politicians. A ‘menu-auctions’ approach is used in modelling policy bidding by interest groups. Multiple principals, namely, the various organized lobbies, try to influence the common agent, namely the government. The government's objective function is a weighted sum of political contributions and aggregate welfare, while each lobby maximizes its welfare net of political contributions. Most importantly, especially from the empirical angle, the level of protection for each industry is derived as an estimable function of industry characteristics and other political and economic factors. Protection to organized sectors is negatively related to import penetration and the (absolute value of) import demand elasticity, while protection to unorganized sectors is positively related to these two variables. With everything else held constant, organized sectors are granted higher protection than unorganized sectors.

While Grossman and Helpman in their models take the existence of organized lobbies as given, Mitra (1999) extends their framework to endogenize lobby formation. He shows that we are closest to free trade when the government cares too little or too much about aggregate welfare relative to political contributions. While the former leads to the formation of a large number of mutually opposing lobbies, the latter situation is one where hardly any lobbies get formed. Mitra also shows that a higher concentration of asset ownership in the economy leads to the formation of a larger number of organized lobbies representing sectors that are heavily protected. Magee (2002) analyses a single lobby's organization problem in the context of the collection of political contributions in a repeated game setting. (See also Pecorino, 1998, for an analysis of the same issue with a tariff-formation function approach.)

**Theoretical applications**

**Trade agreements**
The first important theoretical application we discuss is the issue of trade agreements. Using their political-contributions approach, Grossman and Helpman (1995a) analyse trade policy in a setting with two large countries, where they show an additional terms-of-trade component in the tariff expression in a non-cooperative setting. This component gets eliminated in a cooperative setting of international trade negotiations, and the relative size of protection in any sector in the two countries then depends on the relative political power of the same industry in the two countries. Thus there is a rationale for ‘trade talks’ as opposed to ‘trade wars’. Using what is very close to a ‘political-support’ function approach, Bagwell and Staiger (1996; 1999) show that, even when political economy considerations are taken into account, the only rationale for (reciprocal) trade agreements is the elimination of terms-of-trade externalities. They use this approach to develop a rationale for the General Agreement on Tariffs and Trade (GATT)/World Trade Organization (WTO) and its different rules. (See Bagwell and Staiger, 2002, for an in-depth discussion.)

The next natural question then is whether free trade agreements are of any value to countries whose actions have no impact on the international terms of trade. Maggi and Rodriguez-Clare (1998) have a political economy explanation for the unilateral commitment to free trade agreements by small countries. Their setting is one in which owners of capital first decide in which sector to invest, and then those who invest in a particular sector (the import-competing sector) lobby the government for protection. The lobbying is modelled as a Nash bargaining game between the lobby and the government. While the lobby at least compensates the government for the deadweight losses generated in the second stage, it may not compensate the government for the welfare loss through the inter-sectoral misallocation of capital in the first stage in the expectation of protection in the second stage. In such a situation, it is possible that a government will commit to a free trade agreement in a prior stage ‘zero’. Mitra (2002) builds on the Maggi–Rodriguez-Clare version of the Grossman–Helpman framework, augmenting it with the decision to incur fixed costs (to build relationships with politicians in power and/or to form a lobby) prior to the actual lobbying, but, importantly, not providing room for any capital mobility. However, the main result of the Maggi–Rodriguez-Clare model goes through even in this newly modified set-up. This is the result that generally governments with low bargaining power with respect to domestic lobbies are the ones that precommit to free trade agreements. Grossman and Helpman (1995b) have provided a detailed analysis of political-economy factors responsible for the emergence of free trade agreements. Using their ‘political-contributions’ approach, they show that such agreements between two countries are impossible if in every sector one country has a higher tariff than the other. These agreements might be politically feasible only when tariffs on some goods are higher in one country while other tariffs are higher in its partner country. The possibility of exclusion of certain sectors from the trade agreement also raises the chances that the agreement will be signed.

**Reciprocity and unilateralism in trade policy**

I now move to the issue of reciprocity and unilateralism in trade policy. Bagwell and Staiger (1996; 1999; 2002) have analysed the issue of reciprocal trade liberalization in considerable detail in both bilateral and multilateral settings (see also Hillman and Moser, 1996). In their models, reciprocity is a way of eliminating terms-of-trade externalities in the setting of trade policy. While considerable work
has been done on the role of reciprocity in trade policy, the causal interaction between unilateral and reciprocal trade liberalization has been a somewhat neglected issue. Krishna and Mitra (2005) modify the Mitra (1999) lobby-formation framework to study exactly this link. (See Bhagwati, 1990, for an early informal discussion of this idea. See also Coates and Ludema, 2001, for an alternative channel based on risk sharing through which unilateralism induces reciprocity.) While reciprocal reduction in trade barriers can reasonably be expected to occur in contexts involving trade negotiations between countries, Krishna and Mitra examine instead the question of whether unilateral trade liberalization by one country can induce reciprocal liberalization by its partner in the absence of any communication or negotiations between the two countries. In this context, they show that unilateral liberalization by one country can affect the political economy equilibrium in the partner country through the formation of an export lobby there, in a manner that induces it to liberalize trade.

The political economy of regionalism versus multilateralism

An important question raised by Bhagwati (1993; 1994) in several of his writings is whether regionalism is a ‘stumbling block’ or a ‘stepping stone’ to multilateralism. (For a purely economic answer that relies on coordination failure based on sector-specific sunk costs and ‘friction’ in trade negotiation, see McLaren, 2002.) Levy (1997) uses a Heckscher–Ohlin set-up with monopolistic competition and a median-voter approach to address this issue. He finds that bilateral agreements between countries similar in factor endowments result in the subsequent blocking of multilateral trade agreements. He also finds that bilateral agreements can never increase the political support for multilateralism. Krishna (1998) addresses the same issue in a political economy set-up where profits get a much greater weight than other components of welfare in the government's objective function (political-support function approach). The set-up is one of Cournot oligopoly. He finds greater political support for trade-diverting bilateral agreements (regionalism) than for trade-creating ones. Such agreements can also make previously feasible multilateral agreements politically infeasible. This effect turns out to be increasing in the magnitude of the trade diversion that takes place under bilateralism.

Free trade areas versus customs unions

Next I move to the determinants of the actual shape or form a preferential trading arrangement will take. Panagariya and Findlay (1996) study the choice between a customs union and a free-trade area in the context of how they affect lobbying activity and the structure of external tariffs. Using a tariff-formation function approach, they focus on the free-rider problem in lobbying in the case of customs union arising from the requirement of a common external tariff. Richardson (1994) is similar in spirit and finds the same free-rider effect under a customs union, due to which free-trade areas are preferred by import-competing producers. McLaren (2004) takes a different approach to the choice between a free trade area and a customs union. He analyses what he calls the ‘dynamics of political influence’. As the external tariff is common across members of a customs union, it has to be set jointly by all the members, which can be done only if an agreement is reached among them. This makes the external tariff relatively less reversible under a customs union than under a free-trade area. It is this relative irreversibility that McLaren focuses on,
even though he abstracts from the uniformity aspect. Using a political contributions approach with Nash bargaining between the capitalists and the government, he finds that a customs union is more likely when the government has a short lifespan and firms have a long lifespan. This is because the more permanent nature of trade policy under a customs union requires the upfront payment of contributions, which is the government's share in the present value of the stream of surpluses generated over time.

The choice of policy instruments

The next important application concerns the choice of policy instruments. One of the major propositions of the theory of commercial policy is that, if distortions or policy goals are not directly trade-related, then direct subsidies are more efficient than tariffs (Bhagwati and Ramaswami, 1963; Johnson, 1965; Bhagwati, 1971). One simple explanation for the existence of tariffs despite their low efficiency is that they generate revenues while subsidies use them up (see for instance Bhagwati and Ramaswami, 1963). However, in a Bhagwati and Srinivasan (1980; 1982) framework of fully competitive revenue seeking, subsidies can be preferable to tariffs as they are not subject to revenue seeking. Rodrik (1986) is the first author to look at this issue by endogenizing policy. He does this by using a simplified version of the Findlay–Wellisz model. He argues that, since tariffs are general to an industry and subsidies can, in principle, be firm-specific, the free-rider problem in lobbying for tariffs may result in a smaller level of endogenous tariffs than endogenous subsidies, thereby possibly reversing the conventional welfare ranking of tariffs and subsidies. Mitra (2000) argues that, even from the point of view of the import-competing firms, tariffs may be preferable to subsidies since lobbying in the latter may face a congestion problem while in the former the free-rider problem may offset the congestion problem.

This issue of the choice of instruments is also addressed by Grossman and Helpman (1994). They argue that, when the policy instrument used for redistribution is more efficient, it creates greater competition among lobbies and thus results in a larger proportion of the surplus in the hands of the government. Therefore, lobbies themselves may want to tie the hands of the government to using relatively inefficient instruments. Wilson (1990) makes a similar argument in a model with electoral competition where he shows that a higher efficiency of redistributive instruments leads to more contributions and more transfers in equilibrium.

The choice between tariffs and subsidies has also been considered in a voting framework in a series of papers by Mayer and Riezman (1987; 1989; 1990). They show that tariffs can be chosen in equilibrium outcome when voters differ along dimensions other than factor endowments, such as tastes and preferences, treatment under income taxes, and so forth. Besides, income tax progressivity might mean that the cost of financing subsidies is borne unevenly, which might lead some individuals to prefer tariffs whose costs are more evenly distributed.

Feenstra and Lewis (1991) argue that tariffs are informationally more efficient than subsidies. When the world price of importables falls, a tariff equivalent to this decline will compensate the losers without making others worse off relative to the initial situation. This will be possible without any knowledge on the part of the government of individual production and consumption levels. Magee, Brock and Young (1989) propose another information-based explanation, which they call the principle of ‘optimal obfuscation’. Indirect policies such as tariffs are less observable by those who bear its costs.
Staiger and Tabellini (1987) argue that, when governments provide surprise protection to those hurt by world price fluctuations, the time-inconsistency problem might be less severe with more inefficient policies.

**Hysteresis in trade policy**

A model that helps us understand status quo bias in trade policy is Fernandez and Rodrik (1991). They consider a two-sector economy that initially has a certain given tariff on its imports. Eliminating this tariff will result in a movement of workers from the import-competing sector to the export sector. What is *ex ante* unknown is which of the workers initially in the import-competing sector will be successful in moving to the export sector. All the workers who are in the export sector right from the beginning will gain, while those who are always in the import-competing sector and remain there after the reforms will lose. Another group that gains is the group of movers from the contracting import-competing sector to the expanding export sector. Suppose 30 per cent of the population is in the export sector and 70 per cent in the import-competing sector to start with. After the reforms, let us suppose that this split is 60 per cent and 40 per cent respectively. This means that 60 per cent of the population will gain *ex post* from the reform. While 30 per cent who are initially in the export sector know for sure *ex ante* they are going to benefit, the remaining 70 per cent do not know which 30 per cent out of them will lose and which 40 per cent will gain. If they know for sure that the loss incurred by the losing 40 per cent is greater than the gain to the remaining 30 per cent, then all the voters who are initially in the import-competing sector will vote against the reform. Due to the individual-specific uncertainty faced by workers in the import-competing sector, each of them will vote on the basis of an expected loss, arising from the fact that losers in this sector lose much more than gainers in that sector gain. Thus, even though *ex post* a majority gain from the reforms, *ex ante* a majority of the workers vote against the trade reforms. However, if a dictator or an international financial institution forces a reform upon these people, it will not be reversed since as we know in this case *ex post* there is going to be majority support for the reforms.

**Beyond the monolithic government**

In the existing political economy literature on trade policy determination, a single, monolithic policymaker is often assumed. Until very recently, the paper by Feenstra and Bhagwati (1982) was the only exception. McLaren and Karabay (2004) make a departure from such a simple structure to study trade policy setting in the presence of parliamentary or congressional institutions. They also incorporate electoral competition between political parties and show that in their setting the equilibrium tariff is the optimum of the median voter in the median district. They find that the relationship between the likelihood of import protection and the geographical concentration of import-competing interests is non-monotonic, with a maximum occurring at moderate levels of concentration. Too much concentration leads to a control of too few seats, while too much dispersion leads to no control of any seats. A paper by Grossman and Helpman (2005) allows actual policy formation to be the interplay between the policy platform announced by the party leadership and the actions of individual legislators who want to maximize political success. Maximization of political success involves resolving the trade-off...
Empirical evidence

The old empirical literature

The empirical literature in this area has evolved from being highly ‘reduced form’ and atheoretical to
being fairly ‘structural’ and guided by tight theoretical models. Important papers in the earlier literature
(1993). (See Rodrik, 1995, for a detailed survey of this literature.) The main finding of this early
empirical literature is that protection is higher for sectors that are labour-intensive, low-skill and low-
wage, for consumer-goods industries, for industries facing high import penetration, where geographical
concentration of production is high but that of consumers is low, and in sectors with low levels of intra-
industry trade. (For an examination of the cross-national variation in average protection levels across
industrialized countries, see Mansfield and Busch, 1995. They find that non-tariff barriers are increasing
in country size, unemployment rate and number of parliamentary constituencies, and are higher for
countries that use proportional representation as their electoral system.)

