In principal-agent analysis we often apply the revelation principle to find the incentive-compatible mechanism that is optimal for the principal. If the principal would be tempted to use revealed information opportunistically, then there could be loss of generality in assuming that the agents reveal all their private information to the principal. But we should not confuse the principal with the mediator. The revelation principle can still be applied if the principal can get a trustworthy mediator to take the agents' reports and use them according to any specified mechanism.

There are often questions about whether the allocation selected by a mechanism could be modified by subsequent exchanges among the individuals. An individual's right to offer his possessions for sale at some future date could be accommodated in mechanism design by additional moral-hazard constraints. For example, suppose the principal can sell an object each day, on days 1 and 2. The only buyer's value for such objects is either low $1 or high $3, low having probability 0.25. To maximize the principal's expected revenue with the buyer participating honestly, an optimal mechanism would sell both objects for $3 if the buyer's type is high, but would sell neither if the buyer is low. But if no sale is recommended then the principal could infer that the buyer is low and would prefer to sell for $1.

Suppose now that the principal cannot be prevented from offering to sell for $1 on either day. With these additional moral-hazard constraints, an optimal mechanism uses randomization by the mediator to conceal information from the principal. If the buyer reports low then the mediator recommends no sale on day 1 and selling for $1 on day 2. If the buyer reports high, then with probability 1/3 the mediator recommends no sale on day 1 and selling for $3 on day 2, but with probability 2/3 recommends selling for $1.50 on both days. A no-sale recommendation on day 1 implies probability 0.5 of low, so that obedience yields the same expected revenue $0.5 \times (0 + 1) + 0.5 \times (0 + 3)$ as deviating to sell for $1 on both days.

A proliferation of such moral-hazard constraints may greatly complicate the analysis, however. So in practice we often apply the revelation principle with an understanding that we may be overestimating the size of the feasible set, by assuming away some problems of mediator imperfection or moral hazard. When we use the revelation principle to show that a seemingly wasteful mechanism is actually efficient when incentive constraints are recognized, such overestimation of the incentive-feasible set would not weaken the impact of our results (as long as this mechanism remains feasible).

Centralized mediation is emphasized by the revelation principle as a convenient way of characterizing what people can achieve with communication, but this analytical convenience does not imply that centralization is necessarily the best way to coordinate an economy. For fundamental questions about socialist centralization versus free-market decentralization, we should be sceptical about an assumption that centralized control over national resources could not corrupt any mediator. The power of the revelation principle for such questions is instead its ability to provide a common analytical framework that applies equally to socialism and capitalism. For example, a standard result of revelation-principle analysis is that, if only one producer knows the production cost of a good, then efficient incentive-compatible mechanisms must allow this monopolistic producer to take positive informational rents or profits (Baron and Myerson, 1982). Thus the revelation principle can actually be used to support arguments for decentralized multi-source production, by showing that problems of profit-taking by an informational monopolist can be just as serious under socialism as under capitalism.

Nash (1951) advocated a different methodology for analysing communication in games. In Nash's approach, all opportunities for communication should be represented by moves in our extensive model of the dynamic game. Adding such communication moves may greatly increase the number of possible...
strategies for a player, because each strategy is a complete plan for choosing the player's moves throughout the game. But if all communication will occur in the implementation of these strategies, then the players' initial choices of their strategies must be independent. Thus, Nash argued, any dynamic game can be normalized to a static strategic-form game, where players choose strategies simultaneously and independently, and Nash equilibrium is the general solution for such games.

With the revelation principle, however, communication opportunities are omitted from the game model and are instead taken into account by using incentive-compatible mechanisms as our solution concept. Characterizing the set of all incentive-compatible mechanisms is often easier than computing the Nash equilibria of a game with communication. Thus, by applying the revelation principle, we can get both a simpler model and a simpler solution concept for games with communication. But, when we use the revelation principle, strategic-form games are no longer sufficient for representing general dynamic games, because normalizing a game model to strategic form would suppress implicit opportunities for communicating during the game (see Myerson, 1986). So the revelation principle should be understood as a methodological alternative to Nash's strategic-form analysis.

Reverse capital deepening is the property whereby it may be efficient to associate a lower (higher) rate of interest with a lower (higher) capital per worker. This property is inconsistent with the traditional belief that, by virtue of the substitution principle, production techniques that are more ‘capital intensive’ will become optimal as the rate of interest is lowered. Reverse capital deepening is an important instance of the apparent paradoxes associated with indirect effects in a production economy. It entails that technical choice cannot be considered a monotonic function of the rate of interest, and questions the widespread policy implications of the traditional view.

Article
It has long been taken for granted that there is an inverse monotonic relationship between the rate of interest (or the rate of profit) and the quantity of capital per worker. This belief was founded on the principle of substitution, whereby ‘cheaper’ is substituted for ‘more expensive’ as the relative price of two inputs is changed. In the field of capital theory, the principle of substitution persuaded many economists, such as E. von Böhm-Bawerk (1889), J.B. Clark (1899) and F.A. von Hayek (1941), that a lower rate of interest (which is equal to the rate of profit in equilibrium) is associated with the use of more ‘capital intensive’ techniques, and thus with the substitution of capital for other productive factors, such as labour or land. This process is called capital deepening. Recent discussions have shown that this is not necessarily true, since a lower rate of interest might be associated with lower, rather than higher, capital per worker. This phenomenon is called reverse capital deepening.

This discovery was made at the same time as it was realized that it is not generally possible to order ‘efficient’ techniques in such a way that technical choice becomes a monotonic function of the rate of interest (and of the rate of profit). It can be shown that both reverse capital deepening and reswitching of technique are related to the same fundamental property of the economic system: the possibility (in fact, the near generality) of nonlinear wage–profit relationships. To illustrate this proposition, it is useful to begin by considering the hypothetical case of linear wage–profit relationships (see Figure 1).
The linearity of the three wage-profit relationships makes reswitching impossible as \( r \) increases between 0 and \( r^*(C) \) (which is the maximum rate of profit with technology C).
reason is that no wage–profit line can ever be crossed more than once by another wage–profit line. In this special case, there is an inverse monotonic relationship between the rate of profit and the quantity of capital per worker. This may be shown as follows. We can read the net final output per worker on the $w$-axis of Figure 1 at the point at which $r=0$. (At that point the net final output per worker coincides with the maximum wage.) The net final output per worker associated with technology A is higher than the net final output per worker associated with technology B. The net final output per worker associated with technology B is higher than the net final output per worker associated with technology C. At switchpoints $s_1$ and $s_2$ the wage is the same for both technologies between which substitution takes place. It follows that, at switchpoint $s_1$, profit per worker is higher with technology A than with technology B. Similarly, at switchpoint $s_2$, profit per worker is higher with technology B than with technology C. Assuming that the rate of profit is uniform across technologies, we find that, at $s_1$, A is associated with higher capital per worker than B. A higher rate of profit (or rate of interest) is thus associated with substitution of ‘less capital’ for ‘more capital’. In this particular case, the traditional approach to capital theory would seem to be well founded.

However, these properties disappear altogether once we drop the assumption of linear wage–profit relationships. (It might be interesting to inquire into the economic meaning of straight wage–profit relationships, which are possible only in the case of a technology characterized by a uniform proportion between labour and intermediate inputs in all production processes: only in this case a change in the rate of profit leaves relative prices unaffected.) But in general wage–profit relationships are of the nonlinear type, which means that the proportion between labour and intermediate inputs is generally different from one production process to another. This feature of the wage–profit frontier makes it possible for wage–profit curves to intersect more than once, thus bringing about the possibility of multiple switching. Under the same circumstances it can be shown that the relationship between the rate of profit and capital per worker is no longer of the inverse monotonic type. This can be seen in the reswitching case (Figure 2), but it can also be seen in the case in which the wage–profit curves never intersect more than once on the efficiency frontier (Figure 3). (See also Pasinetti, 1966.)

Figure 2
Figure 3
In Figure 2, reswitching is associated with reverse capital deepening. Technology A is the more profitable at levels of the rate of profit lower than \( r_1 \), it is 'overtaken' by technology B at rates of profit between \( r_1 \) and \( r_2 \), it becomes again the more profitable at rates of profit higher than \( r_2 \). At the same time, switchpoint \( s_1 \) is associated with the substitution of the technology with lower value of capital per worker (B) for the technology with the higher value of capital per worker (A), whereas at switchpoint \( s_2 \) the opposite happens: the technology with higher capital per worker (A) is substituted for the technology with lower capital per worker (B), in spite of the fact that the rate of profit is higher (reverse capital deepening).

In Figure 3, there is no reswitching but we still have a reverse capital deepening. For no wage–profit curves cross one another more than once on the efficiency frontier, but at switchpoint \( s_2 \) an increasing rate of profit is associated with the substitution of a technology with higher capital per worker (C) for a technology with lower capital per worker (B). Complementarity in production is often at the root of apparently perverse price behaviour (see Broome, 1978). One reason for this had been noted by John Hicks, when he wrote that the 'net effect' of a change in the price of productive factor \( x \) upon the price of complementary factor \( y \) ‘is … compounded out of two contrary tendencies, a direct effect tendency to raise it, and indirect effect tendency to reduce it; either may be dominant’ (Hicks, 1946, p. 107). Reverse capital deepening is an especially important instance of a widespread phenomenon associated with indirect effects in a production economy. This possibility is associated with other phenomena which are not compatible with traditional beliefs about capital and capital accumulation. Simple inspection of Figure 2 or 3 shows that at a switchpoint associated with reverse capital deepening (\( s_2 \) in either figure) a technology with higher capital per worker and higher net final product per worker is substituted for a technology with lower capital per worker and lower net final product per worker. At such switchpoints a higher rate of profit (and rate of interest) could be associated with a higher ratio of capital per worker to net final product per worker, that is, with a higher capital–output ratio.

Figures 2 and 3 also alert us as to the possibility that a technology adopted at a high rate of interest is associated with higher maximum consumption per head than a technology adopted at a lower rate of interest. In addition, transition to a lower rate of interest may involve the switch to a lower maximum consumption per head. (This can be seen at switchpoint \( s_2 \) in either figure, where maximum consumption per head can be read on the \( w \)-axis at point \( r=0 \).) This behaviour of consumption per head in relation to the rate of interest is clearly incompatible with the view that a higher rate of interest brings about a special type of exchange, in which less consumption in the current period is substituted against higher consumption in the future. Reverse capital deepening alerts us as to the possibility that a higher rate of interest might be associated with greater current consumption per head than the consumption per head feasible with the technology adopted at a lower rate of interest (see Bruno, Burmeister and Sheshinski, 1966; Samuelson, 1966).

The relevance of reverse capital deepening is that the foundation of the traditional view that technical choice is a monotonic function of the rate of interest is seriously questioned. Similarly, the widespread policy implications of the traditional view are also questioned. However, there is as yet no full agreement as to the main consequences of this result. For example, Christopher Bliss (1975, p. 279) has noted that reverse capital deepening makes it impossible to see the accumulation of capital as a process associated with ‘a continuous increase in consumption per capita,…a continuous decline in the rate of interest and … a continuous increase in the real wage rate’. He also called attention to the fact that the ‘extended accumulation history’ of an economic system moving through real time is normally different from the hypothetical history we can tell by ‘travelling’ across steady states (1975, pp. 194, 280–1). In particular, he emphasized that the statement that the rate of interest may be expected to fall as capital deepening takes place ‘cannot be interpreted’ in the case of extended accumulation history, as we would have, in that case, ‘a whole structure of interest rates … not a single rate of interest’ (1975, p. 294). A different point of view has
been expressed by Pierangelo Garegnani, who has maintained that capital paradoxes in general, and reverse capital deepening in particular, by making traditional beliefs untenable, suggest a ‘correction’ to traditional theory, which would make it reasonable to expect ‘instabilities or tendencies to zero of wages, or of net returns on capital’ (Garegnani, 1990, p. 76). This author’s view is that, rather than introducing such a correction, one should drop any idea of a causal connection from marginal products to the distribution of the social product, and further develop the conjecture that distribution is brought about by ‘more complex economic and social forces like those envisaged by the old classical economists’ (Garegnani, 1990, pp. 76–7). As it is common in theoretical sciences (see Kuhn, 1970; 2000), the discovery of an apparent anomaly has induced economists to look for a more general theory, or to switch to an altogether different framework.

Rhetoric is the study and practice of persuasive expression, an alternative since the Greeks to the philosophical programme of epistemology. The rhetoric of economics examines how economists persuade – not how they say they do, or how their official methodologies say they do, but how in fact they persuade colleagues and politicians and students to accept one economic assertion and reject another.

Some of their devices arise from bad motives, and bad rhetoric is what most people have in mind when they call a piece of writing ‘rhetorical’. An irrelevant and inaccurate attack on Milton Friedman's politics while criticizing his economics would be an example, as would a pointless and confusing use of mathematics while arguing a point in labour economics. The badness does not reside in the techniques themselves (political commentary or mathematical argument) but in the person using them, since all techniques can be abused. Aristotle noted that ‘if it be objected that one who uses such power of speech unjustly might do great harm, that is a charge which may be made in common against all good things except virtue itself’. Cato the Elder demanded that the user of analogy (or in our time the user of regression) be vir bonus dicendi peritus, the good man skilled at speaking. The protection against bad science is good scientists, not good methodology.

Rhetoric, then, can be good, offering good reasons for believing that the elasticity of substitution between capital and labour in American manufacturing, say, is about 1.0. The good reasons are not confined by syllogism and number. They include good analogy (production is just like a mathematical function), good authority (Knut Wicksell and Paul Douglas thought this way, too), good symmetry (if mining can be treated as a production function, so should manufacturing). Furthermore, the reasonings of syllogism and number are themselves rhetorical, that is, persuasive acts of human speech. An econometric test will depend on how apt is an analogy of the error term with drawings from an urn. A mathematical proof will depend on how convincing is an appeal to the authority of the Bourbaki style.
'The facts’ and ‘the logic’ matter, of course; but they are part of the rhetoric, depending themselves on the giving of good reasons. Consider, for example, the sentence in economics, ‘The demand curve slopes down’. The official rhetoric says that economists believe this because of statistical evidence – negative coefficients in demand curves for pig iron or negative diagonal items in matrices of complete systems of demand – accumulating steadily in journal articles. These are the tests ‘consistent with the hypothesis’. Yet most belief in the hypothesis comes from other sources: from introspection (what would I do?); from thought experiments (what would they do?); from uncontrolled cases in point (such as the oil crisis); from authority (Alfred Marshall believed it); from symmetry (a law of demand if there is a law of supply); from definition (a higher price leaves less for expenditure, including this one); and above all, from analogy (if the demand curve slopes down for chewing gum, why not for housing and love too?). As may be seen in the classroom and seminar, the range of argument in economics is wider than the official rhetoric allows.

The rhetoric of economics brings the traditions of rhetoric to the study of economic texts, whether mathematical or verbal texts. It is a literary criticism of economics, or a jurisprudence, and from literary critics like Wayne Booth (1974) and lawyers such as Chaim Perelman (Perelman and Olbrechts-Tyteca, 1958) much can be learned. Although its precursors in economics are methodological criticisms of the field (such as Frank Knight, 1940), censorious joking (such as Stigler, 1977), and finger-wagging presidential addresses (such as Leontief, 1971, or Mayer, 1980), the main focus of the work has been the analysis of how economists seek to persuade, whether good or bad (Klamer, 1984; Henderson 1982; Kornai, 1983; McCloskey, 1986). Econometrics has its own rhetorical prehistory, more self-conscious than the rest (Leamer, 1978), reaching back to the founders of decision theory and Bayesian statistics. The movement has parallels in other fields. Imre Lakatos (1976), Davis and Hersh (1981), and others have uncovered a rhetoric in mathematics; Rorty (1982), Toulmin (1958), and Rosen (1980) in technical philosophy; and numbers of scientists in their own fields (Polanyi, 1962; Medawar, 1964). Historians and sociologists of science have since the 1960s accumulated much evidence that science is a conversation rather than a mechanical procedure (Kuhn, 1977; Collins, 1985). The analysis of conversation from scholars in communication and literary studies (Scott, 1967) has provided ways of rereading various fields (a sampling of these is contained in Nelson, Megill and McCloskey, 1987).

A rhetoric of economics questions the division between scientific and humanistic reasoning, not to attack quantification or to introduce irrationality into science, but to make the scientific conversation more aware of itself. It is a programme of greater, not less, rigour and relevance, of higher, not lower, standards in the conversations of mankind.

The Ricardian equivalence theorem states that government bonds and lump-sum taxes are equivalent means to finance government spending. Thus, a lump-sum tax cut financed by the issuance of government bonds would not affect consumption. Consumers could hold the newly issued bonds, and use them to pay the higher taxes when the government increases taxes to repay the principal and interest on the bonds. Intergenerational altruism implies that Ricardian equivalence holds even if the recipients of a tax cut die before future taxes are increased to fully repay the bonds. This article explores situations where Ricardian equivalence does or does not hold.

Article

The Ricardian equivalence theorem is the proposition that the method of financing any particular path of government expenditure is irrelevant. More precisely, whether government purchases are financed by levying lump-sum taxes or by issuing government bonds does not affect the consumption of any household, nor does it affect capital formation. In this sense, financing government purchases by lump-sum taxes is equivalent to financing these purchases by issuing bonds. The fundamental logic underlying this proposition was presented by David Ricardo in Chapter XVII (‘Taxes on Other Commodities than Raw Produce’) of The Principles of Political Economy and Taxation. Although Ricardo clearly explained why government borrowing and taxes could be equivalent, he warned against accepting the argument on its face: ‘From what I have said, it must not be inferred that I consider the system of
borrowing as the best calculated to defray the extraordinary expenses of the state. It is a system which tends to make us less thrifty – to blind us to our real situation’ (1821, pp. 162–3).

The question of whether lump-sum taxes and government debt are equivalent arises in the specification of the consumption function. The aggregate consumption function plays an important role in models of national income determination, and aggregate consumption is often specified to depend on contemporaneous aggregate disposable income and on aggregate wealth. The question is whether the public’s holding of bonds issued by the government should be treated as part of aggregate net wealth. Indeed, this is the eponymous question of Barro’s (1974) classic article on Ricardian equivalence. If consumers recognize that government bonds, in the aggregate, represent future tax liabilities, then these bonds would not be part of aggregate wealth. If, on the other hand, consumers do not recognize, or for some reason do not care about, the implied future tax liabilities associated with these bonds, then they should be counted as part of aggregate wealth in an aggregate consumption function. Patinkin (1965, p. 289), citing Carl Christ and Christ’s discussions with Milton Friedman, recognized this question and specified that a fraction $k$ of the stock of outstanding government bonds is to be treated as wealth. Under the Ricardian equivalence view, $k$ would equal zero; under the view that consumers ignore all future tax liabilities, $k$ would equal 1. Bailey (1971) also examined the question of whether future tax liabilities affect aggregate consumption in a model of national income determination, though his formulation of the aggregate consumption function does not explicitly include aggregate wealth.

The question of whether government bonds are net wealth and the question of the effects of alternative means of financing a given amount of government expenditure are, in many contexts, basically the same question. For purposes of exposition, it is clearest to focus on one particular formulation of the question. The discussion here will focus on the question of the choice between current taxation and debt finance. The underlying logic of the Ricardian equivalence theorem is quite simple and can be displayed by considering a reduction in current lump-sum taxes of 100 dollars per capita. This reduction in government tax revenue is financed by the sale of government bonds on the open market in the amount of 100 dollars per capita. For simplicity, suppose that the bonds are one-year bonds with an interest rate of five per cent per year. In addition, suppose that the population of taxpayers is constant over time. In the year following the tax cut, the bonds are redeemed by the government. In order to pay the principal and interest on the bonds, taxes must be increased by 105 dollars per taxpayer in the second year.

Now consider the response of households to this intertemporal rearrangement of their tax liabilities. Households can afford to maintain their originally planned current and future consumption by increasing their current saving by 100 dollars. In fact, the additional 100 dollars of private saving could be held in the form of newly issued government bonds. In the second year, when the government increases taxes by 105 dollars to redeem the bonds, households pay the extra tax using the principal and interest on the bonds. Thus, the originally planned path of consumption continues to be feasible after the tax change. In addition, since the originally planned path of consumption was chosen by the consumer before the tax change, it would continue to be chosen after the tax change since all relative prices remain unchanged. Therefore, household behaviour is invariant to the switch between tax finance and debt finance for a given amount of government spending.

In the basic example, the tax cut in the current year is financed by the issuance of one-year government bonds. However, the invariance result continues to hold if the current tax cut is financed by the issuance of N-year bonds. The argument is that once again each consumer uses the extra 100 dollars of disposable income in the first year to purchase 100 dollars of newly issued government bonds. If these government
bonds pay interest in years before the bond is redeemed, then the government must increase lump-sum taxes in those years to service the bonds. Consumers who are holding the bonds and receive interest use the interest on their bonds to pay the increased taxes. Then, when the bonds mature after \( N \) years, each consumer uses the principal and final interest on these bonds to pay the higher taxes that are levied to redeem the debt. Once again, consumers can afford to maintain the originally planned path of current and future consumption and find it optimal to do so.

Having seen that the Ricardian equivalence theorem holds even if long-term bonds are issued to pay for the current tax cut, it is natural to ask whether the invariance result continues to hold even if some or all of the currently living consumers die before the bonds are redeemed. The first answer to this question would appear to be that consumers who are alive during the tax cut, but who die before the newly issued bonds are retired, would have a reduction in the present value of their taxes and thus an increase in the present value of their disposable income. Equivalently, such consumers could afford to increase their current and future consumption. It is not necessary for these consumers to hold the extra bond that is issued in the first year because they will not have to use the bonds to pay for the future tax increase needed to redeem the bonds. Therefore, these consumers would tend to increase their current and future consumption, ceteris paribus.

A self-interested consumer who receives a tax cut financed by government bonds will increase his consumption if he knows with certainty that he will die before future taxes are collected to fully repay the newly issued bonds. But if the consumer is uncertain about when he will die, the situation involves some additional considerations. I begin by ignoring survival-contingent assets such as annuities and life insurance, and I will assume that all consumers have positive net financial assets so that I can put aside issues related to borrowing costs for consumers who may die before repaying their loans. To keep the argument simple, suppose that lump-sum taxes are reduced in the current year by 100 dollars per taxpayer, and the government finances the tax cut by issuing 20-year zero-coupon bonds. Twenty years in the future the government will increase lump-sum taxes to pay off these bonds. The present value of the future tax increase is 100 dollars per current taxpayer. If the number of taxpayers 20 years in the future is the same as in the current year, then tax increase in the future will be \( 100(1 + r)^{20} \) per taxpayer, where \( r \) is the annual interest rate on the government bonds. In this case, the current tax cut will not affect the current consumption of any taxpayer. A current taxpayer could use the 100 dollars from the current tax cut to buy 100 dollars of government bonds, and simply plan to hold on to the bonds for 20 years. In the event that the consumer is still alive and consuming 20 years in the future, he can use his bonds, which will have grown in value to \( 100(1 + r)^{20} \) to pay the additional lump-sum taxes in that year, without changing consumption in that year (or in the current year). In the event that the consumer dies before 20 years elapse, he will, of course, consume the same level, namely zero, as in the absence of the tax cut. Thus, buying and holding 100 dollars of government bonds in the current year just allows the consumer to maintain consumption unchanged at all ages and in all states (that is, the state in which the consumer is alive in 20 years and the state in which he is not alive in 20 years). Therefore, Ricardian equivalence holds in this case.

The example in the preceding paragraph illustrates that Ricardian equivalence can hold even when selfish consumers receive a bond-financed tax cut and, with some unpredictability, die before the taxes are levied to fully repay the bonds. A crucial step in the argument is the assumption that the number of future taxpayers is the same as the number of current taxpayers. But with some taxpayers dying over
time, the only way to maintain a constant number of taxpayers is for new taxpayers to arrive – through birth or immigration – at the same rate at which taxpayers are dying. In an economy with a growing population, that is, in an economy in which the sum of the birth rate and net immigration rate exceeds the death rate, the increase in future lump-sum taxes per taxpayer will be smaller than $100(1 + r)^{20}$, because the cost of paying off government bonds is spread among a larger number of taxpayers. Therefore, a consumer who receives a tax cut of 100 dollars in the current year will face a future tax increase that has a present value smaller than 100 dollars, and so will increase consumption in the current period (and in the future period, if he is alive). Alternatively, in an economy with a shrinking population, a lump-sum tax increase will have the opposite effect and will reduce current consumption. (An analytic version of this example is in Abel, 1989.)

Ricardian equivalence is often illustrated in the context of perfect markets. If consumers face uncertainty about the length of their lives, and if they do not have bequest motives of any sort, they will want to hold annuities, which are assets that pay off if the owner of the annuity is alive, but pay zero if the owner is not alive. If all consumers face the same publicly known probability, $p$, of dying each year, then the actuarially fair annual gross rate of return on annuities will be $\frac{1 + r}{1 - p}$. If all consumers invest one dollar in an annuity that pays a lump sum in 20 years, then in 20 years each survivor will receive $\frac{(1 + r)}{(1 - p)}^{20}$ dollars. Whether consumers who receive a 100 dollar lump-sum tax cut in the current year will change their current consumption depends on the amount of the tax increase per taxpayer 20 years in the future when the bonds used to finance the tax cut are paid off. If the birth rate and the net immigration rate are both zero, then the population of taxpayers in 20 years will be a fraction $(1 - p)^{20}$ of the population in the current year. Thus, to repay the principal and interest on the 100 dollars of bonds issued per current taxpayer, the lump-sum tax will have to increase by $\frac{(1 + r)}{(1 - p)}^{20}$ dollars per current taxpayer. Thus, a current taxpayer could use the 100 dollar tax cut in the current period to purchase 100 dollars of annuities in the current period. If the consumer survives for 20 years, the payoff of the annuity, $\frac{(1 + r)}{(1 - p)}^{20}$, will be just sufficient to pay the increased lump-sum tax in that year. Thus, Ricardian equivalence holds in this case with perfect annuities and a zero birth rate and zero net immigration rate. Ricardian equivalence will fail to hold, however, if the birth rate is positive, because the tax burden in 20 years will be spread among a group of taxpayers consisting of surviving taxpayers from the current period plus additional taxpayers. In this case, the tax increase per future taxpayer will be smaller than $\frac{(1 + r)}{(1 - p)}^{20}$. Thus, recipients of the tax cut in the current period would be able to increase consumption in the current period somewhat and use the remainder of the tax cut to buy enough annuities to pay the increased lump-sum tax and to increase consumption in 20 years.

The examples with uncertain longevity illustrate that, as emphasized by Weil (1989), the departure from Ricardian equivalence does not result solely from the chance of dying before the future tax increase. In the examples in which the tax cut in the current year induces an increase in current consumption, the effect results from the fact that future increase in taxes per future taxpayer is smaller than the current tax cut per taxpayer. In the case of perfect annuities, this effect is made possible by a positive birth rate, and in the case without annuities the effect was made possible by growing population resulting from a death rate lower than the birth rate plus the net immigration rate.
Altruistic consumers

If consumers are entirely self-interested, then escaping future taxes through death can lead to departures from the Ricardian equivalence theorem, as discussed above. However, Robert Barro (1974) presented an ingenious argument that extends the Ricardian equivalence theorem to situations in which consumers die before future taxes are increased to repay the bonds that are issued to finance the current tax cut. Before discussing the substantive content of Barro's argument, it is interesting to observe that the term ‘Ricardian equivalence theorem’ apparently was first used by James Buchanan (1976) in a published comment on Barro's paper. Buchanan's comment begins by pointing out Barro's failure to credit Ricardo with the idea that debt and taxes may be equivalent and, indeed, the comment is titled, ‘Barro on the Ricardian Equivalence Theorem’. Previously, Buchanan had referred to this result as the ‘equivalence hypothesis’ (1958, p. 118).

Barro postulated that consumers have bequest motives of a particular form that has been labelled ‘altruistic’. An altruistic consumer obtains utility from his own consumption as well as from the utility of his children. Therefore, a consumer who is altruistic toward all of his children cares not only about his own consumption but also indirectly about the consumption of all his children. Furthermore, if all of the altruistic consumer's children are also altruistic and care about the utility of all of their children, then the altruistic consumer cares indirectly about the consumption of all of his grandchildren. Provided that all consumers are altruistic, the argument can be extended ad infinitum with the important implication that an altruistic consumer cares, at least indirectly, about the entire path of current and future consumption of himself and all of his descendants.

Barro's insight that an intergenerationally altruistic consumer cares about the entire path of his family's consumption defuses the argument that consumers who know they will escape future taxes through death will increase consumption in response to a current tax cut. For altruistic consumers, it does not matter whether they themselves or their descendants pay the higher taxes necessary to pay the principal and interest on the newly issued bonds. In response to a 100 dollar tax cut in the current year, an altruistic consumer will not change his consumption but will hold an additional 100 dollars of government bonds. If the bonds are not redeemed until after the consumer dies, he will bequeath them to his children who can then use the bonds to pay the higher taxes in the year in which the bonds are redeemed, or else bequeath the bonds to their children if the bonds are not redeemed during their lifetimes.

The fact that a consumer leaves a bequest is not prima facie evidence that he is altruistic in the sense defined above. Bequests may arise as the accidental outcome of an untimely death or they may arise for motives other than altruism. For instance, if the utility that a consumer obtains from leaving a bequest depends only on the size of the bequest, then he will not care about tax increases that may be levied on his children or his children's children. In this case Ricardian equivalence would not hold.

The argument that each current and future consumer in a family of intergenerationally altruistic consumers cares about his own consumption as well as the consumption of all of his descendants for ever raises the question of whether the government must ever pay off the newly issued government bonds. If the government could roll over the principal and interest on this debt for ever, so that it would never be necessary to increase future taxes, it would seem that a current tax cut financed by issuance of government bonds would reduce the present value of the taxes paid by the current and future members of the family and hence would lead to an increase in the family's consumption. If the government...
attempted to roll over its debt each year by issuing new bonds, the quantity of these bonds would grow in perpetuity at the rate of interest. If the rate of interest exceeds the economy's growth rate, then these bonds would not willingly be held in private portfolios. Alternatively, if the rate of interest falls short of the economy's growth rate – a condition that signals an inefficient over-accumulation to capital – then, as pointed out by Feldstein (1976), it is possible for the government to roll over the debt permanently. Carmichael (1982) has shown that in this case the altruistic bequest motive will not be operative (that is, the non-negativity constraint on bequests will bind) but that an altruistic gift motive from children to parents (which specifies that a consumer's utility depends on his own consumption and the utility of his parents) may be operative. If the gift motive is operative, then Carmichael argues that Ricardian equivalence will hold, despite the fact that government bonds may be regarded as net wealth.

Departures from Ricardian equivalence

Now that we have described a fairly general set of conditions under which Ricardian equivalence holds, it is useful to discuss several of the conditions that might lead to a violation of Ricardian equivalence. A clear overview of reasons why the Ricardian equivalence theorem may not provide an accurate description of the actual effects of debt finance vs. tax finance is provided by Tobin (1980). The basic argument underlying the Ricardian equivalence theorem is that it makes no difference whether the government issues debt in the amount of 100 dollars per capita or whether it collects taxes of 100 dollars per capita since in the latter case consumers can borrow 100 dollars per capita to pay the higher taxes. In the former case, public borrowing is increased by 100 dollars per capita, and in the latter case private borrowing is increased by 100 dollars per capita. Under the appropriate conditions it makes no difference whether the borrowing is by the public sector or by the private sector. In order for the choice between debt finance and tax finance to have an effect, it must be the case that any changes in government borrowing cannot be fully offset by changes in private sector behaviour. Equivalently, there must be something that the government can do in credit markets that the private sector cannot do. The government can borrow by issuing bonds, but in some situations consumers may not be able to borrow. For instance, a young consumer with a high prospective income might like to borrow to increase his consumption when young with the intention of repaying the loan when his income is higher in the future. However, for a variety of reasons it may simply not be possible for the young consumer to borrow the desired amount; if this is the case, the consumer is described as ‘liquidity-constrained’. A liquidity-constrained consumer who receives a tax cut in the current period may choose to consume some, or even all, of the tax cut rather than save the entire tax cut. In effect, the current tax cut allows the consumer to borrow in order to increase current consumption, which is what the liquidity-constrained consumer wanted to do anyway. The current tax cut financed by an issue of government bonds can be viewed as the government borrowing on behalf of the consumer. Although this example makes it seem clear that a liquidity-constrained consumer would increase his current consumption in response to a current tax cut, some caution is required in interpreting this result. Unless the reason for the liquidity constraint is specified, one cannot determine what will be the effect of the tax cut. For example, suppose that a consumer is able to borrow some funds, but is liquidity-constrained in the sense that he would like to borrow even more funds. If his creditors determine how much they are willing to lend by looking at his ability to repay the loan, then, in response to the prospective tax increase accompanying the current tax cut, his lenders may reduce the amount they are willing to lend by the
The Ricardian equivalence theorem requires not only that consumers be intergenerationally altruistic, but that their bequest motives be operative in the sense that consumers can bequeath whatever amount they choose subject to their budget constraint. To be more precise, it is possible that an altruistic consumer may like to leave a negative bequest to his children, but he is constrained from leaving a bequest less than zero. The fact that a consumer may want to leave a negative bequest does not necessarily violate the assumption that the consumer is altruistic. It may be that the consumer's children will all be so much wealthier than the consumer that, even though the consumer cares about the utility of his children, he could achieve higher utility by taking some of his children's resources and consuming them himself. Formal conditions that imply that altruistic consumers would like to leave negative bequests have been presented by Drazen (1978) and Weil (1987). Under these conditions, if the consumer is constrained from leaving a negative bequest, he will instead leave a zero bequest. In such cases, a tax cut that is followed by a tax increase after the consumer's death will reduce the present value of the taxes paid by the consumer and he will increase his consumption. In effect, the current tax cut helps the consumer achieve the desired negative bequest by giving him current resources and taking resources away from his descendants.

Another reason for departure from the Ricardian equivalence theorem is that policy may redistribute resources among families that have different marginal propensities to consume. For instance, suppose that one half of the consumers receive a 200 dollar tax cut in the current year and the other half of the consumers have unchanged taxes in the current year. The government finances the tax cut by issuing bonds in the amount of 100 dollars per capita, and in the following period it redeems the bonds and pays the interest. For simplicity, suppose that the population is constant and that the interest rate on government bonds is five per cent per year. Then in the year following the tax cut there is a tax increase of 105 dollars per consumer. Finally, suppose that this tax increase is levied on all consumers equally. In this case, the tax cut in the current year redistributes resources from the consumers whose taxes are unaffected to the consumers whose taxes are reduced in the current year. The recipients of the transfer will increase their consumption and the other consumers will reduce their consumption. The reallocation of consumption across consumers may be viewed as a violation of Ricardian equivalence. Whether aggregate consumption rises or falls depends on the marginal propensities to consume of the recipients of the transfer compared with the marginal propensities to consume of the other consumers. If all consumers have equal marginal propensities to consume, then there will be no effect on aggregate consumption or capital accumulation. However, if, for instance, the recipients of the transfers have a higher marginal propensity to consume than the other consumers, then aggregate consumption would increase. It should be pointed out that, in some sense, this example does not represent a violation of the Ricardian equivalence theorem, because it ignores the possibility that there might exist an insurance market for individual tax liabilities. If there were such a market, then consumers could have insured themselves against the redistribution of taxes. Such markets do not generally exist, but whether the Ricardian equivalence theorem holds may depend on the reason why these markets do not exist.

To see the role of insurance markets in a different context, consider consumers who each contribute 100 dollars to a social security fund during their working life. Suppose that at the end of their working lives some of the consumers die and the others survive and live in retirement. Although the number of consumers who die at retirement may be predictable, the identities of those who will die are not predictable. The surviving retired consumers each receive an equal share of the social security fund
Ricardian equivalence theorem: The New Palgrave Dictionary of Economics

(with accrued interest) to which they contributed while they were working. Each survivor's social security income is greater than the 100 dollars (plus interest) which he contributed, because the fund contains the contributions plus interest of his peers who died at the end of the working life.

Does the introduction of this type of social security system affect consumption and capital accumulation or does Ricardian equivalence imply that consumption and capital accumulation will be unaffected? To answer this question, it is useful to observe that this stylized social security system has the characteristics of an actuarially fair annuity. That is, consumers pay a premium when young (the social security tax) and receive a payment if, and only if, they survive to old age. Furthermore, if all consumers face the same probability of dying, the rate of return to the survivors is equal to the actuarially fair rate of return. If there were a competitive annuity market offering the actuarially fair rate of return, the social security system would have no effect on consumption or capital accumulation. Workers who are taxed 100 dollars are essentially forced to hold 100 dollars of the publicly provided actuarially fair annuity called social security; however, these consumers can afford, and will choose, to maintain their originally planned consumption and bequests by reducing their holdings of privately supplied annuities by 100 dollars. This reduction in the holding of private annuities allows consumers to re-establish their initial portfolios of annuities and other assets while maintaining consumption unchanged. Thus, the Ricardian equivalence theorem holds in this example, provided that consumers each originally planned to hold at least 100 dollars of private annuities.

If the probability of surviving until retirement differs across consumers, and if individual consumers are better informed about their own survival probabilities than are insurance companies, then the funded social security system described above will affect consumption. The reason is that, if an insurance company offered annuities at a price that would be actuarially fair to the average consumer, it would suffer from what is known as ‘adverse selection’. As a simple example, suppose that insurance companies know the average mortality probability but have no additional information about the mortality probabilities of individual consumers. If an insurance company offered annuities at a price that would be actuarially fair to the average consumer, then consumers who believe they are healthier than average would view these annuities as a bargain; consumers who believe they are less healthy (or engage in more dangerous activities) than average would view these annuities as overpriced because these consumers have a smaller chance of living to reap the rewards. As the healthy consumers would buy a disproportionately large share of annuities, they would, on average, inflict losses on the sellers of these annuities and would induce these sellers to charge a higher price for annuities. However, the social security system can supply its annuities at the actuarially fair price for the average consumer because a compulsory social security system is immune to adverse selection. That is, because the government can determine the amount of the publicly provided annuity held by each individual, it does not have to worry that a disproportionately large share of annuities are held by healthy consumers. Therefore, as shown in Abel (1986), the annuity offered by the social security system would yield a higher rate of return than private annuities, or, equivalently, would be made available at a lower price to consumers. Because of the difference in the prices of the publicly provided and privately supplied annuities, consumers could not exactly offset the effects of social security by transacting in private annuity markets.

The example in which adverse selection leads to violation of the Ricardian equivalence theorem was constructed to obey the strict set of rules demanded by strong adherents to the view that the choice between debt finance and tax finance is irrelevant. In particular, the following assumptions were maintained: (a) consumers are forward-looking and understand that a bond-financed tax cut implies an
increase in future taxes; (b) consumers have operative altruistic bequest motives so that they care about taxes after their death; (c) there is a complete set of competitive markets; and (d) only lump-sum taxes are changed. However, actual economies display several important departures from each of these assumptions. Violations of these assumptions are discussed below.

First, despite the widespread appeal of rational expectations in modern economics, it may simply be that consumers do not fully appreciate the link between a current tax cut and an increase in future taxes. If consumers did not understand this link at all, then a current tax cut would tend to increase current consumption.

Second, consumers may not have a bequest motive, either because they have no children or because they do not care about the welfare of anyone else. Even if consumers do have a bequest motive, it may not be operative as discussed above. Even if the bequest motive is operative, it may not be of the appropriate form for the Ricardian equivalence theorem to hold. If a consumer's utility depends directly on the size of the bequest he leaves rather than on the utility of his heirs, then a current tax cut followed by a tax increase on his heirs, would tend to raise the current consumption of the consumer. The reason is that he does not care about his heirs' utility per se. His bequest yields utility directly just as any other consumption good. As a result of the decrease in taxes he must pay over his lifetime, the consumer will have a higher level of lifetime income and can increase his own consumption and the bequest he leaves. If his own consumption and the bequest are both normal goods in his utility function, then he will choose to increase both.

Even if all consumers have operative altruistic bequest motives, a tax cut may increase current consumption. If all consumers have several children, but if each consumer cares about the utility of only one of his children, then there will be consumers in future generations whose utility is ignored by all current consumers. To the extent that future taxes are levied on these consumers, some part of future tax liabilities associated with a current tax cut will be ignored by current consumers. In this case, a tax cut would increase contemporaneous aggregate consumption.

Bernheim and Bagwell (1988) have challenged the plausibility of the assumption of intergenerational altruism by showing that this assumption leads to some untenable conclusions. If consumers A and B are unrelated to each other and both are altruistic toward consumer C, then A and B are effectively linked to each other, if both consumers A and B both plan to give positive transfers (bequests) to consumer C. For example, unrelated grandparents (consumers A and B) who plan to make positive transfers to their common grandchildren (consumers C) are effectively linked to each other. If the government transfers a dollar from consumer A to consumer B, these consumers can, and will choose to, undo this transfer and maintain their originally chosen patterns of consumption. The mechanism for undoing the government transfer is for consumer A to reduce his transfer to consumer C by one dollar and for consumer B to increase his transfer to consumer C by one dollar. Bernheim and Bagwell have argued that, if one takes intergenerational altruism seriously, such linkages are so widespread that all consumers are effectively linked to each other. In this case, all government transfers among consumers, including a transfer from future taxpayers to current taxpayers in the form of a bond-financed tax cut, would have no effect. Bernheim and Bagwell go on to show that even non-lump-sum taxes, and indeed prices themselves, would not affect consumption. Rather than conclude that all taxes and prices are irrelevant, Bernheim and Bagwell conclude that their findings cast doubt on the policy conclusions, including Ricardian equivalence, that are based on the assumption of intergenerational altruism.

Third, various types of insurance markets may be absent or, as described above, may suffer from adverse
Ricardian equivalence theorem: The New Palgrave Dictionary of Economics

selection. Chan (1983) and Barsky, Mankiw and Zeldes (1986) have argued that, if there are no markets for insuring against unpredictable fluctuations in after-tax income, then a current tax cut could increase current consumption. The argument, which was outlined by Barro (1974, p. 1115) and Tobin (1980, p. 60), is that to the extent that individual tax liabilities are proportional to income the tax system provides partial insurance against fluctuations in individual disposable income. Therefore, the increase in tax rates that follows a lump-sum tax cut in the current year will reduce the variability of future disposable income. The reduction in the riskiness of future disposable income reduces current precautionary saving that consumers undertake to guard against low future consumption. The counterpart of the reduction in precautionary saving is an increase in current consumption.

Fourth, most taxes are not lump-sum taxes. Generally, taxes are levied on economic activities, and changes in these taxes provide incentives to alter the levels of these activities. Although the existence of distortionary taxes does not in all cases imply that Ricardian equivalence is violated when applied to lump-sum tax changes, it does strain the interpretation of empirical tests of Ricardian equivalence that examine historical data on deficits and consumption.

As discussed above, there are many potential sources of departure from the Ricardian equivalence theorem, and ultimately the importance of these departures is an empirical question. The existing literature that attempts to test empirically whether Ricardian equivalence holds has produced mixed results, some claiming to show that it holds, and others the opposite. In judging the empirical relevance of the Ricardian equivalence theorem, however, the important question from the viewpoint of fiscal policy formulation is not whether the theorem holds exactly but whether there are departures from it that are quantitatively substantial. Existing empirical work has not yet produced a consensus on this question.

**Article**

Ricardian trade theory takes cross-country technology differences as the basis of trade. By abstracting from the roles of cross-country factor endowment differences and cross-industry factor intensity differences, which are the primary concerns of factor proportions theory (such as Heckscher–Ohlin and Specific Factor models), Ricardian trade theory offers a simple and yet powerful framework within which to address many positive and normative issues of international trade. It is particularly well-equipped to examine the effects of country sizes, of technology changes and transfers, and of income distributions. Furthermore, its simple production structure makes it relatively easy to allow for many tradable goods and many countries, and hence capable of generating valuable insights which are lost in the standard two-country, two-goods model of international trade.

Let us start with the Ricardian model with a continuum of tradable goods, adopted from Dornbusch, Fischer and Samuelson (DFS) (1977). The world consists of two countries, Home and Foreign. There is a continuum of competitive industries, indexed by $z \in [0, 1]$, each producing a homogenous tradable good, also indexed by $z$. There is only one non-tradable factor of production, called labour. (Or, if there are many non-tradable factors, they can be aggregated into a single composite factor.) Let $a(z)$ and $a^*(z)$ be the Home and Foreign unit labour requirements of good $z$, that is, labour input required to produce one unit of output $z$ at Home and Foreign. Without loss of generality, we can index $z$ so that Home's relative efficiency, $\mathcal{A}(z) = \frac{a^*(z)}{a(z)}$, is non-increasing in $z$. In Figure 1, it is strictly decreasing. In short, Home (Foreign) has a comparative advantage in low-indexed (high-indexed) goods.

**Figure 1**

The equilibrium factor terms of trade and patterns of specialization

\[
\frac{w}{w^*}
\]
Let $w$ and $w^*$ denote the wage rates at Home and Foreign. Then, the prices in autarky are given by $p(z) = wa(z)$ at Home and $p^*(z) = w^*a^*(z)$ at Foreign. Under free trade (and in the absence of any trade costs), the price of each good is equalized across the two countries and is given by $p(z) = p^*(z) = \min\{wa(z), w^*a^*(z)\}$. Then, for a given relative wage rate or a
given level of the factorial terms of trade, \( \frac{w}{w^*} \), there is a marginal good, \( m \), defined by

\[
\frac{w}{w^*} = A(m),
\]

such that Home produces only goods in \([0,m]\), and Foreign produces only goods in \([m,1]\), and the prices become

\[
p(z) = p^* (z) = w\alpha(z), \quad z \in [0, m]; \quad p(z) = p^* (z) = w^* \omega^*(z), \quad z \in [m, 1].
\]

To pin down the relative wage rate, we must specify the demand conditions. To keep it simple, let us assume that there are \( L(L^*) \) households at Home (Foreign), each supplying one unit of labour, and that every household shares the symmetric Cobb–Douglas preferences defined over \( \bar{z} \in [0, 1] \), as

\[
U = \int_0^1 \log \{ \epsilon(z) \} \, dz \quad \text{and} \quad U^* = \int_0^1 \log \{ \epsilon^*(z) \} \, dz.
\]

Then, the world income (and the world total expenditure), \( wL + w^*L^* \), is also equal to the world expenditure on each good. Since Home produces the goods in \([0,m]\), the total expenditure on the Home goods is \( m(wL + w^*L^*) \), which must be equal to the Home income, \( wL \), in equilibrium. This condition yields

\[
\frac{w}{w^*} = \frac{m}{1 - m} \left[ \frac{l^*}{l} \right]
\]

which is depicted by the upward sloping curve in Figure 1. It is upward-sloping because a higher \( m \) means that a larger fraction of the world expenditure goes to the goods produced by the Home labour, hence its relative wage goes up. As shown by the intersection of the two curves in Figure 1, eq. (1) and eq. (3) jointly determine the equilibrium relative wage rate, \( \frac{w}{w^*} \), and the equilibrium patterns of trade and specialization, \( m \), as Home exports and Foreign imports goods in \([0,m]\) and Home imports and Foreign exports goods in \((m,1]\). In short, the patterns of trade follow the patterns of comparative advantage.

The standard two-country, two-goods Ricardian model, found in many college textbooks, may be recovered as a special case of this model, where \( A(z) = A_1 \) for \( \bar{z} \in [0, \alpha] \) and \( A(z) = A_2 \) for \( \bar{z} \in (\alpha, 1] \), with \( A_1 > A_2 \), as shown in Figure 2. By aggregating all the goods in \([0, \alpha]\) as a composite good, called Good 1, and all the goods in \((\alpha, 1]\) as another composite good, called Good 2, the model becomes a two-sector model, where the households have the preferences, \( U = \alpha \log(C_1) + (1-\alpha) \log(C_2) \) and \( U^* = \alpha \log(C_1^*) + (1-\alpha) \log(C_2^*) \). Viewed this way, the model highlights the restrictive feature of the two-good assumption in the textbook Ricardian model.

Figure 2
The two-goods case
Gains from trade and country size effects

The Home and Foreign welfares are measured by $U = \int_0^1 \log \left( \frac{w(z)}{p(z)} \right) dz$ and $U^* = \int_0^1 \log \left( \frac{w^*(z)}{p^*(z)} \right) dz$, respectively. In autarky, they are equal to

$$U_A = -\int_0^1 \log \left( a(z) \right) dz, \quad U^*_A = -\int_0^1 \log \left( a^*(z) \right) dz,$$

and, under free trade, they are equal to

$$U_T = -\int_0^1 \log \left( a(z) \right) dz + \int_0^1 \log \left( \frac{w}{w^* a^*(z)} \right) dz, \quad U^*_T = \int_0^1 \log \left( \frac{w}{w^* a(z)} \right) dz - \int_0^1 \log \left( a^*(z) \right) dz.$$

Subtracting (4) from (5) and using (1) show that the welfare changes from autarky to free trade by:

$$\Delta U = U_T - U_A = \int_0^1 \log \left( \frac{A(m)}{A(z)} \right) dz, \quad \Delta U^* = U^*_T - U^*_A = \int_0^1 \log \left( \frac{A(z)}{A(m)} \right) dz,$$

both of which are strictly positive in the case depicted in Figure 1. More generally, both countries gain from trade, as long as $0 < m < 1$ and $A(0) > A(m) > A(1)$. Note that this condition could hold even when one country, say Home, has absolute advantage over the other, say Foreign, that is, $A(z) > 1$ for $z \in (0, 1]$. Clearly, such absolute advantage allows Home households to enjoy higher wage income and hence a higher standard of living than Foreign households, $w > w^*$, and $U_T - U_A = \log \left( w \right) - \log \left( w^* \right) > 0$. Yet both countries gain from trade as long as trade allows them to specialize in the goods that they are relatively good at producing.

In the two-goods case, shown in Figure 2, both countries gain from trade only when $m = \alpha$ and $A_1 > w^*/A_2$, which requires that $A_2(1-\alpha)/\alpha < L^*/L < A_1(1-\alpha)/\alpha$. Home does not gain from trade if $w^*/w = A_2$, which occurs when $L^*/L \leq A_2(1-\alpha)/\alpha$, and Foreign does not gain from trade if $w^*/w = A_2$, which occurs when $L^*/L \geq A_1(1-\alpha)/\alpha$. This result of the two-sector model is often interpreted as saying that a large country cannot gain from trade, as it remains incompletely specialized, or that a country must fully specialize in order to gain from trade, but this is due to an artificial feature of the two-goods model which restricts the cross-country differences in technology.

What is generally true is that, as one country becomes large (small) relative to the rest of the world, its gains from trade become smaller (large). As shown in Figure 1, an increase in $L^*/L$, which shifts the upward-sloping curve to the left, leads to a higher $w^*/w$ and a lower $m$, which implies a higher $\Delta U$ and a lower $\Delta U^*$, as seen from (6). For example, a faster population growth in the South (Foreign) allows the North (Home) to specialize further, which improves its factoral terms of trade and its standard of living at the expense of the South. (The same phenomenon might be described by the protectionist in the North as saying, ‘because of the cheap labour in the South, the North loses its competitive advantage and industries move from the North to the South’.)

This also suggests that a country with a small population could enjoy higher per capita income even with limited technological superiority. In Figure 3, Home's technologies are inferior in almost all the goods, yet, thanks to its relatively small population, Home enjoys higher per capita income. This may explain why countries like Norway and Switzerland
enjoy a high standard of living even though their geography and climates are not particularly suitable to most economic activities. With smaller populations, they can maintain a high standard of living by specializing in a narrower range of activities that they are particularly good at. This effect is difficult to see within a two-goods model.

Figure 3
Gains from trade and country size effects
These results suggest diminishing returns to scale (DRS) at the country level, even though technologies satisfy the constant returns to scale (CRS) property. This is because the endogeneity of the terms of trade, \( \frac{w}{w^*} \), introduces de facto diminishing returns. To see some macroeconomic implications, let us reinterpret the model in the following way. Home and Foreign produce their GDPs, \( Y \) and \( Y^* \), by the CRS aggregate production function, \( \log(Y) = \int_0^1 \log[c(z)] \, dz \) and \( \log(Y^*) = \int_0^1 \log[c^*(z)] \, dz \), where \( c(z) \) and \( c^*(z) \) denote the inputs of the tradeable intermediate goods, \( z \in [0, 1] \). The representative household at Home and at Foreign supplies \( L \) and \( L^* \) units of the composite of the primary factors, which may include not only labour but also physical and human capital. Then, the expressions analogous to (5) become

\[
\log \left[ \frac{Y}{L} \right] = \int_0^1 \log \left[ \frac{w}{w^*} \cdot \frac{1}{a(z)} \right] \, dz - \int_0^1 \log[a(z)] \, dz;
\]

\[
\log \left[ \frac{Y^*}{L^*} \right] = \int_0^1 \log \left[ \frac{w^*}{w^* a^*(z)} \right] \, dz - \int_0^1 \log[a^*(z)] \, dz.
\]

The effect of a change in \( L \) and \( L^* \) can be seen by totally differentiating the above expressions, which yields the following growth accounting:

\[
\frac{dY}{Y} = \frac{dL}{L} + (1 - m) \left[ \frac{dW}{W} - \frac{dW^*}{W^*} \right];
\]

\[
\frac{dY^*}{Y^*} = \frac{dL^*}{L^*} + m \left[ \frac{dW^*}{W^*} - \frac{dW}{W} \right].
\]

If \( L \) and \( L^* \) grow at the same rate, \( \frac{w}{w^*} \) remains constant, and hence both \( Y \) and \( Y^* \) also grow at the same rate. However, if \( L \) grows faster than \( L^* \), then \( Y \) grows slower than \( L \) and \( Y^* \) grows faster than \( L^* \) through the terms of trade effect. This example also suggests that, even when there are increasing returns to scale (IRS) in the aggregate production technologies, naive cross-country growth regression exercises which do not take into account interdependence among countries might fail to uncover economies of scale. See also Acemoglu and Ventura (2002), which studies how such a terms-of-trade mechanism generates stable cross-country distribution of income in the world even when different countries accumulate factors at different rates.

**Technology changes and transfers**

Because it takes cross-country technology differences as the basis of trade, the Ricardian model is well-suited to study the effects of technology changes. Let \( g(z) \equiv -\frac{d}{dz} \log[a(z)] \) and \( g^*(z) \equiv -\frac{d}{dz} \log[a^*(z)] \) denote the rate of productivity change in industry \( z \) at Home and Foreign. By totally differentiating (5), the Home welfare changes can be expressed as
where $\xi(z) \equiv -d\log[A(z)]/dz$. For example, it is easy to see that Home always gains from productivity growth in its export sectors, $g(z)>0$ for $z \in [0, m]$. Does Home gain from productivity growth abroad, as well? If Foreign experiences a uniform productivity growth in its export sectors (that is, $g^*(z)=g^*>0$ for all $z \in [m, 1]$), then the answer is yes because

$$
dU = \int_0^m g(z) dz + \int_m^1 g^*(z) dz + \left[ \frac{1-m}{1+\xi(m)m(1-m)} \right] \left[ g(m) - g^*(m) \right]
$$

unless $\xi(m)=0$, in which case productivity gains in the Foreign export sectors are entirely offset by the terms of trade change.

On the other hand, Home may lose from Foreign productivity growth if it is concentrated around the marginal sector, $m$. The following example, taken from Jones (1979), illustrates this possibility. Let $A(z) = A_1 = a_1^*/a_1$ for $z \in [0, \alpha_1]$; $A(z) = A_2 = a_2^*/a_2$ for $z \in (\alpha_1, \alpha_1+\alpha_2]$, and $A(z) = A_3 = a_3^*/a_3$ for $z \in (\alpha_1+\alpha_2, 1]$, with $A_1>A_2>A_3$. Again, we may view this example as a three-sector model, by aggregating all the goods within each segment, as Goods 1, 2, and 3. When the upward-sloping curve intersects with $A(z)$ at its middle segment, $w^*/w^*=A_2$. Then, the Home and Foreign welfares are given by

$$
U_T = (1-\alpha_1+\alpha_2)\log(a_2^*/a_3^*),
U_T^* = -(\alpha_1+\alpha_2)\log(a_2^*) - (1-\alpha_1+\alpha_2)\log(a_3^*),
$$

where we normalize $a_1=a_2=a_3=1$ without loss of generality to simplify the expression. The Home welfare declines (and the Foreign welfare improves) unambiguously when Foreign productivity growth takes the form of a reduction in $a_2^*$, depicted by the arrow in Figure 4. The reason for the Home loss is that the Home purchasing power measured in Good 2 remains unchanged as Foreign productivity growth is completely offset by the increase in the Foreign wage, while the Home purchasing power measured in Good 3 declines, as the increase in the Foreign wage makes it more expensive.

Figure 4
The three-goods case
The above example again demonstrates the restrictiveness of the two-goods assumption. In particular, it suggests that the widely used distinction between 'export-biased' and 'import-
biased” technology changes in two-sector models, first introduced by Hicks (1953), is of very limited value, as it can be applied only when these changes are uniform across all the export (or import) sectors. Indeed, it can be misleading because the effects of technology changes that take place in some export sectors may be very different from those of ‘export-biased technological changes’ in the two-sector model. (A similar point can be made for the analysis of trade policies. In the standard competitive two-sector model of trade, the government cannot improve its national welfare by providing export subsidies to its export sector. This should be interpreted as saying that export subsidies provided uniformly to all of its export sectors cannot improve its national welfare. Indeed, using the Ricardian models similar to the one above, Itoh and Kiyono, 1987, showed that selective export subsidies that target sectors around the marginal sector can improve the national welfare.)

The same mechanism could operate when the technologically lagging country succeeds in catching up with the technologically leading country. Suppose \( a(\tau) = 1 \) for all \( \tau \in [0,1] \) and \( A(\tau) = \Lambda \Gamma(\tau) = \Lambda - \tau \), where \( \Lambda > 1 \) is a parameter, representing the extent to which Foreign ‘lags behind’ Home technologically. For example, each tradable good is produced by performing two tasks by \( x_1 \) and \( x_2 \), with the Cobb–Douglas production function, \( F_z(x_1, x_2) = x_1^{z} x_2^{1-z} \), and that the unit labour requirement for task 1 is equal to one everywhere, while the unit labour requirement for task 2 is one at Home and \( \Lambda > 1 \) at Foreign. One may think that \( \Lambda \) reflects the technology gap, which affects when performing task 2, but not task 1. Then, Home has absolute advantage in all the goods, but Foreign has comparative advantage in the high-indexed goods, which can be produced mostly by performing the simple task 1. (Krugman, 1986, offered another story behind a similar parameterization of \( A(\tau) \).) With this parameterization, we have

\[
U_T = \frac{(1-m)^2}{2} \log \Lambda, \quad U_T^* = -\frac{1-m^2}{2} \log \Lambda,
\]

where \( m \) is determined by the condition, \( mL^* / (1-m) L = \Lambda - m \). Home could lose if Foreign succeeds in narrowing the gap (that is, a reduction in \( \Lambda \)). The reason is easy to understand. As the gap narrows, Foreign becomes more similar to Home, and Home gains little from trading with a country similar to itself. Indeed, if Foreign catches up completely, \( \Lambda = 1 \), Home loses all the gains from trading with Foreign because the two countries become identical. Note that the underlying mechanism in this example is the same as in the three-goods example. When Foreign narrows the gap, their productivity growth is not uniform across its export sectors. It is larger in the sectors in which Home has bigger absolute advantages. However, it is false to say that Home suffers because Foreign productivity growth is ‘import-biased’. The Home loss is caused by Foreign productivity growth around the marginal sector, not at the lower end of the spectrum.

**Nontraded goods, trade costs, and effects of globalization**

We have been examining the effects of trade by comparing the two extreme cases: autarky, where no goods are traded, and ‘free’ trade, where all goods are costlessly tradeable. Let us now introduce some trade costs and examine the effects of (partial) trade liberalization by reducing the trade costs. Matsuyama (2007c) conducts such exercises by following DFS (1977), which proposed two alternative ways of introducing trade costs in their model: traded–nontraded dichotomy and uniform iceberg costs.

**Traded–nontraded dichotomy**

Suppose that only the goods in \([0,k]\) are tradable at zero cost and \( A(\tau) \equiv a^*(\tau) / a(\tau) \) is continuous, and strictly decreasing in \( \tau \), within this range. On the other hand, trade costs are so high for the goods in \((k,1]\) that they need to be produced locally. At this point, we do not have to specify the production technologies for these nontradables. Given the marginal good, \( m \in [0,k] \), defined by \( A(m) = w / w^* \), Home produces all the goods in \([0,m]\) for both countries and Foreign produces all the goods in \((m,k]\). In addition, each country produces all the goods in \((k,1]\) locally. Therefore, the total expenditure on the goods produced at Home is equal to \( m (w L + w^* L^*) + (1-k) w L^* \), which must be equal to the Home income, \( w L^* \), in equilibrium. This condition yields

\[
\frac{w}{w^*} = m \left[ \frac{k - m}{k} \frac{l}{l^*} \right].
\]
The equilibrium is determined jointly by eq. (1) and eq. (7), as shown in Figure 5. DFS (1977) used this extension to study the classical transfer problem. In the presence of the nontraded goods, the German households spend a larger share of their income on the goods produced in Germany than the households abroad. Because of this ‘home bias’ in demand, an exogenous income transfer from Germany to the Allies (the war reparations after the Treaty of Versailles of 1919) shifts demand away from the German goods, which leads to a deterioration of the German terms of trade, imposing the additional burden on the German economy.

Figure 5
Non-uniform globalization
Let us use this model to study the effects of a globalization. Imagine that some nontradables become tradable. For example, the governments might decide to lift the bans on trading some goods that can be traded costlessly. Or advances in information and communication technologies might open up the possibility of trading some labour services at zero cost. The effects, of course, depend on the relative efficiency of the two countries in producing these newly tradables. Consider the case where \( A(z) = A \) for all \( z \in (k, 1] \), and that a fraction \( g \) of these goods becomes newly tradable at zero cost. Then, if \( w/w^* > A \), all of the newly tradables are produced at Foreign. Therefore, given the marginal good, \( m \in [0, k] \), Home produces all the goods in \([0, m]\) for both countries and \((1-g)(1-k)\) fraction of the goods (those which remain nontradable) locally. Hence, in equilibrium, \( w_L = (m + g(1-k)(w_L + w^*L^*) + (1-g)(1-k)w_L \). On the other hand, if \( w/w^* < A \), all of the newly tradables are produced at Home. Therefore, Home produces \( m + g(1-k) \) fraction of the goods for both countries and \((1-g)(1-k)\) fraction of the goods locally. Hence, in equilibrium, \( w_L = [m + g(1-k)](w_L + w^*L^*) + (1-g)(1-k)w_L \). Thus, we have, instead of (7),

\[
\frac{w}{w^*} = \frac{m + g(1-k)}{k-m} \left[ \frac{l^*}{L} \right] \text{ for } \frac{w}{w^*} < A, \quad \frac{w}{w^*} = \frac{m}{k + g(1-k) - m} \left[ \frac{l^*}{L} \right] \text{ for } \frac{w}{w^*} > A
\]

and \( w/w^* = A \), otherwise. Note that setting \( g = 0 \) in eq. (8) recovers eq. (7). A higher \( g \) shifts the graph to the right above \( w/w^* = A \) and to the left below \( w/w^* = A \). For each value of \( g \), eq. (1) and eq. (8) jointly determines the marginal good and the Home relative wage, which we denote by \( m(g) \) and \( A(m(g)) \).

Suppose that, before globalization, \( g = 0 \), the equilibrium Home relative wage, \( A(m(0)) \), is higher than \( A \), as shown in Figure 5. The arrow indicates the shift caused by an increase in \( g \), which is small enough to keep the Home relative wage higher than \( A \). When some nontraded sectors are opened up, Home abandons the production of these new tradeables, and instead starts producing and exporting the goods in \((m(0), m(g))\), which Home imported previously. The Home relative wage declines as a result, from \( A(m(0)) \) to \( A(m(g)) \). The Home and Foreign welfares may be evaluated by

\[
U(g) = \int_{m(g)}^{k} \log \left[ \frac{A(m(g))}{A(z)} \right] \, dz + g(1-k) \log \left[ \frac{A(m(g))}{A} \right];
\]

\[
U^*(g) = m(g) \log \left[ \frac{A}{A(m(g))} \right] + \int_{m(g)}^{k} \log \left[ \frac{A}{A(z)} \right] \, dz - \log A
\]

where we use the normalization, \( A(z) = a^*(z)/a(z) = a^*(z) \) for all \( z \in [0,1] \), to simplify the expressions. A globalization (an increase in \( g \)) affects the Home welfare through two effects
Ricardian trade theory: The New Palgrave Dictionary of Economics

that operate in the opposite directions. On one hand, it allows Home to reallocate its labour to the sectors where they have higher relative efficiency, that is, from $A$ to $A(m(g))$ or higher. On the other hand, its relative wage rate, or the factorial terms of trade, $w/w^*=A(m(g))$, deteriorates. The overall effect is generally ambiguous. However, if an increase in $g$ brings down its relative wage rate $A(m(g))$ sufficiently close to $A$, the positive reallocation effect is dominated by the negative terms of trade effect, so that a further globalization harms the Home welfare. In contrast, a globalization unambiguously improves the Foreign welfare, because both effects operate positively. The possibility that Home could lose when a globalization takes this form should not be too surprising, because it can be viewed as a form of non-uniform technological changes. Indeed, this mechanism may capture some of the widely held concerns that high-wage countries might lose from ‘outsourcing’ simple tasks to low-wage countries.

Uniform iceberg cost

Suppose now that all the goods, $z \in [0,1]$, are tradeable but subject to the iceberg cost. Each good, when shipped abroad, melts away in transit and only a fraction $g<1$ arrives at the destination. Thus, in order to supply one unit of each good, the exporter must produce $1/g>1$ units of the good. Then, Home exports to Foreign only when $a(z)w/g<a^*(z)w^*$, or $w/w^*>A(z)$, and Foreign exports to Home only when $a(z)w>A(z)w^*/g$, or $wg/w^*>A(z)$. Thus, there are two marginal goods, defined by

$$\frac{w}{w^*g} = A(m^-) > A(m^+) = \frac{wg}{w^*},$$

(9)

such that Home produces all the goods in $[0, m^-)$ for both countries; Foreign produces all the goods in $(m^+, 1]$ for both countries, and each produces the goods in $[m^-, m^+]$, which becomes (endogenously) nontraded goods. The demand condition now becomes

$$\frac{w}{w^*} = \frac{m^-}{1-m^+} \left[ \frac{k^*}{1} \right].$$

(10)

Eqs (9) and (10) jointly determine three endogenous variables, $m^-, m^+$, and $w/w^*$.

One could proceed to examine the effects of a reduction in the trade cost, by increasing $g$. This is left as an exercise for interested readers.

Multiple countries

The two-country assumption is clearly restrictive for certain purposes, such as analysing the income distribution across countries, studying the patterns of bilateral trade flows, let alone the issues related to the regional integration, such as NAFTA. It is relatively straightforward to extend the two-goods Ricardian model for an arbitrary number of countries; see, for example, Becker (1952) for a finite number of countries and Matsuyama (1996) and Yanagawa (1996) for a continuum of countries. It has been a challenge to allow for an arbitrary number of goods and countries in a tractable way. For example, Wilson (1980) extended the DFS model in many dimensions, including a finite number of countries, but it does not permit more than a local perturbation analysis. Acemoglu and Ventura (2002), in their analysis of the cross-country income distribution, assumed the extreme form of technological heterogeneity by adopting the Armington assumption, which prevents the patterns of specialization from changing endogenously.

Eaton and Kortum (2002) developed a parsimonious representation of the Ricardian model with a continuum of goods, which allows for an arbitrary number of countries with the iceberg costs that are uniform across sectors but vary across country pairs. Their key idea is to view the technology heterogeneity across countries as a realization from the Frechet distributions, instead of trying to index the goods in a particular order. This yields simple expressions relating the bilateral trade volumes to technology and geographical barriers, and they use these expressions to estimate the parameters needed to quantify the effects of various policy experiments. For further development, see Alvarez and Lucas (2004).
Multi-stage trade and vertical specialization

Sanyal (1983) proposed a reinterpretation of the DFS model, according to which the final good is produced through many stages of production, $z \in [0,1]$, in order to analyse trade in intermediate inputs and vertical specialization. If the order in which these inputs need to be produced in the vertical chain of production perfectly coincides with the pattern of comparative advantage, as Sanyal assumed, these inputs are traded only once, as one country specializes in the earlier stages of production and the other specializes in the later stages. Under more general patterns of comparative advantage, however, these inputs may be traded back and forth many times. In such a setting, even a small reduction in trade costs could cause a large and nonlinear increase in the volume of trade, as documented by Hummels, Ishii and Yi (2001).

More general preferences

With the Cobb–Douglas specification, each good receives a constant share of the expenditure regardless of the prices. Its homotheticity implies that the rich and the poor consume all the goods in the same proportions (when they all face the identical prices), so that the demand compositions are independent of the income distribution within each country. These features, while greatly simplifying the analysis, are too restrictive for addressing many important issues related to growth and development.

Consider, for example, the Fisher–Clark–Kuznets thesis, that is, the changing patterns of sectoral compositions, with the decline of agriculture, the rise and the fall of manufacturing, and the rise of the service sectors. To understand such patterns of structural change in the context of a global economy, Matsuyama (2007b) relaxed the Cobb-Douglas assumption to allow for non-unitary price and non-unitary income elasticities in the three-goods (two tradable and one nontradable) Ricardian model. Non-homothetic preferences also play the key roles in many models of North–South trade. Flam and Helpman (1987), Stokey (1991), and Matsuyama (2000) all built two-country (North and South) Ricardian models with a continuum of goods, with the open-ended goods space, $z \in [0,\infty)$, and considered non-homothetic preferences with the property that, as the household's income goes up, its demand compositions shift towards higher-indexed goods. When the South, the poorer country, has comparative advantages in lower-indexed goods, the demand has home biases (in spite of the absence of any trade costs). Furthermore, the asymmetry of demand generates many comparative statics results that are absent in the standard Ricardian model. For example, in Matsuyama (2000), immiserizing growth might occur; uniform productivity growth in the South might make the South worse off, as all the benefits go to the North. Or, as the South's population grows, some industries migrate from the North to the South, and new industries are born in the North, generating the patterns of product cycles. Flam and Helpman (1987) and Matsuyama (2000) also looked at the roles of income distributions within each country by endowing different households with different amounts of labour.

Endogenous technologies and increasing returns

So far, we have taken the cross-country differences in technology as exogenous and examined their effects on patterns of specialization and trade. However, the patterns of trade and specialization may also affect technologies. Many Ricardian models with endogenous technologies have been developed to examine such two-way causality between technology and trade. Endogenous technologies have also been used as a natural way of introducing increasing returns in production. Due to the space constraint, we cannot do justice to this vast literature, which contains many alternative approaches to endogenize technologies (static external economies of scale, dynamic increasing returns due to learning-by-doing with or without inter-industry spillovers, agglomeration economies with endogenous product varieties, R&D activities, and so on) with a wide range of results with different policy implications. The interested reader should start with a survey by Grossman and Helpman (1995).

Beyond technologies: policy-induced and institution-based comparative advantage

The Ricardian set-up has also been used to explain how the differences in national policies and institutions give rise to the patterns of comparative advantage, even in the absence of any inherent technology differences. In Copeland and Taylor (1994), the clean environment is a normal good, so that the rich North chooses a higher pollution tax than the poor South. As a result, the North (South) ends up having comparative advantages in less (more) polluting industries. In Matsuyama (2005), Costinot (2006), and Acemoglu, Antras and Helpman (2007), industries differ according to the severity of agency or contractual problems, and the country with a better (worse) institutional set-up to deal with these problems has comparative advantages in industries that are more (less) subject to these problems. One may view this line of research as an attempt to endogenize technology differences. Unlike the literature surveyed by Grossman and Helpman (1995), however, the main objective here is to look at the deeper or more fundamental causes of technology differences, rather than looking at the two-way causality between technology and trade.

Finally, because the Ricardian trade theory abstracts from the roles of factor endowment differences across countries and factor intensity differences across industries as the basis of
Ricardian trade theory: The New Palgrave Dictionary of Economics

trade, it is an ideal set-up in which to isolate the roles of factor endowments and intensity differences that are unrelated to the basis of trade. For example, Matsuyama (2007a) uses a two-country Ricardian model to examine how factor intensity affects the extent of globalization and how globalization affects factor prices when certain factors are used more intensively in international trade than in domestic trade. The model is Ricardian in the sense that the patterns of comparative advantage are determined entirely by the exogenous technological differences. The factor proportions matter, however, because they determine the extent of globalization, as the effective trade costs vary with the relative endowments of the factor used intensively in international trade.

Ricardo, David (1772–1823)

Terry Peach

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article discusses the life and work of David Ricardo. The first section provides a comprehensive overview of his life, his contributions to political economy and his political activities. This is followed by more detailed consideration of his monetary writings (including the ‘law of markets’ and ‘comparative advantage’), his early writings on profits and the ‘corn model’ interpretation, the labour theory of value, the ‘new view’ and ‘neoclassical’ interpretations of his work, and his Sraffa-inspired interpretation as a ‘classical’ economist.

Article
David Ricardo was one of the most outstanding political economists of the 19th century and one of the most influential of all time. Born on 18 April 1772 at 36 Broad Street Buildings in the City of London, he was the third of 15 surviving children of Abraham Israel Ricardo (1733–1812) and his wife, Abigail Delvalle (1753–1801). Abraham's family were Sephardic Jews who had emigrated from Portugal to Holland at the end of the 16th century. His father (David's grandfather) is described as ‘a non-official broker in funds and stocks’ on the Amsterdam exchange (Heertje, 2004, p. 283). Abraham also became a stockbroker, first in Amsterdam and then in London, where he moved in 1760. He married Abigail (from an established London Sephardic family of tobacco and snuff merchants) in 1769 and was granted citizenship in 1771. As related by David's brother, Moses Ricardo, their father was a man of good intellect, but uncultivated. His prejudices were exceedingly strong; and they induced him to take the opinions of his forefathers in points of religion, politics, education &c., upon faith, and without investigation. Not only did he adopt this rule for himself, but he insisted on its being followed by his children; his son [David], however, never yielded his assent on any important subject, until after he had thoroughly investigated it. It was perhaps in opposing these strong prejudices that he was first led to that freedom and independence of thought for which he was so remarkable. (Ricardo, 1951–55, Works, X, p. 5; hereafter ‘Works’)

According to Moses Ricardo, the young David was allotted a ‘common-school education’, typical of ‘those who are destined for a mercantile line of life’ (Works X, p. 3), the emphasis being on reading, writing and arithmetic. Less typically, at the age of 11 David was sent to Amsterdam for two years. Details of the visit are sketchy. It has been suggested that he attended the famous Talmud Tora, attached to the Portuguese Synagogue in Amsterdam, although recent scholarship has favoured a more mundane account in which he was privately tutored in the ‘common-school’ subjects with the addition of French and Spanish (Heertje, 2004). Following his return to London, David's full-time education continued only until he reached the age of 14, when he began working for his father as a clerk and messenger on the London Stock Exchange, although he was allowed ‘any masters for private instruction whom he chose to have’ during his spare time (Moses Ricardo, Works X, p. 3). He was later to complain bitterly of years of neglected education ‘at the most essential period of life’ (Works VII, p. 305), to which he frequently attributed his difficulties in written composition.

In 1792 the Ricardo family moved to Bow, close to the house of Edward Wilkinson, a Quaker and surgeon. Before long, David was romantically involved with Wilkinson's daughter, Priscilla Ann (1768–1829), whom he married on 20 December 1793. The young couple was promptly disowned by both sets of parents. Although the breach with the Wilkinson's was short-lived, it is said that David neither spoke to nor saw his mother again. He was also disinheritied and removed from his father's business (he was reconciled with his father after his mother's death). The marriage was the occasion of his breach with the Jewish faith, which, according to Sraffa, was ‘the culmination of a gradual estrangement [with Judaism] … in progress for some time before’ (Sraffa, Works X, pp. 38–9). He was subsequently to attend the meetings of the non-conformist Unitarians.

The break with his father was not to prove an insurmountable obstacle to David's financial prospects. With the assistance of City friends, he embarked on his spectacularly successful career as a jobber on the
stock market and a loan contractor for government stock. Before long he had amassed a considerable fortune, and in 1815, the year in which he made his single most profitable transaction, he began a gradual retirement from business. The total value of his estate at death has been estimated at between £675,000 and £775,000, roughly equivalent to more than £500 million ($950,000,000) at 2006 prices. As Ricardo's wealth grew, so too did his family and social standing. Eight children were born between 1795 and 1810. From 1812, the family's prestigious London address was 56 Upper Brook Street, Grosvenor Square. To this was added in 1814 Ricardo's country seat of Gatcombe Park near the small village of Minchinhampton, where he is reported to have financed almshouses, endowed a school, provided an infirmary and started a savings bank. His petition for his own coat of arms was also granted in 1814. Having entered the squirearchy (he was High Sheriff of Gloucestershire in 1818), acquired his reputation as a leading intellectual and political economist and become a prominent Member of Parliament (he took his seat in 1818), his company was sought increasingly by luminaries of the aristocracy, the political classes and the intelligentsia. Ricardo was highly gratified by his success, no more so than as a recognized authority on his favourite subject, namely, as he described it, ‘political economy’.

It is said that Ricardo's interest in political economy was stimulated by chancing upon a copy of Adam Smith's *Wealth of Nations* in a travelling library while on a visit to Bath. Prior to this time, we are told by his brother that a predilection for subjects of an abstract and general nature had led to a leisurely interest in science, including mathematics, chemistry, geology and mineralogy (in 1807 he was a founding member of the London Institution for the Advancement of Literature and the Diffusion of Useful Knowledge, which was charged with promoting science, as well as literature and the arts, and in 1808 he joined the Geological Society of London). Yet, although his interest was awakened, to the point where he become an avid reader of the early articles on political economy in the *Edinburgh Review*, he was for several years too preoccupied with furthering his financial career to treat political economy as anything more that ‘an agreeable subject for half an hour's chat’ (as he later reminisced to his old friend Hutches Trower, *Works* VII, p. 246). The turning point came in 1809.

The free convertibility of paper currency into gold had been suspended under the Bank Restriction Act of 1797, following the run on the Bank that had been provoked by fears of a French invasion (in the context of the French wars of 1792–1815). In the aftermath of restriction, the market price of gold (in terms of the now unconvertible paper currency) had risen above the (fixed) mint price and the ‘exchanges’ had become ‘unfavourable’, so that premiums were now to be paid on bills of exchange drawn on overseas banks for the purposes of settling international debts. This gave rise to the first phase of the ‘Bullion Controversy’ (c.1797–1801), with contributions from writers including Henry Thornton and Lord Peter King. The controversy was concerned with the reasons for the depreciation of ‘paper’ relative to gold and the deterioration in the exchanges, with the ‘bullionists’ (as represented by King) arguing that the fault lay with the Bank of England for overissuing paper, while the ‘anti-bullionists’ (including Thornton) emphasized the role of special government payments overseas and poor domestic harvests, independently of the Bank’s issues (this was the debate that dominated the early entries on political economy in the *Edinburgh Review*). After 1801, however, the price of gold fell back towards the mint price, the exchanges improved and the controversy duly subsided, to be revived in 1808 by a further marked depreciation of paper relative to gold (of around 20 per cent) and an accompanying fall in the exchanges. It was to this second phase of the controversy that Ricardo's first publication was directed, taking the form of an anonymous letter to the *Morning Chronicle* newspaper,
published 29 August 1809.

With uncharacteristic rhetorical excess (Ricardo intoned gravely about the ‘present evil’ of the depreciation of paper and the ‘disastrous consequences’ and ‘future ruin’ that might follow) the argument in the letter followed the standard bullionist position that the root cause of the ‘ills’ was the ‘over-issues of the Bank [of England]’, the remedy being (in a remark that anticipates his later ‘Ingot Plan’) that ‘the Bank be enjoined by Parliament gradually to withdraw … notes from circulation, without obliging them, in the first instance, to pay in specie’ (Works III, p. 21). The argument was developed in further letters to the Morning Chronicle, and in his (signed) pamphlets, The High Price of Bullion (1810–11) and the Reply to Mr. Bosenquet (1811). The Bullion essay was a straightforward elaboration of Ricardo's position (in which he acknowledged that he ‘can add but little to the arguments which have been so ably urged by Lord King’, Works III, pp. 51–2), with an appendix to the fourth edition in which he developed his plan to resume convertibility by requiring the Bank of England to pay on demand in bullion ingots (not specie) bank notes of the value of at least £20, the alleged advantages being that this would reduce the supply of domestic paper, prevent an excessive demand on the Bank for gold (since the demand for bullion ingots would be less than the demand for specie), and prevent the withdrawal of low face-value bank notes (although Ricardo was later to acknowledge that a secondary market in bullion could facilitate the exchange of small notes pro rata). The second pamphlet was a reply to criticisms of the parliamentary Bullion Committee Report (1810), with which Ricardo broadly agreed, and of Ricardo's own currency writings.

The contributions to the Bullion Controversy brought Ricardo to the attention of political and intellectual figures including Thomas Robert Malthus and James Mill (Ricardo was also in correspondence with Spencer Perceval, the Tory Prime Minister, and the opposition Whig leader, George Tierney). Both Malthus and Mill were to play critical roles in the development of Ricardo's subsequent career, although their influences were profoundly different. At the time of Ricardo's entry on the public stage, Malthus was a seasoned writer, the author of the Essay on Population and, arguably, the leading political economist of the day. Although he and Ricardo became, and remained, close friends, their relationship was marked by disagreement over many areas within the new ‘science’ of political economy. While Ricardo borrowed from some of Malthus's writings (including population theory and the theory of differential rent) other aspects of his work evolved dialectically from epistolary skirmishes with his contemporary.

Malthus introduced himself to Ricardo by letter in June 1811, by which time it seems that Mill was already considered a close friend and an ally on the bullion question. Mill had been an early contributor to the Edinburgh Review, but by this time his attention had turned to writing his A History of British India and it seems unlikely that he had much influence over the content of Ricardo's political economy with the exception of the ‘law of markets’ (in short, the doctrine that ‘supply creates its own demand’). But that is not to detract from Mill's influence on Ricardo in other respects. Mill advised, encouraged, cajoled and even (only semi-humorously) bullied the ever-reticent Ricardo, who almost certainly would not have completed his major work without Mill's incessant prodding (see J.S. Mill, 1873, p. 42). It was also James Mill, as associate and disciple of Jeremy Bentham (with whom Ricardo also became personally acquainted), who was to coach the initially sceptical Ricardo in political utilitarianism and persuade him to enter parliament.

Currency issues dominated the early Ricardo–Malthus correspondence, but by late summer of 1813 their attention began to turn to a new subject, the forces governing movements in the general rate of profit.
Up to this point Ricardo had robustly endorsed Adam Smith's 'competition of capitals thesis', according to which the general rate of profit is regulated by the intensity of competition in the labour market (determining movements in wage rates) and in the output market (determining prices). Exactly how Ricardo himself interpreted Smith's doctrine is not clear, nor is it possible to pinpoint the reason for the change of focus in the Ricardo–Malthus correspondence. However, it is certain that Ricardo was newly emphasizing the conditions of producing food as an influence on profits. His position was developed in lost ‘papers on the profits of Capital’, following which, in response to a clamour by the landed aristocracy for a revision of the old Corn Law, and the report in May 1814 of the Parliamentary Committee on the Corn Trade, his deliberations become more narrowly centred on the effects on profits of restrictions on the free importation of corn. The outcome was his Essay on The Influence of a Low Price of Corn on the Profits of Stock; Shewing the Inexpediency of Restrictions on Importation (1815; reprinted in Works IV).

The central argument of the Essay may be given as follows. On the assumption of an economy closed to the importation of foreign corn (the principal subsistence commodity and wage good), the increasing demand for corn from a growing population must be met either by the more intensive cultivation of land or by cultivating land that is less fertile or more disadvantageously situated relative to the final market. Either way, the expansion of output will encounter diminishing returns which in turn lead to a higher corn price, higher money wages and, therefore, a lower agricultural rate of profit. Only the landlords benefit, because they receive more differential rent: following Malthus, rent is the difference in return from the ‘best’ and the ‘worst’ land on the assumption that the return from the ‘worst’ land is sufficient only to give farmers the general rate of profit; ergo, landlords benefit as that difference increases. To complete the argument, the reduction in profitability is transmitted to capitalists generally by means of higher money wages. As for labourers, the argument appears to be that they might also suffer in consequence of a (‘temporary’) fall in labour demand, itself the result of lower profitability. Hence Ricardo's provocative conclusion that ‘the interest of the landlord is always opposed to the interest of every other class in the community’ (Works IV, p. 21).