The new empirical literature

In the Heckscher–Ohlin version of the Mayer median-voter model, a simple comparative static exercise
produces the result that a rise in asset inequality will make trade policy more pro-trade in a labour-
abundant economy and more protectionist in a capital-abundant economy. Dutt and Mitra (2002) find
strong support for this result using cross-country data on inequality, capital-abundance and diverse
measures of protection. (In this context, it is also important to mention Milner and Kubota, 2005, who
use a median-voter approach to empirically investigate the relationship between democratization and
trade reforms in developing countries.)

Dutt and Mitra (2005) also perform a cross-country empirical investigation of the role of political
ideology in trade policy determination. They use a political-support function approach within a two-
sector, two-factor Heckscher–Ohlin model (see Milner and Judkins, 2004, on this issue. Hiscox (2001)
studies six Western nations to look at how historically the nature and structure of partisanship on trade
issues change over time and depend on the extent of inter-sectoral factor mobility. Hiscox (2002) looks
at the same question exclusively for the United States, analysing major pieces of congressional trade
legislation between 1824 and 1994.

Two empirical papers, Goldberg and Maggi (1999) and Gawande and Bandyopadhyay (2000), estimate
the Grossman–Helpman ‘Protection for Sale’ tariff expressions using industry-level data from the
United States. The two papers are similar in the questions they address, but are somewhat different in the
details of their approaches. While Goldberg and Maggi restrict their focus to the protection expressions,
Gawande and Bandyopadhyay concentrate more on the lobbying aspects and the determinants of the
magnitude of contributions. Goldberg and Maggi use the basic Grossman–Helpman framework, while Gawande and Bandyopadhyay introduce intermediate goods. The econometric specifications are therefore somewhat different in the two papers. However, the results in the two papers are very similar. Both confirm empirically the Grossman–Helpman prediction regarding the relationship of protection to import penetration and import-demand elasticity. With everything else held constant, organized sectors are granted higher protection than unorganized sectors. Both papers find that the weight on aggregate welfare in the government’s objective function is several times higher than that on contributions. Also, the estimates of the proportion of the population organized are very high in both papers. Mitra, Thomakos and Ulubasoglu (2002) and McCalman (2004) obtain similarly high parameter estimates of the Grossman–Helpman model for Turkey and Australia respectively. An interesting result that comes out of the empirical exercise by Mitra, Thomakos and Ulubasoglu is that the relative weight on aggregate welfare was higher in the democratic regimes than under the dictatorial regimes in Turkey. Gawande, Krishna and Robbins (2006) empirically investigate ‘the susceptibility of government policies to lobbying by foreigners’. Using a new data-set on foreign political activity in the United States, they investigate the empirical relationship between trade protection and lobbying activity. Their theoretical framework is an extension of the ‘Protection for Sale’ model to include foreign lobbies. They find that foreign lobbying activity has significantly affected US trade barriers in a negative direction, as predicted by their model. They conclude: ‘If the policy outcome absent any lobbying by foreigners is characterized by welfare-reducing trade barriers, lobbying by foreigners may result in reductions in such barriers and raise consumer surplus (and possibly improve welfare).’

In another empirical application through an extension of the Grossman–Helpman model, Gawande and Krishna (2005) investigate the effects of lobbying competition between upstream and downstream producers for US trade policy. Their parameter estimates are a significant improvement over those in the earlier literature even though they do not completely resolve the puzzle. Thus, we see that the political economy literature on trade policy has evolved a great deal on both the theoretical and the empirical sides, as well as in terms of the complexity of applications it can handle.

trade, technology diffusion and growth

Jonathan Eaton and Samuel Kortum
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Invention is a fundamental driver of growth in living standards around the world. Trade and technology diffusion are two ways the benefit of an invention spreads to other countries. Impediments to diffusion give rise to differences in living standards and to comparative advantage in production, providing an incentive to trade. We review some basic facts. We then provide a simple model of the connections among these processes, showing how it can explain these facts.

Keywords

balanced growth; capital goods trade; Cobb–Douglas functions; diffusion of technology; economic growth; economic growth in the very long run; endogenous growth; international trade; invention; patents; product life cycle; Schmookler, J.; technical change

Article

‘That the creation and diffusion of technological knowledge is at the heart of modern economic growth is now widely accepted’ (Jacob Schmookler, 1966). While technological advances drive world growth, differences in the ability of countries to exploit inventions create wide disparities in income. Understanding how such disparities arise requires identifying how the benefits of technological progress spread. A country might benefit from a new technique through trade, importing goods embodying that technique, or through diffusion, learning the technique and using it. Impediments to technology diffusion mean that some countries have techniques that others lack, generating comparative advantage in production, as in Ricardo's model of trade. Over time, diffusion can eliminate or even reverse comparative advantage. As Vernon’s (1966) product cycle posited, if diffusion is slow more inventive countries will export goods associated with recent inventions while importing goods embodying older technology. More recent work has modelled how technologies arise and spread across countries, driving world growth.
Before turning to how economists have modelled trade, diffusion and growth, we fill in this picture with some observations.

An overview of the evidence

When we look at trade in goods, several features stand out: (1) Over the second half of the 20th century, trade has grown as a share of GDP. (2) Nevertheless, geography continues to matter: countries buy much more from themselves and their neighbours than their shares in world production would imply. (3) Rich countries trade more among themselves and with poor countries than poor countries trade among each other.

Our ability to quantify invention is limited to observations on resources devoted to it (for example, research scientists and engineers) or on activities related to inventive output (for example, patents). These two measures paint a very similar picture: invention is concentrated in a small number of rich countries, although many rich countries are not particularly inventive. The patent data, like the trade data, have a further bilateral dimension as inventors from one country seek protection at home and elsewhere. As with merchandise trade, most patenting is done at home or nearby. Yet, most countries issue a majority of their patents to foreign inventors.

Income measures for the post-war era come from national accounts. Sifting through various pieces of evidence, economic historians, in particular Maddison (2003), have constructed measures going back several centuries. The basic picture here is that many countries have experienced sustained growth over a long period of time, with only infrequent switches in relative position.

Other evidence on invention and diffusion comes from longer ago. Diamond (1997) describes archaeological findings on when and where great innovations in agriculture, the domestication of plants and animals for farming, occurred, and how they diffused across continents. Sheep and wheat, for example, originated in south-western Asia around 8,500 bc and within a few millennia had diffused throughout the Eurasian land mass. Corn and turkeys had originated in Mesoamerica by 3,500 and slowly found their way through much of the Americas. Before Columbus, however, the two sets of technologies remained confined to their hemisphere of origin.

A model

We now turn to a model of international technology diffusion, international trade and economic growth that is consistent with these observations.

A world of ideas

We think about technology as a set of ideas that can be applied to production. New ideas generate technological advances if they lead to new goods and services or improve existing ones.

Ideas are inherently non-rival. An idea can be used in many places at the same time. Yet it may take a long time for an idea to spread. We sketch a simple formulation of this process, building on Nelson and Phelps (1966) and Krugman (1979).

We distinguish among three classes of a country's technology at any moment: (i) the measure of ideas $T_i$
that country $i$ invented itself, (ii) the measure of ideas $T^A_i$ available to $i$, and (iii) the measure $T^E_{ni}$ of exclusive ideas invented in $i$ that are not yet available in $n$. Defining $T^W$ as the set of ideas in the world:

$$T^W = \sum_i T^i.$$

New ideas arrive to country $i$ at rate $\dot{T}_i$. Initially they are exclusive to $i$. They become known in country $n \neq i$, thus transiting from $T^E_{ni}$ to $T^A_n$, with a hazard $\epsilon_{ni}$.

Two sets of dynamic equations describe the evolution of technology. The first applies to the increase in available technology in country $n$:

$$\dot{T}_n^A = \dot{T}_n + \sum_{i \neq n} \epsilon_{ni} T^E_{ni}.$$  

The second applies to the change in its exclusive technologies:

$$\dot{T}_n^E = \dot{T}_i - \sum_{n \neq i} \epsilon_{ni} T^E_{ni}.$$  

The literature has related invention to human effort and to research spillovers, acknowledging that inventors stand on the shoulders of others. A simple formulation highlighting research spillovers, used by Krugman (1979), is:

$$\dot{T}_i = \lambda_i T^A_i,$$

where $\lambda_i \geq 0$ is an exogenous rate of invention in $i$. Romer (1990) models the determination of $\dot{T}_i$, turning it into an endogenous growth model. A simple formulation, highlighting human input, in the spirit of the semi-endogenous growth model of Jones (1995), is:
Here $L_i$ is the labour force in country $i$, which grows at a constant rate $g_L > 0$ in each country.

With an arbitrary number of countries, under general assumptions about the parameters of invention (the $\tau$'s) and diffusion (the $\varepsilon$'s), patterns of the distribution of technology can be complex. Nevertheless, if these parameters remain constant, with the matrix of $\varepsilon$'s indecomposable (ensuring that every proper subset of countries can absorb technology from outside), the world will evolve toward a balanced growth path with all $T$'s growing at rate $g_T$. In the research spillover case $g_T$ is given by an eigenvalue (the Frobenius root) of the matrix of $\varepsilon$'s and $\tau$'s, and is increasing in both sets of parameters. In the human input case $g_T$ equals the population growth rate $g_L$. In either case more inventive countries and those quicker to adopt technologies from elsewhere will have more ideas at any moment. Countries that are slow to adopt eventually fall far enough behind that they can draw from a stock of unknown technologies large enough to pull them along at the same growth rate as the most advanced (Eaton and Kortum, 1999). Diamond's archaeological examples illustrate the phenomenon nicely.

A two-country example, using the human input specification of invention (so that $g_L = g_T > 0$) provides some basic results. With two countries we can simplify $T_{ni}^E = T_{i}^E$ and $\varepsilon_{ni} = \varepsilon_i$, and define the measure of ideas that have spilled out of either country's exclusive technology as $T^C$. It is straightforward to calculate the various technology measures along a balanced growth path:

$$T_{ij} = \frac{\varepsilon_i}{g_L} L_i T_{i}, \\
\dot{T}_{ij} = \dot{\varepsilon}_i L_i T_{i}. $$

These equations show us how the various measures of technology, each growing at rate $g_L$, relate to the underlying parameters of invention and diffusion. In particular, a higher rate of diffusion $\varepsilon_1$ out of country 1 leads to more technology available in country 2.

For an idea to affect economic welfare it has to be connected with a good or service that people enjoy. We can then ask how the distribution of ideas relates to production and trade, and thus how ideas ultimately affect welfare. To make this connection we need to be concrete about preferences. We assume that utility can be represented as a constant-elasticity-of-substitution function of consumption over a wide variety of differentiated goods indexed by $j$. The implied price index is:

$$p_{ij} = \frac{1}{\varepsilon} \left( \frac{q_{ij}}{q_{ij}} \right)^{1-\varepsilon}.$$
where $p(j)$ is the price of good $j$, $J$ is the measure of goods, and $\sigma > 0$ is the elasticity parameter.

Idea as new goods

A particularly simple case equates an idea to a new good, with one worker required to produce one unit, as in Krugman (1979) and Romer (1990). We let $J \to \infty$ in (2) so as not to limit growth. A good not yet invented has an implicit price of infinity, hence to bound utility we require $\sigma > 1$.

Without trade countries can consume only the goods they know how to produce themselves. Under perfect competition a unit of any good that is produced will cost the local wage. Since $T_i$ is the measure of goods produced in country $i$, the real wage in country $i$, which is the inverse of the price index there, is simply:

$$\frac{w_i}{p_i} = \left(\frac{T_i}{T_i}\right)^{1/(\sigma-1)}.$$ 

An increase in country $i$'s available technology raises welfare by increasing the variety of available goods. More rapid technology diffusion out of country 1 helps country 2 while doing no harm to country 1. The dynamics of technology diffusion lead to parallel growth in living standards around the world, at rate $g_T(\sigma -1)$.

International trade allows a country to consume goods that it doesn't know how to make itself. In the two-country case with costless trade there are two cases to consider.

In the first, the countries' relative labour forces are in line with their access to technology. More precisely:

$$\frac{T_1^E}{T^W} < \frac{L_1}{L^W} < \frac{T_1^E + T^C}{T^W},$$

where $L^W = L_1 + L_2$. In this case $w_1 = w_2 = w$. Both countries will produce some goods using the common technology and all goods sell at a price equal to the common wage. The common real wage is:
Comparing this wage to the autarky wage above, trade perfectly substitutes for diffusion. Faster technology diffusion would require less trade, but leave welfare in both countries unchanged. The other case emerges if one country, say country 1, is advanced technologically relative to the size of its labour force, or if:

\[
\frac{T^E_1}{W_1} > \frac{L_1}{L W_2}.
\]

Now \(w_1 > w_2\), and country 1 produces only goods associated with \(T^E_1\), while 2 produces goods associated with all its available technology, which includes \(T^E_2\) and \(T^C\). Country 1 exports its exclusive goods in exchange for both country 2's exclusive goods and the goods that both could in principle make. The demand for any good produced in country 1 relative to any good produced in country 2 is:

\[
\frac{c_1}{c_2} = \left(\frac{w_1}{w_2}\right)^{-\sigma}.
\]

Since total demand for country 1 relative to country 2 labour is:

\[
\frac{L_1}{L_2} = \frac{T^E_1 c_1}{T^A_2 c_2},
\]

the relative wage satisfies:
Country 1 has a higher standard of living the smaller it is and the higher the ratio of its exclusive ideas to the ideas available to country 2. The real wage in country 1 is

\[
\frac{w_1}{w_2} = \left( \frac{l_1}{l_2} \right)^{-1/\sigma} \left( \frac{T_1}{T_2} \right)^{1/\sigma}.
\]

which exceeds \( (T_w)^{1/(\sigma-1)} \).

The two cases with international trade illustrate basic points about the relationship between technology diffusion, trade, and welfare. In the case of equal wages and costless trade the rate of diffusion does not matter for income or welfare. With unequal wages, more diffusion necessarily benefits country 2, while the effect on country 1 is ambiguous. If \( T_2^A \) starts off very small relative to \( T_w \), an increase in diffusion benefits country 1 by allowing it to import more goods at a low price. But at higher values of \( T_2^A \) the gain from being able to import more goods at a low price is offset by the increase in the price it pays for all imports. At some point \( T_2^A \) gets so large that \( w_1 = w_2 \) and we are back in the previous case (bounding country 1's loss from 2's access to its technology).

In the equal wage case technology diffusion can act as a substitute for trade: once a good enters the common technology it may no longer be traded. In the second case, diffusion from country 1 to country 2 reverses the direction of trade. What 1 once exported it now imports.

A straightforward extension allows for multiple inventive, high-wage countries and multiple low-wage countries relying on the common technology. Innovative countries exchange goods associated with their exclusive technologies among themselves. They export these goods to low-wage countries in exchange for goods in the common technology. But low-wage countries have no incentive to trade goods in the common technology among themselves.

Ideas as better goods

Alternatively, an idea may not be a new good but rather a new technique for producing an existing good. This approach appears in Grossman and Helpman (1991), Aghion and Howitt (1992), Kortum (1997), and Eaton and Kortum (1999). Since there are no new goods, we set \( J=1 \) in (2) and drop the restriction that the substitution elasticity exceeds 1.

Let's begin with a stark case of international trade, along the lines of Armington (1969), in which
country 1 produces only goods \( j \leq 1/2 \) and country 2 only goods \( j > 1/2 \). The efficiency with which country \( i \) produces its range of goods is \( T_i \). The demand for any good produced in country 1 relative to any good produced in country 2 is:

\[
\frac{c_1}{c_2} = \left( \frac{w_1 / T_1}{w_2 / T_2} \right)^{-\sigma},
\]

Since the total demand for country 1 relative to country 2 labour is:

\[
\frac{L_1}{L_2} = \frac{c_1 / T_1}{c_2 / T_2},
\]

the relative wage satisfies:

\[
\frac{w_1}{w_2} = \left( \frac{L_1}{L_2} \right)^{-1/\sigma} \left( \frac{T_1}{T_2} \right)^{(\sigma - 1)/\sigma}.
\]

As above, country 1's relative wage is higher the smaller it is, but its technological lead has an ambiguous effect, depending on \( \sigma \).

Consider technological stagnation in country 2 so that \( T_2 = 1 \) for ever while \( T_1 \) grows at rate \( g_T > 0 \) (with relative labor forces not changing). If \( \sigma < 1 \) the stagnant country 2 actually grows faster while \( \sigma > 1 \) means faster growth for country 1. With Cobb–Douglas preferences \( (\sigma = 1) \) wages grow at the same rate: country 1's greater inventiveness is exactly offset by its worsening terms of trade. Oil-exporting countries, for example, can grow faster than the rest of the world even though they do not rank highly in standard technology indicators.

If we remove the Armington assumption, so that either country can in principle produce anything, the possibilities for parallel growth expand. Suppose that to produce a unit of any good in country 2 requires one worker, as does producing any good \( j > 1/2 \) in country 1. Country 1 can produce any good \( j \leq 1/2 \) with efficiency \( T_1 > 1 \). If \( \sigma < 1 \), the stagnant country 2 cannot grow faster for ever. Once \( w_2 \) hits \( w_1 \), thenceforth \( w_2 = w_1 \) as country 1 produces an ever greater range of goods \( j > 1/2 \), approaching its share of the world labour force asymptotically. In this case with inelastic demand, even with no technology diffusion trade spreads the benefits of 1's technological advances evenly. If \( \sigma > 1 \), on the other hand, then as country 1's technology improves it remains specialized in goods \( j \leq 1/2 \) and its relative wage
While this two-country example illustrates some basic points about innovation, diffusion and trade very neatly, it fails to account for a number of the basic facts discussed earlier. In particular, the world consists of many countries displaying varying degrees of innovative activity. While countries trade with each other, barriers to international trade remain substantial.

Eaton and Kortum (1999; 2002) develop a framework in which the same basic forces drive growth and trade among many heterogeneous countries separated by trade barriers. They treat an idea as a way to produce some good \( j \in [0,1] \) with some efficiency \( q(j) \) drawn from a Pareto distribution with parameter \( \theta \). The implication is that, if country \( i \) has access to a measure \( T_i^A \) of ideas, its best technology for making good \( j \), \( Z_i(j) \), is a realization drawn from:

\[
G(z, T_i^A) = \Pr[Z_i \leq z] = e^{-T_i^Az^{-\theta}},
\]

a type II extreme value distribution. Looking across the unit continuum of goods, \( e^{-T_i^Az^{-\theta}} \) is the fraction that country \( i \) can produce with an efficiency no more than \( z \).

With no international trade, the price of good \( j \) in country \( i \) is \( p_i(j) = w_i / Z_i(j) \). The real wage in country \( i \) as well as the standard of living there, is thus

\[
\frac{w_i}{p_i} = \left[ \int_0^\infty z^{\sigma-1}dG(z, T_i^A) \right]^{1/(\sigma-1)} = \gamma(T_i^A)^{1/\theta},
\]

(3)

(where \( \gamma \) is constant that depends on \( \theta \) and \( \sigma \)). Trade provides the potential to exploit comparative advantage. An iceberg transport costs \( d_{ni} \) separates country \( n \) from country \( i \) (meaning that delivering 1 unit of a good to country \( n \) requires shipping \( d_{ni} \geq 1 \) units from \( i \)). In the case of no diffusion \( T_i^A = T_i^E \). The real wage in country \( i \) then becomes:

\[
\frac{w_i}{p_i} = \gamma \frac{w_i}{\left[ \sum_{k=1}^N T_k^E (w_k d_{ik})^{-\theta} \right]^{1/\theta} - 1/\theta} \geq \gamma(T_i^E)^{1/\theta}.
\]

Trade thus gives consumers in country \( i \) access to everyone's technologies, appropriately weighted by
input and transportation costs.

With two countries we get the Ricardian model of Dornbusch, Fischer and Samuelson (1977). Ordering goods in decreasing order of country 1’s relative efficiency \( A(j) = z_1(j) / z_2(j) \) yields:

\[
A(j) = \begin{cases} 
(1 - j \frac{T_1^E}{T_2^A})^{1/\theta} & j < \frac{T_1^E}{T^W} \\
1 & \frac{T_1^E}{T^W} \leq j \leq \frac{T_1^A}{T^W} \\
(1 - j \frac{T_1^A}{T_2^E})^{1/\theta} & j > \frac{T_1^A}{T^W}
\end{cases}
\]

Note that the range of goods over which \( A(j) = 1 \) is governed by the extent of technology diffusion. With no transport costs and symmetric Cobb–Douglas preferences the equilibrium is characterized by a cutoff good \( j^* \) such that country 1 produces goods \( j \in [0,j^*) \) while country 2 produces \( j \in (j^*,1] \). The relative wage \( \frac{w_1}{w_2} \) and \( j^* \) satisfy the conditions for labour market clearing and comparative advantage:

\[
\frac{w_1}{w_2} = \frac{l_2}{l_1} \frac{j^*}{1 - j^*} \frac{w_1}{w_2} = A(j^*).
\]

This two-country case is analyzed in Eaton and Kortum (2007a) with research effort determined endogenously. Rodriguez-Clare (2007) derives quantitative implications of an N-country case with research exogenous.

**Ideas embodied in inputs**

Our discussion so far has considered two ways in which the benefits of invention spread around the world: through trade in final goods that embody the technology, and through the diffusion of the disembodied idea itself. Ideas embodied in goods used for production provides a third conduit. Trade in capital goods is an important example. As Eaton and Kortum (2001) document, the production and export of capital goods is concentrated in a small number of research-intensive countries. For example, many countries have airlines that fly wide-bodied aircraft, but much of the technology for producing
Macroeconomists attribute a significant share of income growth to advances in capital equipment, causing its relative price to decline over time. Costless trade would imply the same relative price of capital goods everywhere, allowing all countries to benefit equally from inventions embodied in capital goods.

In fact, trade and price data suggest enormous geographic fragmentation of markets, with poor countries facing a systematically higher relative price of capital. A simple growth model translates differences in the relative price of capital goods to differences in per worker output. If capital has a share $\alpha$ in a Cobb–Douglas production function and depreciates at rate $\delta$, country $i$ with a savings rate $s_i$ will have a steady-state level of output per worker $y_{it}$ given by:

$$y_{it} = \left( \frac{s_i}{\delta + g^K \cdot \left( \frac{P^K_{it}}{P^C_i} \right)} \right)^{\alpha/(1-\alpha)}.$$

Here $P^K_{it}/P^C_i$ is the relative price of capital goods in country $i$ at time $t$ and $g^K$ is the rate at which the price of capital goods declines. With constant iceberg trade barriers, $g^K$ is the same everywhere in the world, but $P^K_{it}/P^C_i$ is lower in countries with better access to capital goods. The formulation is thus consistent with a common world growth rate, but with persistent differences in levels over time.

**Summary**

We have sketched a simple model of trade, diffusion and growth motivated by some basic facts. A body of work has sought to quantify various models of this type. Eaton and Kortum (2007b) review some of this work.

tragedy of the commons

Elinor Ostrom
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

‘The tragedy of the commons’ arises when it is difficult and costly to exclude potential users from common-pool resources that yield finite flows of benefits, as a result of which those resources will be exhausted by rational, utility-maximizing individuals rather than conserved for the benefit of all. Pessimism about the possibility of users voluntarily cooperating to prevent overuse has led to widespread central control of common-pool resources. But such control has itself frequently resulted in resource overuse. In practice, especially where they can communicate, users often develop rules that limit resource use and conserve resources.

Keywords

collective action; common-pool resources; common property; free rider problem; Hardin, G.; open-access resources; private property; social dilemmas; state property; tragedy of the commons

Article

The term ‘the tragedy of the commons’ was first introduced by Garrett Hardin (1968) in an important article in Science. Hardin asked us to envision a pasture ‘open to all’ in which each herder received large benefits from selling his or her own animals while facing only small costs of overgrazing. When the number of animals exceeds the capacity of the pasture, each herder is still motivated to add more animals since the herder receives all of the proceeds from the sale of animals and only a partial share of the cost of overgrazing. Hardin (1968, p. 1244) concluded:

Therein is the tragedy. Each man is locked into a system that compels him to increase his herd without limit – in a world that is limited. Ruin is the destination toward which all men rush, each pursuing his own best interest in a society that believes in the freedom of the commons.
Hardin's article is one of the most cited publications of recent times as well as among the most influential for ecologists and environmental policy researchers. Almost all textbooks on environmental policy cite Hardin's article and discuss the problem that Hardin so graphically identified.

Hardin's article deals in general with a broad class of resources that are referred to in the more technical literature as ‘common-pool resources’. Common-pool resources yield finite flows of benefits (such as firewood, fish and water) where it is difficult and costly to exclude potential users (Ostrom, Gardner and Walker, 1994). Each person's use of a resource system subtracts resource units from the quantity of units available to others, as Hardin so dramatically described. The initial theoretical studies of common-pool resources tended to analyse simple systems. It has frequently been assumed that the resource generates a predictable, finite supply of one type of resource unit (for example, cubic feet of water or tons of fish) in each time period. Users are assumed to be short-term, profit-maximizing actors who have complete information and are homogeneous in terms of their assets, skills, discount rates and cultural views. In this theory, anyone can enter a resource and take resource units.

Hardin thought of users as being trapped in this situation – largely because he did not envision that users could self-organize and devise institutions to extract themselves from tragic overuse. In the conventional textbook theory (Clark, 1976), scholars have tended to agree with Hardin that the users could not extract themselves from this situation. Organizing so as to create rules that specify who is an authorized user and the rights and duties of authorized users creates a public good for those involved. All users benefit from this public good, whether they contribute or not (Olson, 1965). Thus, getting ‘out of the trap’ is itself a second-level dilemma. Since much of the initial problem exists because the individuals are in a dilemma whereby they impose negative externalities on one another, it is not consistent with the conventional theory that individuals can solve a second-level dilemma when they are already predicted to be unable to solve the initial social dilemma. Thus, extensive free-riding is predicted in most efforts to self-organize and govern a resource as a community of users.