The Essay was a transitional work in which Ricardo repudiated some of the fundamental tenets of the prevailing orthodoxy, as derived from Adam Smith and upheld by Malthus, but failed to supply a fully convincing logical alternative. It was James Mill who persuaded Ricardo to develop his ideas in the form of a major treatise. Two years later Mill's exhortations were rewarded with the publication of On the Principles of Political Economy and Taxation (1817; reprinted in Works I). However, before Ricardo could begin serious work on the Principles he had to fulfil his commitment to Pascoe Grenfell M.P., who had enlisted Ricardo's support for an assault on the Bank of England. Ricardo was more than happy to oblige ('I always enjoy any attack upon the Bank', Works VI, pp. 268–9), and the result was his Proposals for an Economical and Secure Currency; with Observations on the Profits of the Bank of England, as they regard the Public and the Proprietors of Bank Stock (1816; reprinted in Works IV). In language suggested by James Mill, Ricardo lamented that ‘a great and opulent body like the Bank of England’ should ‘wish to augment their hoards by undue gains wrested from the hands of an overburthened people’ (Works IV, p. 93). It was intolerable that a mere ‘company of merchants’ should make vast profits by overcharging on the management of the public debt and other public business, through their ‘seignorage’ on the issue of paper money and by reducing their unprofitable stock of bullion (as they were enabled to do by the Restriction Act). For the longer term (after the expiry of the Bank Charter in 1833), Ricardo's preferred solution was to strip the Bank of its management of the
money supply, which he would entrust to ‘commissioners responsible to parliament only, the state’ (Works IV, p. 114) (this plan was developed in the Plan for the Establishment of a National Bank [1824], drafted by Ricardo in 1823, reprinted in Works IV). For the shorter term, he suggested that the government should seek more favourable terms for the management of the debt. Above all, however, he again advocated a swift return to a fully convertible paper currency, to be achieved by his Ingot Plan. The result would indeed be an ‘economical and secure currency’ which, along with its other advantages (of cheapness in comparison with a fully metallic currency and of stability by constraining movements in the market price of gold) would facilitate short-term, compensating changes in the money supply in response to fluctuations in the availability of credit.

With the Proposals dispatched to the printers, the way was open for Ricardo to commence work on his Principles; or, be more precise, it was almost so, for he still had to contend with a hectic social life, recurring bouts of lethargy and defeatism, continuing business interests, the demands of a large family and a ‘temptation of being out in the air in fine weather’ (Works VI, p. 263). Fortunately for posterity, the summer of 1816 offered very few outdoor temptations and Ricardo dedicated himself to his task. The Principles was published on 19 April, 1817. It was the result of little more than six or seven months' sustained activity on Ricardo's part.

The ‘principal problem in Political Economy’ is defined in the Principles as the determination of the ‘laws’ which regulate ‘the natural course of rent, profit, and wages’ over time. These issues had been addressed in the Essay and, indeed, the Principles was initially conceived as an Essay writ large. In the process of writing the later work, however, its scope was enlarged in previously unforeseen ways as Ricardo developed his ideas. The result was a volume comprising 31 chapters, covering not only the ‘laws’ governing rent, profit and wages, but also a labour theory of value, a theory of international comparative advantage, monetary theory, several chapters devoted to ‘the influence of taxation on different classes of the community’, and strictures on the writings of predecessors and contemporaries. The ‘core’ theoretical analysis as it relates to ‘the natural course’ may be summarized as follows.

In terms of the newly adopted ‘pure’ labour theory of value, (changes in) the exchangeable value of competitively produced, freely reproducible commodities are determined exclusively by (changes in) the quantities of labour expended on their production, where the relevant quantity of labour is the greatest quantity expended per unit of output sold. The theory applies only when commodities exchange at their natural prices, defined by uniform wage and profit rates (rent is excluded as a component of price, as explained shortly). In addition, it is assumed that one domestically produced commodity, gold (not to be confused with its real-world namesake), serves as the ‘invariable standard’ (the numéraire) in terms of which all prices are expressed, its ‘invariability’ defined in terms of a given and unchanging labour input per unit of its output. It follows that any change in a commodity's gold-denominated natural price is an exact reflection of a corresponding change in the labour expended on its production. This theory of value was used by Ricardo beyond the first chapter of the Principles.

Next, there is the theory of differential rent, derived from Malthus. As Ricardo explained, the relevance of the theory is not confined to agriculture but applies whenever units of the same (homogeneous) class of commodity are produced by different quantities of labour. If all units sell at the same natural price, determined by the greatest labour input per unit; and, if the rate of profit from the sale of the unit requiring the greatest labour input is equal to the general (uniform) rate; then, an additional surplus revenue will be earned on units requiring a lower labour input, and it is this additional surplus that constitutes (differential) rent. (If we assume with Ricardo that capitalist producers, in agriculture and
elsewhere, are profit-maximizers, they will always extend production to the point where revenue from the sale of the incremental output, requiring the greatest labour input, is sufficient only to yield the general rate of profit; moreover, this greatest labour input must determine price, otherwise the general rate of profit could not be received and the output would never be produced.

On wages, Ricardo introduces the distinction between the market price of labour (or market wage) and the natural price (or natural wage), the latter defined (in money terms) as ‘that price which is necessary to enable the labourers, one with another, to subsist and to perpetuate their race, without either increase or diminution’ (Works I, p. 93). The price that is necessary depends on the ‘real’ natural wage: on ‘the quantity of food, necessaries, and conveniences [which] become essential … from habit’ (Works I, p. 93). Habits may change over time (perhaps under the influence of education, as Ricardo hoped) but, for analytical purposes, the natural (real) wage is a datum. In the event that the market wage is above or below the natural wage, a Malthusian-style population mechanism is triggered: population expands (or contracts) and the market wage returns to the natural level.

To turn to profits, the eponymous chapter in the Principles is chiefly a revision of the central argument from the Essay, although it does contain the ingredients for a more general theory of the rate of profit. Now in terms of the labour theory of value, the attempt to expand the output of corn in a closed economy encounters diminishing returns in the form of a greater labour input per unit of output; hence, the (natural) price of corn rises proportionately. This in turn increases money wages, because corn enters the given real wage. The rate of profit (calculated with reference to the output produced by the greatest labour input) must therefore fall (since the rise in the natural price of corn is proportionate only to the increase in the quantity of labour expended on its production and does not reflect the increased cost of that labour) and, by the reasoning explained above, differential rent increases. Natural prices outside agriculture are either unchanged or, if corn is required as a material input, rise only to reflect the increase in the labour expended on their production; hence, the fall in the agricultural rate is communicated to other sectors by an increase in money wages. Perforce, the ‘natural course or rent, profit, and wages’ is for rent to increase, the rate of profit to fall and (money) wages to rise, although it must be stressed that this ‘prediction’ is entirely contingent on a host of assumptions and should not be taken as evidence of a gloomy or pessimistic attitude by Ricardo to Britain's economic prospects (such an inference, although commonly made, could not be further from the truth).

Finally, the more general theory from Ricardo's analysis is that (changes in) the rate of profit depend exclusively on (changes in) the labour expended on the production of the given real wage where, to borrow J.S. Mill's distinction, the ‘labour expended’ covers the ‘direct’ labour and the ‘indirect’ labour expended on the production of the non-labour inputs to the production of wage-goods. Provided one grants him his assumptions (of a labour theory of value, a given real wage and known labour conditions of production), Ricardo had thus produced a strong candidate for the first logically coherent theory of the determination of the general rate of profit in the history of economic thought.

There was a great deal riding on the success of the Principles, not just Ricardo's growing reputation as a political economist. Mill had suggested in 1815 that Ricardo should enter Parliament, a suggestion from which the latter had recoiled with horror. One year later he was becoming more amenable to Mill's plan, writing to his friend: ‘If my book succeeds … perhaps my ambition may be awakened, and I may aspire to rank with senators’ (Works VII, p. 113). Much to Ricardo's relief, the book did succeed to an extent far surpassing his self-deprecatory expectations.

Ricardo entered Parliament on 26 February 1819 as the independent member for the rotten borough of
Portarlington in Ireland: a constituency which he never visited, with 12 or so electors in the ‘pocket’ of Lord Portarlington to whom Ricardo had advanced £25,000 as a loan on the mortgage of his estates. Ricardo availed himself of every opportunity to educate the House of Commons in the ‘true principles of political economy’. These principles dictated the gradual repeal of trade restrictions generally and the of the Corn Law in particular; the gradual repeal of the Poor Laws; the repayment of the National Debt (his heroic proposal to replay the debt over two or three years by the imposition of a property tax was met with widespread incredulity); minimal taxation and a balanced budget; and a return to a convertible currency. With the signal exception of convertibility (Peel's Bill of 1819 for the Resumption of Cash Payments owed much to his proposals), Ricardo mostly found himself on the losing side, but that did nothing to shake his convictions. His parliamentary contributions are testimony to his belief in political economy as a subject of direct empirical relevance (the view of Ricardo as a pure theorist is a travesty). They also mark him as a zealous advocate of a free-market capitalist system with minimal government interference, who believed that Great Britain ‘would be the happiest country in the world, and its progress in prosperity would be beyond the power of imagination to conceive, if we got rid of two great evils – the national debt and the corn laws’ (Works V, p. 55). Additionally, he spoke out on a range of ‘liberal’ issues including religious tolerance, slavery, freedom of speech and the right to petition. He also aligned himself with the ‘radical’ cause for the reform of parliament.

The contention that ‘good government’ would not be achieved without a reform of parliament had been put to Ricardo by James Mill in 1815 but was at that time rejected on the grounds that Mill exaggerated the ‘sinister interest’ of politicians in pursuing their own selfish interests and undervalued the corrective influence of enlightened public opinion. Three years later Ricardo's position had changed. Partly as a result of Mill's bombardment of Ricardo with ‘radical’ messages, partly because of his growing conviction that the Tory government was failing to pursue ‘right measures’, and after reading Jeremy Bentham's Plan of Parliamentary Reform, Ricardo was won over to the ‘radical’ cause. As he came to argue, ‘good government’ – government ‘administered for the happiness of the many, and not for the benefit of the few’ (Works VII, p. 299) – required that politicians should ‘legislate for the public benefit only, and not … attend to the interests of any particular class’ (Works VIII, p. 275); yet, under present arrangements, politicians fell prey to the interests of particular classes, particularly the landed class; hence the necessity for reform. However, Ricardo's proposals fell some way short of those of his ‘radical’ contemporaries. The introduction of the secret ballot was, for him, an almost sufficient basis for securing good government under existing circumstances, although he did make a case for triennial parliaments and a modest extension of the franchise to include householders. He might therefore be described as a moderate reformer in the utilitarian tradition of Bentham and Mill.

The infamous proposal for the speedy repayment of the national debt was also presented to the public in an invited article on the Funding System (1820), written in autumn 1819 for publication in the Supplement to the Encyclopaedia Britannica. This article is noteworthy for its exposition of what has come to be known, misleadingly, as the ‘Ricardian equivalence theorem’. To take Ricardo's own argument, suppose that a war involves the expenditure of £20 million. This can be financed either by raising £20•m in taxes or by borrowing £20•m and repaying by taxes £1•m per annum in perpetuity (at an assumed annual interest rate of five per cent), or by borrowing the £20•m and (for example) repaying by taxes £1.2•m per annum, which would clear the interest (at five per cent) and the initial £20•m over a period of 45 years. ‘In point of economy’, as Ricardo stated, ‘there is no real difference in either of the modes’, because the present value of £1•m per annum in perpetuity or £1.2•m over 45 years, both at five
per cent annually, is £20m, hence the idea of *equivalence*. But, he continued, ‘the people who pay the taxes never so estimate them, and therefore do not manage their private affairs accordingly’: the different modes are *not* equivalent because, according to him, individuals are prone to undervalue the true cost of repaying a loan over time. That being so, Ricardo's proposal was for the pay-as-you-spend mode of financing which, he believed, would make people ‘less disposed wantonly to engage in an expensive contest [namely war], and if engaged in it … be sooner disposed to get out of it’ (*Works IV*, p. 186).

While Ricardo was writing his *Funding System*, his friend Malthus was putting the finishing touches to his own *Principles*, published in April 1820, which contained an unsparing critique of Ricardo's central doctrines (*Malthus's Principles* together with Ricardo's comments are reprinted in *Works II*). Of all Malthus's criticisms, those levelled at Ricardo's treatment of value were the most acute, thus prompting Ricardo to a major revision of his first chapter for the third edition of his *Principles* (1821) (a lightly revised second edition of the *Principles* had been published in 1819). In addition to the defence against Malthus, the third edition is distinguished by a new chapter ‘On Machinery’ in which Ricardo, stimulated by the work of John Barton, famously declared that ‘the opinion entertained by the labouring class, that the employment of machinery is frequently detrimental to their interests, is not founded on prejudice and error, but is conformable to the correct principles of political economy’ (*Works I*, p. 392). To avoid misunderstanding, although there may be a very distant family resemblance between Ricardo's analysis and the standard ‘neoclassical’ case of factor substitution in response to changes in factor prices within a timeless framework, a principal difference is that Ricardo was describing a process over time, in which the substitution of machinery for labour was likely only to apply to new ventures. Nor did his analysis end there, since the capitalists were expected to expand accumulation in consequence of their higher profits, so tending to reverse the fall in the demand for labour (and wages).

Following the third edition of the *Principles*, Ricardo's next and last publication within his own lifetime was *On Protection to Agriculture* (1822; reprinted in *Works IV*): a veritable tour de force, written in little more than three weeks.

A new Corn Law had been passed in 1815 which prohibited the importation of foreign corn until the price had been at least 80 shillings per quarter for six weeks, by which time the ports could be opened to duty-free importation. Imports had been triggered in 1817–19, with prices first rising too 111 shillings in June 1817 and then (under the pressure of importation, followed by good domestic harvests) falling steadily to 55 shillings in the second half of 1820. After more bumper harvests, 1822 then witnessed the lowest average corn prices since 1792, with a fall to 34 shillings in November. The ‘agricultural distress’ was widespread and severe, and the powerful landed interest turned to Parliament for assistance. A parliamentary committee was established to investigate the causes and possible remedies for the distress, with Ricardo as one of its members.

Ricardo was not optimistic that Parliament would, or could, shift its position towards a free trade in corn; as he wrote in correspondence, ‘I have no hope of good measures being adopted, the landlords are too powerful in the House of Commons to give us any hope that they will relinquish the tax which they have in fact contrived to impose on the rest of the community’ (*Works IX*, p. 158). He was proved right. *On Protection* was his response to the protectionist report of the committee, in which he maintained his position that free trade was the only long-term solution while proposing a revised version of the 1815 Act (with measures for dampening price fluctuations). The pamphlet is also distinguished by sharp restatements of Ricardo's central doctrines, a wealth of detailed empirical analysis and a pungent defence
of his own position with regard to Peel's Bill of 1819 for the resumption of cash payments. *On Protection* shows him at the peak of his career, a true master of his subject and a political economist in the most rounded sense.

In the summer of 1822 Ricardo embarked with his family on a four-month grand tour of Continental Europe. Upon his return he resumed his hectic life as an active parliamentarian, attended meetings of the Political Economy Club (which he had co-founded in 1821), drafted his plan for an independent national bank, and continued with his deliberations on ‘value’. He was also looking forward to hosting a visit to Gatcombe from his old friend Hutches Trower, to whom he wrote: ‘we shall walk and ride, we will converse on politics, on Political Economy, and on Moral Philosophy, and neither of us will be the worse for the exercise of our colloquial powers (*Works* IX, p. 377). But it was not to be. On 11 September 1823 Ricardo died from the effects of an abscess in the middle ear. He was buried at Hardenhuish Park, Wiltshire, on the estate of his daughter, Henrietta, and her husband, Thomas Clutterbuck.

The newspaper obituaries of the time were lavish in their praise of Ricardo's achievements, both as a political economist and as a ‘Senator’ (see Peach, 2003). By his friends, he was applauded for having virtually revolutionized economic theory, not merely for its own sake but as means of guiding government policy and thus promoting the ‘general happiness’ of society. Of course, his critics were to assess his contributions less kindly, but in producing what was arguably the first coherent supply-side analysis of value, distribution and growth – never mind anything else – his place in doctrinal history was assured.

The following sections consider in more details various aspects of Ricardo's work and a selection of the main interpretative disputes that continue to surround it.

### Monetary contributions, the law of markets and comparative advantage

As Peake (1978, p. 31) rightly observed, ‘Ricardo's total productive output was dominated by monetary questions’, and it was in this area that he had the greatest practical influence in his own lifetime.

A simple approximation to Ricardo's ‘model’ includes the following assumptions: the domestic currency consists entirely of paper money (‘paper’) issued by a central bank; money prices are a function of the supply of paper (*ceteris paribus*); the bank allows the free convertibility of paper into gold on demand at a permanently fixed mint price, initially equal to the globally determined market price in terms of paper; and all profit-seeking economic agents have virtually perfect market information. Now suppose that the bank increases its supply of paper. Domestic commodity prices rise, as does the market price of gold in terms of paper. (Ricardo treated gold as just another commodity, a view that later ensnared him in the position that the exchangeable value of gold is determined by the labour expended on its production even though its value is *incessantly* fluctuating in response to changes in the volume and pattern of world trade.) Gold has become relatively cheaper (or ‘redundant’) because, by assumption, it may be purchased at the lower mint price. Profit-seeking agents therefore exchange paper for gold which, because of its new relative cheapness compared with other domestic commodities, is now exported in preference to those commodities in exchange for foreign produce. Hence, the supply of domestic paper contracts, domestic prices fall, the market price of gold (in paper) returns to the mint price and the *status quo ante* is restored.

Now suppose that paper is no longer freely convertible into gold at the mint price. As before, the supply
of paper is increased, but the ‘stimulus which a redundant currency gives to the exportation of the coin [namely gold] … cannot, as formerly, relieve itself’ (Works III, p. 78), so the market price of gold remains above the mint price. In addition, the paper cost of bills of exchange drawn on foreign banks will increase to reflect the fall in paper relative to gold (the foreign exchange becomes ‘unfavourable’). Hence (following Lord King) Ricardo’s ‘two unerring tests’ of a depreciation in Bank-notes, ‘the rate of exchange and the price of bullion’ (Works III, p. 75). (Ricardo flatly rejected the measurement of depreciation either in terms of changes in the exchangeable value of gold for domestic commodities – because commodities ‘are continually varying in value’ among themselves – or in terms of subjectively perceived ‘enjoyment’, ‘because two persons may derive very different degrees of enjoyment from the possession of the same commodity’; Works IV, pp. 59, 61.)

As to the consequences of ‘depreciation’, the picture is mixed. Ricardo stressed that the rate of interest is determined by the rate of profit in the ‘real’ economy (by the ‘competition of capitals’ or by the conditions of producing wage goods, in the earlier and later writings respectively); and that the ‘trifling’ effect on the rate of profit (hence on output) of an increase in paper is confined to an interval ‘of momentary duration’ before money wages adjust to restore the (assumed) given real wage (Works III, pp. 91–2, 318–19, 329; Works V, p. 446; Works VI, pp. 16–17). This dominant position supports a (mostly) neutral money interpretation, but it also raises the question of why Ricardo became so exercised by depreciation if its real effects were insignificant. The answer is possibly to be found in his concern with the effects of rising prices on recipients of fixed money incomes, especially ‘monied men’ (see Works III, pp. 21, 95–6; Works VI, p. 68), regarded by Sayers (1953, p. 65) as a ‘shattering’ inconsistency with the view ‘that long-run effects come quickly and easily’. In addition, the later Ricardo was also to remark on the danger of an ‘easy’ inconvertible paper-money regime in facilitating speculation and over-trading (Works V, pp. 397, 446).

Whatever the economic costs of depreciation, Ricardo campaigned tirelessly for a resumption of convertibility at the pre-restriction mint price of gold. In his evidence before the Parliamentary Committees on Cash Payments (1819) he argued, with heroic simplicity, that, in the prevailing circumstances of a four per cent premium in the market over the mint price of gold, a reduction in paper currency of about four per cent would be sufficient to restore parity, with a consequent fall of domestic prices generally also of around four per cent (Works V, pp. 416–17). This objective could be achieved ‘in a few months’ (Works V, p. 396). However, ‘by a consideration of the fears which I think many people very unreasonably entertained’, he was ‘reconciled’ to a plan for the phased return to the old mint price over one or two years (Works V, p. 451). The logic, if not the detail, of Ricardo's argument was accepted by the committees, leading to Peel's Bill (1819) with its provision for a staged return to convertibility at the old par over a period from February 1820 to May 1823. Payments were to be made only in bullion ingots in the first two stages, in line with Ricardo's recommendation. Contrary to his proposals, however, the third stage gave the Bank the option of making payments in specie, while the fourth and final stage saw a return to full convertibility at par.

Ricardo regretted that Parliament had not adopted his plan in its totality, but was otherwise supportive of the bill. Certainly, he did not foresee the events that were to follow which led, on his 1822 estimation, to a ten per cent depreciation of paper, thus making ‘the reverting to a fixed currency as difficult a task to the country as possible’ (Works IX, pp. 140, 152). The fault lay not with his analysis, however, but with the Bank of England, who had (in his opinion) needlessly purchased large quantities of gold in anticipation of resumption, thus raising its market price independently of note issues.
Ricardo may have been justified in blaming the Bank, but he must also stand accused of reasoning as if his simple model had captured all relevant aspects of reality. He was aware, on one level, that nominal inflation or deflation was not determined exclusively by changes in the Bank’s supply of paper, and that the market price of gold could differ from the mint price independently of changes in the domestic money supply. He had noted in his early monetary writings that the ‘regulator of prices’ must include not only the quantity of money, but also ‘the rapidity of its circulation’ and ‘the mass of commodities’ (Works III, p. 311); later (1815–16), in response to post-war economic conditions, he allowed that the quantity of money was also determined by the independent behaviour (in context, the bankruptcy) of the country banks, and he conceded that ‘bullionists’, himself included, had underrated the effects on the market price of gold from changes in world demand for the metal (Works VI, p. 344; Works IV, p. 62); finally, under hostile questioning from some members of the Parliamentary Committees on Resumption, he admitted the further qualification that changes in the general state of confidence could affect domestic prices by influencing the availability of credit, itself a substitute for currency (Works V, p. 419). Yet, for the most part (as with his ‘four per cent’ calculation, noted above), he argued as if these counteracting influences were nugatory to the point that they could be ignored completely. This was a treacherous foundation on which to build economy policy.

It was also Ricardo’s habitual presumption that real-world economic actors behaved ‘rationally’ and it is for this reason that he was highly critical of the Bank for purchasing gold when (on his analysis) it was not in their interest to do so. The same presumption was at the heart of his version of the law of markets, described by Keynes as the (flawed) doctrine that ‘supply creates its own demand in the sense that the aggregate demand price is equal to the aggregate supply price for all levels of output and employment’ (Keynes, 1936, 21–2).

The ‘law’ is commonly attributed to Jean-Baptiste Say although its roots extend back to Adam Smith’s Wealth of Nations. It seems likely, however, that it was derived by Ricardo from James Mill, who had sketched out the argument in his 1808 review of William Spence’s Britain Independent of Commerce in the Edinburgh Review. It was first used by Ricardo in his early monetary writings to argue that foreign markets will never be so ‘glutted’ by British produce as to constrain further British exports when money becomes comparatively dearer (that is, the opposite of ‘redundancy’). Later, it was used to bolster the argument that the only cause of a permanent reduction in general profitability is an increase in the labour expended on the production of wage goods. It was also invoked by Ricardo in the distressed aftermath of the French wars to support his unshakably optimistic view that recovery was always imminent.

Ricardo’s version of the ‘law’ may be reduced to the following propositions: first, commodities will continue to be produced only if they return at least the going general rate of profit; second, capitalist producers (and only capitalist producers) are not ‘for any length of time … ill-informed of the commodities which [they] can most advantageously produce’ (Works I, p. 290); third, the desire to consume something is ‘implanted in every man’s breast; nothing is required but the means’ (Works I, p. 292); fourth, all money income is spent, either by the direct recipients or by those to whom the recipients lend (all) their unspent money income (there is no hoarding). If, to take the extreme case, commodities always exchange at natural prices (which implies that the producers earn precisely the going general rate of profit) and all income is always spent (on the same output), we have ‘Say’s identity’ version of the law, defined by an excess demand for money of zero at all times. This is the version that Keynes attributed to Ricardo. Yet, although Ricardo’s emphasis was always on equilibrium or long-period tendencies, he did (as he was forced to by external events) allow for strictly ‘temporary’ periods of
capital misallocation in which capitalists produce the ‘wrong’ commodities and demand money (to satisfy creditors) in excess of revenue. The ‘Say's equality’ version of the ‘law’, allowing for ‘temporary’ disequilibria of excess demand for money, would therefore better describe his position. Above all, however, what is most striking is his belief that the ‘law’ encapsulated real-world tendencies, to the extent that he condemned out of hand all proposals for relief works (because only the capitalists knew best how to allocate capital) and, ultimately, was left totally bemused by the scale and duration of the post-war distress (see *Works* VIII, p. 277).

Economists have been considerably more impressed by his statement of comparative advantage in the chapter ‘On Foreign Trade’ in the *Principles*. Following Ricardo's own example, assume two commodity bundles of cloth \((x_1)\) and wine \((x_2)\), both of which could in principle be produced in England or Portugal \([x_1, x_2]\) and \([x_1^*, x_2^*]\) respectively. To produce the bundles in England would require 100 labourers for cloth \((a_1)\) and 120 labourers for wine \((a_2)\); and to produce them in Portugal would require 90 labourers for cloth \((a_1^*)\) and 80 labourers for wine \((a_2^*)\). Portugal therefore has an absolute advantage in the production of both bundles. Labour (alias 'capital') is immobile internationally, trade initially takes place by way of real barter and, implicitly, bundles are produced under constant returns to scale in both countries.

As Ricardo states, it will be advantageous for England to specialize in making cloth and Portugal to specialize in wine, because both countries thereby obtain more of the other commodity per unit of their domestic labour than if they attempted to make it themselves. For example, if Portugal used 80 labourers to make cloth she could obtain only 0.89\(x_1\), but if she can exchange \(1x_2\) (also the produce of 80 labourers) for \(1x_1\), as Ricardo supposes, then it would be ‘advantageous for her to export wine in exchange for cloth’ (*Works* I, p. 135). Similarly, if England used 100 labourers to produce wine she could obtain only 0.833\(x_2\), so she also benefits by exchanging \(1x_1\) (the produce of 100 labourers) for \(1x_2^*\).

Ricardo's example implies that the pattern of specialization is dictated by the ‘four magic numbers’ (Samuelson, 1972, p. 378), namely, \(a_1 / a_2 < a_1^* / a_2^*\). However, the principal purpose of the analysis was not so much to illustrate comparative advantage per se, but to show that the ‘same [labour theory] rule which regulates the relative value of commodities in one country, does not regulate the relative value of the commodities exchanged between two or more countries’ (*Works* I, p. 133). If, as Ricardo supposes, there is a rate of exchange of \(1x_1\) for \(1x_2\), ‘England would give the produce of the labour of 100 men, for the produce of the labour of 80’: something that ‘could not take place between the individuals of the same country’ (*Works* I, p. 135).

It was also Ricardo's purpose to show that the introduction of money (gold) would leave the analysis unaffected: gold will be ‘distributed in such proportions amongst the different countries … as to accommodate [itself] to the natural traffic which would take place if no such metal existed, and the trade between countries were purely a trade of barter’ (*Works* I, p. 137). To give the flavour of the argument, suppose England and Portugal each produce both commodities and that the initial gold prices are \(p_{x_1}^* = p_{x_1}\) which, given the ‘magic numbers’, implies \(p_{x_2} > p_{x_2}^*\). Wine is therefore exported from Portugal to England and is paid for by gold. But, on Ricardo's quantity theory reasoning, the influx of gold to Portugal, and its efflux from England, will raise prices in the former country and reduce them in
Ricardo, David (1772–1823) : The New Palgrave Dictionary of Economics

the latter. Hence, the specie-flow mechanism ensures that $p x_1 = p x_1^*$ is unsustainable (the same would apply to $p x_2 = p x_2^*$, by similar reasoning) and that the price of Portuguese cloth must exceed the price of English cloth (just as the price of wine must be higher in England than in Portugal), thus leading to complete specialization. Contrary to Ricardo, however, ‘the natural traffic which would take place if no such metal existed’, hence relative world prices, are not unique (as he implied), with the range of possible outcomes defined by the condition of $a_1 / a_2 \leq p_1 / p_2 \leq a_1^* / a_2^*$.

Debate continues as to whether Ricardo was the true originator of the comparative advantage doctrine, or whether that accolade should be awarded to his contemporary, Robert Torrens (see Ruffin, 2002; 2005, for a recent case in Ricardo's favour). But, regardless of who may have crossed the line first, it is with Ricardo's name that comparative advantage has become indelibly linked.

**Early writings on profit (1813–15) and the ‘corn model’ interpretation**

In the introduction to his masterful edition of Ricardo's *Collected Works* it was suggested by Piero Sraffa that the early Ricardo had devised a model in which corn is the sole agricultural input and output, thus supplying a ‘rational foundation’ for the ‘principle of the determining role of the profits of agriculture’, putatively articulated by Ricardo in 1814 with the words ‘it is the profits of the farmer which regulate the profits of all other trades’ (*Works* VI, p. 104). By implication, when Ricardo wrote that agricultural profits ‘regulate’ other profits, he had intended a statement of *unique determination* in full awareness of the logically required assumptions. Sraffa revealed, however, that the corn model (or ‘corn ratio theory of profits’) was ‘never stated by Ricardo in any of his extant letters and papers’ although, on the basis of indirect textual evidence, he claimed that Ricardo ‘must have formulated it’ either in lost papers or conversation (*Works* I, p. xxxi). Later, with the publication of Sraffa (1960), it transpired that the corn model had additional significance as a simple precursor of Sraffa's own ‘Standard system’ in which corn is the sole ‘basic commodity’; and Sraffa also disclosed that the interpretation was the outcome of his *own* theoretical work: ‘it was only when the Standard system and the distinction between basics and non-basics had emerged in the course of the present investigation that the [‘corn model’] interpretation of Ricardo's theory suggested itself as a natural consequence’ (Sraffa, 1960, p. 93).

The corn model interpretation was widely embraced. With a beguiling pedagogical simplicity, it could ‘explain’ Ricardo's regulatory statements and his later development of the pure labour theory, with Malthus entering the story to remind Ricardo that agricultural capital does *not* consist entirely of corn, thus necessitating a new (labour) theory of value. However, beginning in the early 1970s with the work Samuel Hollander, doubts have increasingly been aired about the textual basis for the interpretation. What follows is the view of one such critic. (For a sample of critical interpretations, see Faccarello, 1982; Hollander, 1973; 1975; 1979; and Peach, 1984; 1993; 2001. The case for the defence has been made by Eatwell, 1975, and Garegnani 1982, among others.)

If Ricardo's writings are sifted for confirmation for the interpretation – in other words, if the corn model is *presumed* – then it is easy enough to find ‘evidence’ in its favour. Without that presumption, the picture is rather different. Thus, Ricardo's assertion in correspondence that the ‘rate of profits and of interest must depend on the proportion of production to the consumption necessary to such production’ (*Works* VI, p. 108) is said by Sraffa to be the ‘nearest that Ricardo comes to an explicit
statement on these [corn model] lines’ (Works I, p. xxxii). Yet, although it is possible to conceive of such a ‘proportion’ in material terms, the expression itself provides no evidence of the way it was conceived by Ricardo; moreover, very similar expressions had been used by him in his earlier monetary writings in which there is no question of him having adopted corn model assumptions. As for the regulatory statements, while it is possible to impose a corn model rationalization, the problem is in establishing that the same rationalization was applied by Ricardo. Here, too, the evidence is disobliger.

The Essay (1815) is replete with such statements (for example, ‘The general profits of stock depend wholly on the profits of the last portion of capital employed on the land’; Works IV, p. 21), but we can be sure they were not thought by Ricardo to depend on the corn model because he explicitly assumed heterogeneous inputs to agriculture (including ‘buildings, implements, &c.’; Works IV, p. 10). Indeed, an arresting feature of the Essay is that its specious corn model appearance derives from the use of corn (alias wheat) to value the physically heterogeneous agricultural capital. It was Ricardo’s ‘failure’ to revalue this capital as corn became more difficult to produce (in the initial agricultural phase of the argument) that drew Malthus’s criticism and led, ultimately, to Ricardo's adoption of the labour theory, not an assumption that agricultural capital comprises of corn alone.

A question for those who reject the corn model is how the pre-Essay Ricardo could arrive at his ‘regulatory’ position if, as he believed at the time, a rise in the price of corn would be followed by a rise in prices generally. Samuel Hollander has conjectured that Ricardo may have invoked a monetary constraint, so that an agriculturally induced rise in money wages would not be passed on in higher prices. Alternatively, it may have been that his view of pricing was integral to the analysis: with price rises common to output and the heterogeneous inputs to agriculture, Ricardo might have reasoned that an increase in the capital–output ratio must reduce profitability. Admittedly, these alternative interpretations do not have the simple elegance and logical consistency of the corn model but, then again, the period 1813–15 was one in which Ricardo was struggling to establish new ideas within an inherited theoretical framework, much of which was later to be discarded. The existence of contradictions and unresolved theoretical issues during this period is unsurprising.

The labour theory of value

The unmodified or ‘pure’ labour theory of value (PLTV) was adopted by Ricardo in early 1816, on the basis of which he drafted material that would form the first seven chapters of the Principles (up to and including the chapter ‘On Foreign Trade’). But then he discovered a source of modification to the PLTV resulting from differences in capital structure between production processes. At first, the discovery impeded his progress, but then it seems he had the inspiration to turn it to his advantage (so he thought) in the form of the ‘curious effect’: the iconoclastic demonstration that prices fall following a general rise in wages and consequent reduction in the rate of profit. What he did not do, however, was provide any justification for using the PLTV in the light of the ‘curious effect’ analysis.

A simple ‘dated labour’ framework may serve to illustrate Ricardo’s position. Assume three commodities \(x_1, x_2, x_3\), each produced by ten units of homogeneous labour \(L\) applied over two discrete production periods \((t-1, t)\), with the following conditions of production:

\[10L_t \rightarrow x_1, \quad 5L_t + 5L_{t-1} \rightarrow x_2, \quad 10L_{t-1} \rightarrow x_3.\]

If we denote the uniform wage and profit rates as \(w\) and \(r\), each taking period \(t\) values, the natural price equations for the commodities are:
A PLTV requires $p_x_1 = p_x_2 = p_x_3$, because each commodity is produced with the same quantity of labour. However, it is evident (with $r > 0$) that $p_x_3 > p_x_2 > p_x_1$. Moreover, if distribution (between $w$ and $r$) changes, there will be price fluctuations even though labour inputs are unchanged. Thus, assume that $x_1$ is the numéraire commodity (so that $p_x_1 = 1$); in principle, on the basis of (1) a new (lower) $r$ can be calculated for a given rise in $w$, and these numbers may be entered into (2) and (3) to obtain the new natural prices of $x_2$ and $x_3$. With the ‘compounding’ (or magnification) of the effect of the lower $r$ on $p_x_2$ and, even more so, on $p_x_3$, the result will be a fall of both prices (expressed in terms of $x_1$) with $p_x_3$ falling to the greater extent.

To relate the above to the chapter ‘On Value’ in the first two editions of the Principles, the differences in production conditions (or capital structure) are, in Ricardo's terms, a reflection of differences in (a) the durability of fixed capital; (b) the ratios of fixed to circulating capital; (c) the durability of circulating capital (added in the second edition), where the fixed–circulating capital distinction depends, essentially, on the time required to repay a capital expenditure (the longer the time, the more ‘fixed’ the expenditure). In the case given by Ricardo, the two extremes (corresponding to $x_1$ and $x_3$) are a commodity produced by unassisted labour in one year and a commodity produced by unassisted machinery that lasts 100 years. Then, taking the former commodity as his ‘invariable standard’ (alias numéraire), he calculates that a fall of seven per cent in the rate of profit would reduce the price of the latter by 68 per cent: a vivid illustration of the ‘curious effect’ (Works I, p. 60).

The effect implies, by Ricardo's own testimony, that the PLTV is subject to a (truly) ‘considerable modification’ from differences in capital structure, but the really curious feature of the first two editions
of the *Principles* is that the PLTV (used beyond the first chapter) had been undermined by its own author. This does, indeed, deserve the obloquy of a shattering inconsistency, and one not lost on Malthus, who, in his *Principles* (1820, *Works* II), employed the ingenious tactic of using Ricardo's own analysis to demonstrate the untenability of the PLTV. His criticisms hit home. Ricardo comprehensively rewrote the chapter ‘On Value’ for the third edition of the *Principles*, newly adopting two strategies for the defence of the PLTV. First, he ruthlessly extirpated all the numerical examples that had suggested a ‘considerable modification’ to the PLTV and replaced them by others, according to which the ‘greatest effects which could be produced on the relative prices of … goods from a rise of wages, could not exceed 6 or 7 per cent’ (*Works* I, p. 36). Second, he introduced a new section ‘On an invariable measure of value’, where he indicated his desire to find a ‘perfect measure of value’ in terms of which prices would change *only* to reflect changes in the quantities of labour expended on production. This was tantamount to claiming that the discovery of the ‘perfect’ standard would itself sanction a PLTV, his problem being, however, that any commodity standard must be produced with *some* capital structure and, as he had demonstrated, the ‘unwanted’ price fluctuations are inescapable if capital structures differ. Hence his second-best solution of assuming that the standard is produced using an (unweighted) ‘average’ capital structure (cf. $x_2$, above), allegedly characteristic of ‘most commodities’: at least for *them* a PLTV would apply. There would still be a ‘curious effect’ with a fall in profitability, just as some commodities (such as our $x_1$) would now *rise* in price, but this was announced *sotto voce* (*Works* I, p. 46) and the effect was nowhere near as ‘curious’, at least in its magnitude, as it had been before.

Through this process of ‘double indemnification’ Ricardo had, *for the first time*, justified his use of the PLTV in explicit acknowledgement of the problems caused by differences in capital structures: either the differences are small and can be ignored, or (really a variation on the same theme) all the relevant commodities, including the standard, are part of a ‘general mass’ with the same capital structure. The ‘exceptions’ to the PLTV may therefore be ignored. If we leave aside the dubious merit of the defence, its very inclusion is evidence that Ricardo was not retreating in his advocacy of the PLTV, contrary to claims by earlier commentators including J. Hollander (1904) and Cannan (1929, p. 177). That view was laid to rest by Sraffa, who opined that ‘the theory of edition 3 appears to be the same, in essence and in emphasis, as that of edition 1’ (*Works* I, p. xxxviii): a view that may itself be criticized for undervaluing the scale and significance of the changes (cf. Hollander, 1979, p. 217). But why was the theory so important to him?

One attraction is that it provided him with (in its own terms) a logically coherent framework for establishing his central theoretical propositions, particularly of the dependency of the general rate of profit on the conditions of producing wage goods.

A second possibility is that the theory appealed because of its (supposed) empirical relevance; hence Stigler's attribution to Ricardo of ‘an empirical labour theory of value, that is, a theory that the relative quantities of labour … are the dominant determinants of relative value’ (Stigler, 1958, p. 60; emphasis in original). However, although Ricardo did make empirical claims on behalf of theory (for which, it must be said, no evidence was adduced), those claims were arguably more a reflection of his commitment than its basis.

There was also an increasing tendency on Ricardo's part to identify the very *essence* of value with expended labour time. This ‘value’, referred to him at different times as ‘natural value’, ‘positive value’
and ‘real value’, was conceived as an attribute of individual commodities; hence the criticism, fully accepted by Ricardo, that he had moved beyond a purely relative usage of ‘value’ (as in Stigler's interpretation) and had turned it into something absolute (Works IX, p. 38). From this perspective, the role of the ‘perfect’ standard was to harmonize the ‘labour values’ with (relative) cost-of-production ‘values’ (or natural prices), since (changes in) the latter would become an exclusive reflection of (changes in) the former. As Ricardo forlornly conceded, however, ‘perfection’ is ruled out by unequal capital structures: the point he develops in Absolute Value and Exchangeable Value (Works IV, pp. 361–412), poignantly truncated by his final illness.

The analytical and ‘philosophical’ attractions are therefore central to understanding Ricardo's PLTV commitment. Of course, with the benefit of nearly two centuries of hindsight, it could be (and has been) argued that the labour theory can be jettisoned, to be replaced (say) with Sraffa's physically specified input–output equations. That argument may be formally correct, but we would no longer have Ricardo's theoretical and conceptual system. For him, the labour theory of value was both fundamental and indispensable.

The ‘new view’

The inappropriately styled ‘new view’ (anticipated by Cannan, 1893, pp. 247–53, 350, with modern restatements by Casarosa, 1978, Hicks and Hollander, 1977, and Hollander, 1990; 2001; 2002, among others) can be treated either as a stand-alone interpretation of Ricardo's treatment of wages or as part of a more far-reaching attempt to assimilate Ricardo's work to ‘neoclassical’ economics.

In the second great ‘rehabilitation’ of Ricardo (the first was J.S. Mill's attempt to have him reinstated as ‘the greatest political economist’: Mill, 1848, p. 397), Alfred Marshall applied his principle of ‘generous interpretation’ to distance Ricardo from the labour theory of value (by that time with its Marxian connotations) and absorb him within the mainstream intellectual tradition. Thus he averred that Ricardo had been ‘feeling his way’ towards a subjective utility analysis and that, despite appearances, he had attributed coordinate importance to supply and demand in the determination of natural prices (Marshall, 1920, Appendix I). Interestingly, however, Marshall's generosity deserted him when it came to Ricardo's treatment of wages, which he regarded as indefensible (Pigou, 1925, p. 413).