Because of these predictions and because many open-access resources have indeed resulted in tragic levels of overuse and sometimes destruction, many scholars and public officials have relied upon the conventional analysis to justify the need for centralized control of all common-pool resources. National legislation has been passed in many countries, and administrative responsibilities for managing natural resources have been turned over to centralized agencies. Unfortunately, the results of many of these efforts have been the opposite of what was hoped. Evidence has now been amassed that central regulation has frequently accelerated resource deterioration, complicated by several problems of corruption and inefficiency. In-depth case analyses have documented the accelerated overharvesting of forests that occurred after national governments declared themselves to be the owners of forested land (National Research Council, 1986; Ascher, 1995). Similar problems have occurred with inshore fisheries when national agencies presumed that they had exclusive jurisdiction over all coastal waters (Finlayson and McCay, 1998).

Policy analysts tend to look for certainty and want to know whether the tragedy of the commons theory is either right or wrong. A more productive approach is to ask under what conditions it is correct and when it makes the wrong predictions. In settings where there is a large group, no one communicates, and where no rights to the resource exist, Hardin's theory is supported by considerable evidence. There are many settings in the world where the tragedy of the commons has occurred and continues to occur – ocean fisheries and the atmosphere being the most obvious.
Contrary to the conventional theory, however, multiple studies have demonstrated that users have overcome social dilemmas to craft institutions to govern their own resources (National Research Council, 1986; 2002; McCay and Acheson, 1987; Ostrom, 1990; 2005). The possibility, however, that the users would find ways to organize themselves was not mentioned in basic economic textbooks on environmental problems until recently (compare Clark, 1976, with Hackett, 1998). The design principles that characterize robust, long-lasting, institutional arrangements for the governance of common-pool resources have been identified (Ostrom, 1990) and supported by further testing (Guillet, 1992; Morrow and Hull, 1996; Weinstein, 2000).

A recent National Research Council (2002) report provides an excellent overview of the substantial research showing that many common-pool resources are governed successfully by non-state provision units and that some government and private arrangements also succeed. No simple governance system has been shown to be successful in all settings (Dietz, Ostrom and Stern, 2003). Many of the robust resource governance systems documented in the above-cited research do not resemble the textbook versions of either a government or a strictly private for-profit firm, especially when participants have constituted self-governing units. Scholars who draw on traditional conceptions of ‘the market’ and ‘the state’ have not recognized these self-organized systems as potentially viable forms of organization and have either called for their removal or ignored their existence. It is paradoxical that many vibrant, self-governed institutions have been wrongly classified or ignored in an era that many observers consider to be one of ever greater democratization.

Careful laboratory experiments have also shown that when a group of individuals are given unrestricted access to harvest from a common-pool resource, they substantially overuse it. What is rather striking is that in the laboratory using exactly the same parameters, but changing only one variable, namely, the capacity to communicate with one another, individuals can come to agreements and keep them to harvest very close to an optimal level (Ostrom, Gardner and Walker, 1994). This result has been replicated many times (see, for example, Casari and Plott, 2003).

Thus, Hardin opened a discourse on a fascinating and difficult puzzle of why individuals in some settings can overcome the threat to long-term sustainable use of a resource whereas other resources are so threatened. Scholars from multiple disciplines have wrestled with this question for several decades, including the creation of the International Association for the Study of Common Property (IASCP), the Scientific Committee on Problems of the Environment (SCOPE) (see Burger et al., 2001), considerable research in the field and in the experimental laboratory, and the development of sophisticated agent-based models of human-environmental relationships (Janssen, 2003).

In the decades since Hardin's article appeared, we have learned that the type of resource must be analysed separately from the type of property arrangement. Common-pool resources exist wherever natural resources or human-made facilities exist and where excluding users is costly and consumption by some subtracts from the benefits available to others. Many types of property arrangements exist in relationship to these kinds of resources, including government ownership, private property and common property. Hardin incorrectly presumed that most common-pool resources were open-access resources where property rights had not been well-defined.

It is now known that the users of a common-pool resource will:

- expend considerable time and energy devising workable institutions for governing
and managing common-pool resources;
follow costly rules so long as they believe that others also follow these rules;
monitor each other's conformity with these rules; and
impose sanctions on each other at a cost to themselves.

The likelihood that resource users themselves will develop effective institutions for regulating the use of common-pool resources is increased by the following factors:

- low discount rates (most resource users have secure tenure, and plan on using the resource for a long time into the future);
- homogeneous interests (most resource users share similar technologies, skills, and cultural views of the resource);
- the cost of communication among individuals is low; and
- the cost of reaching binding and enforceable agreements is relatively low.

Thus, in field settings where there are relatively small- to moderate-sized groups, and where there is autonomy to make their own agreements and authority to do so, many user groups have self-organized to extract themselves from the tragedy.

Large groups have more difficulty governing common-pool resources, but usually because size is negatively associated with the factors listed above. In relatively homogeneous groups in which mechanisms exist for reaching binding agreements on methods of government and management resource use, even quite large groups are able to arrive at effective rules to limit the use of their resource. Further, when large groups are composed of smaller groups that focus on specific parts of a larger problem, such as how to regulate water distribution on a branch of an irrigation canal, smaller groups can be clustered into ever larger aggregations that may be able to address problems that affect all participants.

One of the key findings of empirical field research on collective action and common-pool resources is the multiplicity of specific rules-in-use found in successful common-pool resource regimes around the world. One of the most important types of rules is boundary rules, which determine who has rights and responsibilities and what territory is covered by a particular governance unit. Many different boundary rules are used successfully to control common-pool resources around the world, but an important aspect of these rules is the match between the organization of users and the resource rather than the specific rule used. The 35th anniversary of the publication of Hardin's original article was celebrated with a special issue of Science (Dietz, Ostrom and Stern, 2003), demonstrating that all forms of ownership could succeed or fail and that more critical than the form of ownership was the establishment of legitimate and agreed-upon boundaries that were effectively enforced.

Some governance units face considerable biophysical constraints in dealing with a natural common-pool resource such as a groundwater basin, a river or an air shed. Such resources have their own geographic boundaries, and creating a match between the boundary of those who are authorized users and the resource itself is a challenge. On the other hand, the biophysical world does not have as strong an impact on the efficacy of using diverse boundaries for governing and managing forest resources. More important is the agreement of those involved about who is to be included and the appropriate physical boundaries. Rules specifying duties as well as rules for sharing benefits are also crucial. No resource system functions well over time if all that users do is harvest from it with no investment to increase the
Tragedy of the commons: The New Palgrave Dictionary of Economics

productivity of the resource itself. Once basic rules – defining who is a legitimate beneficiary, who must contribute to the maintenance of the resource, and the actions that must or may be taken or are forbidden – have been accepted as legitimate by the users, many users will follow rules so long as they believe others are doing so.

Another lesson learned is that any effort to develop new rules for governing and managing complex resources is likely to generate unexpected results and be subject to initial errors. Thus, all technological and institutional interventions need to be approached as an adaptive process that helps generate information about errors so that those involved and others can learn from errors rather than continue to make them. No panaceas exist. Wholesale solutions imposed on many different resources in a large terrain are more likely to be ineffective than efforts that enhance the institutional environment that encourages responsible self-governance, self-monitoring, and self-enforcement. Thus, a modified theory of the commons is slowly evolving that has identified the factors that are repeatedly mentioned in empirical studies of diverse common-pool resources.

The basic insight that underlies the transaction cost concept is probably as old as human reflection on economic issues itself, it became associated in the 19th century with the notion of economic friction, which was subsequently expressed as a cost. Historically, the transaction cost concept has developed from narrow interpretations typical of the monetary and general equilibrium literature towards relational interpretations, based on particular market microstructural models of how economic agents interact with each other, and finally with institutional interpretations embracing a more general analysis of economic institutions, including market and non-market forms of coordination.

Article

As a concept, transaction costs are used in numerous ways in economics, from simply referring to the fees charged by a financial broker to a much broader concept encompassing the comparative efficiency of alternative modes of resource allocation and economic coordination.

At the most general level, transaction costs are the costs that arise beyond the point of production of a good to effect its allocation. From there on, the literature is fragmented regarding the various facets of the concept. The distinction between production and allocation may not be meaningful in all instances. Transaction costs may or may not include transport costs, may or may not refer only to market exchange, may or may not be reduced to a single alternative category such as information costs or the...
cost of time. Some authors measure transaction costs in monetary terms, others as departures from first-best outcomes, or just on the basis of qualitative comparative rankings of feasible institutional alternatives. Indeed, whether transaction costs should be regarded as costs at all has been subject to controversy, too. Hence, the term can be and has been applied in virtually every conceivable economic and social scientific context. Its wide diffusion has been attributed to the systematic ambiguity inherent in its unqualified application (Klaes, 2001), and its usefulness for serious analysis has been questioned on these grounds (for example, Dixit, 1996, p. 35).

Although often used as a catch-all expression, thinking in transaction cost terms has nevertheless yielded a rich array of models and analytical frameworks that have helped redefine how economists look at economic exchange and coordination. Circumspect definition specific to the particular context in which one seeks to use the concept should help to avoid semantic pitfalls. Furthermore, not only are systematically ambiguous notions common in economics (Clower, 1995), they actually serve a distinct and valuable purpose in the coordination of research (Klaes, 2006). A sceptical stance towards the aggregate ambiguity of the transaction cost concept does thus not necessarily amount to a criticism of particular applications of the term, although a certain tendency can be observed outside of what has become known as a ‘new’ institutional economics (see below) towards alternative expressions such as ‘friction’ (for example, Luttmer, 1996) or ‘link costs’ (for example, Kranton and Minehart, 2001, p. 492).

**Monetary, relational and institutional interpretations**

The various interpretations of the transaction cost concept have traditionally been classified into two general categories, juxtaposing a narrow interpretation typically associated and compatible with a ‘neoclassical’ tradition, and a broader and more institutionally minded interpretation, located in the theory of the firm and the economics of property rights, and calling for more or less radical revisions of this tradition (Coase, 1972; cf. Dahlman, 1979; Allen, 2000). While careful analysis allows one to distinguish between more than two categorically different kinds of transaction cost, the range of extant applications of the concept is best thought of as forming a spectrum of broadening scope: (a) narrow interpretations typical of the monetary and general equilibrium literature; (b) relational interpretations that are based on particular market micro-structural conceptions or models of how economic agents interact with each other beyond the traditional economic dimensions of price and quantity signals; (c) institutional interpretations, which formulate transaction costs as part of a more general analysis of economic institutions, including market and non-market forms of coordination. Institutional interpretations of transaction costs are the result of applying relational interpretations of transaction costs – originally defined on the basis of exchange within markets – to non-market settings such as networks, firms or clans, with the aim of expressing the comparative economic performance of alternative institutional solutions to the coordination problem in transaction cost terms.

In monetary conceptions, transaction costs are the direct costs that an economic agent incurs when engaging in a market transaction, if we leave most or all of the microstructural details of the exchange context unspecified. At the most basic level, these costs are expressed as a reduction in the value of a transaction, technically equivalent to a transaction tax. In more developed interpretations of monetary transaction costs, these costs are conceptualized as the direct monetary costs incurred when engaging in a particular market transaction, resulting from the use of intermediary and adjunct services (brokerage,
Relational transaction cost interpretations rely on a more explicit conceptualization than monetary transaction cost interpretations of how economic agents interact with one another when they engage in market exchange. To some extent, one may subsume economic contract theory under this part of the transaction cost literature, although explicit transaction cost conceptions as such play at best a subordinate role in those approaches (for example, Grossman and Hart, 1986; Holmstrom and Milgrom, 1994).

A relational interpretation of transaction costs has played a more pronounced role in Coase's (1937; 1960) contributions to the theory of the firm and the economics of property rights. While he himself referred to ‘marketing costs’ or the ‘costs of market transactions’ in those seminal papers and did not embrace the term ‘transaction costs’ until relatively late (Coase, 1974, p. 494), his approach to defining these costs heavily influenced the conceptualization of transaction costs in what has become known as a ‘new’ institutional economics (Eggertsson, 1990; Furubotn and Richter, 2005; Ménard and Shirley, 2005), a movement best thought of as part of a renewed interest in the institutionalist traditions in economics during the last decades of the 20th century (Rutherford, 1994). Faced with the considerable theoretical challenge of providing a comprehensive micro-structural theory of exchange, a frequent strategy in this literature has been to follow Coase in decomposing relational transaction costs heuristically according to the different steps involved in concluding a market transaction. While classifications of individual authors differ, most heuristics can be accommodated within a framework that distinguishes between: (a) the costs of locating and attracting potential trading partners and of pre-sale inspection; (b) contracting and fulfilment costs; (c) policing and enforcement costs.

In most instances, relational conceptions of transaction costs still proceed from a contractual (in the legal sense) and therefore market-based understanding of ‘transaction’. Institutional interpretations, by contrast, further broadened the scope of the transaction cost notion by applying it not just to contractual settings but also to alternative forms of economic coordination. The distinguishing characteristic of this third interpretation of transaction costs is not the comparative character of the underlying analysis, since both monetary and relational conceptions allow comparative assessments of alternative solutions to a given coordination problem. Rather, the difference results from the endeavour of applying Coase's ‘marketing’ costs to non-market settings, comparing market coordination alongside non-market forms within a given array of alternative institutional forms. However they are defined on the micro-structural level, once they are institutionally interpreted transaction costs therefore reflect the costs of economic coordination more generally.