Most subsequent commentators have considered Marshall's' interpretation as far too generous, the prominent exception being Samuel Hollander, who goes even further in claiming to find a ‘fundamentally important core of general-equilibrium economics’ in Ricardo's work, implying a ‘strong continuity of doctrine’ between Ricardo's and later ‘neoclassical’ analysis (Hollander, 1987, pp. 6–7; cf. Morishima, 1989). As part of this ‘general equilibrium’ analysis, Ricardo had (allegedly) treated the wage rate as an endogenous variable, and it is this feature that is emphasized by the ‘new view’ interpretation.

The ‘non-wage’ aspects of the ‘neoclassical’ Ricardo may be dealt with briefly. First, with regard to utility (in the sense of subjective satisfaction), there is no question that it was treated as a precondition for exchangeable value and, in circumstances of fixed supplies, it was also conjectured by Ricardo that prices would be proportionate to ‘utilities’ (Works II, pp. 24–5; Works VIII, 276–7). However, there was no attempt by him to develop an analysis of diminishing marginal utility and, for the purpose of explaining exchangeable values (at natural prices), his emphasis was on objective determination by
quantities of labour time. As to the ‘coordinate’ influence of supply and demand, this confuses the
process by which market prices tend to their natural levels (which does involve output variations and,
therefore, a pre-‘neoclassical’ species of supply-and-demand reasoning) with the determination of the
natural price levels: for Ricardo, the latter is independent of supply and demand, thus effectively
denying any theoretical relationship between output and (labour) conditions of production (see, for
example, Works VIII, p. 207). Finally, on ‘general equilibrium’, there is not a single developed instance
of such an analysis in the entire corpus of Ricardo’s writings. It is an interpretation obtained only by
reconstructing his work and, in the process, obliterating his own hallmark emphasis on unidirectional
relationships.

With the ‘new view’, however, there is at least a textual basis. The most compelling evidence is from
three paragraphs in the chapter ‘On Wages’. The first paragraph opens thus: ‘In the natural advance of
society, the wages of labour will have a tendency to fall, as far as they are regulated by supply and
demand’, the assumption being that ‘the supply of labourers will continue to increase as the same rate,
while the demand for them will increase at a slower rate’ (Works I, p. 101). Wages are therefore falling
continuously in ‘the natural advance’ and only reach their ‘natural’ level (defined for a stationary
population) in the terminal stationary state. However, ‘we must not forget, that wages are also regulated
by the prices of the commodities on which they are expended’ (Works I, p. 101) and, particularly, by the
rising price of corn (from diminishing returns on the land). Money wages therefore rise in the ‘natural
advance’ but not by so much as to fully compensate the labourers for the rising corn price, so that real
wages secularly decline as before. The effect of diminishing agricultural returns is in this way ‘shared’
between capitalists and labourers and has come to be known as the ‘shared incidence principle’.

There is no doubt that the new view passages exist, and there are also muted refrains of the analysis
elsewhere in the Principles (Works I, pp. 215, 220). At the same time, the natural wage analysis – with
the natural wage, defined for a stationary population, as the active centre of gravity for market wages in
all stages of society – is by far the dominant analysis in the Principles; and, unlike the new view, it is the
only one consistent with the repeated claim that real-wage variations are of only ‘temporary’
significance, particularly with regard to movements in the general rate of profit. Based solely on the
Principles, the proposition that the new view represents Ricardo’s true position is difficult to sustain.
Malthus, for one, did not recognize Ricardo as a (kindred) new view theorist; hence the trenchant
criticisms of Ricardo’s natural wage analysis in his own Principles (Malthus, 1820. Works II, pp. 256–
64). As Samuel Hollander (2007) has emphasized, however, Ricardo protested that he maintained ‘no
other doctrine than that which has been well explained by Mr. Malthus’ (Works II, p. 288). Yet he also
reaffirmed his own definition of the natural wage (Works II, pp. 227–8), which is inexplicable if he truly
agreed with Malthus (for whom Ricardo’s natural wage would be irrelevant outside the stationary state).
While it cannot be denied, then, that Ricardo was on some level sympathetic to the new view analysis,
he was at no time an unequivocal exponent of that doctrine. Even in his later writings (such as On
Protection to Agriculture, Works IV), in which the natural wage is not mentioned explicitly, the real
wage is treated as a given and fixed entity, without a trace of the new view. It is also significant that
Ricardo was never to criticize the writings of contemporaries, including their avowed representations of
his own position, for the (universal) failure to include the new view (Peach, 2007). His own credentials
as a new view theorist must therefore remain in considerable doubt.

Conclusion: Ricardo as a ‘classical’ economist?
Ricardo was to achieve great fame as a political economist during the tragically short period in which he wrote on the subject, although his ideas, especially his policy proposals, were often bitterly contested by critics of differing political and theoretical persuasions (see Peach, 2003). Following his death, his name, if not always his own doctrines, lived on through the writings of his ‘New School’ disciples, notably James Mill, Thomas De Quincey and the indefatigable J.R. McCulloch, and through the efforts of J.S. Mill. With the advent of ‘neoclassical’ economics, however, Ricardo's stock began to plummet, with Marshall's attempted rehabilitation to no avail. By the time Sraffa's edition of the Collected Works appeared in the 1950s, Ricardo's positive contribution was not uncommonly reduced to anaemic generalities such as the development of a ‘professional frame of mind’ or an ‘abstract deductive approach’, the onward progress of economic science having established the ‘inadequacy’ of much of his substantive work.

The Collected Works prompted a flurry of new scholarly interest in Ricardo, but it was only after the publication of Sraffa (1960) that he was subjected to his third major ‘rehabilitation’, this time not as a ‘mainstream’ economist (as with J.S. Mill and Marshall) but as a precursor of Sraffa’s economics or, as related by Sraffa's followers, as a founder of the ‘classical’ (or ‘surplus’) tradition that Sraffa (1960) had revived. The defining characteristics of ‘classical’ economics are alluded to in the Preface of Sraffa (1960) and amount to the assumption of given outputs and methods of production. The distribution between wages and profits may then be ‘solved’ by taking one distributive variable as given and calculating the other as a residual (or ‘surplus’). But how well does this apply to Ricardo's approach? At one level – the calculation of profit as a ‘surplus’ – it does so well enough. Where the problems arise is with the other attribution of given outputs.

According to Sraffa, ‘The “principal problem in Political Economy” was in [Ricardo's] view the division of the national product between classes and in the course of that investigation he was troubled by the fact that the size of this product appears to change when the division changes’ (Works I, p. xlviii). Hence, ‘the problem of value which interested Ricardo was how to find a measure of value which would be invariant to changes in the division of the product’ (Works I, p. xlviii); and, as Sraffa remarks parenthetically, Ricardo may have come close to solving his ‘problem’ with the ‘average’ standard adopted in the third edition of the Principles: ‘If measured in such a standard, the average price of all commodities, and their aggregate value, would remain unaffected by a rise or fall of wages’ (Works I, pp. xlv–xliv).

Several objections can be made against Sraffa's interpretation. First and foremost, it implies that Ricardo's ‘principal problem’ was with purely ‘notional’ redistributions of a given national product (that is, with given and unchanging outputs). However, Ricardo's own ‘principal problem’, as he defined it himself, was with the ‘natural course of rent, profit, and wages’ over time, and for the purpose of his investigation there will be at least one output, that of corn, that cannot be treated as given and unchanging in terms of its conditions of production. Second, as Ricardo clarified, his analysis of distribution was to be framed at the level of the individual firm, or farm, not in terms of social or ‘national’ aggregates. Third, there is no evidence that he envisaged a ‘price-balancing’ function for his ‘average’ standard (that is, to ensure constancy in the total value of national output); indeed, Ricardo's opinion was that all distributions-induced price changes are evidence of a ‘defect’ in the standard. Ricardo was not a full-fledged ‘classical’ economist in the Sraffa mould. To describe him more loosely...
as a ‘surplus theorist’ is unexceptionable, although by focusing on only one (albeit important) area of Ricardo's writings it is also a ‘thin’ characterization. Ricardo was a towering intellectual force whose work ranged over all the main areas of political economy. Forcing him into classificatory boxes of a later construction is a disservice to him and a hindrance to those who would seek to understand the full richness and extent of his historical significance.

risk aversion

Jan Werner
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

An agent, perhaps an individual or a firm, is said to be risk averse if the agent prefers a deterministic outcome equal to the expectation of a risky outcome over that risky outcome. Risk aversion seems to be a common characteristic; introspection suggests as much. More importantly, it gives qualitative explanation to economic behaviour in many instances where risk is present. If individuals and firms were not risk averse, insurance markets would not exist. Needless to say, there are activities which are inconsistent with agents being risk averse. Gambling is perhaps the best example of such an activity.

Arrow–Pratt theory of risk aversion

The classical theory of risk aversion, due to Pratt (1964) and Arrow (1965), is rooted in the expected utility theory of decision making. An agent's preferences are assumed to have an expected utility representation. The objects of choice are real valued random variables defined either on a finite or infinite set of states of the world with probabilities of states that may be either objective or subjective. The intended interpretation of a random variable is as an agent's risky wealth. An agent whose expected utility representation of preferences is written \( E[u(\tilde{X})] \), where \( u \) is the von
Neumann–Morgenstern utility function and $E$ denotes the expectation (expected value), is risk averse if

$$E[u(\bar{x})] \leq u(E(\bar{x}))$$

for every risky wealth $\bar{x}$. If (1) holds with strict inequality for every non-deterministic $\bar{x}$, the agent is strictly risk averse. Jensen's inequality implies that, if utility function $u$ is concave, the agent is risk averse. The converse is also true. Thus, the concavity of $u$ is a necessary and sufficient condition for risk aversion. Moreover, strict concavity of $u$ is a necessary and sufficient condition for strict risk aversion. Examples of strictly concave von Neumann–Morgenstern utility functions, commonly used in applied work, include the negative exponential utility $u(w) = e^{-\alpha w}$ with $\alpha > 0$, the logarithmic utility $u(w) = \ln(w)$, and the power utility $u(w) = \frac{1}{1-\alpha} w^{1-\alpha}$ with $\alpha > 0$, $\alpha \neq 1$.

It is useful to have a measure of the intensity of risk aversion. The most natural measure is risk compensation. It is by definition the amount $\rho(w, \bar{z})$ of deterministic wealth one could extract from an agent in exchange for relieving her of zero-expectation risk $\bar{z}$ at an initial deterministic wealth $w$,

$$E[u(w + \bar{z})] = u(w - \rho(w, \bar{z})).$$

A risk-averse agent has non-negative risk compensation for every zero-expectation risk, at every level of initial wealth. Risk compensation makes possible interpersonal comparisons of risk aversion and, for any agent, comparisons of risk aversion at different levels of her initial wealth. If risk compensation $\rho_1(w, \bar{z})$ of an agent with von Neumann–Morgenstern utility function $u_1$ is greater than or equal to risk compensation $\rho_2(w, \bar{z})$ of another agent with utility function $u_2$, for every deterministic wealth $w$ and risk $\bar{z}$ with $E(\bar{z}) = 0$, then the agent with $u_1$ is said to be more risk averse than the one with $u_2$. An agent has increasing, decreasing or constant risk aversion if, for every zero-expectation risk, her risk compensation is increasing, decreasing or constant in $w$, for every $\bar{z}$ with $E(\bar{z}) = 0$.

Another measure of risk aversion is certainty equivalent. It is by definition the amount $c(\bar{x})$ of deterministic wealth such that an agent is indifferent between this deterministic wealth and risky wealth $\bar{x}$,

$$E[u(\bar{x})] = u(c(\bar{x})).$$
For a risk-averse agent, certainty equivalent is lower than the expectation of risky wealth. Since certainty equivalent and risk compensation are related by $\ cousins(\), these two measures can be interchangeably used in the Arrow–Pratt theory of risk aversion.

Although with considerable intuitive appeal, risk compensation is not all that practical. It is only implicitly defined in (2). The basic insight of Arrow and Pratt is that there is a simple measure of risk aversion which is in a certain sense equivalent to risk compensation, namely, the Arrow–Pratt measure of absolute risk aversion

$$A(w) = -\frac{u''(w)}{u'(w)}.$$ 

The negative of the second derivative $u''(w)$ is a mathematical measure of the degree of concavity of $u$. It is rescaled by the first derivative (assumed non-zero) which makes the measure invariant under any affine transformation of $u$. For ‘small’ risk $\varepsilon$ with $E(\varepsilon) = 0$, risk compensation $\rho(w, \varepsilon)$ equals approximately half the product of the variance $\sigma^2(\varepsilon)$ and the Arrow–Pratt measure at $w$,

$$\rho(w, \varepsilon) \approx \frac{1}{2} A(w) \sigma^2(\varepsilon)$$ 

as can be demonstrated using quadratic approximation of expected utility $E[u(w + \varepsilon)]$.

The important theorem of Pratt establishes an equivalence of the two measures as criteria for comparative risk aversion. For that theorem, let $u_1$ and $u_2$ be two strictly increasing von Neumann–Morgenstern utility functions, twice differentiable with continuous second derivatives.

**Theorem:** (Pratt, 1964): The following conditions are equivalent:

1. $(a)$ $A_1(w) \geq A_2(w)$ for every $w$.
2. $(b)$ $\rho_1(w, \varepsilon) \geq \rho_2(w, \varepsilon)$ for every $w$ and every random variable $\varepsilon$ with $E(\varepsilon) = 0$.
3. $(c)$ $u_1$ is a concave transformation of $u_2$; that is, $u_1 = f \circ u_2$ for $f$ concave and strictly increasing.

There is a version of the Pratt's theorem which has equalities in $(a)$ and $(b)$ and an affine transformation in $(c)$. This version implies that the Arrow–Pratt measure identifies the von Neumann–Morgenstern utility function up to an affine transformation. For example, the negative exponential utility is (up to an
risk aversion: The New Palgrave Dictionary of Economics

affine transformation) the only strictly concave utility with constant absolute risk aversion. There is also a strict version of the Pratt's theorem with strict inequalities in (a) and (b) and a strictly concave transformation in (c).

A corollary to the Pratt's Theorem says that an agent has increasing, decreasing or constant risk aversion if and only if her Arrow–Pratt measure of risk aversion is increasing, decreasing or constant. One needs only to consider utility functions \( u_1(w) = u(w) \) and \( u_2(w) = u(w + \Delta w) \) for arbitrary \( \Delta w > 0 \).

Arrow (1965) and Pratt (1964) extended their theory of measurement of risk aversion to relative risk, that is, risk per dollar of an agent's wealth. Risk compensation \( \rho_r(w, \zeta) \) for relative risk \( \zeta \) with \( E(\zeta) = 0 \) at initial wealth \( w \) is defined by

\[
E[u(w + w\zeta)] = u(w - w\rho_r(w, \zeta)).
\]

The Arrow–Pratt measure of relative risk aversion is \( R(w) = -\frac{u''(w)}{u'(w)}w \). The measures \( \rho_r \) and \( R \) are related in the same way that their counterparts for absolute risk are related. Power and logarithmic utility functions have constant relative risk aversion.

Risk compensation is defined when the agent's initial position is risk-free. The approximation (5) of risk compensation by the Arrow–Pratt measure holds at a risk-free position, too. Measures of risk aversion that can be used when the initial position is risky have been developed by Ross (1981) and Machina and Neilson (1987).

When random variables are vector-valued (multivariate), the Arrow–Pratt theory can be applied to risk in one coordinate (for example, consumption of one good) when values of other coordinates are deterministic. Alternatively, multivariate risk aversion can be defined by requiring condition (1) to hold for every multivariate random variable \( X \). Multivariate random variables arise when objects of choice are consumption plans of multiple goods or consumption plans over multiple time periods. Multivariate risk aversion is equivalent to concavity of the von Neumann–Morgenstern utility function and implies that the induced ordinal preferences over multiple goods under certainty are convex. The theory of comparative risk aversion has been extended to the multivariate case by Kihlstrom and Mirman (1974) under the restriction that utility functions induce the same ordinal preferences.

Rabin and Thaler (2001) have pointed out a peculiar feature of risk aversion under expected utility. If an agent rejects a small actuarially favourable gamble at every level of wealth (or at a big enough range of wealth), then she will reject a gamble with a modest loss and an arbitrarily large gain. They presented a calibration exercise which shows that any risk-averse agent who rejects an even-chance gamble of losing $10 or winning $11 will turn down an even-chance gamble of losing $1,000 or winning any sum of money. The significance of Rabin and Thaler's observation is a subject of current debate.

Risk aversion without expected utility
A representation of preferences which is closely related to but more general than the expected utility is the state-dependent expected utility. For a finite set $S$ of states of the world, it is written $\sum_{s \in S} \pi_s u_s(x_s)$, where $\pi_s$ is the probability of state $s$ and $u_s$ is the state-dependent utility. Werner (2005a) has shown that an agent with state-dependent expected utility is risk averse in the sense of having a preference for deterministic outcomes over risky outcomes with equal expectations if and only if the utility functions $u_s$ are state independent and concave. When utility functions $u_s$ are state dependent, a risk-free wealth may have risky utility and, more importantly, risky marginal utility. Karni (1985) has developed a theory of aversion to risk in marginal utility defined by an agent being unwilling to take an actuarially fair gamble when starting from a position of risk-free marginal utility of wealth. Measures of risk aversion analogous to the measures introduced by Arrow and Pratt can be defined, and an extension of the Pratt’s theorem obtains for utility functions that have the same set of wealth profiles with risk-free marginal utility. State-dependent utilities arise in instances of behaviour under health risk.

The Arrow–Pratt theory of risk aversion is based on the simple notion that every risky outcome is more risky than the deterministic outcome with equal expectation. For preferences that do not have an expected utility representation (state-independent, or not), this concept of ‘more risky’ is too restrictive to deliver a meaningful notion of risk aversion. A weaker concept of ‘more risky’ has been introduced by Rothschild and Stiglitz (1970). It is a partial ordering of random variables according to the integrals of their cumulative distribution functions. For two random variables $\tilde{x}$ and $\tilde{y}$ with the same expectation, $\tilde{x}$ is more risky than $\tilde{y}$ if

$$\int_{-\infty}^{w} F_{\tilde{y}}(t) \, dt \leq \int_{-\infty}^{w} F_{\tilde{x}}(t) \, dt \quad \forall w,$$

where $F_x$ is the cumulative distribution function assigning to each $w$ the probability $\text{Prob}(\tilde{x} \leq w)$.

An agent whose utility function on random variables is monotone decreasing with respect to the ordering of more risky is said to be strongly risk averse (see Cohen, 1995). It follows that a strongly risk-averse agent, when starting from a risky position $\tilde{x}$, is unwilling to take a gamble $\tilde{z}$ with zero expectation conditional on each possible realization $x$ of $\tilde{x}$, that is, $E(\tilde{z}|\tilde{x} = x) = 0$ for every $x$. The ordering (7) has been known in mathematics as the second-order stochastic dominance and the strongly risk-averse functions have been known as the Schur concave functions (see Marshall and Olkin, 1979). Chew, Karni and Safra (1987) derived necessary and sufficient conditions for strong risk aversion of two types of utility functions: the rank-dependent expected utility of Quiggin (1982), and the dual utility of Yaari (1987). Characterization results for general utility functions can be found in Machina (1982), Chew and Mao (1995), and Dana (2005). For an expected utility, strong risk aversion and risk aversion in the sense of (1) are equivalent. Concavity of the von Neumann–Morgenstern utility function is necessary and sufficient for strong risk aversion of expected utility (see Rothschild and Stiglitz, 1970). An important representation of preferences under uncertainty, more general than the expected utility, is

http://www.dictionaryofeconomics.com.proxy.library.csi.c...edu/article?id=pde2008_R000155&goto=B&result_number=1471
the maxmin (or multiple-prior) expected utility (see Gilboa and Schmeidler, 1989). Under the maxmin expected utility representation an agent has a set $\mathbb{P}$ of probability measures (priors) on states instead of a single probability measure, and a von Neumann–Morgenstern utility function $u$. The set $\mathbb{P}$ is assumed to be closed and convex. An agent's utility of risky wealth $\tilde{x}$ is

$$\min_{p \in \mathbb{P}} E_p[u(\tilde{x})],$$

(8)

where $E_p[u(\tilde{x})]$ is the expectation of $u(\tilde{x})$ with respect to probability measure $P$. Multiplicity of probability measures reflects the agent's ambiguous information about states of the world. Taking the minimum reflects the concern with the ‘worst case’ scenario. If the set $\mathbb{P}$ consists of all probability measures, then the maxmin expected utility (8) equals $\min_x u(x)$ meaning that the agent follows the Wald's criterion of choice. Maxmin expected utility may exhibit risk aversion with respect to some probability measure in the set of priors. If the von Neumann–Morgenstern utility function $u$ is concave, the agent prefers deterministic wealth in the amount of $E_p(\tilde{x})$ over risky wealth $\tilde{x}$ for every probability measure $P$ in her set of priors. Thus the agent is risk averse in the Arrow–Pratt sense with respect to every $P$ in the set $\mathbb{P}$. Wald's minimum utility is also strongly risk averse with respect to every probability measure. Many maxmin expected utility functions are not distribution invariant under any probability measure on states, rendering the question of strong risk aversion meaningless for these functions. Werner (2005b) proposes a concept of more risky, stronger than (7), such that adding a gamble with zero conditional expectation makes an initial risky position more risky, but without identifying random variables with their probability distributions. For many (but not all) sets of priors, maxmin expected utility with concave von Neumann–Morgenstern utility function is risk averse in that sense under some probability measure from the set of priors.

Some implications of risk aversion

The choice of insurance coverage provides a good illustration of implications of risk aversion on agents' behaviour. Suppose that an expected-utility maximizing individual with initial wealth $w$ faces a risk of losing $L$ with probability $\pi$ or not losing it with probability $1 - \pi$. She is offered insurance against the loss at price $p$ per dollar of coverage. A strictly risk-averse individual will choose full coverage giving her risk-free wealth $w - pL$, if the insurance is priced actuarially fair, that is $p = \pi$. If it is priced above the fair value, that is $p > \pi$, then the optimal coverage will be partial. Schlesinger (1997) shows that these results continue to hold under risk aversion without expected utility.

A risk-averse investor who invests her initial risk-free wealth among many risky assets and a risk-free asset will choose an optimal portfolio with risky payoff only if the expected return on that portfolio exceeds the risk-free return. For a strictly risk-averse investor, the expected return on the optimal portfolio must strictly exceed the risk-free return if the payoff is risky. This is the fundamental risk–return trade-off in asset markets and it is a consequence of risk aversion. It continues to hold when the
risk aversion: The New Palgrave Dictionary of Economics

An investor's initial position includes an endowment portfolio of assets. In an equilibrium in competitive asset markets where many strictly risk-averse investors trade their endowment portfolios, the market portfolio (that is, the outstanding supply of assets) must have expected return that exceeds the risk-free return. This is so because the return on the market portfolio is a weighted sum of the returns on investors' optimal portfolios, with weights equal to the respective shares of total wealth. Expected returns on optimal portfolios exceed the risk-free return, with some exceeding it strictly, if the payoff of the market portfolio is risky. Thus, risk aversion provides a qualitative explanation of the expected return in equity markets exceeding the risk-free return. Attempts to give a quantitative explanation of the observed high excess return on equities over risk-free bonds have led to the *equity premium puzzle* (see Mehra and Prescott, 1985).

risk sharing

Ethan Ligon
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Agents increase their expected utility by using state-contingent transfers to share risk; many institutions seem to play an important role in permitting such transfers. If agents are suitably risk-averse, then in the absence of any frictions the benchmark Arrow–Debreu model predicts that all risk will be shared, so that idiosyncratic shocks will have no effect on individuals; we call this full risk sharing. Real-world tests of full risk sharing tend to reject it; accordingly, researchers have devised models incorporating various frictions to try to explain the partial risk sharing evident in the data.

Keywords

Arrow–Debreu economy; commitment; credit; Euler equations; financial markets; full risk sharing; idiosyncratic risk; insurance; Lagrange multipliers; Pareto efficiency; partial risk sharing; permanent-income hypothesis; risk aversion; risk sharing; separability; sharecropping; state-contingent transfers; von Neumann–Morgenstern preferences; von Neumann–Morgenstern utility functions

Article

Any two agents may be said to share risk if they employ state-contingent transfers to increase the expected utility of both by reducing the risk of at least one. A very wide variety of human institutions seem to play an important role in risk sharing, including insurance, credit, financial markets, and sharecropping in developing countries.

To be precise, consider a set of agents indexed by $i = 1, \ldots, n$ each with von Neumann–Morgenstern utility function $U_i$ and a finite set of possible states of the world $s = 1, \ldots, S$, each of which occurs with probability $p(s)$. For simplicity, suppose that each agent $i$ receives a quantity of a single consumption good $x_i(s)$ in state $s$, thus receiving expected utility
where $x_i$ denotes the random variable, $\{x_i(s)\}$ denotes its realizations, and $E$ is the expectation operator. We assume that $U_i$ is strictly increasing, weakly concave, and continuously differentiable for all $i = 1, \ldots, n$, so that all agents are at least weakly risk averse. Define the risk faced by agent $i$ to be a quantity

$$R_i(x_i) = EU_i(x_i) - EU(x_i).$$

This cardinal measure orders probability distributions in the same manner as Rothschild and Stiglitz (1970). We say that $i$ faces idiosyncratic risk if $R_i(x_i) > 0$ and $\text{Cov}(U_i'(x_i), U_j'(x_j)) < 1$ for some $j$, where $U_j'$ denotes $j$'s marginal utility. If any agent $i$ bears idiosyncratic risk, then there exists a set of state-contingent transfers of the consumption good between $i$ and $j$, $\{T_j'(s)\}$ which will strictly increase the expected utility of each, while strictly decreasing the risk of at least one of $i$ and $j$. Implementing such transfers is risk sharing.

**Full risk sharing**

What might be termed full risk sharing (Allen and Gale, 1988; Rosenzweig, 1988) is a situation in which all idiosyncratic risk is eliminated. While agents may still face risk, this risk is shared, so that marginal utilities of consumption are perfectly correlated across all agents. Full risk sharing is a hallmark of any Pareto-efficient allocation in an Arrow–Debreu economy, provided that agents have von Neumann–Morgenstern preferences, no one is risk-seeking, and at least one agent is strictly risk averse.

Let us establish the necessity of full risk sharing for any interior Pareto-efficient allocation in a simple multi-period endowment economy. The environment is similar to that described above, but agents consume in several periods indexed by $t = 1, \ldots, T$, with agent $i$ discounting future expected utility using a discount factor $\beta_i$. Different states of the world are realized in each period, with the probability of state $s_t \in \{1, \ldots, S\}$ being realized in period $t$ allowed to depend on the period, and so given by $P_t(s_t)$. Then consider the problem facing a social planner, who assigns state-contingent consumption allocations to solve
subject to the resource constraints

\[ \sum_{i=1}^{n} \lambda_{it}(s_{t}) \leq \sum_{i=1}^{n} x_{it}(s_{t}), \]

which must be satisfied at every period \( t \) and state \( s_{t} \); the planner takes as given the initial state \( s_{0} \) and a set of positive weights \( \{\lambda_{i}\} \). By varying these weights one can compute the entire set of interior Pareto-efficient allocations (Townsend, 1987).

If we let \( \mu_{t}(s_{t}) \) denote the Lagrange multiplier associated with the resource constraint for period \( t \) in state \( s_{t} \), then the first order conditions for the social planner's problem are

\[ \lambda_{i} \beta_{i}^{t-1} p_{t}(s_{t}) U_{j}(c_{it}(s_{t})) = \mu_{t}(s_{t}). \]  

Since this condition must be satisfied in all periods and states for every agent, it follows that

\[ U_{j}(c_{it}(s_{t})) = \frac{\lambda_{j}}{\lambda_{i}} \left( \frac{\beta_{j}}{\beta_{i}} \right)^{t-1} U_{j}(c_{it}(s_{t})) \]

for any period \( t \), any pair of agents \( (i, j) \) and any state \( s_{t} \), so that \( \text{corr}(U_{j}(c_{it}), U_{j}(c_{jt})) = 1 \), and we have full risk sharing.

Thus far, we've considered risk sharing only in the context of an endowment economy. However, the thrust of the claims advanced above holds much more generally. If we were, for example, to add production and some kind of intertemporal technology (for example, storage), the first order conditions of the planner's problem with respect to state-contingent consumptions (1) would remain unchanged – the effect of these changes would be that the Lagrange multipliers \( \{\mu_{t}(s_{t})\} \) would change. This is an
Risk sharing: The New Palgrave Dictionary of Economics

Illustration of what is sometimes called ‘separability’ between production and consumption, which typically prevails only when there is full risk sharing (see, for example, Benjamin, 1992). Risk sharing can also be thought of as a means to smooth consumption across possible states of the world. This suggests a connection to the permanent-income hypothesis, which at its core involves agents smoothing consumption across periods. And indeed, it’s easy to show that full risk sharing in every period implies the kind of smoothing across periods implied by the consumption Euler equation. However, the consumption Euler equation doesn’t imply full risk sharing.

Tests of full risk sharing

The insight that Pareto-efficient allocation among risk-averse agents implies full risk sharing has led to tests of versions of (1). The usual strategy involves adopting a convenient parameterization of $U_i$, and then calculating the logarithm of both sides of (1). For example, if $\frac{U_i(t)}{1 - \gamma}$, with $\gamma > 0$, then this yields the relationship

$$\gamma \log c_{it}(t) = \log \frac{\mu_t(s_t)}{\rho_t(s_t)} - \log \lambda_i - \log \beta_i.$$  \hspace{1cm} (2)

This is a simple consumption function, which we would expect to be consistent with any efficient allocation. The quantity $\frac{\mu_t(s_t)}{\rho_t(s_t)}$ is related to the aggregate supply of the consumption good. Note that this is the only determinant of consumption which depends on the random state. This reflects the fact that the only risk borne by agents in an efficient allocation will be aggregate risk. The second term varies with neither the state nor the date, and can be thought of as depending on the levels of consumption that agent $i$ can expect (in a decentralization of this endowment economy, $\lambda_i$ could be interpreted as a measure of $i$’s time zero wealth). The final term has to do with differences in agents’ patience.

Now, suppose one has panel data on realized consumption for a sample of agents over some period of time. If we let $c_{it}$ denote observed consumption for agent $i$ in period $t$, (2) implies the estimating equation

$$\log c_{it} = \eta_t + \alpha_i + \delta_i \beta + \epsilon_{it}.$$ \hspace{1cm} (3)

where $\eta_t = \log \frac{\mu_t(s_t)}{\gamma \rho_t(s_t)}$, $\alpha_i = - \log \frac{\lambda_i}{\gamma \beta_i}$, $\delta_i = - \log \beta_i$, and $\epsilon_{it}$ is some disturbance term. Because this final disturbance term isn’t implied by the model, it’s typically motivated by assuming that it’s related

http://www.dictionaryofeconomics.com.proxy.library.csi.c.edu/article?id=pde2008_R000231&goto=B&result_number=1473
either to measurement error in consumption or to some preference shock. The reduced form consumption eq. (3) can be straightforwardly estimated by using ordinary least squares, but this doesn't constitute a test of full risk sharing. To construct such a test, one typically uses data on other time-varying, idiosyncratic variables which would plausibly influence consumption under some alternative model which predicts less than full risk sharing. Perhaps the most obvious candidate for such a variable is some measure of income, for example the observed endowment realizations \( \tilde{X}_{it} \) referred to in the model above. Then one can add (the logarithm of) this variable to reduced form as an additional regressor, yielding an estimating equation of the form

\[
\log \tilde{c}_{it} = \eta_t + \alpha_i + \beta_i \bar{t} + \varphi \log \tilde{X}_{it} + \varepsilon_{it}
\]

(Mace, 1991; Cochrane, 1991; Deaton, 1992; Townsend, 1994). Then full risk sharing and an auxiliary assumption that \( \varepsilon_{it} \) is mean independent of the regressors implies the exclusion restriction \( \varphi = 0 \), which can be easily tested.

**Partial risk sharing**

Restrictions along the lines of (4) have been used to test for full risk sharing in a wide variety of settings, including within-dynasty risk sharing (Hayashi, Altonji and Kotlikoff, 1996) in the United States, risk sharing across countries (Obstfeld, 1994), risk sharing within networks in the Philippines (Fafchamps and Lund, 2003), and risk sharing across households in India (Townsend, 1994), Africa, or the United States (Mace, 1991). A typical finding is that the estimated response of consumption to income shocks is small but significant, leading one to reject the null hypothesis of full risk sharing. In this case it is tempting to interpret the estimated relationship as determining the response of consumption to income. However, this is generally a mistake. By rejecting the hypothesis of full risk sharing one also rejects the model which generated the hypothesis, so that theory no longer supports the interpretation of (4) as a consumption function.

Given this kind of evidence against full risk sharing, scholars have been led to devise and test alternative models in which some kind of friction leads to agents bearing some idiosyncratic income risk. Two promising frictions are private information and limited commitment. In the case of private information, realized or announced incomes may provide a useful signal regarding hidden actions or information, and thus an agent's consumption will optimally depend on this signal, leading to a balance between risk sharing and incentives (Holmström, 1979); Ligon (1998) tests this weaker risk-sharing hypothesis in three Indian villages, and is unable to reject it. In the case of limited commitment, an agent who receives an unusually large endowment realization may be tempted to renege on a pre-existing risk-sharing arrangement unless she receives a larger share of resources (Kocherlakota, 1996); a test of this model in the same three Indian villages by Ligon, Thomas and Worrall (2002) finds that this model predicts a response of consumption to income of just the right magnitude. Still, the construction, estimation, and
risk sharing: The New Palgrave Dictionary of Economics

...testing of well-specified models which predict only partial risk sharing remains in its infancy.

risk

Mark J. Machina and Michael Rothschild
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The phenomenon of risk plays a pervasive role in economics. Without it, financial and capital markets would consist of the exchange of a single instrument each period, the communications industry would cease to exist, and the profession of investment banking would reduce to simple accounting. One need but consult the contents of any recent economics journal to see how the recognition of risk has influenced current research in the discipline. This article presents an overview of the modern economic theory of the characterization of risk and the modelling of economic agents’ responses to it.

Keywords
capital asset pricing model; expected utility hypothesis; mean-standard deviation; portfolio theory; probabilistic sophistication hypothesis; probability distribution; Riemann–Stieltjes integral; risk; risk aversion; risk preference; stochastic dominance; subjective probability; uncertainty; von Neumann and Morgenstern

Article

The phenomenon of risk is one of the key determining factors in the formation of investment decisions, the operation of financial markets, and several other aspects of economic activity.

Risk versus uncertainty

The most fundamental distinction in this branch of economic theory, due to Knight (1921), is that of ‘risk’ versus ‘uncertainty’. A situation is said to involve risk if the randomness facing an economic agent presents itself in the form of exogenously specified or scientifically calculable objective probabilities, as with gambles based on a roulette wheel or a pair of dice. A situation is said to involve uncertainty if the randomness presents itself in the form of alternative possible events, as with bets on a horse race, or decisions involving whether or not to buy earthquake insurance.

The standard approach to the modelling of preferences under uncertainty (as opposed to risk) has been the state-preference approach (for example, Arrow, 1964; Debreu, 1959, ch. 7; Hirschleifer, 1965; 1966; Karni, 1985; Yaari, 1969). Given the absence of exogenously specified objective probabilities, this approach represents the randomness facing the individual by a set of mutually exclusive and exhaustive states of nature or states of the world $S = \{s_1, \ldots, s_n\}$. Depending upon the particular application, this partition of all conceivable futures may either be very coarse, as with the pair of states (it snows here tomorrow, it doesn’t snow here tomorrow) or else very fine, so that the description of a single state might read ‘it snows more than three inches here tomorrow and the temperature in Paris at noon is 73° and the price of gold in New York is over $900.00/ounce’. The objects of choice in this framework consist of state-payoff bundles of the form $(c_1, \ldots, c_n)$, which specify the payoff that the individual will receive in each of the respective states. As with regular commodity bundles, individuals are assumed to have preferences over state-payoff bundles which can be represented by indifference curves in the state-payoff space $\{(c_1, \ldots, c_n)\}$. Even though the state-preference approach has led to important advances in the analysis of choice under uncertainty (see, for example, the above citations), the advantages of being
able to draw on modern probability theory has led economists to hypothesize that an individual's beliefs in such settings can nevertheless still be represented by so-called *personal probabilities or subjective probabilities*, which take the form of an additive *subjective probability measure* \( \mu \) over the state space \( \mathcal{S} \). In such a case, a given state-payoff bundle \((c_1, \ldots, c_n)\) will be viewed as yielding outcome \( c_i \) with probability \( \mu(s_j) \), so that the individual would evaluate the bundle \((c_1, \ldots, c_n)\) in the same manner as he or she would evaluate a casino gamble which yielded the payoffs \((c_1, \ldots, c_n)\) with respective objective probabilities \((\mu(s_1), \ldots, \mu(s_n))\). The hypothesis that individuals have such probabilistic beliefs and evaluate state-payoff bundles in such a manner is termed the *hypothesis of probabilistic sophistication*, and permits a unified application of probability theory to the analysis of decisions under both objective risk and subjective uncertainty. The joint hypothesis of probabilistic sophistication and expected utility risk preferences has been axiomatized by Ramsey (1926), Savage (1954), Anscombe and Aumann (1963), Pratt, Raiffa and Schlaifer (1964) and Raiffa (1968, ch.5), and probabilistic sophistication without expected utility has been axiomatized by Machina and Schmeidler (1992).

**Choice under risk: the expected utility model**

For reasons of expositional ease, we consider a world with a single commodity (for example, wealth). An agent making a decision under either risk or probabilistic uncertainty can therefore be thought of as facing a choice set of alternative univariate probability distributions. In order to consider both discrete (for example, finite outcome) distributions as well as distributions with density functions, we represent each such probability distribution by means of its cumulative distribution function \( F(\cdot) \), where \( F(x) = \Pr(X \geq x) \) for the random variable \( X \).

In such a case we can model the agent's preferences over alternative probability distributions in a manner completely analogous to the approach of standard (that is, non-stochastic) consumer theory: he or she is assumed to possess a ranking \( \succ \) over distributions which is complete, transitive and continuous (in an appropriate sense), and hence representable by a real-valued *preference function* \( V(\cdot) \) over cumulative distribution functions, in the sense that \( F^r(\cdot) \succ F(\cdot) \) (that is, the distribution \( F^r(\cdot) \) is weakly preferred to \( F(\cdot) \)) if and only if \( V(F^r) \succ V(F) \).

Of course, as in the non-stochastic case, the above set of assumptions implies nothing about the functional form of the preference functional \( V(\cdot) \). For reasons of both normative appeal and analytic convenience, economists typically assume that \( V(\cdot) \) is a *linear functional* of the distribution \( F(\cdot) \), and hence takes the form

\[
V(F) = \int U(x) \, dF(x)
\]

for some function \( U(\cdot) \) over wealth levels \( x \), where \( U(\cdot) \) is referred to as the individual's *von Neumann–Morgenstern utility function*. (For readers unfamiliar with the *Riemann–Stieltjes integral* \( \int U(x) \, dF(x) \), it represents nothing more than the expected value of \( U(X) \) when \( X \) possesses the cumulative distribution function \( F(\cdot) \). Thus if \( X \) took the values \( x_1, \ldots, x_n \) with probabilities \( p_1, \ldots, p_n \) then \( \int U(x) \, dF(x) = \sum U(x_i) p_i \), and if \( X \) possessed the density function \( f(\cdot) = F'(\cdot) \) then \( \int U(x) \, dF(x) = \int U(x) f(x) \, dx \).)

Since the right side of (1) may be thought of as the mathematical expectation of \( U(X) \), this specification is known as the expected utility model of preferences over random prospects (for a more complete statement of this model, see expected utility hypothesis). Within this framework, an individual's attitudes towards risk are reflected in the shape of his or her utility function \( U(\cdot) \). Thus, for example, an individual would always prefer shifting probability mass from lower to higher outcome levels if and only if \( U(x) \) were an increasing function of \( x \), a condition which we shall henceforth always assume. Such a shift of probability mass is known as a *first order stochastically dominating shift*.

**Risk aversion**

The representation of an individual's preferences over distributions by the shape of his or her von Neumann–Morgenstern utility function provides the first step in the modern economic characterization of risk. After all, whatever the notion of 'riskier' means, it is clear that bearing a random wealth \( X \) is riskier than receiving a certain payment of \( \mathbb{E}[X] \) (the expected value of the random variable \( X \)). We therefore have from Jensen's inequality that an individual would be *risk averse*, that is, would always prefer a payment of \( \mathbb{E}[X] \) (and obtaining utility \( U(\mathbb{E}[X]) \)) to bearing the risk \( X \) (and obtaining expected utility \( \mathbb{E}[U(X)] \)) if and only if his or her utility function were concave. This condition is illustrated in Figure 1, where the random variable \( X \) is assumed to take on the values \( x^- \) and \( x^+ \) with respective probabilities 2/3 and 1/3.

\[ U(\cdot) \]
Of course, not all individuals need be risk averse in the sense of the previous paragraph. Another type of individual is a risk lover. Such an individual would have a convex utility function, and would accordingly prefer receiving a random wealth $\bar{x}$ to receiving its mean $E[\bar{x}]$ with certainty. An example of such a utility function is given in Figure 2.

Figure 2
Von Neumann–Morgenstern utility function of a risk-loving individual.
Standard deviation as a measure of risk

While the above characterizations of risk aversion and risk preference allow for the derivation of many results in the theory of choice under risk, they say nothing about which of a pair of non-degenerate random variables \( \bar{x} \) and \( \bar{y} \) is the more risky. Since real-world choices are almost never between risky and riskless situations but rather over alternative risky situations, such a means of comparison is necessary.

The earliest and best-known univariate measure of the riskiness of a random variable \( \bar{x} \) is its \textit{variance} \( \sigma^2 = E[(\bar{x} - E[\bar{x}])^2] \) or alternatively its \textit{standard deviation} \( \sigma = E[(\bar{x} - E[\bar{x}])^2]^{1/2} \). The tractability of these measures, as well as their well-known statistical properties, led to the widespread use of mean-standard deviation analysis in the 1950s and 1960s, and in particular to the development of modern portfolio theory by Markowitz (1952; 1959), Tobin (1958) and others. As an example of this, consider Figure 3.