Some economists regard the transaction cost concept as inseparably wedded to a framework of analysis that attempts to reduce institutional features of the economy to the core neoclassical notion of cost, thereby failing to develop conceptual tools more attuned to the complexities of economic institutions. In the eyes of these critics, building an analysis of the institutional features of economic coordination on a concept that invites its own minimization undermines the very starting point of any seriously institutional approach to economics, since a world of zero transaction costs would constitute an institutional void. In other words, one may argue that an important aspect of transaction costs is their reflection of investment in institutional capital. In a way, this point mirrors the various critiques of reducing labour to an economic cost. It has had limited impact on those who have sought to reform and expand economic analysis in the name of the economics of property rights, the field of law and
transaction costs, history of: The New Palgrave Dictionary of Economics

economics, transaction cost economics, the theory of the firm, the economics of organization, and the study of long-term economic change (see Coase, 1988; Williamson, 2000; Alchian, 1991; Demsetz, 1988; North, 1990; Langlois, 2002).

Origins

The basic insight that underlies the transaction cost concept, which one finds embodied in pre-historical emergence of generally accepted media of exchange, is probably as old as human reflection on economic issues itself. It is thus not difficult to identify numerous precursors to the notion of transaction costs as one finds it presently developed in the economic literature, in particular in its monetary branches. When Aristotle (1932, pp. 13–14) wrote on the origin of money for example, he observed that once villages grew and combined into city-states they would require a medium of exchange that was portable and easy to handle. He also noted that impressing a stamp on a piece of metal would help avoiding repeat measurement of its embodied value. Aristotle’s insights have been reiterated time and again whenever subsequent economic writers discussed the origin of money. Crucial steps for the further entrenchment of the concept were the depiction of the various impediments to exchange as an economic cost, followed by the crystallization of the term ‘transaction(s) costs’ itself (probably Scitovsky, 1940, p. 307; cf. Hardt, 2006), which entered the economic literature from the financial markets where it was in popular usage in the 1930s (anon., 1936). Towards the end of the 19th century, economists tended to address the impediments to exchange as ‘frictions’ in the economic system (cf. Davidson, 1896). On the metaphorical level, this interpretation resulted from a general post-Enlightenment tendency to look at the economic system in mechanistic terms, illustrated by recurring metaphors such as Hume's (1752, II, iii, 1) ‘wheels of trade’ or Mill's (1848, III, xxvi, 1) ‘machinery of exchange’. One should not discount the economic cost of the physical friction that a medium of exchange is exposed to either (Say, 1803, I.XXI.xi, 1–3).

A prominent early attempt to describe economic friction as a cost can be found in Menger (1871, pp. 170–1), who notes that every transaction requires economic sacrifices. At the very minimum, these consist of a loss of time, but may also include transport and storage costs, sales costs, taxes, commissions, communication costs, and more generally all the costs associated with intermediaries and the monetary system. While clearly describing these various sacrifices in opportunity-cost terms, Menger does not address them explicitly as a cost and he refers to them merely to define the boundary conditions of the validity of his theory of exchange. It was not until Marx's (1893, pp. 123–46) analysis of Zirkulationskosten, as the ‘costs of circulation’ that result from the continuous exchange of money into goods and back into money again, that one finds an extended conceptual analysis of the costs associated with exchange. Marx regarded these costs as ‘faux frais’, costs which are necessary to sustain the circulation of capital but are nevertheless unproductive in that they do not contribute to the creation of value. ‘Pure circulation costs’, the most important component of circulation cost, refers to bargaining costs, accounting costs, and, following in Say's footsteps, the costs resulting from the wear and tear of the medium of exchange. One may note in passing that Marx's discussion of the costs of exchange in terms of the classical notion of unproductive labour provides one of the most immediate links between classical political economy and modern
transaction costs, history of: The New Palgrave Dictionary of Economics

debates on, for example, the relationship between production, transaction costs, and the question whether the latter are best regarded as a cost in the first instance (for example, Barzel, 1985; Goldberg, 1985).

Conceptual development

In the 1930s, a number of authors explored the implications of ‘selling’ or ‘marketing’ costs as part of the growing literature on advertising, monopolistic competition and the theory of the firm (Braithwaite, 1928; Chamberlin, 1933; Coase, 1937). While the theory of the firm experienced a strong revival three decades later within the emerging new institutional economics (Malmgren, 1961; Cheung, 1969; Williamson, 1970; Alchian and Demsetz, 1972), it was Hicks's (1935) explanation of the holding of cash balances on the basis of the costs one incurs when converting assets into cash (Klaes, 2000) that provided the strongest immediate impetus to the coining and further differentiation of ‘transaction costs’, notably via the post-war neo-Keynesian literature, its inventory approach to the transactions demand for money, and the general question of cash balances in general equilibrium theory (Makower and Marschak, 1938; Marschak, 1950; Baumol, 1952; Tobin, 1956; Patinkin, 1965; Foley, 1970; cf. Ulph and Ulph, 1975).

The monetary economics literature proceeded largely on the basis of a narrow price-based understanding of transaction costs, although comparative issues that pointed towards broader interpretations became a pressing technical concern in its mature phase (for example, Hahn, 1973). Arrow (1965; 1969) provided a crucial conceptual link between the general equilibrium literature on transaction costs and the emerging literature in the new institutional economics by moving from a monetary to a comparative institutional interpretation of transaction costs. By contrast, the economics of property rights and the emerging field of law and economics developed an increasing variety of relational transaction cost interpretations, typically expressed in contractual terms (Coase, 1960; Alchian, 1965; Demsetz, 1967; Calabresi, 1968; Posner, 1972; Macneil, 1981). The overall thrust of the new institutional economics, notably in economic history (Davis and North, 1970; North, 1985) and through the formulation of a ‘transaction cost economics’ by Williamson (1975; 1985), has, however, been the spelling out of the details of a comprehensive institutional analysis of institutional arrangements on the basis of comparative institutional interpretations of transaction costs (see also Aoki, 2001; Langlois, 2002; Greif, 2006).

Empirical studies, even on the basis of monetary transaction costs, which one might have expected to be more amenable to direct measurement than broader interpretations, have displayed considerable divergence regarding the level of observed transaction costs. Once one moves beyond narrow monetary transaction cost conceptions, for example to account for observed bid–ask spreads or for violations of the law of one price, one is forced to delimit those dimensions of transaction costs that are not empirically accessible as such and have therefore to be inferred indirectly. In the absence of a commonly agreed empirical definition of transaction costs this will inevitably lead to results that are sensitive to the particular definition that one employs (Gould and Galai, 1974; Fama, 1991).

Alternative approaches, largely found in the comparative institutional transaction cost literature, have included attempts to infer macroeconomic transaction costs on the basis of the size of the transaction
sector of an economy (Wallis and North, 1986), or to derive proxy measures for transaction costs on the basis of transaction characteristics such as asset specificity (Williamson, 1991; Nooteboom, 1993). The irony of sectoral measures is that economies with less well-developed transaction sectors appear to exhibit lower levels of transaction costs if those costs are measured in terms of sector size, whereas micro-structurally those economies in fact suffer from higher levels of transaction costs due to significant barriers to smooth exchange and coordination of economic activity. Proxy measures, in turn, are at risk of running into difficulty once they seek to embrace institutional transaction cost interpretations, because they have to proceed on the assumption that transactions can be defined in such a way that there is a core to them that remains unaffected across alternative institutional settings. Once one moves to non-market forms of economic coordination, this may become problematic (Masten, 1996), although the modularity literature has begun addressing this issue (Langlois, 2006).

transfer of technology

Wolfgang Keller

Abstract

This article discusses the transfer of technological knowledge with a focus on firms in different countries. The dominant form of such technology transfer is not market transactions at arm's length but technological learning externalities. The article reviews the evidence for technological learning from importing, exporting, and foreign direct investment activities.

Keywords

asymmetric information; foreign direct investment; foreign direct investment spillovers; growth and international trade; innovation; learning externalities; productivity growth; research and development; technology spillovers; trade costs; transfer of technology

Article

Asymmetric information often makes the buying, selling or licensing of technology unfeasible. Instead, international technology transfer tends to occur through non-market channels. In the United States, for example, the figures on trade in services in the balance of payments are much smaller than estimates on US technological externalities (McNeil and Fraumeni, 2005). These externalities are called technology spillovers.

A good starting point is the model of international technology transfer by Howitt (2000). There are many intermediate good sectors each characterized by its own level of technology. Different countries and sectors employ different technologies based on domestic innovation and technology transfer from abroad. At any given time $t$, the technology frontier, $A^\text{max}$, denotes the highest technology level across all countries and sectors. The technology frontier is growing because innovations worldwide push it out over time. An innovation in a particular sector brings this sector's productivity up to the technology frontier. This means that the model includes international and inter-sectoral technology spillovers, since if there had been many innovations in other countries or sectors, the jump to the technology frontier for
sector \(i\) is larger than if there had been few innovations elsewhere. With productivity in successfully innovating sectors jumping to the frontier level, a country's average productivity across sectors (denoted by \(A_i\)) rises. In Howitt's model, average productivity changes according to

\[
\dot{A}_t = \lambda r_t (A_t^{\text{max}} - A_t),
\]  

(1)

where \(r_t\) is a measure of domestic R&D investment, and \(\lambda > 0\) is a parameter. In (1), the change in \(A_t\) is positively related to domestic R&D, and it is positively related to the average technology gap \((A_t^{\text{max}} - A_t)\). Equation (1) leads to a common long-run growth rate shared by all countries; however, those investing more in R&D will enjoy relatively high productivity levels, all else being equal.

The literature emphasizes that technology transfer is facilitated by firms’ international activity, though to date this has not been comprehensively articulated at the theoretical level. International trade and foreign direct investment have long been discussed as some of the most important channels, and the econometric evidence is discussed in the following (see also Keller, 2004).

First, imports may lead to technology transfer. Coe and Helpman (1995) test the prediction of the trade and growth models of Grossman and Helpman (1991) and Rivera-Batiz and Romer (1991), in which foreign R&D creates new intermediate inputs and perhaps generates spillovers for the home country through importing activity. Output is produced with labour and differentiated capital goods that enter in a constant elasticity of substitution (CES) function. The intermediate product range in each country is expanded through R&D, and countries can benefit from other countries’ R&D by importing foreign-developed intermediate goods. Under certain assumptions, a country’s productivity \(f\) is given by

\[
\ln f = \ln B + \alpha \ln n^e,
\]  

(2)

where \(n^e\) is the range of intermediate goods employed in the country, and \(B > 0\) is a parameter. According to (2), productivity is positively related to the intermediate products range employed in this country. A country's demand for intermediates will depend on bilateral trade barriers and transport costs. Coe and Helpman (1995) distinguish between foreign and domestic products, since trade costs are often very different between these:

\[
\ln f_c = \alpha_c + \beta^d \ln n_c + \beta^f \ln n^f_c + \epsilon_c,
\]
where $n^f_c$ is defined as the bilateral import share weighted R&D of country $c$'s trade partners:

$$ n^f_c = \sum_{c' \neq c} m_{cc'} r^f_{c'}. $$

This captures the prediction that if a country imports primarily from high-R&D countries, it is likely to benefit more from foreign technology than if it imports primarily from low-R&D countries.

While Coe and Helpman (1995) estimate a positive and quantitatively large effect from import-weighted foreign R&D, subsequent work by Keller (1998) shows that this per se cannot be taken as evidence for imports-related international technology transfer. Instead of using data on actual bilateral imports, Keller (1998) conducts robustness checks with two alternative foreign variables based on randomly created shares as well as no shares at all: $\hat{n}^f_c = \sum_{c' \neq c} m_{cc'} r^f_{c'}$ and $\tilde{n}^f_c = \sum_{c' \neq c} r^f_{c'}$. Since these alternative variables yield similar or even stronger results, as in Coe and Helpman (1995), the observed import patterns cannot explain the estimated effects.

By making progress on a number of fronts, further work has produced robust evidence for imports-related technology transfer. First, Xu and Wang (1999) and Keller (2000) note that as a matter of theory, foreign technology spillovers are the result of capital goods trade, and not aggregate trade, which Coe and Helpman (1995) use to construct their import shares. Xu and Wang (1999) show that if the foreign variable $n^f_c$ is based on bilateral capital goods trade shares, it performs better than both Coe and Helpman's (1995) original and Keller's (1998) alternative variables. Moreover, since most R&D is conducted in a relatively small part of manufacturing, imports-related technology transfer effects are relatively difficult to estimate with country-level data, as in Coe and Helpman; in a study among Organisation for Economic Co-operation and Development (OECD) countries at the two- and three-digit industry level, Keller (2002) finds robust evidence that imports are a channel for international technology transfer.

Second, the major question regarding exports is whether firms learn about foreign technology through exporting experience. There is abundant evidence that in a given cross-section exporters are on average more productive than non-exporters (Bernard and Jensen, 1999). This does not address the question whether exporting firms become more productive because of learning effects associated with exporting, or whether firms that are more productive to begin with export more. According to much anecdotal evidence, firms do benefit from interacting with the foreign customer, for instance because the latter imposes higher product quality standards than the domestic customer, while at the same time providing information on how to meet the higher standards. The econometric evidence is more mixed, however. While learning-by-exporting has been emphasized primarily for low- and middle-income countries’ firms, there is in principle no reason why it is limited to these countries. Bernard and Jensen (1999) analyse learning-by-exporting using data on US firms. In studying the performance of four different sets of firms – exporters, non-exporters, starters and quitters – separately, Bernard and Jensen (1999) do not model export market participation explicitly. They find that labour productivity growth is about 0.8 per
cent higher among exporters than non-exporters. This estimate is fairly small, and it becomes even smaller (and insignificant) for longer time horizons. At the same time, this is conditional on plant survival. Bernard and Jensen also show that exporters are ten per cent more likely to survive than non-exporters. This difference is indicative of higher productivity growth for exporters than non-exporters, because low productivity growth is the primary reason for plants failing. Thus, there may be learning-from-exporting effects that amount to more than 0.8 per cent, although it is not clear whether they are substantial.

The paper by Clerides, Lach and Tybout (1998) provides evidence on learning externalities from exporting using micro data from Columbia, Morocco and Mexico. By estimating simultaneously a dynamic discrete choice equation that determines export market participation, these authors take into account the consideration that it is on average the already-productive firms that self-select into the export market. The export market participation decision is given by

\[
y_{it} = \begin{cases} 
1 & \text{if } 0 \leq \beta^{X}X_{it} + \beta^{e}e_{it} + \sum_{j=1}^{J} \beta^{j}_{j} \ln(AVC_{it-j}) \\
& + \sum_{j=1}^{J} (F^{0} - F^{j}) y_{it-j} + \eta_{it} \\
0 & \text{otherwise,} 
\end{cases} 
\]  

(4)

and any learning from exporting effects are uncovered by simultaneously estimating an autoregressive cost function

\[
\ln(AVC_{it}) = \gamma_{0} + \sum_{j=1}^{J} \gamma^{k}_{j} \ln(K_{it-j}) + \gamma^{e} \ln(e_{t}) + \sum_{j=1}^{J} \gamma^{c}_{j} \ln(AVC_{it-j}) + \sum_{j=1}^{J} \gamma^{y}_{j} y_{it-j} + \epsilon_{it} 
\]  

(5)

In eq. (4), \( y_{it} \) is the export indicator of plant \( i \) in period \( t \), \( X_{it} \) is a vector of exogenous plant characteristics, \( e_{t} \) is the exchange rate, \( AVC_{it} \) are average costs, \( K_{it} \) is capital, and \( F^{0} \) and \( F^{j} \) are sunk costs of export market participation.

Equation (4) states that one only sees a plant exporting if the profits from doing so are greater than from not exporting (the latent threshold is expressed in terms of observables). Equation (5) asks whether past exporting experience reduces current cost (captured by the parameters \( \gamma^{y}_{j} \), conditional on past costs and
size (proxied by capital). Clerides, Lach and Tybout (1998) show results for the three countries separately, and also by major industry, using maximum likelihood (MLE) and generalized method of moments (GMM) methods. These estimations show no significant positive effects from past exporting experience on current cost. These authors’ descriptive plots of average cost before and after export market entry support this conclusion. Thus, exporting does not facilitate technology transfer. According to the Clerides, Lach and Tybout’s (1998) analysis, exporters are more productive, but that is because they self-select themselves into the export market.

Using similar methods, van Biesebroeck (2005) has revisited the issue by studying productivity dynamics of firms in nine African countries. In contrast to Clerides, Lach and Tybout, he estimates that the firm starting to export boosts productivity by about 25 per cent on average in his sample. Van Biesebroeck (2005) also estimates that the higher productivity growth of exporters versus non-exporters is sustained. By employing instrumental-variable and semi-parametric techniques as alternative ways to deal with the selection issue, Van Biesebroeck’s analysis is more comprehensive than most. His analysis generally supports the notion that exporting leads to the transfer of technological knowledge. In trying to reconcile his findings with some of the earlier results, Van Biesebroeck shows that part of the difference in productivity growth between exporters and non-exporters appears to be due to unexploited scale economies for the latter. This suggests that at least in part his results are due to constraints imposed by demand, and not due to technology transfer in the sense of an outward shift of the production possibility frontier at all levels of production. We need richer data to make further progress on distinguishing these hypotheses.

Third, foreign direct investment (FDI) has long been considered as an important channel for technology transfer. Among the possible mechanisms are knowledge spillovers, labour turnover, linkages, and advanced specialized inputs. Also, multinational companies are well known to be more productive and do more R&D than purely domestic firms, so they are likely sources for such productivity benefits. Moreover, governments all over the world spend large amounts of resources to attract affiliates of multinationals to their jurisdiction. If this is rational economic policy, there ought to be large technology transfers associated with FDI.

Numerous studies have estimated FDI spillovers since 1970. Recently, authors focus on panel data analysis with micro data, since this reduces problems resulting from unobserved heterogeneity across firms and sectors. Typically, a general relationship between productivity growth of domestically owned firms ($\Delta f$) and a measure of the change in inward FDI ($\Delta F$) is specified in order to uncover evidence for FDI spillovers:

$$\Delta f_{ist} = \beta X' + \gamma \Delta F_{ist} + u_{ist},$$

Here, $X$ is a vector of control variables, $u$ is a regression error, and $i$, $s$ and $t$ are firm, industry and time subscripts, respectively. The spillover parameter $\gamma$ is estimated positive if productivity growth of firms in industries that have experienced large increases in FDI exceeds that of firms in industries where FDI
has grown little. Until about 2002, many authors concluded, by and large, that there is no evidence for FDI spillovers. This is also reflected in a number of surveys (Lipsey and Sjöholm, 2005; Görg and Greenaway, 2004; Hanson, 2001). The paper by Aitken and Harrison (1999) even estimates a negative relationship between FDI and productivity for a sample of Venezuelan plants. Since technology learning spillovers can hardly be negative, the analysis probably picks up something else. One possibility, first suggested by Aitken and Harrison (1999), is that the negative coefficient is due to increased competition for local plants through foreign entry. Alternatively, it could be due to endogeneity, if FDI flows to sectors in which firms are relatively weak.

The paucity of evidence has led some to look elsewhere: if there are no spillovers to domestic firms in the same industry, perhaps they exist for domestic suppliers of multinational firms? Contractual relations between foreign-owned affiliates and their domestic suppliers suggest that the technology transfer could, in principle, be specified and paid for – in which case these are not externalities. However, there could be learning effects on top of this. The paper by Smarzynska Javorcik (2004) finds evidence consistent with vertical spillovers between firms in different industries in Lithuania, but no within-industry spillovers.

Haskel, Pereira and Slaughter (2002) and Keller and Yeaple (2003) have returned to the original question of spillovers from FDI in a given industry. The former estimate an equation like (6) for FDI into the United Kingdom, and the latter for FDI into the United States. Haskel, Pereira and Slaughter (2002) estimate positive spillovers, which, however, are relatively small, as the authors note. More importantly, these authors, as is the case for Smarzynska Javorcik (2004), do not fully address the possibility that FDI inflows may be endogenous.

The first paper to show that multinationals can cause economically large productivity benefits to domestically owned firms is Keller and Yeaple (2003). These authors deal with endogeneity concerns using instrumental variable techniques, and they employ the by now well-known Olley and Pakes (1996) method of computing firm productivity. The resulting estimates imply an influence of FDI on productivity growth that is much larger than in existing studies. Using data on about 1,300 US manufacturing firms for the years 1987–96, they estimate that FDI spillovers explain about 11 per cent of productivity growth during this time.

Keller and Yeaple (2003) also reconcile their results with earlier studies that have found no evidence for FDI spillovers. For one, FDI spillovers are heterogeneous, with much stronger effects in the relatively high-technology industries. Secondly, large FDI spillovers are estimated only with the high-quality data on FDI by industry they employ. If, instead, Keller and Yeaple (2003) use FDI data similar to that more commonly available in other studies, they too estimate only a small or zero effect.

Thus, in contrast to the earlier literature, the most recent micro productivity studies tend to estimate positive, and in some cases also economically large spillovers associated with FDI. As one would expect, the effects are heterogeneous across industries, with stronger effects in relatively high-tech industries. It is not clear yet whether strong FDI spillovers occur only in relatively rich but not in relatively poor countries. Another of Keller and Yeaple's findings, that relatively weak firms benefit more from FDI than stronger firms, suggests that FDI spillovers are not limited to rich countries, where firm productivity tends to be relatively high.

To conclude, recent experience with research on the channels of technology transfer in all three areas,
imports, exports and FDI, clearly shows that it is crucial to have access to detailed information or at least proxy variables on the technology being transferred. Given that much of technology transfer is associated with externalities, this may be the single most important issue that future work needs to address.

transfer pricing

Jack M. Mintz
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Governments establish tax rules for setting transfer prices for non-arm's length transactions made by multinationals, following guidelines established by the OECD (1995) under Article 9 of the OECD Model Tax Convention. Various methodologies have been established; the first preference is determining comparable uncontrolled prices according to the arm's length principle. Given the difficulties of achieving comparable transactions in determining price, margins or profitability, other methods, such as allocating profits among members of a corporate group according to a formula, have instead been relied upon for multi-jurisdictional corporate income taxation in some circumstances.

Keywords

arm's length prices; capital intensity; comparable uncontrolled price; competent authority; cost-plus margin; double taxation; formulary apportionment; resale-minus margin; tax treaties; transactional net margin method; transfer pricing

Article

Transfer prices are established for goods and services sold between related parties among members of a multinational group. With the growth of cross-border transactions by multinational businesses, tax authorities increasingly deal with issues related to the proper assessment of transfer prices to measure corporate income, since multinationals may use transfer prices to reduce worldwide payment of taxes by shifting income from high-tax to low-tax jurisdictions. For example, by charging a high price for goods sold to an affiliate purchaser in a high-tax country, the purchaser's reported profits are reduced while higher profits are reported by the vendor affiliate in the low-tax country. The taxes saved by reporting higher costs in the high-tax country are in excess of the additional tax paid on extra income earned in the low-tax country. Similarly, reporting a lower price on goods sold by a company operating in a high-tax jurisdiction to related parties’ purchasers located in
Legal framework of transfer pricing

Governments enact legislation to assess profits earned by multinational companies operating in their jurisdiction based on the “arm’s length principle”, which is a price that would be charged by unrelated businesses undertaking a transaction under similar facts and circumstances. As a basis for national legislation, assessment and adjudication, legislation may draw from the guidelines established by the Organisation for Economic Co-operation (1995) for transfer pricing. Each government is ultimately responsible for the development of its tax policy and process, and many require companies to document contemporaneously their pricing methodologies when determining their taxable profits in a jurisdiction. When a multinational is reassessed by a country for its transfer prices, it could be faced with double taxation of income if other countries choose a different transfer pricing methodology or disagree on the quantum of the inter-company transaction. Many governments have entered into tax treaties that allow corporations to seek an alternative process for double taxation relief (competent authority). In many countries, when taxpayers enter the competent authority programme for double taxation relief they may be obliged to give up their right of appeal and access to tax courts through domestic channels.

Economic value of transfer prices

Even without taxation, transfer prices would be set by multinationals with the objective to improve business performance by efficiently allocating resources amongst the various competing segments of a firm’s value chain, and to appropriately reward employees and shareholders of the multinational group. The pricing strategy could therefore distort resource allocation decisions and profits along with determining managerial compensation or the amount of income earned by minority shareholders owning shares in the parent company or affiliates. To help align the interests of the managers with shareholders to maximize shareholder value and to protect the interests of minority shareholders, transfer prices may be set to reflect market conditions, including a reasonable approximation of the arm’s length price that would be established between two unrelated parties. Some multinationals have kept two sets of books – one for accounting and another for tax purposes – so that control can be separated from tax motives for establishing transfer prices.

Determining the appropriate price for transfer prices is not an easy task, since prices of comparable transactions can be difficult to obtain. Many transactions involve intangible assets and intellectual property related to research and development, marketing and trademarks, which may be unique to a specific firm and embedded and intertwined with service and tangible goods transfers. Risks also need to be compensated through pricing. Costs are influenced by the size of the transaction and market conditions, including the degree of competitiveness, and regulations and consumer preferences and factor endowments also affect pricing. Finding comparable prices is a difficult matter at best, so it is not uncommon for tax authorities to challenge the transfer price methodology used by multinational companies in assessing taxable income earned in a jurisdiction.

Methods for determining transfer prices
Countries have generally agreed upon a ranking of methodologies to determine transfer prices using the OECD guidelines (1995) although the United States has adopted a ‘best method’ approach that allows taxpayers to select the most appropriate method. The OECD guidelines identified three transactional and two profit-based methods. The transactional methods include the comparable uncontrolled price method (CUP), the resale-minus price method (RPM), and the cost-plus method (CPLM). The two profit based methods are the profit splits method (PSM) and the transactional-net-margin method (TNMM). The CUP method as observed on transactions between unrelated parties is viewed as the most appropriate methodology for measuring transfer prices for non-arm’s length transactions made among members of the multinational group. However, to employ a CUP, corporations must show that the transaction that they have chosen has similar terms and conditions to those of a related-party transaction including quality and reliability, availability of volume of supply, provision of services, licensing, type and characteristics of property (patent, trademark or know-how), functions undertaken by the enterprise, business strategies, risks and market conditions. It may be quite difficult to find CUPs that can be adjusted to reflect all potential differences. Therefore, other methodologies might be used instead.