Points A and B correspond to the distributions of a riskless asset with (per dollar) gross return \( r_0 \) and a risky asset with random return \( \bar{x} \) with mean \( \mu \) and standard deviation \( \sigma \). An investor dividing a dollar between the two assets in proportions \( \alpha : (1 - \alpha) \) will possess a portfolio whose return has a mean of \( \alpha \cdot r_0 + (1 - \alpha) \cdot \mu \) and standard deviation \( (1 - \alpha) \cdot \sigma \), so that the set of attainable \( (\mu, \sigma) \) combinations consists of the line segment connecting the points A and B in the figure. It is straightforward to show that, if the individual were also allowed to borrow at rate \( r_0 \) in order to finance purchase of the risky asset (that is, could sell the riskless asset short), then the set of attainable \( (\mu, \sigma) \) combinations would be the ray emanating from A and passing through B and beyond.

Figure 3
Portfolio analysis in the mean-standard deviation model.
If we then represent the individual's risk preferences by means of indifference curves in this diagram, we obtain his or her optimal portfolio (the example in the figure implies an equal division of funds between the two assets). In the more general case of choice between a pair of risky assets, the set of \((\mu, \sigma)\) combinations generated by alternative divisions of wealth between them will trace out a possibly nonlinear locus such as the one between points \(C\) and \(D\) in the diagram, with the curvature of this locus determined by the degree of statistical dependence (that is, covariance) between the two random returns.

As mentioned, the representation and analysis of risk and risk-taking by means of the variance or standard deviation of a distribution proved tremendously useful in the theory of finance, culminating in the mean-standard deviation-based capital asset pricing model of Sharpe (1964), Lintner (1965), Mossin (1966) and Treynor (1999). However, by the late...
1960s the mean–standard deviation approach was under attack for two reasons. The first reason (known since the 1950s) was the fact that an expected utility maximizer would evaluate all distributions solely on the basis of his or her means and standard deviations if and only if their von Neumann–Morgenstern utility function took the quadratic form $U(x) = ax + b x^2$ for $b < 0$. The sufficiency of this condition is established by noting that $E[U(x)] = E(ax^2 + bx^2) = a \cdot E(x^2) + b \cdot (E(x)^2 + \sigma^2)$. To prove necessity, note that the distributions that yield a $2/3:1/3$ chance of the outcomes $(x - \delta)$ and $(x + \delta)$ both possess the same mean and variance for each $x$ and $\delta$, so that $(2/3) \cdot U(x - \delta) + (1/3) \cdot U(x + \delta) = (1/3) \cdot U(x - \delta) + (2/3) \cdot U(x + \delta)$ for all $x$ and $\delta$. Differentiating with respect to $\delta$ and simplifying yields $U'(x + \delta) + U'(x - \delta) = U'(x + \delta) + U'(x - \delta)$ for all $x$ and $\delta$. This implies that $U'(\cdot)$ must be linear and hence that $U(\cdot)$ must be quadratic.

The assumption of quadratic utility is objectionable. If an individual with such a utility function is risk averse (that is, if $b < 0$), then (a) utility will decrease as wealth increases beyond $1/2b$, and (b) the individual will be more averse to constant additive risks about high wealth levels than about low wealth levels – in contrast to the observation that those with greater wealth take greater risks (see for example Hicks, 1962, or Pratt, 1964).

Borch (1969) struck the second and strongest blow to the mean-standard deviation approach. He showed that, for any two points $(\mu_1, \sigma_1)$ and $(\mu_2, \sigma_2)$ in the $(\mu, \sigma)$ plane which a mean-standard deviation preference ordering would rank as indifferent, it is possible to find random variables $\bar{X}_1$ and $\bar{X}_2$ which possess these respective $(\mu, \sigma)$ values and where $\bar{X}_2$ first order stochastically dominates $\bar{X}_1$. However, any person with an increasing von Neumann–Morgenstern utility function would strictly prefer $\bar{X}_2$ to $\bar{X}_1$. In response to these arguments and the additional criticisms of Feldstein (1969), Samuelson (1967) and others, the use of mean-standard deviation analysis in economic theory waned. See, however, the work of Meyer (1987) for a partial rehabilitation of such two-moment models of preferences.

Besides the variance or standard deviation of a distribution, several other univariate measures of risk have been proposed. Examples include the mean absolute deviation $E[|X - E(X)|]$, the interquartile range $F^{-1}(.25) - F^{-1}(.75)$, and the classical statistical measures of entropy $\sum p_i \ln(p_i)$ or $\int f(x) \ln(f(x)) \, dx$. Although they provide the convenience of a single numerical index, each of these measures is subject to problems of the sort encountered with the variance or standard deviation. In particular, the entropy measure is based exclusively on the probability levels of a random variable, and is particularly unresponsive to its outcome values – for example, the 50:50 gambles over the values $\$49:51$ and $\$0: \$100 possess identical entropy levels.

Increasing risk

By the late 1960s, the failure to find a satisfactory univariate measure of risk led to another approach to this problem. Working independently, several researchers (Hadar and Russell, 1969; Hanoch and Levy, 1969; and Rothschild and Stiglitz, 1970; 1971) developed an alternative characterization of increasing risk. The appeal of this approach is twofold. First, it formalizes three different intuitive notions of increasing risk. Second, it allows for the straightforward derivation of comparative statics results in a wide variety of economic situations. Unlike the univariate measures described above, however, this approach provides only a partial ordering of random variables. In other words, not all pairs of random variables can be compared with respect to their riskiness.

We now state three alternative formalizations of the notion that a random variable, and is particularly unresponsive to its outcome values – for example, the 50:50 gambles over the values $\$49:51$ and $\$0: \$100 possess identical entropy levels.

Increasing risk

By the late 1960s, the failure to find a satisfactory univariate measure of risk led to another approach to this problem. Working independently, several researchers (Hadar and Russell, 1969; Hanoch and Levy, 1969; and Rothschild and Stiglitz, 1970; 1971) developed an alternative characterization of increasing risk. The appeal of this approach is twofold. First, it formalizes three different intuitive notions of increasing risk. Second, it allows for the straightforward derivation of comparative statics results in a wide variety of economic situations. Unlike the univariate measures described above, however, this approach provides only a partial ordering of random variables. In other words, not all pairs of random variables can be compared with respect to their riskiness.

We now state three alternative formalizations of the notion that a cumulative distribution function $F^*(\cdot)$ is riskier than another distribution $F(\cdot)$ with the same mean. In the following, all distributions are assumed to be over the outcome interval $[0, M]$ unless otherwise indicated.

The first definition of increasing risk captures the notion that ‘risk is what all risk averters hate’. Thus an increase in risk must lower the expected utility of all risk averters. Formally:

1. $F^*(\cdot)$ and $F(\cdot)$ have the same mean and $\int U(x) \, dF^*(x) \leq \int U(x) \, dF(x)$ for every concave utility function $U(\cdot)$.

Note that this relationship will not be satisfied by every pair of distributions with the same mean. That is to say, there exist pairs $F(\cdot)$ and $F^*(\cdot)$, with the same mean, but such that some risk-averse utility functions prefer $F(\cdot)$ to $F^*(\cdot)$ but other risk-averse utility functions prefer $F^*(\cdot)$ to $F(\cdot)$. This reflects the above-stated fact that comparative risk is a partial rather than a complete order over the family of probability distributions, even over families of distributions with a common mean. (Although comparative risk is not a complete order, it is a transitive order, in the sense that, if the pair $F^*(\cdot)$ and $F(\cdot)$ satisfy condition (A), and the pair $F^*(\cdot)$ and $F^*(\cdot)$ satisfy condition (A), then the pair $F^*(\cdot)$ and $F(\cdot)$ will also satisfy condition (A).)

The second characterization of the notion that a random variable $\tilde{Y}$ with distribution $F^*(\cdot)$ is riskier than a variable $\tilde{X}$ with distribution $F(\cdot)$ is that $\tilde{Y}$ consists of the variable $\tilde{X}$ plus an additional zero-mean noise term $\tilde{\varepsilon}$. One possible specification of this is that $\tilde{\varepsilon}$ is statistically independent of $\tilde{X}$. However, this condition is too strong in the sense that it does not allow the variance of $\tilde{\varepsilon}$ to depend upon the magnitude of $\tilde{X}$, as in the case of heteroskedastic noise. Instead, Rothschild and Stiglitz (1970) modelled the addition of noise by the condition:

http://www.dictionaryofeconomics.com/proxy.library.cs.unc.edu/article?id=pde2008_R0000152&goto=BS&result_number=1&goto=BS&result_number=1
The third notion of increasing risk involves the concept, due to Rothschild and Stiglitz (1970), of a *mean preserving spread*. Intuitively, such a spread consists of moving probability mass from some region in the centre of a probability distribution out to its tails in a manner that preserves the expected value of the distribution, as seen in the top panels of Figures 4 and 5. In the discrete case of Figure 4, probability mass is moved from the pair of outcome values $b$ and $c$ out to the outcome values $a$ and $d$. In the continuous density case of Figure 5, probability mass is moved from the interval $(b, c)$ out to the intervals $(a, b)$ and $(c, d)$. We can unify, generalize, and formalize this condition by saying that $F^*(\cdot)$ differs from $F(\cdot)$ by a ‘mean preserving spread’ if they have the same mean and there exists a single crossing point $x_0$ such that $F^*(x) \geq F(x)$ for all $x \leq x_0$ and $F^*(x) \leq F(x)$ for all $x \geq x_0$ (see the middle panels of Figures 4 and 5). Since it is clear that sequences of such spreads will also lead to riskier distributions, the third characterization of increasing risk is:

- (C) $F^*(\cdot)$ may be obtained from $F(\cdot)$ by a finite sequence, or as the limit of an infinite sequence, of mean preserving spread.
cumulative distribution functions:

\[ F^*(\cdot) \text{ (dashed)} \]
\[ F(\cdot) \text{ (solid)} \]
Figure 5
Mean preserving spread of a density function

density functions

\[ f^*(\cdot) \] (dashed)
\[ f(\cdot) \] (solid)
cumulative distribution functions:

\[ F^*(\cdot) \text{ (dashed)} \]

\[ F(\cdot) \text{ (solid)} \]
Although the single crossing property of the previous paragraph serves to characterize cumulative distribution functions that differ by a single mean preserving spread, distributions that differ by a sequence of such spreads will typically not satisfy the single crossing condition. However, if we consider the integrals of these cumulative distribution functions, we see from the bottom panels of Figures 4 and 5 that a mean preserving spread will always serve to raise or preserve the value of this integral for each $x$, and (since $F^*(\cdot)$ and $F(\cdot)$ have the same mean) will exactly preserve it for $x=M$. In contrast to the single crossing property, this so-called ‘integral condition’ will continue to be satisfied by distributions which differ by a sequence of one or more mean preserving spreads. Accordingly, we may rewrite condition (C) above by the analytically more convenient:

\[(C') \text{ The integral } \int_0^x [F^*(\xi) - F(\xi)] \cdot d\xi \text{ is non-negative for all } x>0, \text{ and is equal to } 0 \text{ at } x=M.\]

Rothschild and Stiglitz (1970) showed that these three concepts of increasing risk are the same by proving that conditions (A), (B) and (C/C') are equivalent. Thus, a single partial
ordering of distribution functions corresponds simultaneously to the notion that risk is what risk averters hate, to the notion that adding noise to a random variable increases its risk, and to the notion that moving probability mass from the centre of a probability distribution to its tails increases the riskiness of the distribution. The original Rothschild–Stiglitz formulation and proofs have since been further strengthened and extended by Machina and Pratt (1997).

This characterization permits the derivation of general and powerful comparative statics theorems concerning economic agents' responses to increases in risk. The general framework for these results is that of an individual with a von Neumann–Morgenstern utility function $U(x, \alpha)$ which depends upon both the outcome of some random variable $x$ for example might be the return on a risky asset, and $\alpha$ the amount invested in it). For convenience, we assume that $F(x; r) = \mathbb{P}(\xi \leq 0) \geq 0$ for all $r$. The first order condition for this problem is then:

$$
\int U_\alpha(x, \alpha) dF(x; r) = 0
$$

(2)

where $U_\alpha(x, \alpha) = \frac{\partial U(x, \alpha)}{\partial \alpha}$, and we assume that the second derivative $U_{\alpha\alpha}(x, \alpha) = \frac{\partial^2 U(x, \alpha)}{\partial \alpha^2}$ is always negative to insure we have a maximum. Implicit differentiation of (2) then yields the comparative statics derivative:

$$
\frac{d\alpha}{dr} = -\int U_\alpha(x, \alpha) dF_r(x; r) \int U_{\alpha\alpha}(x, \alpha) dF(x; r)
$$

(3)

where $F_r(x; r) = \frac{\partial F(x; r)}{\partial r}$. Since the denominator of this expression is negative by assumption, the sign of $\frac{d\alpha}{dr}$ is given by the sign of the numerator $\int U_\alpha(x, \alpha) dF_r(x; r)$. Integrating by parts twice yields:

$$
\int U_\alpha(x, \alpha) dF_r(x; r) = \int U_{\alpha\alpha\alpha}(x, \alpha) \left[ \int_0^X F_r(\xi; r) d\xi \right] d\alpha = \int U_{\alpha\alpha\alpha}(x, \alpha) \left[ \frac{d}{dr} \int_0^X F(\xi; r) d\xi \right] d\alpha
$$

(4)

Thus, if increases in the parameter $r$ imply increases in the riskiness of the distribution $F(\cdot; r)$, it follows from condition (C) that the signs of the square-bracketed terms in (4) will be non-negative, so that the effect of $r$ upon $\alpha$ depends upon the sign of $U_{\alpha\alpha\alpha}(x, \alpha) = \frac{\partial^3 U(x, \alpha)}{\partial x^2 \partial \alpha}$. Thus, if $U_{\alpha\alpha\alpha}(x, \alpha)$ is uniformly negative a mean preserving increase in risk in the distribution of $x$ will lead to a fall in the optimal value of the control variable $\alpha$, and vice versa. Another way to see this is to note that if $U_{\alpha}(x, \alpha)$ is concave in $x$ then a mean preserving increase in risk will lower the left side of the first order condition (2), which (since $U_{\alpha\alpha\alpha}(x, \alpha) \leq 0$) will require a drop in $\alpha$ to re-establish the equality. Economists, mathematicians and scientists routinely use this technique when analysing models involving risk; see for example Rothschild and Stiglitz (1971), Dionne, Eeckhoudt and Gollier (1993), Eeckhoudt, Gollier and Schlesinger (1996), Jewitt (1987), Ormiston (1992), Tzeng (2001), Nowak (2004), Chateauneuf, Cohen and Meilijson (2004), Baker (2006), and Beladi, de la Vina and Firoozi (2006).

2009-1-3 0:15:45
The characterization of risk outlined in the previous section has been extended along several lines. Diamond and Stiglitz (1974), for example, have replaced the notion of a mean-preserving spread with that of a mean utility-preserving spread to obtain a general characterization of a compensated increase in risk. They relate this notion to the well known Arrow–Pratt characterization of comparative risk aversion (see expected utility hypothesis).

In addition, researchers such as Ekern (1980), Fishburn (1982), Fishburn and Vickson (1978), Hansen, Holt, and Peled (1978), Tesfatsion (1976), and Whitmore (1970) have extended the above work to the development of a general theory of stochastic dominance, which provides a whole sequence of similarly characterized partial orders on distributions, each presenting a corresponding set of equivalent conditions involving algebraic conditions on the distributions, types of spreads, and classes of utility functions which prefer (or are averse to) such spreads. The comparative statics analysis presented above may be similarly extended to such characterizations. An extensive bibliography of the stochastic dominance literature is given in Bawa (1982). Finally, various extensions of the notions of increasing risk and stochastic dominance to the case of multivariate distributions may be found in Epstein and Tanny (1980), Fishburn and Vickson (1978), Huang, Kira and Vertinsky (1978), Lehmann (1955), Levhari, Parousch and Peleg (1975), Levy and Parousch (1974), Russell and Seo (1978), Sherman (1951), and Strassen (1965); see also the mathematical results in Marshall and Okun (1979).

Risk is part of life in developing countries. Despite generally imperfect credit and lacking insurance markets, households use a variety of strategies to manage and cope with risk, including savings and informal credit transactions, mutual support networks, and income and asset diversification. Most evidence suggests that these strategies achieve only partial consumption smoothing and risk-sharing, while they are not without long-term costs in terms of investment and poverty. This article discusses the nature and evidence on the typical strategies used, and explores its implications. It also highlights some outstanding questions.

Article
Risk is pervasive, not least in developing countries. A high dependence on agriculture for income and employment means that people's livelihoods are strongly affected by climatic vagaries. Poor health care and immunization means that illness is common, affecting labour supply. Poor infrastructure and market institutions result in limited market integration, leading to a high sensitivity of prices to local shocks. Economic instability, conflict and political instability add further to a high-risk environment in many developing countries.

While risk is widespread, in developing countries insurance markets are typically missing or incomplete. This causes potentially serious welfare losses, especially since government-led alternatives such as
Social security are largely missing, compounded by imperfections in credit markets that limit the extent to which credit can be used as to substitute for insurance. Economic agents are typically risk averse and, even in the poorest settings, the evidence suggests that they do not just passively undergo the consequences of risk. Instead, given risk aversion, they try to make activity and asset portfolio choices to balance their need to make a living, but without exposing themselves to too much risk. The strategies used to achieve this are often referred to as ‘risk management and coping strategies’. The economic analysis of these strategies has been one of the areas in which research based on some of the poorest high-risk rural settings in developing countries has made a substantial contribution to the economic literature in general. Our focus in this overview is on the empirical literature, often drawing on the evidence generated from the sample based on six Indian villages for which the International Crops Research Institute for the Semi-Arid Tropics (ICRISAT) collected exceptionally detailed panel data over ten years in the high-risk environment of the semi-arid tropics of India (Morduch, 2004).

Self-insurance via savings

It is possible to distinguish a number of commonly observed different risk strategies. First, we can consider strategies that aim to cope with the consequences of shocks. Risk aversion is sufficient to induce households to try to smooth consumption or nutrition, and indeed standard models of consumption smoothing when insurance and credit markets are imperfect can shed light on this type of strategy (Deaton, 1992). When shocks occur, households may decide to curb their consumption loss through the sacrifice of existing assets. Households may pre-empt this by trying to self-insure against risk through precautionary savings. A precautionary motive for savings would be sufficient for savings to increase in response to increased risk, so that a buffer stock is built to deplete when shocks occur. Even though formal credit markets in high-risk settings are typically underdeveloped, informal credit transactions may also be used for smoothing purposes.

There is a large literature testing whether households in developing countries smooth consumption, building on standard models of permanent income and often using shocks to identify the relevant effects (for example, Paxson, 1992). Furthermore, which assets tend to be used for this purpose in the face of shocks has occasionally been investigated. (Finding positive evidence of using assets to smooth is not sufficient to show that any savings were built up for precautionary motives to start with. This would require evidence that greater risk indeed increased savings, which is harder to test.) Nevertheless, the evidence suggests that in some settings productive assets are sold off for smoothing, for example in work by Rosenzweig and Wolpin (1993) using the ICRISAT data, while in other settings (for example, in Burkina Faso, as in Fafchamps, Udry and Czukas, 1998) livestock were not sold off despite serious income shocks. Furthermore, there is much anecdotal evidence that, during famines in mixed farming environments, livestock is not being sold despite serious human nutritional losses and risks. Squaring these findings with basic theoretical models remains a challenge, and different suggestions can be made. For example, different technologies may underlie the pattern of returns to different assets, so that optimal portfolio mixes would suggest that assets are depleted at different rates when shocks occur. Another possibility is that asset returns and prices are risky as well, so that the reliability of the buffer is limited. For example, if incomes, asset prices and returns have a high positive covariance, then selling assets when incomes are low may not be the optimal strategy, since the future gains from holding on to
Risk-coping strategies: The New Palgrave Dictionary of Economics

Assets is actually high. Alternatively, behavioural theories based on experiments, such as that risk-loving rather than risk-averse behaviour may be displayed in the face of losses that are potentially very large (as in Kahneman and Tversky, 1979), may provide some insight to these puzzles.

A related strategy to self-insurance observed in poor settings involves the key asset available to the poor, namely, labour. In response to shocks, labour supply is adjusted to increase involvement in productive activities, including off-farm or temporary migration (for example, Kochar, 1995). Furthermore, children may be taken out of school and into work in response to income shocks (Jacoby and Skoufias, 1997).

Risk-sharing through mutual support

A second common strategy to cope with the consequences of risk involves non-market institutions based on risk sharing, whereby households or other economic agents use transfers to smooth outcomes across a group of people when shocks occur. Conceptually, this is the cross-sectional equivalent of standard permanent income models: it is concerned with smoothing over space rather than over time. Unless risk preferences differ between economic agents, unlike self-insurance strategies this strategy is relevant only for idiosyncratic shocks, not covariate risk. Townsend (1994) is the seminal paper on high-risk developing-country environments. The basic prediction of Townsend's model, under specific assumptions, is that household consumption is dependent on average village resources but not on individual income realizations. This provides a clear basis for empirical testing of the perfect risk-sharing hypothesis: do idiosyncratic shocks to income affect consumption or nutrition outcomes within a well-defined setting? Using the ICRISAT data from India, he finds that perfect risk-sharing is rejected within the village, even though substantial risk-pooling takes place. Other studies (including some on the same data) suggest that some risk-sharing typically occurs in villages, but the evidence is typically not consistent with perfect risk-sharing.

The failure of perfect risk-sharing in village settings has attracted much attention in terms of theoretical work. Work has focused on accounting for information asymmetries, private savings and the role of enforceability problems related to these informal risk-sharing contracts _ex post_ in repeated game contexts (for example, Ligon, Thomas and Worrall, 2002). The work on enforceability has found that constrained efficient contracts will contain updating rules offering higher weights in the risk-sharing contracts in particular states of the world to those facing stronger incentives to leave, and that over time, the weights have memory. The consequence is that these risk-sharing contracts take on features more common in credit contracts, leading to their description as ‘quasi-credit’ arrangements. There is some empirical evidence consistent with these models.

The lack of perfect risk-sharing within villages has led to further work investigating whether risk-sharing occurs in other settings, for example within households or extended families, or in other social groupings. Partial risk-sharing has been documented across ethnic groups as well as within families. More recently, risk-sharing across networks has been explored as well. It is relatively straightforward to analyse risk-sharing within networks beyond specifically exogenously defined groupings, such as caste, but for most group or network links network membership has to be endogenously modelled. Theoretical work has emerged analysing the formation and stability of insurance networks, including in the face of group deviations (for example, Genicot and Ray, 2003). Better data-sets focusing on linkages between
households in communities has also allowed further evidence to emerge of the extent and nature of risk-sharing within networks and groups. Integrating the endogeneity of network formation for insurance purposes in empirical analysis nevertheless remains a challenge.

The literatures on intertemporal consumption smoothing and risk-sharing in developing countries appear to converge at least in terms of diagnosis: consumption is relatively smooth in the face of income shocks, but not perfectly. Nevertheless, it is often not clear in the tests whether consumption smoothing in practice occurs through transfers or through self-insurance or credit. Even in the ICRISAT data on India, as used in the Townsend data, this has remained an issue of contention (Townsend, 1995; Morduch, 2004). One strategy is to specifically study the actual responses to shocks (such as dissavings, credit transactions or transfers) and their contribution to smoothing. Deaton and Paxson (1994) provide an alternative test to distinguish whether insurance or credit is responsible for observed smoothing by looking at the changing distribution over time of consumption for a particular cohort in a number of countries, including Taiwan. If consumption smoothing is present due to formal or informal insurance, then inequality can be expected to remain constant over time. If smoothing consumption occurs through credit market transactions, then inequality can be expected to increase over time due to changes in permanent income. Their results suggest that credit markets are more important than insurance for the observed patterns of smoothing.

**Income smoothing**

Households do not just use strategies that aim to cope with the consequences of shocks; they may try to reduce or mitigate the risk they face, not least given the limits to risk-sharing and self-insurance. To put it more directly, they may aim to smooth income (Morduch, 1995). In rural settings, this strategy has been a central force in shaping farming systems and institutions. The most straightforward strategy is income diversification, whereby income sources are combined and the resulting portfolio faces reduced risk even if the underlying income processes are equally risky when taken separately (as long as they are not perfectly covariate). In some cases, risk management may imply diversifying into (or even specializing in) specific low-risk technologies or activities, such as growing drought-resistant crops or gathering firewood for sale. Social institutions have also developed to include means of reducing exposure to risk. Geographically dispersed marriage patterns, such as those observed by Rosenzweig and Stark (1989) in villages in southern India, can be interpreted as linked to risk diversification within extended families. Local institutions to manage commons and natural resources or land tenure arrangements appear to include risk management as part of their rationale.

Testing the specific role of risk in observed diversification patterns in activities and assets is nevertheless not straightforward. Given the multiple market imperfections faced by the poor, for example in labour markets, the fact of observed multiple activities is not sufficient to sustain the conclusion that risk is its cause. Furthermore, the opportunity to shape risk faced by households also implies econometric problems in standard tests of consumption smoothing and risk sharing, requiring exogenous sources of variation in risk faced. While rainfall variation may provide a useful instrument for common risk, finding sources of exogenous variation for the identification of idiosyncratic shocks is more difficult. These problems suggest that further exploration of risk management strategies will remain methodologically challenging. Furthermore, most investigations of risk strategies in developing
countries have been in rural settings, with a focus on agricultural households in relatively stationary environments. This was mainly due to the lack of suitable panel data-sets in urban settings. With more long-term data-sets becoming available, more attention can be paid to the changes in risk strategies following increased integration of local economies and the rise in migration opportunities.

Risk strategies and persistent poverty

All the above hints at an important consequence. While risk strategies contribute to avoiding serious consumption fluctuations, they are not without consequences for welfare, investment and poverty. More specifically, households tend to trade risk and smooth consumption in the short run for lower mean welfare outcomes in the long run. Precautionary motives for saving and credit constraints may induce asset portfolios to focus more on liquidity than on returns. Sales of productive assets for smoothing or taking children out of school to increase labour supply will reduce permanent income. Income smoothing strategies will involve leaving aside profitable opportunities for activity and asset portfolios with a lower mean return. Evidence from villages in the ICRISAT sample in India suggests that these effects may well be substantial, with those households with limited protection against risk (identified by rainfall variability) opting for portfolios with lower returns (Rosenzweig and Binswanger, 1993). More specifically, they find that an increase in rainfall variability by one standard deviation would reduce returns to assets by 35 per cent for the poorest wealth tercile of farmers but have no effect on the richest tercile, which is likely to be better protected against risk through its assets or access to credit. If anything, this type of evidence suggests that risk and the lack of appropriate insurance or protection may well be one of the factors that keep poor people poor.

Risk strategies and policy responses

The perceived failure to keep consumption smooth in the face of risk and the long-run costs attached to existing risk strategies has also stimulated an increasing interest in finding appropriate policy responses, not least since insured risk appears to affect the ability of many poor people to grow out of poverty. Standard transfer schemes, such as food aid or cash transfers, may all provide protection against shocks. However, how existing risk strategies could be strengthened remains less explored (Dercon, 2004). For example, it is clear that self-insurance through savings could offer substantial benefits in terms of protecting against the consequences of risk. Even if insurance and credit markets were not functioning well, improving the availability of better savings product could assist poor people to improve their risk management. Similarly, informal insurance schemes could be strengthened, for example by linking micro-insurance initiatives to indigenous group-based systems. A number of insurance-related initiatives have been taken in this respect by governments and NGOs. For example, weather-indexed insurance contracts that trigger payments if rainfall falls below a predetermined level are being piloted in a number of countries. Health insurance schemes, often based at local health facilities, have also become more widespread. Much work is still needed on developing these initiatives, not least in terms of evaluating their effectiveness with appropriate techniques, for example randomized interventions.

Rist, Charles (1874–1955)

Roger Dehem

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

monetary history; monetary theory; Rist, Charles

Article

Born at Prilly, Switzerland, 1874; died at Versailles, 1955. Professor at Montpellier (1899–1912) and Paris (1913–33), Rist was the most notable and influential thinker and actor in the field of money in France in the first half of the 20th century. As a member of the Comité des experts (1926) and as a vice-governor of the Bank of France (1926–8), he took an active part in monetary reconstruction in the 1920s. He supported the novel idea of stabilization with devaluation (1926–8). He was also involved as an expert in monetary reforms in Romania (1928), Austria, Turkey and Spain. He was France's delegate at the London Economic Conference (1933).

Although Rist is most widely known for his History of Economic Doctrines, written in cooperation with Charles Gide, his lasting claim to fame rests on his profound and consistent interpretation of monetary history and thought as demonstrated in his masterwork, History of Monetary and Credit Theory. Based on his first-hand experience in times of great instability, Rist's critical analysis of monetary thought from a long-run viewpoint provides an impressive perspective on the evolution of money. By emphasizing the 'store of value' function of money, and by postulating the inability of the state to safeguard it, Rist is critical of authors who supported some form of non-metallic currency, such as John Law, Smith, Ricardo, Wicksell, Knapp and Keynes. He is in sympathy with Cantillon, Galiani, Turgot, Thornton, Tooke and Walras. What he describes as the confusion between money and credit is to be dispelled by drawing a distinction between money proper (gold), credit instruments (convertible banknotes and deposits) and inconvertible paper money. In strong opposition to Keynesianism, Rist is a sceptic in regard of managed currencies and international agreements of the Bretton Wood type. Rist provides the key to the understanding of the French position in monetary matters as opposed to the typical Anglo-American stance in the past 60 years.

Lionel Robbins, who in 1961 became Baron Robbins of Clare Market, was one of the major academic economists of the interwar period. He remained active after the Second World War but never really regained the centre of the stage that he had occupied. He was also a great public servant for his country, serving it well and loyally in many aspects of social, political and cultural life. He was truly a ‘Renaissance man’.

Robbins was born in 1898 in Middlesex, the son of Rowland Richard Robbins – for many years President of the National Farmers’ Union – and Rosa Marion Robbins. He spent one year reading for an Arts degree at University College London and then volunteered for war service with the Royal Artillery. He saw active service on the Western Front, was wounded and invalided back to England in 1918. He was an undergraduate at the London School of Economics and Political Science from 1920 to 1923, from which he graduated with a BSc (Econ.) degree, choosing political ideas as his major field of study, and having had the left-wing Harold Laski as his tutor. Beveridge employed him as a research assistant for a year, after which Robbins was a tutor in economics at New College, Oxford. He returned to teach economics at LSE from 1925 to 1927, then back to New College as Fellow (1928–9) and finally, at the incredibly young age of 31, back to the Senior Professorship in Economics at LSE to succeed Allyn Young.

Apart from government service during the Second World War, Robbins remained at LSE as Head of the Economics Department until 1960 when, on accepting the Chairmanship of the Financial Times, the University of London forced him to resign his professorship – a move than brought Robbins great personal distress, although he retained his connection with LSE and taught courses there until a year or
so of his death in 1984.
Outside academic and government advisory activity, Robbins had a distinguished record in arts administration, being connected with both the National Gallery and the Royal Opera House, but he may perhaps be best remembered, in such ‘outside’ activities, for his contribution to the structure of higher education in the United Kingdom. He chaired the committee – commonly referred to as the Robbins Committee on Higher Education – that proposed the criterion that all qualified applicants should receive a place, and financial support, to read for a degree. The acceptance of the ‘Robbins Principle’ led to a vast expansion of degree courses, especially in the social sciences in the 1960s and early 1970s in the UK.

Robbins's contributions to economics may be considered under four headings; economic theory, methodology and philosophy of economics, the theory of economic policy, and the history of economic thought.

Those who only knew Robbins later in his life often forget that he made his initial mark in economics as a theorist. Three contributions here are worth noting; he launched a sustained attack on Marshall's concept of the Representative Firm which was apparently so successful that it drove the concept out of the pages of microeconomic texts. Robbins basically argued that the understanding of the equilibrium neither of the firm nor of the industry was aided by introducing the Representative Firm, hence it should be eliminated from analysis. More recent work has shown a greater sympathy towards Marshall's construct and it seems clear now that Robbins failed to understand the exact dynamic problem that Marshall was trying to cope with and why the Representative Firm was an important contribution to this problem.

Robbins also pioneered the micro-analysis of the labour supply function. Although he did not explicitly use the division of a wage change into an income and substitution effect, he showed clearly why the sign on the response of hours to a real wage rate change would be ambiguous.

In macroeconomics Robbins was a firm exponent of the Austrian theory of the trade cycle and here he was greatly influenced by Frederick von Hayek, whom he brought to LSE from Vienna in 1928. The central feature of the Austrian analysis was that depression was due primarily to under-saving (or excess consumption) and these views, which Robbins expounded as an explanation of the 1930s depression in his book *The Great Depression*, led to a head-on collision between the senior LSE economists and the Cambridge School centred around Keynes. This rift was not finally healed until the wartime collaboration in Whitehall between Robbins and Keynes. After the war in the Marshall Lectures for 1946, published as *The Economic Problem in Peace and War*, Robbins announced his conversion to full employment policies via control of aggregate demand, although it is not clear that he became a Keynesian.

The second area where Robbins made a major contribution and where he wrote what is probably his best known work in economics was that of the methodology and philosophy of economics. His *Nature and Significance of Economic Science* was one of the most cited, if not most read, books on the subject in the period 1932–60, and it influenced greatly economists' views about the nature of their discipline. There are several strands to the book, none original in themselves, but Robbins put them together in beautifully clear prose and in a very persuasive manner. The major themes were; first, that economic science could be clearly demarcated from those discussions of economic issues that involved value judgements – by which latter term Robbins meant evaluative statements of the form ‘better or worse’ where interpersonal comparisons of utility were involved. He also argued that there was a clear demarcation between

economic science and other branches of social enquiry such as social psychology, sociology, politics and so on.

The second major theme was that the subject matter of economic science was not a particular activity (for example, Cannan's view that economics was the science of wealth), but rather an aspect of all human conduct. This aspect was the ‘fact’ of economic scarcity – a manifestation of unlimited ends on the part of individuals and society and means of satisfying those ends that were limited in supply. In words so often quoted in economics texts Robbins defined economic science as ‘that science that studies the relationship between ends and means that have alternative uses’ – a definition that is more than reminiscent of Menger's exposition of the economizing process.

These two aspects of the Nature and Significance were widely accepted by the world of academic economists and are still propagated. But they have always had their critics; in particular, the view that there is a body of scientific economics ‘free from value’ is much disputed.

The third aspect of the book – Robbins's views on the procedures for checking the validity of economic theory – was less fortunate in its effect on the development of the subject. Robbins appeared to argue that the central propositions of economics were derived from very basic, and obvious, assumptions and a process of logical deduction from these assumptions. Moreover, these deductions gave essentially qualitative predictions. Robbins expressed great scepticism about the feasibility and meaningfulness of quantitative work in economics, and by the implication of his message inhibited the development of econometric testing in economics.

Robbins's contributions to discussions of economic policy were basically consistent throughout his career, although the purity of his earlier thoughts was muddled as he grew older. His major policy theme was his advocacy of, what may be loosely termed, economic liberalism. Robbins increasingly argued this on the grounds of some alleged theoretical or a priori superiority of market solutions over collectivist or interventionist plans, but rather as an empirical point that the liberal solution seemed best to combine liberty and efficiency. In his earlier writings, for example The Economic Causes of War (1939a) and The Economic Basis of Class Conflict (1939b) he adopted an extreme free trade position and it was this stance as much as macro-theory debate that led to his conflict with Keynes in the 1930s. His later work revealed a much greater readiness to allow ad hoc exceptions to strict economic liberalism – he espoused, among other measures, the Beveridge plan, grants for higher education, subsidies for the arts, control of the exports of works of art, overall macro-control for full employment. Probably the most rounded statement of his policy beliefs is to be found in his Economic Problem in Peace and War.

Finally, mention must be made of Lionel Robbins's contribution to the teaching and study of the history of economic thought. He, together with one or two other scholars of his generation – like his great friend, Jacob Viner – kept interest in the subject alive and flourishing when many economists regarded it, as they still do, as irrelevant to their studies. Much of his influence came via his masterly teaching of the subject and via the important theses that were produced under his supervision, as much as from his own specific contributions. He also aided the production of important series in the history of economic thought such as the LSE reprints and the collected works of Bentham and J.S. Mill.

Of his specific contributions, two are minor classics, his Theory of Economic Policy in Classical Political Economy (1952) and Robert Torrens and the Evolution of Classical Economics (1958). In the former work, Robbins argued very persuasively, if not entirely convincingly, that the British classical economists did not adhere to the Continental laissez-faire dogma but rather argued for freedom in
economic relationships as a general principle with many ad hoc exceptions. He further tried to clear them of any anti-working class bias.
The book on Torrens is a perfect example of how to survey the collected works of a writer who, though not of the first rank of classical economists, is nonetheless a useful writer by whom to assess the general achievement of the classical school.

Article

Dennis Robertson was born in 1890, the son of a clergyman and schoolmaster, and was educated at Eton and Trinity College, Cambridge. After taking a Part I in Classics and Part II in Economics he was elected a Fellow of Trinity College in 1914 and in 1930 became a Reader in the University of Cambridge. He left Cambridge in 1938 to become a Professor in the University of London but during most of his time in that post he was seconded to the Treasury on war-related work. Elected in 1944 to succeed Pigou in the Chair of Political Economy, he returned to the University of Cambridge, holding that position until his retirement in 1957. He died in Cambridge in 1963.

Economics in Cambridge when Robertson commenced working at it was dominated by Marshall. Not by the man himself (although still alive he had retired in 1908) but by his analytical methods and by his *Principles of Economics*. It was quite natural that the topic selected by Robertson for his fellowship dissertation should involve a ‘Marshallian’ approach to a subject on which Marshall himself had written relatively little: the nature and causes of fluctuations in the general level of economic activity. As Robertson recorded in the introduction to the published version of this dissertation:

> In some of the more abstract portions of this essay I shall make use, without further explanation or apology, of the processes and terminology in common use among the school of economic thought associated in this country chiefly with the name of Dr Marshall. My reason is that after a study of many facts and theories I am deliberately of the opinion that one cause of the obscurity which still surrounds this problem is that in the attack upon it full and systematic use has never hitherto been made of the weapons supplied by this particular intellectual armoury. (1915, p. 11)
Although Robertson did not suspect it then, the refinement and further development of the ideas about cycles and growth in economic activity presented in this study were to occupy him for the next 20 years. Two different sorts of factors led him in this direction. The first was the need to develop a framework for designing an organized policy response to the large-scale dislocation of economic life which had followed the end of the First World War, while the second was a more specific, personal, influence. In the early 1920s Keynes commissioned him to write an introductory textbook (in the Cambridge Economic Handbook series) to be entitled, simply, ‘Money’. The difficulties he encountered in attempting to provide an elementary account of monetary theory made Robertson particularly aware that, even in its more sophisticated variants, existing theoretical work provided an inadequate basis for dealing with the economic problems of the 1920s. The combined influence of these two resulted in a prolonged period of reflection and research, yielding a series of loosely related publications which recorded the development of a fairly comprehensive analytical scheme interrelating the problems of money, the trade cycle, economic growth, and the role of the state in promoting economic progress.

Robertson's approach to this analysis involved the development of successively more complicated, more ‘realistic’ models of economies each of which constituted a different, abstract, ‘type’. All ‘types’ shared the characteristics that production was undertaken on the basis of ‘rational’ decision-making by competing producer ‘groups’, each making different products with a fixed labour force and a productive process involving fixed capital. Now although each type of economy was both a production and an exchange economy it was the possibility that these activities could be ‘organized’ in different ways that distinguished the different types. Production could be organized in two ways, cooperatively or non-cooperatively, while exchange could also be organized in two ways, direct exchange or monetary exchange. In total there were, then, four types of economies. The distinction between the two types of productive organization turned on the decision-making functions of the members of the groups: in a cooperative group decisions were made and carried out by the group members acting together, while in a non-cooperative group ‘entrepreneurs’ made decisions and ‘workers’ carried them out. In respect of the organization of exchange it was on the existence and use of money that the distinction rested, in one case exchange was carried out by ‘direct barter’, while in the other, money supplied through a (potentially) government-controlled banking system provided the means of exchange.

Robertson's basic analytical building block was the ‘cooperative non-monetary economy’, an economy where each competing industrial group made its employment and, thus, output decision cooperatively, and exchanged its output without the use of money. Although in such an economy no distinction was made between the members of the group, a distinction was made between two different categories of producer groups, those providing consumer goods and those producing capital goods. The first group, consumer goods producers exchanged some of their output with the second group for capital goods, thereby providing consumption goods for capital goods producers. Now an economy of this type, Robertson argued, would experience cyclical fluctuations in aggregate output deriving from the effect of gestation lags on the time pattern of the supply of capital goods and of the durability of capital goods on the time-pattern of demand for their replacement.

A non-cooperative non-monetary economy would, though, experience fluctuations of even greater severity than those felt in an otherwise identical cooperative economy. This proposition derived directly from the fact that in a non-cooperative economy production decisions were taken by entrepreneurs who hired workers to carry them out, and workers and entrepreneurs had differing ‘interests’. These divergent interests were reflected most importantly in the different utility attached to leisure by the two
classes. An entrepreneur, for example, would wish to expand output further in the boom and contract it further in the slump than the workers in his group; and since entrepreneurs were in control, their interests prevailed. Although the degree of fluctuation in the non-cooperative economy was more pronounced than in the cooperative, Robertson adopted it as the benchmark which defined the ‘appropriate’ degree of fluctuation to be aimed at by policymakers concerned with stabilization. He did so because he maintained that the failure to recognize that production was, in practice, organized non-cooperatively could lead to an attempt to reduce fluctuations too much. Such attempts, by altering the structure of incentives, could damage the longer-run growth possibilities of the economy.

The cooperative monetary economy construct was built directly on to the foundations provided by the cooperative non-monetary economy and this type of economy exhibited, therefore, a cyclical pattern in the production of fixed capital which generated cyclical fluctuations in output as a whole. Now the introduction of money also required a slight change of focus, since in the monetary case Robertson concentrated not on fixed capital but on the demand for circulating capital, essentially on the demand for consumption goods which were consumed by those engaged in the process of production. This concern with circulating capital was necessarily associated with the analysis of monetary economies because Robertson made the assumption (reflecting British banking practice) that it was with the finance of the acquisition of circulating capital that the banking system was concerned. His analysis then described the policies which, if adopted by the banking system, would lead to fluctuations being of no greater amplitude than in the corresponding non-monetary economy. A failure to implement such policies would lead to fluctuations in the price level, and thus in output, of greater magnitude than was ‘appropriate’.