Two other transactional-based methods include the resale-minus and cost-plus approach. The resale-minus method is typically used for distribution companies in that an inter-company price is determined by subtracting a gross profit margin from the product's resale price. An alternative method is the cost-plus method, which would be appropriate for a manufacturer to consider. A profit margin would be added to manufacturing and other costs to determine the cost-plus margin on goods and services sold from one affiliate to another in the multinational group.

With both the resale-minus and cost-plus approach, the multinational's margin on related party sales or costs can be compared with similar transactions made between unrelated parties. However, as with the CUP methodology, care must be taken to put transactions on a comparable basis. For example, companies might have different capital–labour ratios in producing goods and services. Therefore, it would not be surprising if resale-minus or cost-plus margins, reflecting the ratio of profits to costs, tend to be higher for companies relying on capital-intensive techniques of production. For comparability, an adjustment for capital intensity would be needed.

Given that corporate income is a payment made to shareholders after the deduction of borrowing costs, profit-based methods are used as an approach when it is not appropriate to use transactional approaches. The split-profit method would result in a transfer price for a transactions where both parties to a transaction own valuable and significant intangible assets. The transactional net margin method (TNMM) determines the price of an inter-company transfer of goods and services by comparing an associate affiliate's operating profits, in relation to an appropriate base (sales, costs or assets for example), to profits earned by uncontrolled firms. To establish comparability, adjustments are needed for differences in the age of capital (in part due to the distorting impact of inflation on profits) and risk.

**Economic aspects of transfer pricing**

When businesses choose transfer prices that vary from the ‘true’ price, they trade off the benefits of tax reduction with non-tax costs, including distorting managerial behaviour or greater expected cost of reassessment by tax authorities (Haufler, 2001). Thus, the greater the tax savings from shifting income
Transfer pricing: The New Palgrave Dictionary of Economics

from high to low transactions, the more the transfer prices will be distorted for tax purposes. Governments may counteract transfer pricing by cutting corporate income tax rates or pursuing more aggressively transfer pricing practices of multinationals through the legal process. With tighter transfer pricing, companies find that other income-shifting approaches for reducing worldwide taxes can be simpler, such as shifting debt, leasing, insurance, licensing and other deductible expenses to high-tax countries with income report by affiliates operating in tax havens. Transfer pricing litigation may result if the interest rates, fees and royalties charged are not justified at market rates.

Allocation or apportionment methods as a substitute

Given the constraints in assessing comparable prices, margins and profits, tax authorities will sometimes rely on other approaches to assessing corporation taxes rather than assess transfer prices to determine accounting income earned in a country. One approach is to assess a share of the worldwide income earned by a multinational group that would be allocated or apportioned to a specific jurisdiction (formulary apportionment). The share of profits apportioned to a jurisdiction could be based on one or several factors, including payroll, capital and sales as a portion of worldwide amounts. The allocation or apportionment method (Martens-Weiner, 2006) is used in some federal states, including Canada, Switzerland and the United States, to avoid the necessity of determining accounting profits using the transaction approach under separate accounting. It is also used by California to assess its corporate income tax on multinationals operating in the state (Californian income is assessed by multiplying the tax rate by income, which is a percentage of worldwide income; the percentage is determined by a formula). Some experts have advocated the use of the apportionment method at the international level. At the present time, in 2007, member states of the European Union have been debating proposals to consolidate corporate income tax bases with an apportionment method that would allocate profits to each member state.

transfer problem

Philip Brock
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

A financial transfer of wealth between countries necessitates adjustments in expenditure, production, and relative prices that collectively comprise the transfer problem. Since the 1920s the transfer problem arising from war reparations and other unrequited transfers has occupied the attention of Keynes, several Nobel laureates, and other distinguished economists. The early literature centred on static two-country models of transfers, while more recent research has highlighted the intertemporal dimension of the transfer problem.

Keywords

infinite horizons; intertemporal models; intertemporal terms of trade; overlapping generations model; reparations; representative agent; terms of trade; transfer paradox; transfer problem; Walras's Law

Article

Development of the theoretical literature on the transfer problem mirrors the historical context within which the issue first arose. In 1919, as part of the Treaty of Versailles that followed the First World War, Germany was required to make reparations payments to the European powers to which it surrendered (see Eichengreen, 1986). Initially, much discussion of Germany's capacity to pay proceeded on the basis of constant international prices and assumed that governments could automatically engineer the required changes in spending on traded goods at home and abroad. But Keynes (1929), in an article which introduced the phrase ‘transfer problem’ into the professional literature, argued that a country required to make a fixed transfer of purchasing power to another would suffer a secondary burden in the form of a further decline in its purchasing power due to an induced deterioration in its international terms of trade. Ohlin (1929) argued in response that a secondary benefit – or terms of trade improvement – was as likely to occur due to expenditure effects and the presence of non-traded goods (see especially Mundell, 2002).
Ohlin's central insight can be stated simply, following Pigou (1932), using a two-country, two-commodity model of international trade. To highlight the central point, assume initially that production of both goods is exogenously given and that all income is devoted to consumption. If the markets for both commodities clear, then by Walras's Law we need only consider one, for example the good exported by the home country, where that good is denoted $x$. The total supply of $x$ must equal the sum of domestic and foreign demands:

$$S + S^* = D(y, p) + D^*(y^*, p)$$

where $S$ and $S^*$ designate domestic and foreign supplies, taken as exogenous for the moment (with asterisks denoting foreign values throughout), and $D$ and $D^*$ domestic and foreign demands (each of which depends on real income and relative prices). Now assume that an amount $T$ of purchasing power is transferred from the home to the foreign country. Domestic demand for $x$ falls by $D_y T$, where $D_y$ is the home country's marginal propensity to consume $x$ out of income, while foreign demand for this good rises by $D^*_y T$, where $D^*_y$ is the foreign country's marginal propensity to consume $x$, also its marginal propensity to import. Equilibrium in the market for $x$ at the initial prices requires that an export surplus in the amount $T$ results from income effects alone – in other words, that

$$D_y + D^*_y = 1$$

If

$$D_y + D^*_y < 1$$

the combined marginal propensities to spend on $x$ out of income are too small to generate a sufficient surplus at initial relative prices. This is the 'orthodox' case in which the transfer-making country's terms of trade deteriorate, creating a secondary burden (Samuelson, 1952; 1971). If

$$D_y + D^*_y > 1$$

then to the contrary the transfer-making country's terms of trade improve. Once adjustments in production are introduced, the terms of trade will deteriorate when the bias in tastes in each country towards consumption of the exportable good is greater than the bias in production due to international differences in factor endowments or technologies (Jones, 1975). Transport costs, by increasing the correlation within countries of patterns of production and consumption, reinforce the orthodox presumption of a secondary burden (Samuelson, 1952; 1971). Introducing a third country adds an additional set of supply and demand elasticities and the possibility of complementarity in production and consumption. A number of cases arise – such as a 'transfer paradox' in which a transfer immiserizes the recipient country – whose existence is inconsistent with market stability in two-country two-commodity models (on the stability question, see Samuelson, 1947; 1971; for the case of more than two countries, see Gale, 1974; Bhagwati, Brecher and Hatta, 1983). Extensive literature reviews can be found in Eaton (1989) and Brakman and van Marrewijk (1998).

Research on the transfer problem since 1980 has moved toward intertemporal issues. The analytical tools used are the representative agent and overlapping generations frameworks in either a two-period or infinite-horizon setting. Two-country analyses (for example, Djaji•, Lahiri and Raimondos-Moller,
transfer problem: The New Palgrave Dictionary of Economics

1998) have focused on the adjustment of the intertemporal terms of trade (the world interest rate) to a transfer. The two-country, overlapping-generations model has attracted particular interest because the transfer paradox can occur with just two countries, since the competitive equilibrium need not be Pareto efficient (see Galor and Polemarchakis, 1987; Haaparanta, 1989).

Much recent research concerns the financing of a transfer. As noted by Gavin (1992) and Devereux and Smith (2005), France borrowed an amount equivalent to almost one quarter of its GDP in order to finance its reparations payments to Germany during 1872 and 1873. In contrast with static analyses, intertemporal models allow the initial payment of a transfer to be partially financed by international borrowing (Sachs, 1981; Obstfeld and Rogoff, 1995). As a simple illustration, consider a small open economy with fixed endowment income ($\bar{y}$) and initial foreign debt ($b_t - 1$) that must pay a one-period reparation ($\tau_t$). With a given world interest rate ($r$), the current account at time $t$ will be

$$CA_t \equiv \bar{y} - c_t - rb_t - 1 - \tau_t.$$

Assume perfect foresight and that consumption ($c_t$) can be approximated by permanent income ($\bar{y}$):

$$c_t \equiv \sum_{n=0}^{\infty} \left( \frac{1}{1+r} \right)^n = \frac{1+r}{r}.$$

Then the current account will be determined by the timing and magnitude of current and future reparations payments:

$$\bar{y}_t \equiv - rb_t - 1 + \frac{r}{1+r} \left[ \bar{y} - \tau_t + \frac{\bar{y} - \tau_t + 1}{1+r} + \ldots \right] \equiv \bar{y} - rb_t - 1 - \frac{r}{1+r} \left[ \tau_t + \frac{\tau_t + 1}{1+r} + \ldots \right].$$

Given an initially balanced current account, a reparations payment in period $t$ only will result in a current account deficit of $\left( \frac{1}{1+r} \right)^{\tau_t}$, thereby creating a debt obligation that spreads out the necessary accompanying decline in consumption by $\left( \frac{r}{1+r} \right)^{\tau_t}$ across all periods from time $t$ onward. The imposition of a uniform reparations payment in all time periods ($\tau_t = \tau_t + 1 = \ldots = \bar{\tau}$) will lower consumption by $\bar{\tau}$ so that the improvement in the trade account ($TCA_t \equiv \bar{y} - c_t$) exactly offsets the reparations payment in period $t$ (a condition that is imposed in a static analysis of the transfer problem). In settings involving reproducible capital, reparations payments (or other transfers) may have an additional impact on current account dynamics by setting in motion a gradual adjustment of the capital stock to a new equilibrium (Brock, 1996; Chatterjee, Sakoulis and Turnovsky, 2003).
Beginning with Krugman (1999), the term ‘transfer problem’ has been applied to an abrupt reduction in capital flows during an economic crisis. The formal similarity between adjustment to a capital flow reduction and a reparations payment can be seen from the following trade account identity:

\[ T_A_t \equiv CA_t + rb_{t-1} + \tau_t \]

where \( CA_t \equiv b_t - b_{t-1} \). If we hold the current account constant, an increase in reparations payments (\( \tau_t \uparrow \)) requires an accompanying improvement in the trade account. A reduction of capital flows (\( b_t \downarrow \)) requires a similar improvement in the current and trade accounts. However, since there is a binding borrowing constraint and no direct wealth effect associated with an abrupt reduction in capital flows, this second transfer problem is conceptually distinct from the classical transfer problem, thus supporting Nurkse’s (1961) admonition not to apply indiscriminately the analysis of an unrequited transfer to problems involving international capital movements.

Despite the large literature on the static and intertemporal dimensions of unrequited transfers, there is relatively little empirical research on the transfer problem. Papers by Yano and Nugent (1999), Lane and Milesi-Ferretti (2004), Devereux and Smith (2005), and Rajan and Subramanian (2005) are notable promising exceptions.

transition and institutions

Peter Murrell
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article examines the evolution of institutions and economists’ thinking on institutions during transition. Early in transition, institutions were virtually ignored in the majority of normative prescriptions, but were central in the evolutionary institutional approach. Later, after events influenced intellectual developments, institutions were at the centre of analysis. Growth is strongly related to institutional construction. Transition countries built institutions speedily but with marked variation across countries. Legal systems and independent governmental agencies were sources of institutional growth, while government bureaucracies and informal mechanisms detracted from institutional growth. In China, reforms addressed problems that institutions usually do, but in unusual ways.

Keywords

China, economics in; colonialism; corruption; creative destruction; dual track liberalization; evolutionary-institutional view; institutional development; institutions; liberalization; market institutions; privatization; resource curse; rule of law; shock therapy; social capital; stabilization; transition

Article

‘Transition’ is the widely accepted term for the thoroughgoing political and economic changes that followed the fall of communism in Eastern Europe (EE) and the Soviet Union. Some 29 countries are involved in this continuing process, which began in 1989–91 and involves the types of transformations that usually took a century or more in today's developed countries. A related, but distinct, process has been under way in China since 1978. Transition has been coterminous with a remarkable change in emphasis within economics. In 1989, to highlight the importance of institutions was a distinctly minority activity. Now, institutions are at the heart of both research and policy discussions. Similarly, while many early influential analyses of
transition virtually ignored institutions, current discussions place them at the centre. Developments in transition countries made an important contribution to general trends within economics (Roland, 2000). This article focuses on institutions in the transition process and in economists’ deliberations on that process. It begins with early normative prescriptions, in which institutions were virtually ignored by the majority of contributors, and then examines changing views on institutions, showing how events on the ground influenced intellectual developments. We then provide basic facts on institutional development, describing the impressive progress that has been made, which suggests modification of the standard assumption that institutional construction must be slow. Nevertheless, there is marked divergence across countries. This article examines the sources of institutional growth and the ‘great divide’ between the successful and the unsuccessful institution builders (Berglof and Bolton, 2002). It closes by considering the seemingly anomalous case of China, showing that the anomaly is more apparent than real. China’s reforms addressed the problems that institutions address everywhere, but in ways that are not recognizable to those using a first-best institutional template.