The difference made by the substitution of cooperation in the monetary type turned principally on the effect on decision-making of changes in income distribution. In particular, it was assumed that only entrepreneurial incomes adjusted quickly to changes in the price level, so that variations in the price level over the cycle were an additional source of influence on production decisions. The nature of this influence led entrepreneurs to expand their activities further in the boom (as rising prices increased their profits) and contract them further in the slump (as falling prices reduced their profits) than would have been the case in the corresponding cooperative economy. But these changes in income distribution were not permanent. In the course of the boom workers managed to restore real wages to pre-recovery levels, the expansion of output would be slowed, and in the slump, as entrepreneurs restored profits to their pre-depression levels, the contraction of output would be slowed. The end of the boom and the slump, though, if an ‘appropriate’ monetary policy were adopted, would be dictated by the behaviour of the underlying non-cooperative non-monetary economy. So non-cooperation in the monetary case had additional effects only on the amplitude of cyclical fluctuations.

Robertson also developed a set of tools to analyse the process of cyclical change in monetary economies. He divided time up into a sequence of market periods (during each of which the supply of goods was fixed) and then focused on the dynamics of the transfer of resources from current consumption by those already in employment to those newly employed to increase output during the expansion phase of the cycle. The mechanism generating this transfer was a price-level increase as the newly employed (whose wages had been borrowed from the banking system) outbid the existing employed on the goods market. Robertson's aim was to show how the magnitude of the price-level increase was determined and the nature of the monetary policies which could be adopted in order to minimize it. The rate of inflation was shown to depend upon the relationship between the rate at which the banking system made new loans to
Robertson, Dennis (1890–1963) : The New Palgrave Dictionary of Economics

producers and the rate at which this new money was absorbed into the money-holdings of the existing employed. The faster the new money was absorbed, that is, the faster that the existing employed gave up their claims on current output, the smaller the rise in the price-level accompanying the transfer of resources from the public to the expanding producers. To the extent that this money was not immediately absorbed, the existing employed were forced to share current output with those producers by price-level changes. By minimizing these changes, then, the monetary authority through its control of the banking system would also be able to minimize the amount of ‘forced’ saving which accompanied the recovery. A similar approach was also applied to the non-cooperative case, but here policy design was more difficult because the inflation led to changes in the distribution of income between workers and entrepreneurs. Even so, monetary policy could play a useful role in reducing fluctuations to their ‘irreducible’ non-monetary amplitude.

The central concern of Robertson's analytical work was to provide an explanation of fluctuations in aggregate activity which was closely linked to a broader concern, that of remedying the adverse effects of such fluctuations. The identification of the use of capitalistic (though not necessarily capitalist) production methods as the source of fluctuations, though, left with a rather ambivalent attitude to possible remedies: capitalistic production methods always produced cycles, but also brought with them the possibility of economic progress. And he thought that there was a trade-off between these two, greater stability being associated with slower growth, less stability with faster growth:

> From some points of view the whole cycle of industrial change presents the appearance of a perpetual immolation of the present upon the altar of the future. During the boom sacrifices are made out of all proportion to the enjoyment over which they will ultimately give command: during the depression enjoyment is denied lest it should debar the possibility of making fresh sacrifices. Out of the welter of industrial dislocation the great permanent riches of the future are generated. (1926, p. 254)

He concluded that the choice between these two conflicting goals was ultimately a question of: ‘ethics, rather than economics’.

The theoretical framework sketched above had emerged by the early 1930s. But its further development was interrupted by the publication in 1936 of Keynes's *General Theory of Employment, Interest and Money*. Robertson's response to this book was to examine how the *General Theory* might affect his vision of how the world worked. The central issue for Robertson was whether Keynes had provided a more satisfactory explanation than he had himself of the forces which determined the behaviour of the trend rate of growth of economic activity. The distinguishing feature of Keynes's approach identified by Robertson was in the treatment of the theory of the rate of interest. He interpreted as Keynes's central proposition the contention that there was an inherent tendency for the rate of interest to remain above the level consistent with the maintenance of full employment. And although Robertson was prepared to accept that an argument could, in principle, be made out along such lines he did not accept that Keynes had succeeded in doing so. In particular he maintained that while ‘liquidity preference’ might make the interest rate ‘sticky’ in the short period, with its downward movement resistant to monetary expansion, he rejected such an approach to the long-period theory of interest rate determination, summarizing the argument in the following way:

http://www.dictionaryofeconomics.com.proxy.library.csi.edu/article?id=pde2008_R000162&goto=B&result_number=1476|4|6|2009-1-3 0:18:26
… the rate of interest is what it is because it is expected to become other than it is; if it is not expected to become other than it is, there is nothing left to tell us why it is what it is. The organ which secretes it has been amputated, and yet it somehow still exists – a grin without a cat. (‘Mr Keynes and the Rate of Interest’ in *Essays in Monetary Theory*, 1940, p. 36)

Keynes's theoretical argument was, therefore, flawed. And the associated case for stabilizing the economy at a level other than that identified in Robertson's own analysis as 'appropriate' was consequently not proven.

The first repercussion of this reaction to the *General Theory* was an estrangement between Robertson and Keynes, virtually ending a close friendship which had lasted for more than 20 years (Robertson having been a student of Keynes, then a fellow teacher and collaborator in research). It then motivated Robertson's decision to leave Cambridge for London in 1938. Moreover, even after Keynes's death in 1946, strained and difficult relations with Keynes's disciples in Cambridge left him a somewhat isolated figure. The impact of Keynes's *General Theory* on Robertson's professional life was no less significant, the whole terrain of the area in which he worked was changed: from being on the creative frontier of the subject he felt himself forced into the role of commentator and critic. In the years after 1936 he wrote almost nothing new in what had been his specialist field. An explanation was provided in a letter to a friendly reviewer of one of his collections of essays who had called upon Robertson to prepare a monograph combining and extending his earlier analytical work, and to whom he wrote:

… I'm afraid there is no chance of my responding to your challenge and trying to produce a full length synthetic Theory of Money or Fluctuations or What-you-will. I'm too old and too lazy! But even if I were younger and less lazy, I think history had made it impossible. I believe that once Keynes had made up his mind to go the way he did it was my particular function to … [elucidate and criticise the details of his work] … and to go on pegging away at them (as is still necessary). It will not be easy for anyone for another twenty years to produce a positive and constructive work which is not in large measure a commentary on Keynes, – that is the measure of his triumph. For me, it would now be psychologically impossible, and the attempt is not worth making. (Private letter of D.H. Robertson to T.J. Wilson, 31 October 1953)

Robinson Crusoe

M.V. White

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
capital; commodity exchange; consumer surplus; individualism; marginalist economics; producer surplus; rational behaviour; Robinson Crusoe; supply and demand

Article

Written by Daniel Defoe, Robinson Crusoe was first published in 1719–20. By the end of the 19th century there were many references made to a Crusoe economy to illustrate the principles of supply and demand economic theory. Crusoe thus became a representative rational economic individual, allocating his available resources to obtain maximum satisfaction in the present or future. The figure of Crusoe as the personification of supply and demand economic theory can be found in W.S. Jevons's Theory (1871), C. Menger's Principles (1871), P. Wicksteed's Alphabet of Economic Science (1888), E. Böhm-Bawerk's Theory of Capital (1890), A. Marshall's Principles (1891) and K. Wicksell's Value, Capital and Rent (1893). The principal uses of the device were to show how an isolated individual would allocate consumption items so as to maximize utility in a marginalist fashion and distribute labour effort between producing items for consumption or investment (creating ‘capital’). Calculations were made according to the relative amounts of pleasure and pain immediately or ultimately involved in the various activities. Marshall also used Crusoe to illustrate producer and consumer surplus, while F.Y. Edgeworth's Mathematical Psychics (1881) introduced ‘the black’, Friday, when discussing issues in the theory of commodity exchange.

The role of a Crusoe economy was not simply to illustrate various components of supply and demand theory. It was also utilized to support the claim that the principles of rational behaviour, as defined by that theory, could be applied to any type of economy – from the isolated individual to ‘modern civilization’. This point was made particularly clear in J.B. Clark's The Distribution of Wealth (1899). Similar references to a Crusoe economy can be found in textbooks today.

Two general characteristics of an economic Crusoe's actions are important to note. First, he must be able to calculate in a precise fashion making fine decisions between whether to work or rest, to consume or save/invest. Second, he has no resources other than those available in the island environment. Both
characteristics mean the economic Crusoe bears no relation to the Crusoe in Defoe's novel. Defoe's
Crusoe wastes time because he cannot calculate in a marginalist fashion; he cannot rationally allocate
labour time because labour is as useful in one pursuit as another; and he would not have survived
without items salvaged from the shipwreck. Other decisions, such as whether to consume or save, also
preclude calculation on the basis of relative pleasure and pain (White, 1982). Moreover, the relation
between Crusoe and Friday is not based on voluntary reciprocal exchanges, as in the supply and demand
parable, but rather on power and violence (Hymer, 1980). The economic Crusoe could not, therefore,
have been produced by relying on the letter of Defoe's text.

It is possible to find some references to Crusoe by English political economists during the 1830s, but
these were sporadic and no attempts were made to utilize Crusoe in a systematic fashion. An economic
Crusoe thus appears only after mid-century with references in F. Bastiat's *Economic Harmonies* (1850)
and H. Gossen's *Entwickelung* (Gossen, 1854). These references owed a good deal to the rewriting of
Defoe's text within the literary genre of the 'Robinsonade'.

The Robinsonade literature dates from the early 18th century (Gove, 1941) and includes voyage or
shipwreck narratives, imaginary voyages to 'isolated lands' and more general discussions of colonial
settlements which depicted various stages of societal development. The last group of Robinsonade texts
bears some resemblance to the four-stage theory of societies produced during the Scottish
Enlightenment, remnants of which can be found in the work of the classical political economists (Meek,
1976). One such remnant was the illustrative device, used by A. Smith and D. Ricardo, of hunters
exchanging commodities according to the labour embodied in them. While Marx was critical of this
device, he noted it made sense in the context of the previous century's Robinsonades. However he
considered the later discussion of Crusoe by Bastiat for example, was 'twaddle' because it depicted an
individual 'outside society' (Marx, 1857–8, pp. 83–5).

Bastiat's Crusoe relied on a different type of Robinsonade literature, particularly J.H. Campe's *Robinson
the Younger* (1779/80). Campe rewrote Defoe's tale to show Crusoe's survival on the island was not
dependent on the shipwreck items. Gossen also appealed to Campe's novel to illustrate his marginalist
explanation of work and consumption decisions. By the mid-19th century, then, the 'individualist'
Robinsonade was utilized by those theorists who conceptualized the economy as a series of voluntary
exchanges, where the principles of economic activity were those of the individual writ large.

English supply and demand economists could also draw upon a discernible shift in the readings of
Defoe's text by literary commentators after 1850. Earlier commentary had stressed the novel was useful
for showing, especially to children and the 'working classes', the virtue of work and the need to accept
the given social organization ordained by Divine Providence. Commentary after mid-century
represented Crusoe more as an individual calculating costs and benefits in the manner of an English
shop keeper. It was even argued Crusoe represented a 'national ideology' in that regard. The remarkable
similarity between this Crusoe and the illustrative device of English supply and demand economic
theory suggests the latter was able to appropriate the former as a recognizable referent.

The economic Crusoe served, in effect, as a useful defensive device against 'historical' critics of
economic theory such as T.E. Cliffe Leslie and J.K. Ingram. Writing between the mid-1860s and early
1880s, the critics argued that there were no universal laws of economic behaviour since behaviour could
change according to the type of society being considered. Supply and demand theorists, such as Jevons,
rejected that criticism, claiming historical studies could only confirm the 'universal' laws of behaviour.
assumed in the theory (Jevons, 1876, pp. 196–7). In this context, the economic Crusoe provided an apparently tangible reference point when supply and demand theory began its analysis with the actions of an ‘isolated’ or representative individual. Indeed, Gossen had used Campe's Crusoe in precisely that fashion when criticizing the German ‘National Economists’ in 1854 (Gossen, 1854, pp. 45–7). The role of an economic Crusoe, as both illustrative and defensive device for supply and demand theory, was thus inscribed from its inception.

Article
Austin Robinson was educated at Marlborough College and Christ's College, Cambridge. During the First World War he served as a pilot in the RNAS and the RAF. After finishing his studies at Cambridge he became a Fellow of Corpus Christi College, from 1923 to 1926. In 1926 he married Joan, daughter of Major-General Sir Frederick Maurice and later to become the eminent economist. From 1926 to 1928 Robinson was tutor to the Maharaja of Gwalior. He returned to Cambridge as a university lecturer in economics in 1929, and from then on was an important figure on the Cambridge economics scene. He became Professor of Economics in 1950. He retired in 1965 (and it so happened that Joan Robinson was appointed to his chair). After his retirement, he continued to play a prominent role in Cambridge economics, as well as on the national and international scene.

Austin Robinson's first book, *The Structure of Competitive Industry* (1931), established his reputation as an economist. This seminal work drew on Alfred Marshall's writings on industry, and considered in detail the problems involved in determining the optimum size of firm. But although it emphasized the importance of scale, and inspired much of the later empirical work in this area, it also recognized that low British productivity in manufacturing industry was not primarily the consequence of scale, but of attitudes towards work and competition. All subsequent writing on this subject owed a considerable debt to Robinson. He followed up his work on competitive industry with a book on *Monopoly* (1941), as well as with a number of articles, including work on Africa. He was a member of the group surrounding Keynes when he was formulating the *General Theory*, and wrote a review of it in *The Economist*, insisting on signing it (against the traditions of the paper) because of the exceptionally controversial nature of the subject.

Robinson's long association with the *Economic Journal* began in 1934, as Assistant Editor to Keynes, and was later to be followed by much editorial work. Robinson did distinguished service during the war. He was a member of the Economic Section, War Cabinet Office, from 1939 to 1942, and from 1942 to
1945 was Economic Adviser and Head of Programmes Division, Ministry of Production. This was followed by a period as Economic Adviser to the Board of Trade. He returned to Cambridge in 1946, but served a further period in government on the Economic Planning Staff from 1945 to 1947. He was joint editor of the *Economic Journal* from 1944 to 1970, and played a leading role in the profession in other ways, holding a number of important posts, including that of managing editor of the Royal Economic Society's edition of Keynes's works. He was much involved in the work of the new International Economic Association: he was President from 1959 to 1962 and editor of its publications for many years. A good deal of his subsequent writing and editorial work, much of it on the problems of developing countries, was carried out in the context of the work of the IEA.

Austin Robinson's career was a remarkable one. He combined writing, teaching, editorial work and administration with advising governments in both the developed and developing world. He played a leading role in the economics profession for an exceptionally long period, internationally as well as in Britain, and did so throughout with much distinction.

Article

Joan Robinson (née Maurice) was born at Camberley, Surrey, on 31 October 1903. She died in Cambridge on 5 August 1983.
She is the only woman (with the possible, but controversial, exception of Rosa Luxemburg) among the great economists. In 1975, which was proclaimed Woman's Year, most economists in the United States expected that she would naturally be chosen for the Nobel Memorial Prize in Economics for that year. She had received triumphant acclaim, as a Special Ely Lecturer, at the American Economic Association annual meeting three years earlier, in spite of the harsh hostility that her theories had always met in the United States. The American magazine Business Week, after sounding out the American economics profession, felt so sure of the choice as to anticipate the event by publishing a long article on her, presenting her explicitly as being ‘on everyone's list for this year's Nobel Prize in Economics’. But the Swedish Royal Academy missed that opportunity (and alas, never regained it). Ever since, in shop-talk among economists all over the world, Joan Robinson has become the greatest Nobel Prize winner that never was.

Basic biography

Joan Robinson was the daughter of Major General Sir Frederick Maurice and of Helen Marsh (who was herself the daughter of a Professor of Surgery and Master of Downing College, Cambridge). Sir Frederick pursued a brilliant career in the British Army, but in 1918 he found himself at the centre of a public debate, and he gave up his army career on a point of principle. This was very much in the family tradition. Sir Frederick's grandfather – Joan Robinson's great-grandfather – was Frederick Denison Maurice, the Christian Socialist who lost his chair of theology at King's College London, for his refusal to believe in eternal damnation.

Joan Robinson certainly had many of these traits: toughness and endurance of character, nonconformism and unorthodoxy of views, the absence of any reverential feeling or timidity, even in the face of the world's celebrities, a passionate longing for the new and the unknown.

She was educated at St Paul's Girls' School in London. (Curiously enough, Richard Kahn was educated in the boys' section of the same school.) In October 1922, she was admitted to the University of Cambridge, going up to Girton College, where she read economics at a time when the dominant figures in Cambridge were Marshall and Pigou. Marshall had retired (he died in 1924) but was extremely influential not only in Cambridge but in the whole of the British Isles. Pigou, his favourite pupil and chosen successor, was the Professor of Political Economy, at whose lectures Cambridge students absorbed the official *verbum* of Marshallian economics. Keynes was a sort of outsider, part-time in Cambridge and part-time in London, always involved with government policies, either at the Treasury or in public opposition. In those days he lectured on strictly orthodox monetary theory and policies. His lectures were not given regularly but were well attended.

The intellectual environment must have appeared solidly traditional. Joan graduated in 1925, as a good girl would: with second class honours.

In the following year (1926), she married E.A.G. Robinson (later Professor Sir Austin Robinson), who was six years her senior and at the time a junior Fellow of Corpus Christi College. Together they left Cambridge and set off for India, where they stayed for two years. Austin Robinson served as tutor of the Maharajah of Gwalior. Joan was there as Austin's wife but did some teaching at the local school. When they returned, after their two-year Indian engagement, Austin Robinson took a permanent post as Lecturer in Economics at Cambridge, where they settled for life. They had two daughters.

It was on the return to Cambridge from India (summer 1928) that Joan Robinson began to do some College supervision of undergraduates, and then to do economics research in earnest. The Cambridge intellectual environment had changed dramatically. After Edgeworth's death (1926), Keynes became the sole editor of the *Economic Journal* and was engaged on his *Treatise on Money* (Keynes, 1930). Most of all, he had brought to Cambridge Piero Sraffa, the young Italian economist who had dared to launch a scathing attack on Marshallian economics (Sraffa, 1926). Moreover, some new stars were rising in the firmament of Keynes's entourage – Frank Ramsey, the brilliant mathematician; Ludwig Wittgenstein, the Austrian philosopher whom Keynes persuaded to come to Cambridge; and Richard Kahn, Keynes's favourite pupil. It was with Richard Kahn that Joan Robinson began an intense intellectual partnership that lasted for her whole life.

On a strictly academic level, Joan Robinson slowly ascended the academic ladder: Junior Assistant Lecturer in 1931, Full Lecturer in 1937, Reader in 1949. It was suggested in Cambridge that the fact that her husband was in the same faculty kept her back at all stages of her academic career. She became full professor only on Austin Robinson's retirement, in 1965. Her association with the Cambridge colleges was more irregular. But she was, in succession, a Fellow of Girton College and of Newnham College.
Yet whatever the formal position in the faculty or in the Cambridge colleges, she was for years one of the major attractions in Cambridge for many generations of undergraduates, not only in economics. In the post-war period, she was certainly the best-known member of the Cambridge economics faculty abroad. An indefatigable traveller, she did not limit her foreign visits to universities; she also wanted to know local customs and local conditions of life, even far away from urban centres. Her strong constitution and temperamental toughness helped her enormously. A friend from Makerere University, who took her, when she was already in her seventies, on a month's travel in tribal Africa was amazed at how much she could endure in terms of living in most primitive conditions with raw food, lack of facilities and exposure to harsh tropical weather, day and night.

It would be impossible to list here all the places she visited or the talks, seminars and public lectures she gave all over the world. She rarely stayed in Cambridge during the summer or term vacations or during her sabbatical years, though punctually and punctiliously returning there on the eve of the terms of her teaching. Asia was her favourite continent (especially India and China). But hundreds of students in North and South America, Australia, Africa and Europe also knew her at first hand.

In Cambridge she rarely missed her classes, lectures and seminars and she was a regular attendant of other people's seminars, especially visitors', never avoiding discussion and confrontation. Professor Pigou – a well-known misogynist – had included her in his category of ‘honorary men’.

She was extremely popular with the students – a clear, brilliant, stimulating teacher. She was a person who inspired strong feelings – of love and hate. Her opponents were frightened by her, and her friends really admired, almost worshipped her. Her nonconformism in everyday life and even in her clothing (most of which she bought in India) was renowned.

She retired from her professorship in Cambridge on 30 September 1971. On retirement she did not agree to continue lecturing in Cambridge. (Later on, in the late 1970s, she gave in partially, giving a course of lectures on ‘the Cambridge tradition’.) But her writing and lecturing abroad, at the invitation of economics faculties and students all over the world, continued unabated.

When, in the late 1970s, King’s College (Keynes's college) finally dropped the traditional anachronistic ban on women and became co-educational, Joan Robinson, upon an enthusiastic and unanimous proposal by all economists of the college, became the first woman to be made an Honorary Fellow of King’s College. (She had earlier become an Honorary Fellow of Girton College and of Newnham College.)

Towards the end of her life, she became very concerned and disappointed with the direction in which economic theory had turned and with the ease with which the younger economists could bend their elegant models to suit the new conservative moods and the selfish economic policies of politicians and governments. Her friends also noticed a sort of stiffening rigidity in her views that had not appeared before. This was unfortunate, as it contributed to increasing the hostility of her opponents towards her. She suffered a stroke in early February 1983, from which she never recovered. She lay for a few months in a Cambridge hospital, and died peacefully six months later.

**Distinctive traits of her intellectual personality**

In order to understand better the nature of Joan Robinson's contributions to economic theory, it may be helpful to begin by considering explicitly a few characteristic traits of her intellectual personality. Joan Robinson had a remarkable analytical ability. Since she did not normally use mathematics, this
remarkable intellectual ability was of a nature that defies conventional description. In her early works she made use of geometrical representations, backed up by calculus (normally provided by Richard Kahn). In her mature works, her way of reasoning took up a more personal feature. Her style is difficult to imitate (as when she invites the readers to follow her in the construction of economic exercises) but very effective. The results are always impressive. Those who used to argue with her knew that she could grasp and keep in the back of her mind (to be brought out at the appropriate moment) a whole series of chain effects and interdependences which her interlocutors could hardly imagine.

She was not the type of person who could go on thinking in isolation. The way she could best express herself was by having somebody in constant confrontation. She could put her views best either in opposition or in support of somebody else's position. This made her extraordinarily open to concepts and contributions coming from the people she encountered. The accurate historian of economic ideas will probably find in her works traces of almost every person she met. It is therefore important, in considering Joan Robinson's contributions, to keep in mind at least the most important economists who influenced her. These include her teachers (Marshall through Pigou, Keynes, Shove), her contemporaries (Sraffa, Kaldor, and Kalecki, through whom she went back to Marx, but especially Richard Kahn, who read, criticized and improved every single one of her works) and also a whole series of other (younger) people – pupils and students.

This raises the question of her originality. The prefaces to her books are packed with acknowledgements, sometimes heavy acknowledgements – consider, for example, the following excerpt from the *Economics of Imperfect Competition*:

> … this book contains some matter which I believe to be new. Of not all the new ideas, however, can I definitely say that ‘this is my own invention’. I particularly have had the constant assistance of Mr R.F. Kahn … many of the major problems … were solved as much by him as by me. (Robinson, 1933, p. v)

But one must remember what has been said above. In fact, Joan Robinson was a highly original thinker, but of a particular type. Besides the contributions to economic theory that are distinctly hers she had her own highly original way, even in small details, of presenting other authors' views, which she always did through a distinctly personal re-elaboration. Sometimes the re-elaboration is so personal as to sound parochial. But this trait is not exclusive to Joan Robinson. Cambridge parochialism is shared by almost all purely Cambridge-bred economists since Marshall (Keynes included). It sometimes creates unnecessary difficulties of communication with economists outside Cambridge (that is, with the overwhelming majority!) or introduces a few odd notes into an otherwise impeccable performance. One can clearly detect an evolution in Joan Robinson's approach to economics that with age strengthened her innovative tendencies. It looks as if she was very cautious in her early years, preoccupied at first with building up solid analytical foundations. But as soon as she felt sure of her analytical equipment, she began to venture more and more into the exciting field of innovation. In her mature works her typical style became established. A sort of mixture of educational, temperamental and intellectual factors made her one of the leading unorthodox economists of the 20th century. Always impatient with dogmas, constantly fighting for new unorthodox ideas, relentlessly attacking established beliefs, she acquired a sort of vocation to economic heresies (see Robinson, 1971). Her attitude reminds one of a dictum by Pietro Pomponazzi, the Italian Renaissance philosopher: ‘It is better to be a heretic if

one wishes to find the truth.’

Strongly related to this attitude is the social message that comes from her writings. Her ‘box of tools’ and her logical chain of arguments were not proposed for their own sake; they were always aimed at practical action, with a view to the world's most pressing problems – unemployment before the war, underdevelopment and the struggle of ex-colonial nations after the war (very noticeable is her special concern for Asia and her enthusiasm, at points rather naive, for Communist China). Consistently, she has been among the strongest assertors – second perhaps only to Gunnar Myrdal – of the non-neutrality of economic science and of the necessity of stating explicitly one's convictions and beliefs.

And yet, in spite of her bold attacks and her satirical mood, her literary style is surprisingly feminine – rich with fable-like parables, with down-to-earth examples from everyday life (‘the price of a cup of tea …’) and with similes from scenes and examples taken from nature (the Accumulation of Capital begins with the economic life of the robin). Her sparkling prose and her entertaining asides make Joan Robinson one of the most brilliant writers among economists and certainly one of the most enjoyable and delightful to read.

Her scientific achievements

Joan Robinson wrote numerous books and an enormous number of articles, most of which have been collected in her Collected Economic Papers (1951–79).

They fall neatly into three broad groups, corresponding to the three basic phases of her intellectual development. A first group belongs to the phase of her by now classic Economics of Imperfect Competition (1933). A second group belongs to the phase of explanation, propagation and defence of Keynes's General Theory. Finally, a third group of writings grew around the major work of her maturity, The Accumulation of Capital (1956). Other books and articles have originated from miscellaneous or wider interests or from the desire to provide students with economics exercises or with a non-orthodox economics textbook (Robinson and Eatwell, 1973c). Altogether, they make an impressive list. Even neglecting her articles (most of which are reprinted in the books), her bibliography contains no fewer than 24 books.

The most widely known of Joan Robinson's works is still the first, The Economics of Imperfect Competition (1933). It was the book of her youth, which placed her immediately in the forefront of the development of economic theory. It is a work conceived in Cambridge, at the end of a decade characterized by an intense controversy on cost curves and the laws of returns (see Sraffa, 1926, and the Symposium on the ‘laws of returns’ by Robertson, Sraffa and Shove, 1930). With this controversy in the background, Joan Robinson's book emerges in 1933 as a masterpiece in the traditional sense of the word. The restrictive conditions of perfect competition on which Marshall's theory was constructed are abandoned, and perfect competition is shown to be a very special case of what in general is a monopolistic situation. A whole new analysis of market behaviour is carried out on new, more general, assumptions; and yet the whole method of analysis, the whole approach – though refined and perfected – is still the traditional Marshallian one. Sraffa's criticism of the master is accepted, but is incorporated into the traditional fold by a generalization of Marshall's own theoretical framework. The outcome is extremely elegant and impressive. The whole matter of market competition is clarified. Marshall's ambiguities are eliminated, the various market conditions are rigorously defined, a whole technical apparatus (a ‘box of analytical tools’) is developed to deal with market situations in the general case.
(from demand and supply curves to marginal cost and marginal revenue curves). In a sense, therefore, rather than a radical critique, the *Economics of Imperfect Competition* might well be regarded as the completion and coronation of Marshallian analysis. This may help to explain why Joan Robinson herself came to like that book less and less, as her thought later developed on different lines. In 1969 she came to the point of writing a harsh eight-page criticism of it. Very courageously she published it, on the occasion of a reprint of the book, as a Preface to the second edition!

The book had appeared almost simultaneously with the *Theory of Monopolistic Competition* by Edward Chamberlin (1933); and the two books are normally bracketed together as indicating the decisive breakaway of economic theory from the assumptions of perfect competition. Chamberlin always complained about this association. For although the two books represent the simultaneous discovery of basically the same thing, made quite independently by two different authors, they are in fact substantively different.

It may also be added that, looked at in retrospect, these two books do not appear so conclusive a contribution to the theory of the firm as they appeared to be in the 1930s. The behaviour of firms in oligopolistic markets and the policies of the large corporations have turned out to require more complicated analysis. At the same time, the assumption of perfect competition, far from being completely dead, has recently come back in different guises in the works of many theoretical economists. Yet there is no doubt that the two books remain there to represent a definite turning-point in the development of the theory of the firm – so much so as to be referred to as representing the ‘monopolistic competition revolution’ (Samuelson, 1967). Very characteristically, Edward Chamberlin, after writing the *Theory of Monopolistic Competition*, spent the whole of his life in refining, completing and adding appendices to his masterpiece (no fewer than eight editions!). For Joan Robinson, the *Economics of Imperfect Competition* was only the first step on a very long way to a series of works in quite different and varied fields of economic theory.

It should be added that the *Economics of Imperfect Competition* was not Joan Robinson's only contribution to microeconomic theory in the 1930s. Her name appears again and again on the pages of the avant-garde economic journals of the time. From among her papers, explicit mention must be made at least of her remarkably lucid article on ‘rising supply price’ and of her contribution to clarifying the meaning of Euler's theorem as applied to marginal productivities, in the traditional theory of production (see her *Collected Papers*, vol. 1).

But something of extraordinary importance was happening in Cambridge in the 1930s. Keynes was in the process of producing his revolutionary work (Keynes, 1936). Joan Robinson abandoned the theory of the firm and threw herself selflessly and entirely into the new paths opened up by him. This was a really brave decision, if one thinks that her first book had gained her great reputation in the economic profession. Very rarely do we find someone who, after striking success and becoming a leading figure in a certain field, pulls out of it and puts himself or herself into the shadow of someone else, be this someone else even of the stature of Keynes. Joan Robinson did precisely that. She was one of the members – actually an important member, as is revealed by the recent publication of her correspondence with Keynes (see Keynes, 1973; 1979) – of that group of young economists known as the ‘Cambridge Circus’ (and including Kahn, Sraffa, Harrod, Meade, besides Austin and Joan Robinson) who regularly met for discussion, and played a crucial role in the evolving drafts of Keynes's *General Theory*.

It must be said that the new Keynes's ways were more congenial to her temperament. They were a break with tradition and this suited her nonconformist attitude; they dealt with the deep social problems of
unemployment and this appealed to her social conscience. It is in this vein that she published her *Essays in the Theory of Employment* (1937a) and her *Introduction to the Theory of Employment* (1937b). These twin books were simply meant to be a help to the readers of Keynes's *General Theory*. In fact, they turned out to be much more than that. In particular, Joan Robinson contributes to the clarification of a major piece of Keynesian theory – the process through which investments determine savings – which had remained rather obscure from the *General Theory*. For her, this appeared important because it broke a crucial link in traditional theory, which presented the rate of interest as a compensation for the ‘sacrifice’ of supplying capital (that is, for saving). Joan Robinson stresses the role of investment as an independent variable, while total saving is shown as being determined passively by investment through the operation of the multiplier; the conclusion being that the rate of interest cannot be remunerating anybody's 'sacrifice'. Even more so in depression times, when thrift – a ‘private virtue’ – becomes a ‘public vice’. Other concepts, introduced by Joan Robinson at the time, that were to remain permanently in the following economic literature on the theory of employment are those concerning what she called ‘beggar-my-neighbour’ policies, ‘disguised unemployment’ and the generalization of the Marshall–Lerner conditions on international trade, in terms of ‘the four elasticities’.

Towards the end of the 1930s, Joan Robinson met Kalecki, and discovered that quite independently of, and in fact earlier than, Keynes he had come to the same conclusions. Kalecki had started from a Marxist background, against which Keynes he had come to the same conclusions. Kalecki had started from a Marxist background, against which Keynes was prejudiced. This led her to re-reading Marx and to re-thinking her own position vis-à-vis Marxian theory (Robinson, 1942).

Joan Robinson's flirtation with Marx is very curious. It has all the charm of a meeting and all the clamour of a clash. She is no doubt attracted by Marx's general conception of society. She finds in Marx much that she approves of. But she finds his scientific nucleus embedded in, and in need of being liberated from, ideology. To obtain this, she says, one must work hard. Her writings on Marx are specifically aimed at ‘separating the wheat of science from the chaff of ideology’. Needless to say, this has caused her a lot of trouble with the Marxists. It should be kept in mind that in Continental Europe discussions on Marx have a long and complex tradition of philological heaviness and ideological passion. Joan Robinson's discussion is short and simple. She is always looking at Marx as ‘a serious economist’. Accordingly, she always tries to go straight to what she thinks is his economic analysis. Her insistence on the necessity of rescuing Marx, as a scholar and a first-rate analytical mind, has recently been vindicated, especially after the publication of Sraffa's book (1960; see also, for example, Samuelson, 1971).

But the post-war period was opening up new vistas. With Keynes's *General Theory* in the background, Joan Robinson saw a formidable task ahead, consisting in nothing less than a reconstruction of economic theory. This led, after a decade of intense work, to the publication of her second major contribution to economic theory – *The Accumulation of Capital* (1956), the work of her maturity and the one that expresses Joan Robinson's genius at her best. Here she has chosen to move on new and controversial ground. While in her first book the direction – once established – was clear and she had to fill in the details, here the direction itself is not entirely clear and has to be continually adjusted. The details acquire less importance and may well be abandoned altogether and replaced with others at a second attempt. As a consequence, a lot of re-writing had to be done.

*The Rate of Interest and Other Essays* (1952), with its central essay devoted to a ‘Generalization of the *General Theory*’, turned out to be a sort of preparation. *The Accumulation of Capital* represents the central nucleus of what she perceived as a new framework for economic theory. Then the *Exercises in
Economic Analysis (1960a), the Essays in the Theory of Economic Growth (1962a) and a series of other articles fill in the gaps, clarify obscurities, and take the arguments further.

The ‘Generalization of the General Theory’ represents Joan Robinson's response to an interchange with Harrod, following Harrod's Towards a Dynamic Economics (1948) and also his earlier review of her Essays in the Theory of Employment (1937a). Joan Robinson breaks away from the limitations of the short run, but has not yet defined clearly her direction. Yet, once the process of ‘generalization’, that is, ‘dynamization’ of the General Theory is started, the author is compelled to recast the Keynesian arguments in terms of the more fundamental categories of capital accumulation, labour supply, technical progress and natural resources. Through this recasting, it became inevitable that she should go to the earlier methodological approach (common to Ricardo and Marx) of stating the problems in terms of social aggregates. The evidence of her intense searching may be found at the end of the book in a chapter of ‘acknowledgements and disclaimers’, where she describes in succession the way she has been influenced by, or has reacted to, Marx, Marshall, Rosa Luxemburg, Kalecki and Harrod.

The years of transition from the Rate of Interest and Other Essays (1952) to the Accumulation of Capital (1956) had been marked by a series of intense discussions in Cambridge, especially with Kahn, Sraffa, Kaldor and Champernowne. In the end, Joan Robinson emerged centring her attention on the problem of capital accumulation as the basic process in the development of a capitalist economy. She began with a scathing attack on the traditional concept of ‘production function’ (in a well-known article, now in her Collected Papers, vol. 2, which elicited a chain of angry responses: see, for example, Solow, 1955–6, and Swan, 1956). Then she patiently proceeded to a reconstruction. A crucial step was her own way of rediscovering the Swedish economist Knut Wicksell.

The Accumulation of Capital (1956) bears the same title as Rosa Luxemburg's book, to whose translation into English Joan Robinson wrote an introduction (Luxemburg, 1951). This was a great tribute to another woman economist. But we should not be misled. Joan Robinson's book belongs to an entirely different age and takes an entirely different approach. Set into a Keynesian framework extended to the long run, it takes its origin from a welding together of Harrod's economic dynamics and of Wicksell's capital theory. The main question Joan Robinson poses to herself is by now a typically classical one: what are the conditions for the achievement of a cumulative long-term growth of income and capital (what she characteristically christened a ‘golden age’); and what is the outcome of this process, in terms of growth of gross and net output and of the distribution of income between wages and profits, given a certain evolution through time of the labour force and of technology? To answer these question Joan Robinson builds up a two-sector dynamic model with a finite number of techniques; and goes on to show the interactions of the relations between wages and profits, the stock of capital and the techniques of production, entrepreneurial expectations and the degree of competition in the economy, bringing in the effects of higher degrees of mechanization and both ‘neutral’ and ‘biased’ technical progress. The basic model and the basic answers are all worked out very quickly in the book. The rest is then devoted to relaxing the simplifying assumptions. The whole analysis is carried out without the use of mathematics. This is remarkable. Joan Robinson squeezes out of the model, one by one, all the answers that are needed. The non-use of mathematics has certain obvious disadvantages. Though the analysis need not necessarily be any less rigorous, in many passages it is not so easy to follow. It has, however, some advantages, which Joan Robinson is very ready and able to exploit. She succeeds, for example, in freeing herself from the symmetry that a mathematically formulated model normally imposes. In Joan Robinson's model, certain results are always more likely to happen than their
symmetrical counterpart. Symmetry and formal elegance play no part; only relevance does, or at least it does in the way perceived by the author.

The overall result is, again, impressive. The oversimplified dynamic model of Harrod is enormously enriched by the introduction of the choice among a finite number of alternative techniques. At the same time the Wicksellian analysis of accumulation at a given technology is completed by the new analysis of a constant flow of inventions of various types. And this marriage of Harrod's model to Wicksellian analysis is made to fructify in a number of directions. So many and so rich are in fact these directions that Joan Robinson herself did not pursue all of them, as became evident from the abundant literature that followed.

To this literature, Joan Robinson contributed a whole series of essays and books (see her Collected Papers, vols 2–5, and J. Robinson, 1960b; 1962a), which represent clarifications and further elaborations. They also represent her way of recasting and adjusting her arguments in response to opposition from her critics and to comments, remarks and stimuli of any sort from her friends, as well as her way of coming to grips with results – not always or not entirely compatible with hers – coming from the works of other scholars, colleagues and pupils, who were broadly working on similar problems and with the same aims.

Meanwhile, proceeding on parallel lines, many other separate strands of thinking were emerging from her remarkable intellectual activity. At least a few must briefly be mentioned here.

First, a whole series of concepts and ideas were coming to fruition, which – though not belonging to her major fields of interest – came to complete her overall coverage of economic theory: writings on the theory of international trade (including her professorial inaugural lecture at Cambridge on The New Mercantilism, 1966a), on Marxian economics (at various stages in her career), and on the theory of economic development and planning, reproducing her lectures delivered during her world travels or coming from calm reflection, once she had returned home (see her Collected Papers, and also J. Robinson, 1970b; 1979b).

Second, her deeply felt concern with economics students and economics teaching in general gave origin to books, such as Joan Robinson (1966b; 1971) and especially (with Eatwell) (1973c), which contributed to giving substance to, and disseminating all over the world, her strongly felt conviction that an overall approach to economic reality, alternative to that of traditional economics, does exist and is viable.

Third, the ideas, reflections, rationalizations, accumulated in the course of her life took the form of books such as Economic Philosophy (1962b) and Freedom and Necessity (1970a), which were concerned with wider issues than economics itself, attempting to give an overall conception of the world and a whole philosophy of life. These writings contribute, not marginally, to place Joan Robinson among the influential thinkers of this century. At the same time, they may well be enjoyed, by the general reader, even more than her masterpieces. From a purely literary point of view, they make delightful reading.

It should be added that there are, moreover, many themes which, while not being exclusively connected with any specific work of Joan Robinson's, recur time and again in her writings, so as to have become characteristically associated with her approach. Here are a few: (a) the concept of ‘entrepreneurs' animal spirits’ – an expression picked up from Keynes and developed as an important element contributing to explain investment in capitalist economies; (b) the conviction that Marshall's notions of prices and rate of profit, with reference to industry, are much more akin to Ricardo's notions than to Walras's; (c) a sharp distinction between ‘logical’ time and ‘historical’ time, both of which have a place in economic
analysis but with different roles. On this point Joan Robinson's characterization of the evolution of an economy in historical time as concerning decisions to be taken between 'an irrevocable past and an uncertain future' is well known; (d) an equally sharp distinction between comparisons of equilibrium-growth positions and movements from one equilibrium-growth position to another, in dynamic analysis; (e) a tendency, especially in the later part of her life, to shift nearer and nearer to the positions of Kalecki, as opposed to those of Keynes, in interpreting the overall working of the institutions of capitalist economies, especially with reference to what she found as a more satisfactory integration in Kalecki of the concept of effective demand with the process of price formation. Finally, one must mention specifically an issue which may well continue to give rise to controversial evaluations. This concerns the role that may be assigned to Joan Robinson in the well-known controversy on capital theory that flared up between the two Cambridges in the 1960s (see Pasinetti et al., 1966). One view on this issue is that Joan Robinson had the merit of anticipating the controversy by her (already mentioned) attacks on the neoclassical production function in the mid-1950s (see Harcourt, 1972). Another view is that Joan Robinson, herself a victim of her emotional temperament, started her attacks on the traditional concepts too early and misplaced the whole criticism, by neglecting the really basic point (the phenomenon of reswitching of techniques; see Sraffa, 1960) that in the end delivered the fatal blow to the neoclassical notion of production function. What one can say for certain is that a hint at the reswitching phenomenon does appear in the Accumulation of Capital, but is relegated to the role of a curiosum, in an entirely secondary section. Perhaps the phenomenon had been pointed out to her but she grossly underestimated its importance. What is curious is that she continued to underestimate it even after it was brought to the foreground (see her 'Unimportance of Re-switching' in Collected Papers, vol. 5).

But at this point the works of Joan Robinson merge into those of that remarkable group of Cambridge economists – notably, Piero Sraffa, Nicholas Kaldor and Richard Kahn, among others, besides Joan Robinson herself (on this, see the Preface to Pasinetti, 1981) – who happened to be concentrated in Cambridge in the post-war period and who took up, continued and expanded the challenge that Keynes had launched on orthodox economic theory. This remarkable group of economists started a stream of economic thought which is obviously far from complete. Its basic features, however, are clear enough; they embody a determined effort to shift the whole focus of economic theorizing away from the problems of optimum allocation of given resources, where it had remained for almost a century, and move it towards the fundamental factors responsible for the dynamics of industrial societies. This shift of focus inevitably brings into the foreground the once central themes of capital accumulation, population growth, production expansion, income distribution, and thus technical progress and structural change.

It is perhaps too early to try to evaluate the relative role played by Joan Robinson as a member of this remarkable group of economists. The single components of the group have made contributions which are sometimes complementary, at other times overlapping, and at yet other times even partly contradictory. To mention only one major problem, Piero Sraffa's book appeared too late for Joan Robinson to be able to incorporate it into her theoretical framework; and the brave efforts she later made to this effect are not always convincing. They actually reveal here and there a sort of ambivalent attitude. At the same time, her Accumulation of Capital ventures into fields of economic dynamics which Sraffa does not touch at all. Quite obviously, the common fundamental thrust behind post-Keynesian analysis
does not presuppose complete identity of views or complete harmony of approach. Future developments will clarify issues and will reveal which of the lines of approach proposed are the most useful, fruitful or fecund. There can be little doubt, however, that if this theoretical movement is going to prove successful, quite a lot of rewriting will have to be done in economic theory. If, and when, this rewriting occurs, Joan Robinson's contributions are going to take a major place.

Robust control
Noah Williams
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Robust control is an approach for confronting model uncertainty in decision making, aiming at finding
decision rules which perform well across a range of alternative models. This typically leads to a
minimax approach, where the robust decision rule minimizes the worst-case outcome from the possible
set. This article discusses the rationale for robust decisions, the background literature in control theory,
and different approaches which have been used in economics, including the most prominent approach
due to Hansen and Sargent.

uncertainty

Article

Robust control considers the design of decision or control rules that fare well across a range of
alternative models. Thus robust control is inherently about model uncertainty, particularly focusing on
the implications of model uncertainty for decisions. Robust control originated in the 1980s in the control
theory branch of the engineering and applied mathematics literature, and it is now perhaps the dominant
approach in control theory. Robust control gained a foothold in economics in the late 1990s and has seen
increasing numbers of economic applications in the past few years. (For related surveys see Hansen and
Sargent, 2001; and Backus, Routledge and Zin, 2005. For a more comprehensive view of the leading
approach to robust control in economics, see Hansen and Sargent, 2008.)
The basic issues in robust control arise from adding more detail to the opening sentence above – that a
decision rule performs well across alternative models. To begin, define a model as a specification of a
probability distribution over outcomes of interest to the decision maker, which is influenced by a
decision or control variable. Then model uncertainty simply means that the decision maker faces
subjective uncertainty about the specification of this probability distribution. A first key issue in robust
control, then, is to specify the class of alternative models which the decision maker entertains. As we
discuss below, there are many approaches to doing so, with the most common cases taking a benchmark
nominal model as a starting point and considering perturbations of this model. How to specify and
measure the magnitude of the perturbations are key practical considerations.

With the model set specified, the next issue is how to choose a decision rule and thus what it means for a
rule to ‘perform well’ across models. In Bayesian analysis, the decision maker forms a prior over models
and proceeds as usual to maximize expected utility (or minimize expected loss). Just as we defined a
model as a probability distribution, a Bayesian views model uncertainty as simply a hierarchical
probability distribution with one layer consisting of shocks and variables to be integrated over, and
another layer averaging over models. In contrast, most robust control applications focus on minimizing
the worst case loss over the set of possible models (a minimax problem in terms of losses, or max-min
expected utility). Stochastic robust control problems thus distinguish sharply between shocks which are
averaged over and models which are not. The robust control approach thus presumes that decision
makers are either unable or unwilling to form a prior over the forms of model misspecification. Of
course, decision makers must be able to specify the set of models as discussed above, but typically this
involves bounding the set of possibilities in some way rather than fully specifying each alternative.
Finally, there are some approaches which seek a middle ground between the average case and the worst
case, for example by maximizing expected utility subject to a bound on the worst case loss. These have
been less prominent both in control theory (Limebeer, Anderson and Hendel, 1994, is one example) and
in economics (Tornell, 2003, is one exception), and thus will not be discussed further. For the remainder
of the article robust control will mean a minimax approach.

Robustness and worst case analysis

Broadly speaking, the control theory literature has adopted the worst-case philosophy out of concerns for
stability. A basic desideratum for robust control in practice is that the system remain stable in the face of
perturbations, and since instability may be equated with infinite loss, minimizing the worst case
outcomes will insure stability (when possible). Moreover, many engineering applications have specific
performance objectives which must be maintained, and a cost function penalizing deviations is not
clearly specified. However, in dealing with economic agents rather than controlled machines, decision
theoretic criteria naturally come into play. In this sphere, robust control is closely related to the notions
of Knightian uncertainty, ambiguity and uncertainty aversion, which are all roughly equivalent (although
sometimes differing in formalization).

Starting with the observations of the classic Ellsberg (1961) paradox – that (some) decision makers
prefer environments with known odds to those with uncertain probabilities – there has been a broad
literature in decision theory which has weakened the Savage axioms to incorporate preferences which
display such aversion to uncertainty or ambiguity. The most widely used characterization is due to
Gilboa and Schmeidler (1989), who axiomatized ambiguity preferences with multiple priors. Decision-
making with multiple priors can be represented as max-min expected utility: maximizing the utility with
respect to the least favourable prior from a convex set of priors. More recently, Epstein and Schneider (2003) have extended the static environment of Gilboa and Schmeidler to a dynamic context, where the set of priors is updated over time. Hansen et al. (2006) formally established the links between robust control and ambiguity aversion, showing that the model set of robust control as discussed above can be thought of as a particular specification of Gilboa and Schmeidler's set of priors. Moreover, although the ambiguity preferences are characterized by posing particular counterfactuals which require multiple priors, once the least favourable prior is chosen, behaviour could be rationalized as Bayesian with that prior. Thus from a Bayesian viewpoint Sims (2001) views robust control as a means of generating priors, which then naturally leads to questioning whether the worst case prior accurately reflects actual beliefs and preferences. (See also Svensson, 2001. Hansen et al., 2006, show how to back out the Bayesian prior which rationalizes robust decision-making.)

Finally, in many cases robust or ambiguity-averse preferences are similar to enhanced risk aversion, and in some cases they are observationally equivalent. This insight dates to Jacobson (1973) and Whittle (1981) in the control theory literature, and the relations between robust control and a particular specification of Kreps and Porteus (1978), Epstein and Zin (1989) and Duffie and Epstein (1992) recursive utility with enhanced risk aversion have been shown by Anderson, Hansen and Sargent (2003), Hansen et al. (2006) and Skiadas (2003).

Control theory background

Since many of the ideas and inspiration for robust control in economics come from control theory, we give here just a broad outline of its development. More detail and different perspectives can be found in the books by Zhou, Doyle and Glover (1996), Ba•ar and Bernhard (1995), and Burl (1999). Throughout the late 1960s and early 1970s optimal control came into its own, largely through the work of Kalman on linear quadratic (LQ) control and filtering. While this approach remains widely used today throughout economics, starting in the late 1970s and early 1980s the control theory literature started to change as theory and practice showed some of the limitations of the LQ approach. Although LQ control with full observation (the so-called linear quadratic regulator or LQR) was known to be robust to some types of model perturbations, Doyle (1978) showed that there are no such assurances in the case of partial observation (the so-called linear-quadratic-Gaussian or LQG case, which is an LQR control matched with a Kalman filter). Doyle's paper title and abstract are classic in the literature – title: ‘Guaranteed Margins for LQG Regulators’, abstract: ‘There are none’.

Spurred by this and related work, control theorists started to move away from LQ control to look for a more robust approach. Zames (1981) was influential in the development of $H_{\infty}$ control as a more robust alternative to LQ control. Loosely speaking, in LQ control the quadratic cost means that performance is measured with a 2-norm across frequencies. By contrast, $H_{\infty}$ uses an $\infty$ – norm that looks at the peak of the losses across frequencies. It is also interpretable as the maximal magnification of the disturbances to outputs of interest. While the early robust control literature used a frequency domain approach, in the late 1980s Doyle and others developed state space formulations (see Doyle et al., 1989, for example) which gave explicit solutions and allowed for alternative formalizations. For example, the $H_{\infty}$ approach was given alternative justifications in terms of penalizing disturbances from the nominal model, which
Robust control: the New Palgrave Dictionary of Economics

can be implemented as a dynamic game between a decision maker seeking to minimize losses and a malevolent agent seeking to maximize loss. (See Baar and Bernhard, 1995, for a development of this approach.) Finally, the uncertainty sets in the $H_{\infty}$ approach are unstructured – they represent perturbations of the model which are bounded but have no particular form. The implications of structured perturbations have been studied more recently. Some examples include parametric perturbations, unmodelled dynamics, or uncertainty only about particular channels or connections in a model. Applications with structured uncertainty use the structured singular value (also known as $\mu$) rather than the $H_{\infty}$ norm as a measure of performance. Although there are some important stability and performance criteria, in general constructing control rules is a more daunting task, and the theory is not as fully developed as the unstructured case.

The Hansen–Sargent approach

In the economics literature, the most prominent and influential approach to robust control is due to Hansen and Sargent (and their co-authors), which is summarized in their monograph Hansen and Sargent (2008). This approach starts with a nominal model and uses entropy as a distance measure to calibrate the model uncertainty set. More specifically, the model set consists of those models whose relative entropy or Kullback–Leibler distance from the nominal model is bounded by a specified value. Note that this puts no structure on the uncertainty, but only restricts the alternative models to those which are difficult to distinguish statistically from the nominal model. In practice, a Lagrange multiplier theorem is typically used to convert the entropy constraint into a penalty on perturbations from the model. Then the solution of the control problem is found via a dynamic game implementation: the agent maximizes utility by his choice of control, while an evil agent minimizes utility by his choice of perturbation, while being penalized by the entropy of the deviations. Relative to the control theory literature such as Baar and Bernhard (1995), the main differences are that all models are stochastic, while control theory largely uses deterministic models. One exception is Petersen, James, and Dupuis (2000) who use a similar approach to consider uncertain stochastic systems. In addition, discounting is not typically considered in control theory, while it is natural in economics. In full information problems discounting has relatively little effect, but it raises important issues in problems with partial information (see Hansen and Sargent, 2005a; 2005b). Finally, the Hansen–Sargent approach naturally extends beyond the LQ setting laid out in Hansen, Sargent and Tallarini (1999), with some examples in Anderson, Hansen and Sargent (2003), Cagetti et al. (2002) and Maenhout (2004).

To be more concrete, consider an LQ example where $x_t$ is the state, $i_t$ is the agent's control, and $\varepsilon_t$ is an i.i.d. Gaussian shock. The nominal model is:

$$x_{t+1} = Ax_t + B\varepsilon_t + C\varepsilon_{t+1},$$

(1)
and the agent's intertemporal preferences are:

$$E_0 \sum_{t=0}^{\infty} \beta^t \left( x_t'Qx_t + i_t'Ri_t \right)$$ (2)

where $0 < \beta < 1$ and $Q$ and $R$ are negative definite matrices. The approach of Hansen and Sargent perturbs the nominal model with an additional ‘misspecification shock’ $w_{t+1}$ which is allowed to be correlated with the state $x_t$:

$$x_{t+1} = Ax_t + Bi_t + C(\varepsilon_{t+1} + w_{t+1}).$$ (3)

The shock $w_{t+1}$ is used to represent alternative models. These models are made to be close to the nominal model in an entropy sense by imposing the bound:

$$E_0 \sum_{t=0}^{\infty} \beta^t w_{t+1}'w_{t+1} \leq \eta$$ (4)

for some constant $\eta \geq 0$. The agent then maximizes (2) with respect to the worst case perturbed model (3) from the set (4). Using a Lagrange multiplier theorem, the constraint set can be converted to a penalty and the decision problem can be solved recursively by solving the Bellman equation for a two-player zero sum game:

$$V(x) = \max_{\theta} \min_{\omega} \left\{ x'Qx + i'Ri + \theta \omega'\omega + \beta E[V(Ax + Bi + C(\varepsilon + \omega))|x] \right\}$$ (5)

where $\theta > 0$ is a Lagrange multiplier on the constraint (4) and the expectation is over the Gaussian shock.
ε. Often this multiplier formulation is taken as the starting point, for example Maccheroni, Marinacci and Rustichini (2006) characterize preferences of this form, with θ governing the degree of robustness. As θ → ∞ the penalization becomes so great that only the nominal model remains (thus η → 0), and the decision rule is less robust. Conversely, there is typically a minimal value of θ beyond which the value is V(x)=-∞. This gives the most robust decision rules, allowing for the largest uncertainty set.

Adding structure to the uncertainty set

The approach discussed above uses unstructured uncertainty, and has been well developed and extended in different dimensions. We now discuss some alternative approaches which put more structure on the uncertainty set. There are many reasons to do so. It may be that some of the models that are close to the nominal model in a statistical sense may not be plausible economically. Alternatively, the decision makers may have a discrete set of models in mind, and bounding them all in one uncertainty set may include extraneous implausible models. Perhaps most substantively, the decision maker may be more confident some aspects of the model relative to others. Some examples of this include knowing the model up to the values of parameters, or being more certain about the dynamics of certain variables in the model. Not taking into account the particular structure may give a misleading impression of the actual uncertainty the decision makers face.

There are many ways of building in structured uncertainty, and the distinctions between cases are not always clear. For example, consider the same nominal model (1) as above, but suppose that instead of the unstructured perturbations (3) the uncertainty is instead solely in the values of the parameters A and B. Thus we can represent the parametric perturbed models as:

\[ x_{t+1} = (A + \hat{A}) x_t + (B + \hat{B}) i_t + C \epsilon_{t+1} \]

(6)

for some matrices \( \hat{A} \) and \( \hat{B} \). Of course it's possible to rewrite (6) as a version of (3) with:

\[ w_{t+1} = \hat{A} x_t + \hat{B} i_t \]

(7)

so in principle parametric perturbations are just a special case of the unstructured uncertainty. However what makes a substantive difference is how uncertainty is measured, that is whether we restrict \( w_{t+1} \) as in (4) or whether we restrict the parameters \( \hat{A} \) and \( \hat{B} \), say by bounding them in a confidence ellipsoid around the nominal model. Moreover, as (7) makes clear the differences between the uncertainty
measurements will depend on the actual control rule $i_t$ in place. Onatski and Williams (2003) provide an example of a simple estimated model where the uncertainty specifications matter dramatically for outcomes. In particular, the optimal policy for the largest possible unstructured uncertainty set (that is for the minimal value of $\theta$) leads to instability for relatively small parametric perturbations. Thus the particular structure and measurement of uncertainty can have important implications for decisions. (Peterson, James and Dupuis, 2000, modify the unstructured approach described above to deal with structured uncertainty by separating the entropy penalty for unstructured perturbations from a different penalization for structured perturbations.)

Some economic applications with structured uncertainty include the following:

1. The simplest cases are uncertainty sets with discrete possible models. Some examples include: Levin and Williams (2003), who consider both Bayesian and minimax approaches; Cogley and Sargent (2005); and Svensson and Williams (2006) and who focus on a Bayesian approach, and the recent work of Hansen and Sargent (2006), who have built this type of structure into their robust approach.

2. Another common form is parameter uncertainty within a fully specified model. Brainard (1967) is the classic reference from a Bayesian perspective with many references in this line, while Giannoni (2002) and Chamberlain (2000) consider minimax approaches.

3. Somewhat more broad are cases with different parametric model specifications. For example this includes uncertainty about dynamics (lags and leads), variables which may enter, uncertainty about data quality, and other features which are built into parametric extensions of the nominal model. Examples include the model error modelling approach of Onatski and Williams (2003) and the empirical specifications of Brock, Durlauf and West (2003).

4. Finally, the model sets may be nonparametric but structured in particular ways. For example, Onatski and Stock (2002) consider different structured types of uncertainty such as linear time-invariant perturbations, nonlinear time-varying perturbations, and perturbations which only enter particular parts of the model. Other examples include nonparametric specifications of uncertainty which differs across frequencies as in Onatski and Williams (2003) and Brock and Durlauf (2005).

robust estimators in econometrics

P. Šižek and W. Härdle
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Econometric data are often obtained under conditions that cannot be well controlled, and so partial departures from the model assumptions in use (data contamination) occur relatively frequently. To address this, we first introduce concepts of robust statistics for qualifying and quantifying sensitivity of estimation methods to data contamination as well as important approaches to robust estimation. Later, we discuss how robust estimation methods have been adapted to various areas of econometrics, including time series analysis and general GMM-based estimation.

Keywords

breakdown point; data contamination; generalized method of moments; heteroscedasticity; influence function; instrumental variables; least squares; linear regression; maximum likelihood; maximum-bias curve; measurement errors; M-estimation; Newton–Raphson procedure; nonlinear models; probability distribution; qualitative and quantitative robustness; quantile regression; random variables; robust econometrics; robust statistics; S-estimation; simultaneous equations models; time-series analysis

Article

Econometrics often deals with data under, from the statistical point of view, non-standard conditions such as heteroscedasticity or measurement errors, and the estimation methods thus need either to be adapted to such conditions or to be at least insensitive to them. Methods insensitive to violation of certain assumptions – for example, insensitive to the presence of heteroscedasticity – are in a broad sense referred to as ‘robust’ (for example, robust to heteroscedasticity). On the other hand, there is also a more specific meaning of the word ‘robust’, which stems from the field of robust statistics. This latter notion defines robustness rigorously in terms of the behaviour of an estimator both at the assumed (parametric) model and in its neighbourhood in the space of probability distributions. Even though the methods of robust statistics have been used only in the simplest settings, such as estimation of location, scale or linear regression for a long time, they have motivated a range of new econometric methods, which we focus on in this article.

The concepts and measures of robustness are introduced first (Section 1), followed by the most common types of estimation methods and their properties (Section 2). Various econometric methods based on these common estimators are discussed in Section 3, covering tasks from time-series regression over.
GMM estimation to simulation-based methods.

1 Measures of robustness

Robustness properties can be formulated within two frameworks: qualitative and quantitative robustness. **Qualitative robustness** is concerned with the situation in which the shape of the underlying (true) data distribution deviates slightly from the assumed model. It focuses on questions like stability and performance loss over a family of such slightly deviating distributions. **Quantitative robustness** is involved when the sensitivity of estimators to a proportion of aberrant observations is studied.

A simple example can make this clear. Suppose one has collected a sample on an individual's income (after say ten years of schooling) and one is interested in estimating the mean income. If \( \{x_i\}_{i=1}^n \) denotes the logarithm of this data and we suppose that they have a cumulative distribution function (cdf) \( F \), assumed to be \( N(\mu, \sigma^2) \), the maximum likelihood estimator (MLE) is \( \bar{x} = \frac{1}{n} \sum_{i=1}^n x_i \), where \( F_n(u) = \frac{1}{n} \sum_{i=1}^n I(x_i \leq u) \), and \( \mu = \int u dF(u) = T(F) \). Qualitative robustness asks here the question: how well will \( \mu \) be estimated if the true distribution is in some neighbourhood of \( F \)? Quantitative robustness would concentrate on the question: will \( T(F_n) \) be bounded if some observations \( x_i \to \infty \)? In fact, the latter question is easy to answer: if \( x_i \to \infty \) for some \( i \), \( T(F_n) = \bar{x} \to \infty \) as well. So we can say here in a loose sense that \( \bar{x} \) is not quantitatively robust.

1.1 Formalities

In the following we present a mathematical set-up that allows us to formalize our thoughts on robustness. The notion of the sensitivity of an estimator \( T \) is put into theory by considering a model characterized by a cdf \( F \) and its neighbourhood \( \mathcal{G} \): distributions \( (1-\varepsilon)F + \varepsilon G \), where \( \varepsilon \in (0,1/2) \) and \( G \) is an arbitrary probability distribution, which represents data contamination. Hence, not all data necessarily follow the pre-specified distribution, but the \( \varepsilon \)-part of data can come from a different distribution \( G \). If \( H \in \mathcal{G} \), the estimation method \( T \) is then judged by how sensitive or robust the estimates \( T(H) \) are to the size of \( \mathcal{G} \), or alternatively, to the distance from the assumed cdf \( F \). Two main concepts for robust measures analyse the sensitivity of an estimator to infinitesimal deviations, \( \varepsilon \to 0 \), and to finite (large) deviations, \( \varepsilon > 0 \), respectively. Despite generality of the concept, easy interpretation and technical difficulties often limit our choice to point-mass distributions (Dirac measures) \( G = \delta_x, x \in \mathbb{R} \), which simply represents an (erroneous) observation at point \( x \in \mathbb{R} \). This simplification is also used in the following text.

1.2 Qualitative robustness

The influence of infinitesimal contamination on an estimator is characterized by the **influence function**, which measures the relative change in estimates caused by an infinitesimally small amount \( \varepsilon \) of contamination at \( x \) (Hampel et al., 1986). More formally,

\[
IF(x; T, F) = \lim_{\varepsilon \to 0} \frac{\frac{T((1-\varepsilon)F + \varepsilon \delta_x) - T(F)}{\varepsilon}}.
\]
For each point \( x \), the influence function reveals the rate at which the estimator \( T \) changes if a wrong observation appears at \( x \). In the case of sample mean \( \bar{x} = T(F_n) \) for \( \{x_i\}_{i=1}^n \), we obtain

\[
IF(x; T, F_n) = \lim_{\varepsilon \to 0} \left[ (1 - \varepsilon) \int u dF_n(u) + \varepsilon \int u d\delta_x(u) - \int u dF_n(u) \right] / \varepsilon = \lim_{\varepsilon \to 0} \left[ - \int u dF_n(u) + \int u d\delta_x(u) \right] = x - \bar{x}.
\]

The influence function allows us to define various desirable properties of an estimation method. First, the largest influence of contamination on estimates can be formalized by the *gross-error sensitivity*,

\[
\gamma(T, F) = \sup_{x \in \mathbb{R}} IF(x; T, F),
\]

which under robustness considerations is finite and small. Even though such a measure can depend on \( F \) in general, the qualitative results (for example, \( \gamma(T, F) \) being bounded) are typically independent of \( F \). Second, the sensitivity to small changes in data, for example moving an observation from \( x \) to \( y \), can be measured by the *local-shift sensitivity*

\[
\lambda(T, F) = \sup_{x \neq y} \frac{\|IF(x; T, F) - IF(y; T, F)\|}{\|x - y\|}.
\]

Also, this quantity should be relatively small since we generally do not expect that small changes in data cause extreme changes in values or sensitivity of estimates. Third, as unlikely large or distant observations may represent data errors, their influence on estimates should become zero. Such a property is characterized by the *rejection point*,

\[
\rho(T, F) = \inf_{r > 0} \left\{ r; IF(x; T, F) = 0, \|x\| \geq r \right\}.
\]
which indicates the non-influence of large observations.

1.3 Quantitative robustness

Alternatively, the behaviour of the estimator $T$ can be studied for any finite amount $\varepsilon$ of contamination. The most common property looked at in this context is the estimator's bias $b(T, H) = E_H(T(H)) - E_F(T(F))$, which measures a distance between the estimates for clean data, $T(F)$, and contaminated data, $T(H)$, $H \in G, \varepsilon, C$. The corresponding maximum-bias curve measures the maximum bias of $T$ on $G, \varepsilon, C$ at any $\varepsilon$:

$$B(\varepsilon, T) = \sup_{x \in \mathbb{R}} b\left\{ T, (1 - \varepsilon)F + \varepsilon \delta_x \right\}.$$

Although the computation of this curve is rather complex, Berrendero and Zamar (2001) provide general methodology for its computation in the context of linear regression.

The maximum-bias curve is not only useful on its own, but allows us to define further scalar measures of robustness. The most prominent is the breakdown point (Hampel, 1971), which is defined as the smallest amount $\varepsilon$ of contamination that can cause an infinite bias:

$$\varepsilon^*(T) = \inf_{\varepsilon \geq 0} \left\{ \varepsilon : B(\varepsilon, T) = \infty \right\}.$$

The intuitive aim of this definition specifies the breakdown point $\varepsilon^*(T)$ as the smallest amount of contamination that makes the estimator $T$ useless. Note that in most cases $\varepsilon^*(T) \leq 0.5$ (He and Simpson, 1993). This definition and the upper bound, however, apply only in simple cases, such as location or linear regression estimation (Davies and Gather, 2005). The most general definition of breakdown point formalizes the idea of ‘useless’ estimates in the following way: an estimator is said to break down if, under contamination, it is not random anymore, or, more precisely, it can achieve only a finite set of values (Genton and Lucas, 2003). This definition is based on the fact that estimates are functions of observed random samples and are thus random quantities themselves unless they fail. Although the latter definition includes the first one, the latter one may generally depend on the underlying model $F$, for example in time-series context.

2 Estimation approaches
Denote by $F_n$ an empirical distribution function (edf) corresponding to a sample $(x_i)_{i=1}^n \in \mathbb{R}$ drawn from a model based on probability distribution $F$. Most estimation methods can be defined as an extremum problem, minimizing a contrast $\int h(z, \theta) dF(z)$ over $\Theta$ in a parameter space, or as a solution of an equation, $\int g(z, \theta) dF(z) = 0$ in $\Theta$. The estimation for a given sample utilizes finite-sample equivalents of these integrals, $\int h(z, \theta) dF_n(z)$ and $\int g(z, \theta) dF_n(z)$, respectively.

Consider the pure location model $X_i = \mu + \sigma \varepsilon_i$, $i = 1, \ldots, n$, with a known scale $\sigma$ and $\varepsilon \sim F$. The cdf of $X$ is then $F((x-\mu)/\sigma)$. With a quadratic contrast function $h(x, \theta) = (x-\theta)^2$, the estimation problem is to minimize $\int (x-\theta)^2 dF((x-\mu)/\sigma)$ with respect to $\theta$. For known $F$, this leads to $\theta = \mu$ and one sees that, without loss of generality, one can assume $\mu = 0$ and $\sigma = 1$. For the sample $(x_i)_{i=1}^n$ characterized by edf $F_n$, the location parameter $\mu$ is estimated by

$$\hat{\mu} = \arg \min_{\theta} \int (x-\theta)^2 dF_n(x) = n^{-1} \sum_{i=1}^n x_i = \bar{x}.$$ 

Note that for $g(x, \theta) = x-\theta$, the parameter $\mu$ is the solution to $\int g(x, \theta) dF(x) = 0$. The estimator may therefore be alternatively defined through $\mu = T(F) = \int x dF(F)$.

As indicated in the introduction, this standard estimator of location performs unfortunately rather poorly under the sketched contamination model. Estimating a population mean by the least squares (LS) or sample mean $\bar{x} = T(F_n)$ has the following properties. First, the influence function (1)

$$IF(x; T, F) = \lim_{\varepsilon \to 0} \frac{T((1-\varepsilon)F+F\varepsilon x) - T(F)}{\varepsilon} = \lim_{\varepsilon \to 0} \frac{((1-\varepsilon)\int u dF(u) + \varepsilon x) - \int u dF(u)}{\varepsilon} = \lim_{\varepsilon \to 0} \frac{-1}{-\varepsilon} \left\{ -\varepsilon \int u dF(u) + \varepsilon x \right\} = x - \int u dF(u) = x - T(F).$$

Hence, the gross-error sensitivity (2) $\gamma(T, F) = \infty$, the local-shift sensitivity (3) $\Delta(T, F) = 0$, and the rejection point (4) $\rho(T, F) = \infty$. Second, the maximum-bias (5) is infinite for any $\varepsilon > 0$ since

$$\sup_{x \in \mathbb{R}} \left\| T((1-\varepsilon)F+F\varepsilon x) - T(F) \right\| = \sup_{x \in \mathbb{R}} \left\| -\varepsilon T(F) + \varepsilon x \right\| = \infty.$$ 

Consequently, the breakdown point (6) of the sample mean $\bar{x} = T(F_n)$ is zero, $\epsilon^*(T) = 0$. Thus, none of robustness measures characterizing the change of $T$ under contamination of data (even infinitesimally small) is finite. This behaviour,
robust estimators in econometrics: The New Palgrave Dictionary of Economics

typical for LS-based methods, motivated alternative estimators that have the desirable robust properties. In this section, the $M$-estimators, $S$-estimators and $\tau$-estimators are discussed as well as some extensions and combination of these approaches. Even though there is a much wider range of robust estimation principles, we focus on those already studied and adopted in various areas of econometrics.

2.1 M-estimators

To achieve more flexibility in accommodating requirements on robustness, Huber (1964) proposed the $M$-estimator by considering a general extremum estimator based on $\int \rho(z, \theta) dF(z)$, thus minimizing $\int \rho(z, \theta) dF_N(z)$ in finite samples. Providing that the first derivative $\psi(z, \theta) = \partial \rho(z, \theta) / \partial \theta$ exists, an $M$-estimator can be also defined by an implicit equation $\int \psi(z, \theta) dF_N(z) = 0$.

This extremely general definition is usually adapted to a specific estimation problem such as location, scale or regression estimation. In a univariate location model, $F(z)$ can be parameterized as $F(z - \theta)$ and hence one limits $\rho_0(z, \theta)$ and $\psi_0(z, \theta)$ to $\rho(z - \theta)$ and $\psi(z - \theta)$. In the case of scale estimation, $F(z) = F(z / \theta)$ and consequently $\rho(z, \theta) = \rho(z / \theta)$ and $\psi(z, \theta) = \psi(z / \theta)$. In linear regression, $z = (x, y)$ and a zero-mean error term $\varepsilon = y - x^T \theta$. Analogously to the location case, one can then consider $\rho(z, \theta) = \rho(y - x^T \theta)$ and $\psi(z, \theta) = \psi(y - x^T \theta)$, or more generally, $\rho(z, \theta) = \rho(y - x^T \theta, x)$ and $\psi(z, \theta) = \psi(y - x^T \theta, x)$ ($GM$-estimators). Generally, we can express $\rho(z, \theta)$ as $\rho_\eta(z, \theta)$, $\psi_\eta(z, \theta)$, where $\eta(z, \theta) \sim F$.

Some well-known choices of univariate objective functions $\rho$ and $\psi$ are given in Table 1; functions $\rho(t)$ are usually assumed to be non-constant, non-negative, even and continuously increasing in $|t|$. This documents flexibility of the concept of $M$-estimators, which include LS and quantile regression as special cases.

On the other hand, many of the $\rho$ and $\psi$ functions in Table 1 depend on one or more constants $a$, $b$, $c \in \mathbb{R}$. If an estimator $T$ is to be invariant to the scale of data, one can apply the estimator to rescaled data, that is, to minimize $\int \rho\left((z - \theta)/s\right) dF_N(z)$ or to solve $\int \psi\left((z - \theta)/s\right) dF_N(z) = 0$ for a scale estimate $s$ like the median absolute deviation (MAD). Alternatively, one may also estimate parameters $\theta$ and scale $s$ simultaneously by considering...
Let us now turn to the question how the choice of functions $\rho$ and $\psi$ determines the robust properties of $M$-estimators. First, the influence function of an $M$-estimator can generally depend on several quantities such as its asymptotic variance or the position of explanatory variables in the regression case, but the influence function is always proportional to function $\psi(z,b)$. Thus, the finite gross-error sensitivity, $\gamma(T,F) < \infty$, requires bounded $\psi(t)$ (which is not the case with LS). Similarly, the finite rejection point, $\rho(T,F) < \infty$, leads to $\psi(t)$ being zero for all sufficiently large $t$ (the $M$-estimators defined by such a $\psi$-function are called redescending). Hampel et al. (1986) shows how, for a given bound on $\gamma(T,F)$, one can determine the most efficient choice of $\psi$ function (for example, the skipped median, $\psi(t) = \text{sign}(t)l(|t| < K)$, $K > 0$, in the location case).

More formally, the optimality of $M$-estimators in the context of qualitative robustness can be studied by the asymptotic relative efficiency (ARE) of an estimator $\hat{\theta}$ relative to another estimator $\hat{\theta}'$:

$$\text{ARE}(\hat{\theta}, \hat{\theta}') = \frac{\text{as. var}(\hat{\theta})}{\text{as. var}(\hat{\theta}')}$$

For example, at the normal distribution with $\hat{\theta}$ and $\hat{\theta}'$ being the least absolute deviation (LAD) and LS estimators, ARE equals $2/\pi \approx 0.64$. Under the Student cdf $t_5$, the ARE of the two estimators climbs up to $\approx 0.96$. For Huber’s $M$-estimator, we see that its limit cases are the median for $\xi \to 0$ and the mean for $\xi \to \infty$. At the normal distribution and for $\xi = 1.345$, we have ARE of about 0.95. This means that this $M$-estimator is almost as efficient as MLE, but does not lose so drastically in performance as the standard mean under contamination because of the bounded influence function.

Whereas the influence function of $M$-estimators is closely related to the choice of its objective function, the global robustness of $M$-estimators is in a certain sense independent of this choice. Maronna, Bustos and Yohai (1979) showed in linear regression that the breakdown point of $M$-estimators is bounded by $1/p$, where $p$ is the number of estimated parameters. As a remedy, several authors proposed one-step $M$-estimators that are defined, for example, as the first step of the iterative Newton–Raphson procedure, used to minimize $\int \rho(z, \theta)dF(z)$, starting from initial robust estimators $\hat{\theta}^0$ of parameters and $\hat{\xi}^0$ of scale (see Welsh and Ronchetti, 2002, for an overview). Possible initial estimators can be those discussed in subsections 2.2 and 3.3. For example for an M-estimator of location $\hat{\theta}$ defined by a function $\psi(x, \theta) = \psi(x - \theta)$, its one-step counterpart can be defined at sample $\{x_i\}^{n}_{i=1}$ by
where $\hat{\theta}^0$ and $\hat{\varsigma}^0$ represent initial robust estimators of location and scale like the median and MAD, respectively. Such one-step estimators, under certain conditions on the initial estimators, preserve the breakdown point of the initial estimators, and at the same time have the same first-order asymptotic distribution as the original M-estimator (Simpson, Ruppert and Carroll, 1992; Welsh and Ronchetti, 2002). Further development of such ideas includes an adaptive choice of parameters of function $\psi$ in the iterative step (Gervini and Yohai, 2002).

2.2 S-estimators

An alternative approach to $M$-estimators achieving high breakdown point (HBP) was proposed by Rousseeuw and Yohai (1984). The S-estimators are defined by minimization of a scale statistics $s^2(z, b) = s\{\eta(z, b)\}$ defined as the $M$-estimate of scale,

$$\int \rho[\eta(z, b) / s(\eta(z, b))] dF_n(z) = K = \int \rho(t) dF(t),$$

at the model distribution $F$; the functions $\rho$ and $\eta$ are those defining $M$-estimators in subsection 2.1. More generally, one can define S-estimators by means of any scale-equivariant statistics $s^2$, that is, $s\{c\eta(z, b)\} = |c|s\{\eta(z, b)\}$. Under this more general definition, S-estimators include as special cases LS and LAD estimators. Further, they encompass several well-known robust methods including least median of squares (LMS) and least trimmed squares (LTS): whereas the first defines the scale statistics $s^2\{\eta(z, b)\}$ as the median of squared residuals $\eta(z, b)$, the latter uses the scale defined by the sum of $h$ smallest residuals $\eta(z, b)$. In order to appreciate the difference to $M$-estimators, it is worth pausing for a moment and to present LMS, the most prominent representative of S-estimators, in the location case:

$$\text{arg min } \text{med} \left\{ (x_1 - \theta)^2, \ldots, (x_n - \theta)^2 \right\}.$$

Due to its definition, the S-estimators have the same influence function as the $M$-estimator constructed from the same function $\rho$. Contrary to $M$-estimators, they can achieve the highest possible breakdown point $\varepsilon^* = 0.5$. For example, this is the case of LMS and LTS. For Gaussian data, the most efficient (in the sense of ARE (7)) among the S-estimators with $\varepsilon^* = 0.5$ is, however, the one corresponding to $K = 1.548$ and $\rho$ being the Tukey
biweight function (see Table 1). Given the HBP of S-estimators, their maximum-bias behaviour is of interest too. Although it depends on the function \( \rho \) and constant \( K \) (Berrendero and Zamar, 2001), Yohai and Zamar (1993) proved that LMS minimizes maximum bias among a large class of (residual admissible) estimators, which includes most robust methods. An important shortcoming of HBP S-estimation is, however, its low ARE: under Gaussian data, efficiency relative to LS varies from zero per cent to 27 per cent. Thus, S-estimators are often used as initial estimators for other, more efficient methods. Nevertheless, if an S-estimator is not applied directly to sample observations, but rather to the set of all pairwise differences of sample observations, the resulting generalized S-estimator exhibits higher relative efficiency for Gaussian data, while preserving its robust properties (Croux, Rousseeuw and Hossjer, 1994; Stromberg, Hossjer and Hawkins, 2000).

2.3 \( \tau \)-estimators

The S-estimators improve upon M-estimators in terms of their breakdown-point properties, but at the cost of low Gaussian efficiency. Although one-step M-estimators based on an initial S-estimate can remedy this deficiency to a large extent, their exact breakdown properties are not known. One alternative approach, proposed by Yohai and Zamar (1988), extends the principle of S-estimation in the following way. Assuming that \( \rho_1 \) and \( \rho_2 \) are non-negative, even, and continuous functions, the M-estimate of scale can be defined as in the case of S-estimation,

\[
\int \rho_1 \left( \eta(z, \theta) / s \left( \eta(z, \theta) \right) \right) dF_n(z) = K = \int \rho_1(t) dF(t).
\]

Next, the \( \tau \)-estimate of scale is defined by

\[
\tau^2(z, \theta) = \left( \eta(z, \theta) \right) \int \rho_2 \left( \eta(z, \theta) / s(\eta(z, \theta)) \right) dF_n(z)
\]

and the corresponding \( \tau \)-estimator of parameters \( \Theta \) is then defined by minimizing the \( \tau \)-estimate of scale, \( \tau^2(z, \theta) \).

As a generalization of S-estimation, the \( \tau \)-estimators include S-estimators as a special case for \( \rho_1 = \rho_2 \) because then \( \tau^2(x, \theta) = \theta s^2(z, \theta) \). On the other hand, if \( \rho_2(t) = t^2 \), \( \tau^2(z, \theta) = \int \eta^2(z, \theta) dF_n(z) \) is just the standard deviation of model residuals. Compared with S-estimators, the class of \( \tau \) estimators can improve in terms of relative Gaussian efficiency because its breakdown point depends only on function \( \rho_1 \), whereas its asymptotic variance is a function of both \( \rho_1 \) and \( \rho_2 \). Thus, \( \rho_1 \) can be defined to achieve the breakdown point equal to 0.5 and \( \rho_2 \) consequently adjusted to reach a pre-specified relative efficiency for Gaussian data (for example, 95 per cent).
The concepts and methods of robust estimation discussed in Sections 1 and 2 are typically proposed in the context of a simple location or linear regression models, on the assumption of independent, continuous and identically distributed random variables. This, however, rarely corresponds to assumptions typical for most econometric models. In this section, we therefore present an overview of developments and extensions of robust methods to various econometric models. As the $M$-estimators are closest to the commonly used LS and MLE, most of the extensions employ $M$-estimation. The HBP techniques are not that frequently found in the economics literature (Zaman, Rousseeuw and Orhan, 2001; Sapra, 2003) and are mostly applied only as a diagnostic tool.

In the rest of this section, robust estimation is first discussed in the context of models with discrete explanatory variables, models with time-dependent observations, and models involving multiple equations. Later, robust alternatives to general estimation principles, such as MLE and generalized method of moments (GMM), are discussed. Before doing so, let us mention that dangers of data contamination are not studied only from the theoretical point of view. There is a number of studies that check the presence of outliers in real data and their influence on estimation methods. For example, there is evidence of data contamination and its adverse effects on LS and MLE in the case of macroeconomic time series (Balke and Fomby, 1994; Atkinson, Koopman and Shephard, 1997), in financial time series (Sakata and White, 1998; Franses, van Dijk and Lucas, 2004), marketing data (Franses, Kloek and Lucas, 1999), and many other areas. These adverse effects include biased estimates, masking of structural changes, and creating seemingly nonlinear structures, for instance.

### 3.1 Discrete variables

To achieve a HBP, many robust methods such as LMS often eliminate a large portion of observations from the calculation of their objective function. This can cause non-identification of parameters associated with categorical variables. For example, having data on income $\{ Y_i \}_{i=1}^n$ of men and women, where gender is indicated by $\{ d_i \}_{i=1}^n \in \{ 0, 1 \}$, one can estimate the mean income of men and women by a simple regression model $Y_i = a + bd_i$. If a HBP method such as LMS or LTS is used to estimate the model and it eliminates a large portion of observations from the calculation (for example, one half of them), the remaining data could easily contain only income of men or only income of women, and consequently the mean income of one of the groups could not be then identified. Even though this seems unlikely in our simple example, it becomes more pronounced as the number of discrete variables grows (see Hubert and Rousseeuw, 1997, for an example).

A common strategy employs a robust estimator with a HBP for a model with only continuous variables, and using this initial estimate, the model with all variables is estimated by an $M$-estimator. Such a combined procedure preserves the breakdown point of the HBP estimator: even though a misclassified values of categorical explanatory variables can bias the estimates, this bias will be bounded in common models as the categorical variables are bounded as well. See Hubert and Rousseeuw (1997) and Maronna and Yohai (2000), who combine an initial $S$-estimator with an $M$-estimator.

### 3.2 Time series

In time series, there are several issues not addressed by the standard theory of robust estimation because of time-dependency of observations. First, the asymptotic behaviour of various robust methods has to be established; see Koenker and Machado (1999) and Koenker and Xiao (2002) for $L_1$ regression; Künsch (1984); and Bai and Wu (1997) for $M$-estimators and Sakata and White (2001), Zinde-Walsh (2002) and •iz•ek (2006) for various $S$-type estimators. In these cases, the results are usually established for general nonlinear models.

Second, the effects of data contamination are more complex and widespread due to time dependency: an error in one observation is transferred, by means of a model, to others close in time. The possible effects of outliers in time series are elaborated by Chen and Liu (1993) and Tsay, Pena and...
Pankratz (2000), for instance. The first work also offers a sequential identification of outliers (an alternative procedure based on $\tau$ -estimators is offered by Bianco et al., 2001). Consequently, the robust properties in time series differ from those experienced in cross-sectional data. For example, the breakdown point is asymptotically zero in the case of $M$-estimators (Sakata and White, 1995) and can be much below 0.5 for various $S$-estimators (Genton and Lucas, 2003).