Idea and institutions in the earliest phase of transition

Economists began to deal with the transition with a deluge of normative prescriptions. The majority view in its most stark incarnation came to be called shock therapy, the notion that the best way forward was as fast as possible on all fronts, taking advantage of a political window of opportunity. These types of reforms were certainly the aim of the first post-communist governments and their Western advisers in Poland, Russia and many other countries. According to shock therapy’s proponents, the soon-to-be-observed dissonance between objectives and follow-through was variously due to the absence of a clear vision, lack of willpower, and a nefarious political opposition.

Institutions were ignored within the shock therapy approach for a variety of reasons. They could be built so easily that they did not require much attention (Sachs, 1991). They were not deemed important enough to mention (Blanchard et al., 1991). They would take so long to develop that other elements of policy came first (Fischer and Gelb, 1991). Or, they could not be built without first creating the actors who would demand them within the political process (Boycko, Shleifer and Vishny, 1995).

In shock therapy analysis, political economy considerations led to emphasis on the destruction of the old institutions and trumped any concerns about the dangers of an institutional void. Macroeconomics governed microeconomic institutional change, as exemplified by the International Monetary Fund’s short-term focus on raising taxes in Russia, while largely ignoring sensible tax reforms (Black, Kraakman and Tarassova, 2000). Rapid liberalization was advocated, while downplaying its effects on the governance of contractual relations. The transaction costs of ownership change and corporate governance after privatization were deemed of secondary importance.

When economic performance in the early years of transition proved disappointing, diagnoses followed the earlier analyses: strong, but necessary, stabilization programmes had led to recessions (Blanchard, Froot and Sachs, 1994); that is, in the early 1990s, the most influential analyses did not associate the steep, sometimes catastrophic, recessions with institutional problems. For example, such analyses led to the conclusion that liberalization, privatization and stabilization should move even faster in Russia in 1992 than they had in Eastern Europe two years earlier.

Kogut and Spicer (2004; 2005) use numerical citation analyses to analyse patterns in the early
The New Palgrave Dictionary of Economics

Transition and institutions. The New Palgrave Dictionary of Economics.

They document the links among a core group of economists subscribing to the shock therapy approach. This group had strong connections to the international financial institutions and the US government, and were able to spread their views in reforming countries under the auspices of these powerful organizations. Kogut and Spicer also identify dissenters from this point of view, in particular Murrell (1992), Dewatripont and Roland (1992), and McKinnon (1991).

Early in transition the dissenting view was labelled evolutionary or gradualist, but was later given the much more felicitous name, evolutionary-institutional (Roland, 2000).

The evolutionary-institutional view emphasized the importance of institutions, suggesting, for example, that the nature and timing of liberalization, privatization and stabilization depended critically on the existing institutional framework. Some institutions were prerequisites for a functioning market economy, and the absence of these might necessitate the slowing of reforms. Because new market economy institutions were hard to create, it might be better to use crude second-best institutions, even some of the old ones, while maintaining a focus on building new ones. This might lead to a two-sector approach, where a nascent private sector was governed by new institutions, while some of the old mechanisms of governance prevented convulsions in the old state sector, negatively affecting the development of the new capitalism. This approach was particularly congenial for those who thought that the growth of the new private sector was crucial (Kornai, 1990) or whose advice reflected elements of Chinese reforms (McMillan and Naughton, 1992).

The suggestion that economic reform should be gradual was a conclusion, rather than a starting point. It grew out of analyses that were standard in the literature (North, 1990). Because ideas and organizations adapt to an institutional framework, there is no certainty of an immediate functional response to new institutions. Difficulties in creating new institutions suggest a wariness of quick reforms when their success depends on functioning institutions. Instead, a nascent private sector produces the most nimble response in a new environment of fast-changing institutions.

Evolving ideas on the role of institutions

Events changed ideas. All transition countries experienced deep recession. Recovery began after several years, with its inception unrelated to any specific policy initiatives. If anything, recovery began on retreat from the earlier policies. The degree of adherence to standard policy advice could not explain the cross-country pattern of recession and growth.

Although these facts were consistent with the evolutionary-institutional view, the most influential contribution in changing the terms of debate was a paper co-authored by one of shock therapy's main proponents (Blanchard and Kremer, 1997). Undoubtedly, this paper had such a large effect because one of its authors was an influential economist who had previously attributed little importance to institutions (see Blanchard et al., 1991; Blanchard, Froot and Sachs, 1994; and the review of the latter in Murrell, 1995). The paper formalizes ideas already present in the earlier evolutionary-institutional literature in a simple, but powerful model. The model highlights the incentives to break agreements in the absence of effective governance, leading to a loss of production. Output decline comes later but is larger where the complexity of old production relations is greater. If opportunities improve over time, the model generates a U-shaped path for production. These predictions are consistent with the comparative profiles of growth in the transition countries, with recession initially steeper but ultimately shallower in Eastern
transition and Institutions: The New Palgrave Dictionary of Economics

Europe than in the former Soviet Union (FSU).

There is much to learn about the relationship between institutional change and production decline, but there is general agreement in some areas. Pre-transition institutions contributed to enterprise productivity. These institutions offered credibility in the negotiating of agreements, contract enforcement, specification of control rights over assets, mechanisms for the generation and allocation of working and investment capital, and many other services. When the communist systems fell apart and market institutions were still on the drawing board, these crucial services were no longer supplied. The lack of institutional support was particularly critical at the beginning of transition for several reasons: socialist firms were large, implying a need for sophisticated governance mechanisms; inter-firm relationships were highly particularized, implying great potential for hold-up problems; and necessary adjustments were enormous, implying the need for effective financial markets.

Even without effective institutions, production rebounded due to the spontaneous growth of private sector opportunities. Nascent small businesses could take advantage of these opportunities if they received a minimal amount of institutional support, that is, protection from extreme criminality, prevention of civil chaos, and the benign neglect of the state. Such businesses develop their own self-enforcing agreements and do not need sophisticated courts or contract law. Physical possession solves many concerns about property rights. Closely held firms that are self-financed do not need corporate governance institutions.

But to rebound from recession is not the same as sustained growth. The latter requires more than the benign neglect of the state: it requires a set of institutions that support non-self-enforcing agreements, secure property without possession, enable firms to expand beyond the limits of self-finance, and undertake many other activities that are not feasible without effective rules of the game. While such ideas seem commonplace now, they were not to the fore in the debates at the start of transition, except in the evolutionary-institutional perspective.

In addition to the institutional interpretation of the causes of collapse and recovery, two further factors contributed to economists’ changing views. First, econometric studies showed that differences in the application of the standard policies did not explain differences in economic performance (for example, de Melo et al., 2001; Falcetti, Raiser and Sanfey, 2002). Second, variations in performance became more noticeable in the trajectories out of recession. Countries appeared to be sorting themselves into two groups. Those in EE were generally performing better than those in the FSU, but there were enough exceptions (for example, the Baltics, Serbia) to suggest that the EE–FSU distinction was not the key. As Berglof and Bolton (2002, p. 77) noted, ‘A growing and deepening divide has opened up between transition countries where economic development has taken off and those caught in a vicious cycle of institutional backwardness and macroeconomic instability’.

Beck and Laeven (2005) were the first to test this new institutional paradigm of growth in transition in a rigorous framework, although their study is naturally characterized by a paucity of data points. They find that there is very large divergence in the performance of transition countries and that institutional development is the key factor in explaining the divergence. Moving from Russia's level of institutional development in 1996 to Poland's level would lead to a growth rate increase of 4.4 per cent a year. In contrast, differences in policies are unimportant. Papers studying privatization, agricultural markets and foreign direct investment contain results on economic performance at a more disaggregated level that complement those of Beck and Laeven. While relative neglect of institutions characterized the early stages of transition, the centrality of institutions is now conventional wisdom.
Evolving institutions

One reason why institutions were not emphasized in early transition was the widely held assumption that institutional construction would be very slow. The transition countries provided an ideal testing ground for this assumption. Having rejected a set of old institutions and turned to creating new ones, how fast and how successful could institutional construction be? The answer, for some countries only, is: surprisingly quick and successful. Transition experience refutes one element of conventional wisdom, that institutional development is inevitably very slow, while bolstering another, that failure is commonplace.

Murrell (2003) concluded that there had been widespread, large, continuing improvements in institutional quality from 1990 to 2000. An updating especially for this article extends this analysis to 2004, using the popular institutional measures developed by Kaufmann, Kraay and Mastruzzi (2005). This updating shows that institutional scores for transition countries as a whole are no better and no worse than one would expect given levels of economic development. This is remarkable, since it implies that in less than 15 years the transition countries built institutions that match those in countries that have had capitalist systems for much longer. For example, on the rule of law, Hungary, Slovenia and Estonia are comparable to Chile, Israel, Greece, Italy, Spain and Taiwan. On regulatory quality, Estonia ranks above Sweden, while Hungary, Lithuania, Slovakia, Latvia and the Czech Republic are grouped with the United States, Japan, Italy and Spain.

These results, which are based on expert opinions and surveys, are supported by studies examining the micro details of institutional development. Djankov et al. (2002) collect data on highly specific aspects of the functioning of legal systems, such as collecting on a bad cheque. They find that the ex-socialist countries fare better than both French-legal-origin and German-legal-origin countries. Pistor, Raiser and Gelfer (2000) examine the quality of laws on shareholder and creditor rights, finding the transition countries superior to many developed economies.

The second distinctive feature in institutional development is the divergence between one group of countries whose institutions are at a comparatively high level and improving and another group that has not crossed the great divide and is even losing some of the gains from the 1990s. By 2004, the EE–Baltic group has institutional scores higher than expected, given general levels of economic development on all six of the Kaufmann, Kraay and Mastruzzi (2005) indicators, and these scores improved dramatically in the preceding decade. The Commonwealth of Independent States (FSU minus the Baltics) scores below expected levels and has been regressing from 1996 to 2004, after showing remarkable signs of institutional improvement in the early 1990s.

It is difficult to exaggerate the importance of this empirical evidence on basic hypotheses on institutional development. Before transition, the assumption was that modern institutional development is a very long process, fraught with the possibility of failure. The first element of this assumption has been refuted. In the years before 1990, capitalism and democracy were absent in EE and the USSR. Then there was a mammoth fall in national income, due to institutional lacunae. Yet now a large group of countries seems set on the road to sustainable institutional development. In contrast, the second element of standard assumptions has been verified. In a significant number of transition countries, slow initial progress on institutional development has been followed by severe regression.
The sources of institutional development

There are two alternative perspectives to take when viewing the sources of institutional development. First, one can analyse which country-level factors best explain aggregate institutional outcomes. Second, one can ask which particular mechanisms or organizations inside a country contributed most to institutional performance. Evidence on both is only currently being generated, and is very scant. This is true both of transition and in general.

Beck and Laeven (2005) have carried out the most systematic study of the causes of aggregate institutional development in transition. They find two principal determinants: the strength of the incumbent socialist elite and the importance of natural resources (the resource curse). Both are negatively related to improvement in institutions. They also confirm the analysis of Black, Kraakman and Tarassova (2000) that certain types of privatization might have been inimical to institutional development. Early macroeconomic policies, belonging to the FSU and being eligible for the European Union do not affect institution building. These negative results are important since they reject prominent hypotheses. One popular theory not explored by Beck and Laeven is that colonial heritage might have influenced institutional development, particularly in the case of countries influenced by the Austrian, Ottoman or Russian empires.

One can also ask which particular mechanisms contributed most to institutional performance (Murrell, 2003). Formal institutions have played a more beneficial role than informal institutions, such as culture or pertinent elements of social capital. Of the formal institutions, political and legal structures and independent governmental agencies contributed relatively more to institutional development. State administrative bodies detracted from institutional performance, changing slowly and contributing to relatively high levels of corruption. These facts are generally consistent with the old Schumpeterian message of creative destruction, but applied to non-market organizations.

One very surprising feature of transition is the relatively strong role of some legal institutions. A series of empirical observations on the courts suggests a divergence from prevailing views on the role of the legal system (see the essays in Murrell, 2001 for example). The legal system has never been identified as playing a strong role in developing countries, and transition was not conducive to the effectiveness of the law. Yet current evidence suggests that it is easier than usually assumed to fashion a legal system that facilitates economic processes, even when that system is far from the standards of developed countries.

Institutions in the Chinese reforms

On the surface, Chinese reforms might be cast as a refutation of the above. China began its reforms with a basic constraint on institutional change – movement from the existing system could not be too great or too fast. This meant that new institutions would not be best practice, but had to be incremental variations on existing ones. Hence, China does not fare well when matched against standard criteria for judging institutions. This stands in contrast to the astounding success of the Chinese economy. Nevertheless, China's reforms can be interpreted as bolstering the basic conclusion of the centrality of institutions in transition. China created successful, transitional institutions (Qian, 2003). By experiment,
by confining itself to incremental changes that could be easily understood, and by implementing Pareto-improving changes in the early years of reform, China pursued a deft, but previously untrodden path of institutional change.