A further issue specific to time series is testing for stationarity of a series. Effects of outliers are in this respect similar to those of neglected structural changes. To differentiate between random outliers and real structural changes, robust tests for change-point detection have been proposed by Gagliardini, Trojani and Urga (2005) and Fiteni (2002; 2004); the last of these papers uses $\tau$ -estimation. The asymptotics of $M$-estimators under unit-root assumption and the corresponding tests have been established, for example, by Lucas (1995), Koenker and Xiao (2004), and Haldrup, Montans and Sanso (2005). An early reference is Franke, Härdle and Martin (1984).

3.3 Multivariate regression

An important application of robust methods in economics concerns the multivariate regression case. This is relatively straightforward with exogenous explanatory variables only, see Koenker and Portnoy (1990), Bilodeau and Duchesne (2000), and Lopuhaä (1992) for the $M$-, $S$- and $\tau$ -estimation, respectively. Estimating general simultaneous equations models has to mimic either three-stage LS or full information MLE (Marrona and Yohai, 1997). Whereas Koenker and Portnoy (1990) follow with the weighted LAD the first approach, Krishnakumar and Ronchetti (1997) use $M$-estimation together with the second strategy.

3.4 General estimation principles

There are naturally many more model classes for which one can construct robust estimation procedures. Since most econometric models can be estimated by means of MLE or GMM, it is however easier to concentrate on robust counterparts of these two estimation principles. There are other estimation concepts, such as nonparametric smoothing, that can employ robust estimation (Härdle, 1982), but they go beyond the scope of this article. First, recent contributions to robust MLE can be split to two groups. One simply defines a weighted maximum likelihood, where weights are computed from an initial robust fit (Windham, 1995; Markartou, Basu and Lindsay, 1997). Alternatively, some erroneous observations can be excluded completely from the likelihood function (Clarke, 2000; Marazzi and Yohai, 2004). This approach requires existence of an initial robust estimate, and thus it is not useful for models for which there are no robust methods available. The second approach is motivated by the $S$-estimation, namely, LTS, and defines the maximum trimmed likelihood as an estimator maximizing the product of the $h$ largest likelihood contribution, that is, those corresponding only to $h$ most likely observations (Hadi and Luceño, 1997). This estimator has been studied mainly in the context of generalized linear models (Müller and Neykov, 2003), but its consistency is established in a much wider class of models ($\tilde{n}\v{z}ek$, 2004).

Second, more widely used GMM has also attracted attention from its robustness point of view. A special case – instrumental variable estimation – has been studied, for example, by Wagenvoor and Waldman (2002) and Kim and Muller (2007). See also Chernozhukov and Hansen (2006) for instrumental variable quantile regression. More generally, Ronchetti and Trojani (2001) have proposed an $M$-estimation-based generalization of GMM, studied its robust properties, and designed corresponding tests. This work became a starting point for others, who have extended the methodology of Ronchetti and Trojani (2001) to robustify simulation-based methods of moments (Genton and Ronchetti, 2003; Ortelli and Trojani, 2005).

Article

Rogers was educated at King's College London, and Magdalen College, Oxford. From 1859 until his death he held the first Tooke Professorship of Statistics and Economic Science at King's College London. In 1862 he was elected Drummond Professor of Political Economy in the University of Oxford, a post he lost in 1868 largely because of his outspoken radical views, but to which he was re-elected in 1888. He was ordained but abandoned the clerical profession. From 1880 to 1886 he served as a rather inconspicuous member of the House of Commons.

His chief work is his monumental *History of Agriculture and Prices*, where he did much to turn economic history into the field of distribution and attempted to use more exact methods in economic historical investigations on a large scale. His work is marred by his casual deductions. He argued for a high standard of living of the English labourer during the Middle Ages and explained the subsequent deterioration by legislative interference by the landowners controlling the government. Politically, he was greatly influenced by his friend and brother-in-law Richard Cobden. He was firmly opposed to extensive government intervention. He did however support trade unions as providing the remedy for nearly all social ills. His advocacy of laissez-faire separates him from the rest of the English Historical School, his allies in attacking theoretical economics in looking to economic history as a realistic foundation for the proper understanding and solution of contemporary social and economic problems.

Roos, Charles Frederick (1901–1958)

Karl A. Fox
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
Econometric Society; econometrics; mathematical economics; Roos, C. F.

Article

Born on 18 May 1901, in New Orleans, Roos completed his Ph.D. in mathematics at Rice Institute in 1926. Influenced directly by his supervisor Evans (1922; 1924; 1930) and indirectly by Volterra, his main interests in graduate work were the calculus of variations, integral equations, and applications of those areas of mathematics to problems in dynamic economics. Although he published several brilliant articles (Roos, 1925; 1927a; 1927b; 1927c; 1928; 1930), Roos found no journal which would readily accept manuscripts in which he combined economics, mathematics and sometimes statistics at suitably advanced levels (cf. Roos, 1934, p. xiii). Spurred by similar frustrations, Frisch and Roos jointly took the initiative which led to creation of the Econometric Society in 1930 (of which Roos became President in 1948) and publication of its journal, *Econometrica*, from 1933 on.

In 1930 Roos set out to write a treatise on dynamic economics; he published an important book under that title in 1934. It was reviewed enthusiastically by Tintner (1936) and uncomprehendingly by Freeman (1935). *Dynamic Economics* (1934) is a brilliant combination of mathematical economic theory and applied econometrics. Roos's mathematical approach inspired Tintner to write a dozen articles on dynamic economic theory (for example, Tintner, 1938).

Roos held a series of administrative positions during 1931–7 and published a major book on *NRA Economic Planning* (1937). In 1938 he founded an econometric consulting firm in New York and directed it until his death. Examples of his later work are Roos and von Szeliski (1939a; 1939b) and Roos (1955; 1957). He died in Milwaukee on 7 January 1958.

Hotelling (1958) describes Roos as 'a unique and outstanding figure’, while Davis (1958) presents a complete list of his writings.

Article

Roscher was born in Hannover into a well-established civil service family. He studied history and political science in Göttingen and Berlin. In 1840 he became lecturer in both subjects at Göttingen, in 1843 he was appointed extraordinary professor of political economy, and in the next year was promoted professor. In 1848 he transferred to Leipzig, where he taught for the rest of his life. Roscher had a Protestant background and was deeply religious, adhering to a rather ‘primitive form of religious belief’ (Max Weber, 1903–6).

Roscher may be considered as one of the most important German economists of his time. He was one of the founders and the leading exponent of the German ‘older’ Historical School. He did not develop any new theory: his main contribution to political economy lay in the field of method. He adhered to what he called the ‘historical-physiological method’, as opposed to the ‘idealistic method’ (1842; 1854–94, vol. 1, pp. 43–56). This inductive method intended to provide a description of the actual course of economic development and of real economic life. Thus, Roscher tried to analyse laws of economic development by comparing the history of different people and nations and showing analogies in stages of their development. The emphasis was on historical relativism: economic behaviour depended to a large extent on the specific national and historic conditions of the different people and nations. This implied that a nation had to be regarded as a whole, as an ‘organic unity’, and not as the mere sum of individuals. This was opposed to what Roscher called the ‘idealistic method’, which intended to provide an ideal picture, logically derived from abstract principles, of the functioning of the economic system. An example of this was the classical economists’ deduction of economic laws from a system of hypotheses. Although Roscher emphasized that in economic analysis there existed generally no definite causal relationships but reciprocal ones, he did not reject the existence of ‘laws of motion’ within economic life. However, these laws were distinct from laws of natural science in that they dealt with free human

beings gifted with reason and hence with changing motives for action (1854–94, vol. 1, pp. 26–9). Roscher was closer to the theoretical system of the classics than the exponents of the ‘younger’ historical school. He tended to regard it as the appropriate system of analysis of the current stage of economic development. He only modified and supplemented it with a careful historical analysis, but he may still be regarded as being in the classical tradition.

The first volume of Roscher's main work, System der Volkswirtschaft (1854–94: 1854) still looked very much like a traditional textbook. It analysed essentially the same topics as the classical economists – production, distribution and prices. Roscher was already strongly influenced by supply and demand approaches, but still determined the exchange value of a commodity by its cost of production. His theory of rent was Ricardian and his thinking about population development followed Malthusian patterns. Differing from classical textbooks, Roscher supplemented the theoretical analysis with a historical description – the reader finds the history of rent, interest and wages, of population development, of the prices of necessary and luxury commodities, and of luxury in general. Roscher accepted the classical notion of individual self-interest as a central axiom of modern economic behaviour, but he did not follow the classical patterns in deriving his economic principles from this assumption. As a result of his religious beliefs, he included human conscience as a regulating mechanism into his analysis of the role of self-interest (1854–94, vol. 1, pp. 20–3).

The other four volumes of the System der Volkswirtschaft (1859; 1881; 1886; 1894), which may be perceived as his main contribution to applied economics, were even more historically oriented and focused on agriculture, trade and industry, public finance, social policy and poor relief. Roscher classified economic development into stages of maturity. The economic factors that govern the development of nations were land, labour and capital which subsequently dominated the different stages (1861, ch. 1). Later, Roscher presented a more detailed analysis of stages of political and societal development (1892) on the basis of a classification of the different forms of government during history: early patriarchal kingdom, aristocracy of knights and priests, absolute monarchy, democracy. The latter then degenerated into a plutocracy, which is followed by a military dictatorship Roscher called ‘Caesarismus’. Roscher did not systematically attempt an integration of his theory of political development and the stages of economic evolution.

He wrote several contributions on the history of economic thought. His compendium on the history of political economy in Germany (1874) was his most outstanding work and has remained important. Roscher may be regarded as the most eminent historian of cameralism and early German political economy. His treatise on economic problems of the location of large towns (1871) was an original contribution to economic theory.

Roscher supported German imperialism. In order to secure raw materials and markets for German goods, as well as to relieve the national labour market and prevent social unrest, he advocated an expansive German colonial policy, especially towards Eastern Asia, where he saw Germany's colonial future (1885). He was a conservative but he remained all his life unaffiliated to any political party or group.

Abstract

Sherwin Rosen made fundamental contributions in equilibrium theory, human capital theory, income distribution theory and investment theory. One characteristic feature of Rosen's work is the minimal use of heterogeneity of individuals. His work explains price disparities, differential earnings, and investment cycles. Underlying differences in characteristics produce price differences. Human capital theory is enriched by characterization of accumulation beyond schooling. Skewed income distributions arise from outcomes of tournaments, superstars from economies of scale or hierarchical complementarities. Rational investment cycles occur when the capital stock is large relative to investment, and when the breeding stock is large relative to the overall stock.

Article

Rosen was born in Chicago on 29 September 1938. He died in Chicago on 17 March 2001. He earned his BS in economics from Purdue University in 1960. He obtained his graduate economics degrees from the University of Chicago: his MA in 1962 and his Ph.D. in 1966. His first appointment was as assistant professor of economics at the University of Rochester in 1964. Promoted to associate professor in 1968...
and full professor in 1970, he became the Kenan Professor of Economics in 1975. Rosen returned to the University of Chicago in 1977, and became the Bergman Professor of Economics in 1983. From 1992 until his death he served as the Edwin A. and Betty L. Bergman Distinguished Service Professor. In addition, he served as department chairman during 1988–94. He was a Senior Research Associate of the National Bureau of Economic Research from 1968 and a Senior Research Fellow of the Hoover Institution during 1983–96 before becoming a Senior Fellow in 1997.

Rosen was elected a fellow of the Econometric Society in 1976, and a fellow of the American Academy of Arts and Sciences in 1984. He became a member of the National Academy of Sciences in 1998. He was President of the Midwest Economic Association during 1996–7, President of the Society of Labor Economists in 2000, and President of the American Economics Association for 2001.

Rosen was a prolific scholar and one of the leading economists of his generation. His contributions spanned many fields, including equilibrium theory, human capital theory, income distribution theory and investment theory. His research provided the theoretical underpinnings of labour economics, urban economics and health economics. A unifying aim of his research is to explain differential market outcomes. Price differences of goods can be explained by their differential amounts of characteristics. These price differences could be driven by differences in preferences arising from wealth differences or differences in technologies available to firms. For example, cars sell for different prices because they contain different attributes, and workers earn different amounts across jobs because the jobs have different characteristics. Earnings may differ if workers differ in their human capital. Life-cycle earnings are explained from the characterization of human capital accumulation beyond formal schooling. Returns to higher education are best modelled as arising from revealed preference of workers, both college-educated and non-college educated. Earnings may differ between identical workers because they are in different job classifications. Small differences in worker productivity can manifest themselves in large earnings differences if there are production scale economies (creating superstars, for example), strong complementarities, or increasing returns in skill use. Finally, differences in returns and investments can arise from predictable future demand shifts or unpredicted contemporaneous demand shocks. Rational investment cycles are likely if investment is small relative to the stock of capital, and if the seed capital is a large proportion of the stock of capital.

**Equilibrium theory**

Rosen's 1974 article ‘Hedonic prices and implicit markets: product differentiation in pure competition’ is the quintessential example of his work in equilibrium theory. Consider the following labour market application. Rosen's analysis allows for a job to be characterized by N dimensions, but for clarity we focus on only two, its wage and its dirtiness. Some jobs are dirtier than others. They provide meaner working conditions including unheated and/or non-air-conditioned workplaces, less pleasant coworkers, few or no promotion possibilities, high unemployment risk, large variability in hours demanded by the employer, inflexible hours of work, fewer vacations, worse fringe benefits like poor or no health insurance or disability insurance, poor pensions, and so on. Consider aggregating all of these features
into a single measure called ‘dirt’. A worker likes wages and dislikes dirt. Employers can offer any combination of wages and dirt as a package to prospective workers. Assume that (a) worker preferences are convex; hence a worker's dislike for dirt increases with the level of dirt on the job, and he or she requires ever larger increases in wages to accept an additional unit of dirt as the level of dirt increases; and (b) firm production technologies are convex; firms require greater wage reductions for a unit reduction in dirt as the job becomes less dirty. There are three extreme cases. First, if all workers are identical in wealth and preferences, and all employers have access to the same technology of production, then there is a single equilibrium point. This occurs at the tangency of the representative worker's iso-utility curve and the representative employer's iso-profit curve. With free entry, competition drives the equilibrium to the zero profit iso-profit curve. In the second case, suppose all workers are identical in wealth and preferences, but employers have different technologies. For example, mining firms find it more costly than software design firms to provide cleaner work environments. In equilibrium the economist will observe a locus of points, which traces out the representative worker's iso-utility curve, and each observed increase in dirt is associated exactly with the worker's compensating differential to accept the increased dirtiness. Finally, suppose workers have different preferences, say because of wealth differences. Assume that dirt is an inferior good. Let all firms have access to a single technology. In equilibrium the economist observes a locus of points, which traces out the representative firm's zero iso-profit curve. The second example identifies preferences, the third example identifies technology. Of course, the world is not so stark or clean for an economist. Preferences are heterogeneous, workers have differing skill levels, firms have different technologies. Thus, econometrically the problem is one of finding controls that allow for identification (see Ekeland, Heckman and Nasheim, 2004). One important application to the labour market is Murphy (a Rosen student) and Topel (1987).

Rosen's (1974) paper serves as the benchmark for thinking about how markets link customers of multiple characteristic goods and services with the suppliers of these complex goods and services. One important application of this model is by Roback (1982), a Rosen student. Her model examines the compensating differentials in worker wages and land rents arising from differences in location-specific amenities, say, climate or population density. Another application of this hedonic approach is the examination of the increased wages that firms pay to workers in order to induce them to accept greater risks to their health or, in particular, their lives. Rosen and Thaler (1976) allow variation in earnings due to variation in on-the-job risks to life, controlling for productivity (schooling and experience) and in other job characteristics to identify the reservation price of mortality risk for the typical worker. This allows for the calculation of the economic value of a life. Rosen (1988) revisits this arena by examining the valuation placed on increasing longevity. These two papers served as inspiration for an entire subfield of health economics, highlighted by Murphy and Topel (2003).

Rosen (1978) examines the assignment solution of workers to tasks within an organization, in a world with a fixed number of inputs and many worker types. Rosen shows that the division of labour corresponding to the optimum assignment determines the marginal rates of substitution between worker types or between job categories. Thus the division of labour determines the extent of product and factor market substitutions in the economy. This paper provides an application of economics to the optimal determination of job types, or the efficient bundling of activities into a job. Rosen (1982b) extends the analysis. It is further generalized in Tamura (1992); with a continuum of intermediate tasks, and N different worker types, each of measure 1, output can be shown to come from the following reduced form:
where type \( i \) workers have \( h_i \) units of human capital and \( 0 < \rho < 1 \). With each individual a set of measure zero, each worker is paid the marginal product of his or her human capital and, given the constant returns to scale in the distribution of human capital, output is completely exhausted. However, since \( \rho < 1 \), there is an agglomeration economy in participation. Earnings for an individual of type \( j \) are the product of the marginal product of human capital of type \( j \) workers, \( w_j \), and the amount of human capital of type \( j \) workers, \( h_j \), or:

\[
\gamma_j = w_j h_j = \left( \sum_{i=1}^{N} h_i^\rho \right)^{\frac{1-\rho}{\rho}} h_j^{\rho-1} h_j = \left( \sum_{i=1}^{N} h_i^\rho \right)^{\frac{1-\rho}{\rho}} h_j^\rho
\]

Assume that the human capital of worker type \( j \) grows at rate \( \lambda_j \). Suppose workers of type \( j \) have more human capital than workers of type \( i \). If the growth rates of human capital differ across type, then the relative earnings of these two worker types will change. In particular, notice:

\[
\frac{\gamma_{jt+1}}{\gamma_{tt+1}} = \left( \frac{\lambda_j h_{jt}}{\lambda_i h_{tt}} \right)^\rho = \left( \frac{\lambda_j}{\lambda_i} \right)^\rho \frac{\gamma_{jt}}{\gamma_{tt}}
\]

Thus earnings become more (less) unequal if \( \lambda_j > (\leq) \lambda_i \). Nothing about differences in firm investments in technical change is required, merely differences in the abilities of workers to continue to accumulate human capital. As Rosen (1972a; 1972b) notes, higher education can help individuals become better learners. Thus rising wage inequality can be the result of rising task specialization of the more skilled. Hence the works of Acemoglu (1998; 2002) can be thought of as arising from underlying primitives of differential worker abilities to learn.

Rosen also made fundamental contributions with Li, Mussa, and Suen. Mussa and Rosen (1978) provide
an equilibrium analysis of the product quality choice of monopolists. Li and Rosen (1998) examine the
effect of breaches of contracts, unravelling, on optimal assignments of workers to firms when worker
quality is uncertain. Li, Rosen and Suen (2001) examine the role of committees in information
aggregation. If individuals have idiosyncratic information, committees help to aggregate the
information. However, if committee members have conflicting preferences, the only equilibrium truth-
telling rules are binary: yes or no, promote or do not promote, hire or not hire, keep or fire.

Human capital theory

Rosen applied his characteristics approach in order to make fundamental contributions to human capital
theory. Rosen (1972a) models jobs as producing both output and learning opportunities for workers.
Jobs differ in their learning opportunities. These opportunities are costly to firms; they produce less
market output in return for producing more skills for workers in the future. With identical workers and
many firms in equilibrium, young workers seek out the firms with the best learning opportunities.
Workers accept lower earnings to pay the firm for the learning opportunities associated with their job.
As they gain experience and skill, but have fewer years of work remaining, they switch to jobs offering
less rapid learning and greater production. The theory produces occupational switching and the typical
age-earnings profile. With heterogeneity in ability, the model is capable of producing a distribution of
outcomes by age. The most able learners choose jobs with the most rapid learning possibilities, while
less able learners choose to forgo those jobs entirely. Rosen (1972b) displays an early grasp of dynamic
programming. He formulates the optimal accumulation of knowledge from learning by producing by
analysing the excess valuation of production over and above current profits for the acquisition of higher
future profits. He formulates a model of optimal knowledge accumulation as an explanation for
technological progress. Curiously, Rosen notes that a stationary solution to an infinite horizon problem
is not possible. However modern endogenous growth models in fact do take his first functional form in
the paper. As long as output grows at a constant rate, knowledge growth will continue at a constant rate.
Rosen presages Romer (1986) and Lucas (1988) by arguing that knowledge creation is likely to have
important spillovers across workers and industries.

In a contribution to a Feschrift volume for his advisor H. Gregg Lewis, on the occasion of his retirement
from the University of Chicago, Rosen (1976) applies a novel twist on the problem of life-cycle
earnings. He considers the standard formulation of time $t$ wealth value of human capital:

$$ W(t) = \int_t^N y(s) e^{-r(s-t)} ds $$

(4)

where $N$ is an exogenously specified retirement age, $y(s)$ is the earnings at age $s$, and the individual faces
a constant interest rate, $r$. Differentiating (4) with respect to $t$ and rearranging produces:
The standard interpretation is to consider the first term as the potential earnings, the second term as the dollar cost of human capital investment and the right-hand side as observed earnings. In his words (1976, p. S46), ‘The method adopted here is to go behind the scenes of (5) and use the theory to parameterize \( y(t) \) directly in the form of restrictions on the unobservable \( W(t) \).’

Rosen considers the accumulation of human capital as a self-directed process as in Ben-Porath (1967); \( y = Rk(1-s) \), where \( s \) is the proportion of knowledge spent on learning. Rosen considers two possible tractable formulations on the earnings generating function: (a) the learning function depends on total capital resources spent on accumulation, \( k = h(sk) \), which produces \( y = Rk - h^{-1}(k) \), and (b) the learning function is linear in the stock of knowledge, \( k = h(s)k \), which produces \( y = Rk[1 - h^{-1}(\frac{k}{k})] \).

Rosen chooses the latter functional form. The reader familiar with endogenous growth models will immediately see that his preferred specification is the \( Ak \) model of Jones and Manuelli (1990), Rebelo (1991) and Lucas (1988). Rosen also assumes that children are born with a fixed fraction of their parents’ capital, such that at age 0, \( k^{t+1}(0) = yk^t(0) > k^t(0) \); thus he formulates Lucas (1988) without the human capital externalities, but with perpetual growth! Despite the difficulty imposed by finite time horizon models, Rosen derives closed form solutions for the optimal rate of human capital accumulation, \( s(t) \), as well as for \( k(t) \) and \( y(t) \). Unfortunately, economists appear to have misgivings about working with hyperbolic sines, cosines and cotangents! Rosen (1976) produces the standard life-cycle shapes of observed earnings, potential earnings and human capital investments. From his explicit analytic solutions, Rosen is able to estimate the structural parameters of this model using census data. His estimates are broadly consistent with empirical results on rates of returns to schooling. More interestingly, he conducts counterfactual experiments about the nature of college. Schooling could be purely vocational in substance, increasing the knowledge of the future worker. It could also make the individual permanently more productive at future learning. Rosen posits different pairs of learning efficiencies and initial knowledge immediately after college completion that make the college graduate indifferent to college or work after high school graduation. He conducts the same counterfactual for high school graduates. Clearly, this thought experiment is one that foreshadows his seminal work with Robert Willis.

Willis and Rosen (1979) present a version of the Roy (1951) model for educational choice. Individuals can choose between stopping after high school graduation and continuing on to college. In their model there exists comparative advantage. Revealed preference implies that those workers that stopped after high school chose optimally to ignore college because their own rate of return to college education would be less than their cost of funds. Revealed preferences of college graduates imply the opposite. Now, if in addition high school graduates have an absolute advantage in high school occupations relative to what college graduates could earn in those jobs as high school graduates, estimated rates of return to college would be biased. The estimated rate of return to college would be below the true return to the college graduate, but more than the prospective return to the high school graduate. This revealed

preference of educational-occupational selection indicates that there might not exist much ability bias in estimated rates of return to college. After nearly 30 years of empirical work, this is the dominant view in the economics profession (see Ashenfelter and Krueger, 1994; Ashenfelter and Zimmerman, 1997; Ashenfelter and Rouse, 1998).

Rosen (1983) identifies an increasing returns feature to human capital. The key point is that the marginal cost of creating human capital is independent of the intensity of use of human capital. That is to say, human capital investment is like a sunk cost. Once acquired, the marginal cost of using human capital is zero. The more intensely an individual uses his or her human capital, the greater the return to the human capital. Identical workers have an incentive to specialize their human capital or to endogenously choose their comparative advantage. This endogenous comparative advantage is a further extension of Willis and Rosen (1979). Thus, more specialized workers spend their careers in large markets that more fully utilize their skills. The largest metropolitan areas will be home to the most specialized human capital, in any field. Medical specialists will agglomerate in large metro areas and not smaller cities or rural areas; see Baumgardner (1988a; 1988b), a Rosen student. The increasing returns to utilization and endogenous comparative advantage model he envisions are explored in Tamura (1992; 1996; 2002; 2006).

Income distribution theory

Rosen made seminal contributions to understanding the functional distribution of earnings in the economy. Underlying his work is a search for the answer to the fundamental question: ‘Why are earnings so skewed?’ Furthermore, his work operates under the constraint that the answer should arise from a minimal amount of heterogeneity in underlying individual talent. Ideally, ex ante identical individuals would produce the observed skewed earnings distribution. One can view Rosen's work in human capital theory specifically as producing answers to this question with close to this ideal assumption of identical initial human capital endowments. In addition to his human capital programme, his research in this category includes Lazear and Rosen (1981) and his solo authored works (1981; 1982a; 1986a; 1997a). In Lazear and Rosen (1981) and Rosen (1986a), workers are paid as a result of internal relative comparisons. Assume that worker effort is not observable. If individual worker productivity is measured with noise, but a large proportion of that noise is common for all workers of the firm or for workers at similar levels within the firm, the use of relative productivity in order to determine compensation is efficient. This is because, by using relative comparisons, the effects of the unmeasured noise tend to be eliminated or greatly mitigated. For all workers, the wage bill must equal the value produced by the workers. However, workers are paid in relation to their place in the tournament, and hence paid in line with their job title. Increasing the spread between job levels or ranks raises the effort level of workers in the tournament. The larger the total wage bill, with the number of workers at the firm held constant, the greater is the average effort level, and the greater the average ability of workers. In noisier environments, the spread between winning and losing workers must be greater than the earnings spread in more predictable environments. This larger spread is required because increasing noise dissipates the return to worker effort. Thus, in order to elicit the same level of effort, noisier industries must have greater earnings disparity.

Lazear and Rosen (1981) deals with a single contest. However, internal hierarchies are tournaments with many rounds. As a worker successfully progresses up the job ladder, there are fewer and fewer rounds...
left to play. In order to maintain the efficient level of effort, the prize gap must increase. Hence the gap between the CEO and the second in command of the firm must be larger than the gap between the second in command and his or her direct subordinates. Even if the CEO is only marginally better than the second in command, this larger prize must be given in order to provide the correct incentives throughout the organization. The pay gap serves to motivate not only the CEO but all workers in the internal hierarchy, and especially those close to the CEO in rank. As Lazear (2003, p. 13) notes, ‘(t)he theory helps explain why there is a larger spread in earnings between the top and bottom in new industries than in old ones.’ As a consequence newer industries often pay workers in stocks or stock options in order to enlist greater effort levels. When the winners of these new companies in new industries are anointed, the stock options induce huge pay differentials within and across firms in this industry. Rosen (1986a) also shows that the single elimination tournament among players with heterogeneous talents is more likely to be the efficient tournament design than a round robin format. It promotes survival of the fittest at a more rapid rate. Rosen (1986a) shows this in an environment of ‘symmetric ignorance’, or the ‘veil of ignorance’, in which all players know only the common distribution from which all players’ talents are drawn, including their own. Through Bayesian updating, survival in each round provides information about the ability of the contestant. These papers were among the first to apply game theory to labour economics. Furthermore, in the conclusion, Rosen (1986a) identifies the interesting area of further research, namely, the effects of player optimism or pessimism. His conjectures again presage the seminal works of Benabou and Tirole (2002; 2003; 2004) on micro models of behavioural attitudes.

On the question of skewed income distribution from small initial differences, Rosen (1981) shows that markets where costs of reproduction are trivial overwhelmingly choose to reward the individual who is perceived to be the best, even when the best is only trivially better than the second-best performer. Hence the entertainment industry with low-cost reproduction of movie prints greatly increases the skewness of the earnings distributions of actors, producers and directors in comparison with the earnings distributions of these same labour inputs in the days of the travelling show, or the Broadway theatre. Adding books, LPs, video tapes, CDs, DVDs, and so on continues to lower the cost of ‘owning’ a performance. Hence, an individual perceived by the market to be the best will harvest the overwhelming bulk of the demand. The individual performance is captured or recorded once, and then can be replicated at near zero marginal cost. An additional example is the falling costs of journal publication, producing rising skewness in the earnings distribution in academics. This research leads directly to Rosen (1982a). The CEO can supply the same effort level working for a family firm with $1 million of revenue or a publicly traded firm with $100 billion of revenue. The marginal return to talent, however, greatly varies between the two. Hence, those workers with the lowest disutility of effort, or the greatest productivity of effort, will be more valuable working for organizations with greater sales. Essentially, managers are distributing their efforts across a greater scope of inputs, just as superstar performers spread their efforts to ever larger groups of customers. Once again, marginally better managers will earn significantly more than slightly less able managers because they work with a much larger scale of complementary inputs.

Rosen's (1997a) presidential address to the Society of Labor Economists shows that there is an endogenous reason for income inequality among ex ante identical workers. His model relies on non-convexity of preferences. These can arise from a variety of primitives: Friedman (1953) provides one; Bergstrom (1986) utilizes state dependent utility functions; Becker, Murphy and Werning (2005) use
status; Becker, Murphy and Tamura (1990) and Tamura (1994) produce one with non-convexities in human capital. With these assumptions, Rosen demonstrates that the equilibrium and efficient outcome includes occupation lotteries or specialized investment in order to convexify the non-convex portion of utility. The winners get to enjoy higher utility, and the losers enter a lower level of utility. Ex ante, individuals are better off for entering into the lottery.

Investment theory

Another area that receives considerable attention from Rosen is investment theory. Rosen applies his customary analytical insights to understanding the dynamics of investment, particularly in areas where the ‘time to build’ aspect is significant (see, for example, Kydland and Prescott, 1982). This occurs in Rosen (1983), where the costs of acquiring human capital are separable from the rate of intensity of use. Furthermore, Rosen (1987) focuses on the role that investment in anticipation of future demand plays in price and quantity dynamics. These issues are explored in more detail in Rosen and Topel (1988), who produce a rational explanation for boom–bust cycles, observed in the hog market and elsewhere. With a rising supply price, rational individuals build in anticipation of demand. When investment is a small fraction of the stock of the durable good, anticipated future demand shocks produce contemporaneous price changes. If an anticipated large permanent increase in demand will occur five years into the future, then investment will occur today. The immediate rise in investment and the slow shifting out of supply leads to a reduction in current rentals to the service flow. Investment continues rising because the value of the durable good continues to rise as the number of periods before the permanent demand shift shrinks. Until the demand shock appears, rental rates continue to fall; this is the bust phase of the cycle. When the demand shift arrives, rental rates jump, but less than they would have with no anticipatory investment; this is the boom phase of the cycle. Rosen and Topel produce a bust-boom cycle that is created because of the anticipated nature of the demand shock. Unanticipated shocks would produce even more dramatic changes in the rental rate of the durable, but no boom–bust characteristics. These insights are evident in Rosen (1992) and, from two dissertations he supervised, Siow (1984) and Zarkin (1985).

One might ask when known future demand shocks would arise. Two examples are the baby boom and Disney World. The baby boom, starting in 1946 and continuing through 1964, produced above-trend rates of fertility in American women. It is known that by age six a child must be enrolled in school. Hence, with generally little uncertainty, college students in the mid-1940s would have foreseen an increase in the demand for primary school teachers starting in 1951, for secondary school teachers in 1959, and for college faculty in the 1960s. In the second example, Walt Disney announced the construction of Disney World in Orlando, Florida, in the mid-1960s. It opened to the public only in 1970; but the model predicts increased construction of hotels, housing, schools, shopping areas, and so on in anticipation of the future increase in population. Examples of unexpected shocks would be the space race induced by Sputnik, the Soviet satellite, in the late 1950s, the space-science bust of the late 1960s, and the unexpected end of the baby boom.

Murphy, Rosen and Scheinkman (1994) apply the dynamic model of investment to the cattle industry. The long gestation cycle of cows (eight months) and their relatively short reproductive life (eight to ten years) implies that the breeding stock is likely to be a very large portion of the overall cattle herd. Thus,
demand shocks are likely to greatly affect the breeding stock and hence the industry's ability to respond to future demand shocks. The authors show that their model does an excellent job of fitting the data from 1875 to 1990, despite the change in technology arising from corn feeding as opposed to range feeding, introduced in the 1930s and 1940s, which halved the time of the beef production cycle.

Rosen (1999) re-examines the Irish potato famine. He disproves the idea that potatoes were a Giffen good. As in the cattle industry, seed potatoes are a large proportion of the crop. Rosen argues that rational expectations of Irish potato farmers, who assumed that the potato blight was a temporary and not a permanent productivity shock, sealed their doom, since they did not consume their seed stock. When the blight turned out to be permanent, their exposure to imminent starvation was \textit{ex post} predictable and tragic.

Conclusion

A measure of Rosen's influence on the economics profession can be seen by the number of published academic tributes to him (see, for example, Hartog, 2002; Lazear, 2003; Sanderson, 2001). In addition to his fertile research, Rosen possessed a great talent for synthesis, not only in his own work, as testified by Lazear (2003), but in entire fields. This is evident by his seminal contributions in this regard for human capital theory in ‘Human capital: a survey of empirical research’ (1977), ‘Implicit contracts: a survey’ (1985), ‘The theory of equalizing differences’ (1986b), ‘Public employment taxes and the welfare state in Sweden’ (1997b) and ‘Theories of the distribution of earnings’ (Neal and Rosen, 2000). Rosen was influential in much of Lazear's work (1995) on personnel economics.

Sherwin Rosen married Sharon Girsburg from Chicago. They were the embodiment of the marriage covenant, a beacon to all who knew them. They shared their love for 40 years, and had two daughters, Jennifer and Adria. Sherwin Rosen was a beloved professor at the University of Rochester and the University of Chicago. He was treasured by his colleagues and affectionately admired by graduate students. His concern for the success of his junior colleagues and of graduate students was legendary. His keen insight lit the seminars and classes, and his infectious laughter filled the hearts of his colleagues and graduate students. His work continues to illuminate the way for the economics profession, and his memory inspires and warms his former colleagues and students.

Rosenstein-Rodan, Paul Narycz (1902–1985)

Richard S. Eckaus

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

development economics; disguised unemployment; Rosenstein-Rodan, P.N.

Article

Rodan was one of the founders and first leaders of the field of development economics. His formative intellectual years were in the Austrian School of economics at the University of Vienna. He moved to the Department of Political Economy at University College London, in 1931.

Rodan's early essays in economics show a preoccupation with themes which reappeared throughout his professional career: the interaction and complementarity of economic processes (1933) and their temporal patterns (1934). Rodan's seminal article on developing countries (1943) argued that complementarities and externalities in demand and production created a need for the programming of investment. The arguments were subsequently extended to justify the need for an across-the-board 'big push' for a successful start to the development process (1963). He was among the first to apply the concept of ‘disguised unemployment’, described by Joan Robinson (1936), to developing countries as a persisting rather than cyclical problem.

Rodan first became actively engaged in development policy during his tenure at the World Bank from 1947 to 1954. In 1954 he moved to the Department of Economics at the Massachusetts Institute of Technology, where he produced an influential article (1961) which demonstrated that feasible levels of assistance to developing countries would substantially improve their growth performance. After retirement from MIT in 1968 he moved to the University of Texas and then to Boston University in 1972, where he established and worked in the Center for Latin American Development Studies until his death. Rodan was an active policy adviser to international agencies and governments of many countries and served on the Panel of Experts, the ‘Nine Wise Men’ of the Alliance for Progress, from 1961 to 1966.

Robert W. Rosenthal (1944–2002) was an economic theorist whose thoughtful papers inspired a wide range of new ideas. As Radner and Ray (2003) point out, Rosenthal (1978) gives one of the first formal statements of the revelation principle, a result noted in Myerson’s first paper (1979) on the subject. Rosenthal (1979) initiated the study of repeated games with varying opponents, a modelling device used by Milgrom, North and Weingast (1990), Kandori (1992), and others to study social norms and other issues. He also wrote influential papers on pricing (Rosenthal, 1980; 1982), multi-unit auctions (Krishna and Rosenthal, 1996), purification of mixed strategy equilibria (Radner and Rosenthal, 1982; Aumann et al., 1983), sovereign debt (Fernandez and Rosenthal, 1990), analysis of experimental data (Brown and Rosenthal, 1990), and many other topics.

He is arguably best-known for his 1981 *Journal of Economic Theory* paper in which he discussed what Binmore (1987) named the ‘centipede game’. Like its older cousin, the Prisoner’s Dilemma, the centipede game beautifully summarizes a fundamental and intriguing strategic problem. Like the game which inspired but was overshadowed by it, Selten’s (1978) chain store paradox, the centipede calls into question one of the most basic principles of game theory, namely, backward induction.

Consider the game shown in Figure 1. In this game, backward induction predicts that 1 plays $A$ and 2 plays $D$. The reasoning seems very compelling. If 2 is rational, then, faced with a choice between a payoff of 3 and a payoff of 4, he obviously chooses 4. Hence 2 will play $D$. If 1 knows that 2 is rational, 1 knows that 2 will play $D$. Hence, if 1 is rational, he will choose $A$ to get 4 instead of playing $B$ which would yield 3. Thus the hypothesis that each player is rational and knows the other is rational seems to predict the backward induction solution. In longer games, there will be longer chains of reasoning, of course. However, the reasoning above has led many to conclude that backward induction is the implication of rationality and common knowledge of rationality.
A version of Rosenthal's centipede is shown in Figure 2. Here backward induction predicts that 1 chooses $d$ at his first choice node, ending the game right away. Now the reasoning seems more suspect. If 2 is rational, he should choose $D$ at the end rather than $A$. If 1 anticipates this, he should choose $d$ at his last decision node. Similar reasoning shows that 2 should choose $D$ at his first decision node and that 1 should choose $d$ at his first node. Yet it is clear that each player must be virtually certain about his opponent's choice at the next move to justify choosing down rather than across, a certainty that seems extremely implausible in practice.

Many writers have argued that Rosenthal's centipede shows the paradoxical nature of backward induction. Consider player 1 at his second decision node. Here he is supposed to be certain that player 2 will choose $D$ at the following node, justifying his own choice of $d$. Yet he also knows that 2 should have chosen $D$ at the previous node and did not. If 2 failed to be rational in the past, why should 1 remain confident that he will be rational in the future? If 1 does have doubts, perhaps he should play $a$ — a move which would make 2 glad to

Interestingly, McKelvey and Palfrey's (1992) experiments with the centipede game led them to develop the notion of quantal response equilibrium (McKelvey and Palfrey, 1995), an idea which echoes Rosenthal's own analysis. Rosenthal suggested that players might make 'mistakes' where these mistake probabilities would be decreasing in the cost of the mistakes, an idea he explored further in Rosenthal (1989). Quantal response equilibrium is another formulation of this idea.

Douglas Calvin Dacy
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
development economics; Harrod–Domar growth model; International Economic Association; Rostow, W.

Article

Walt Whitman Rostow, economic historian, historian of economic thought, pioneer of modern development economics, and social scientist with interests in demography, politics, sociology and cultural aspects of development, was born in 1916. A professor of economics and history at the University of Oxford in 1946–7, Cambridge University, 1949–50, Massachusetts Institute of Technology 1950–61 and University of Texas at Austin 1968–2003, he is best known for his *Stages of Economic Growth: A Noncommunist Manifesto* (1960) and for his service as National Security Advisor to US President Lyndon B. Johnson during the Vietnam War. He led an active intellectual life engaged in public policy issues up to his death in 2003.

Several themes developed in his first publication, ‘Investment and the Great Depression’ (1938), recur in his first book, *Essays on the British Economy in the Nineteenth Century* (1948), and his *Process of Economic Development* (1953). His book co-authored with A.D. Gayer and Anna J. Schwartz, *The Growth and Fluctuation of the British Economy* (1952), was considered a classic study, and his work co-authored with Max Millikan, *A Proposal: Key to an Effective Foreign Policy* (1957), made his reputation in the field of foreign policy. These books established Rostow as one of the world's foremost economic historians of his age.

His *Stages of Economic Growth* was a blockbuster. It stepped on many toes, assuring his reputation as the one of the most controversial economists of the last half of the 20th century. At the time, his model clashed with that of Harrod–Domar. They modelled steady-state (equilibrium) growth, with no historical context, and focused on two variables: saving and output–capital ratios. Naturally, an economic historian would ask how an economy got there in the first place. Rostow though he saw a pattern in how countries got there. Development proceeded through five stages: traditional society, preconditions for take-off, take-off to sustained growth, drive to maturity and age of high mass consumption. His critics saw these
Walt Whitman Rostow (1916–2003) stages as ‘empty boxes’, not empirically verifiable and devoid of predictive power. Most were especially critical of the take-off stage. He had not demonstrated empirically the necessity of a significant rise in the saving and output–capital ratios. His critics were not convinced about his dating of stages for the seven countries he studied. Besides, he had not heeded Marshall's dictum, Natura non facit saltum – nature does nothing in jumps. Controversy swirled over his discontinuous, disequilibrium approach to economic growth.

His work was so upsetting to many of the world's most distinguished researchers in the field of development that the International Economic Association convened a conference in Konstanz in 1960 devoted exclusively to Rostow's work. This exclusivity was a first for the Association, and is indicative of the importance placed on his work. If Rostow did not convince his critics, or they him, the conference gave him worldwide notoriety, and his ideas were embraced by many economists in developing countries. Twenty years later the controversy continued.

Seizing on earlier criticism, Rostow published a massive volume, The World Economy: History and Prospect (1978). It examines world economic history from 1790 to 1976 in terms of population dynamics, long-term trends, cyclical fluctuations in production, prices and international trade. It extends the work of Stages with later data, and expands coverage to 20 countries.

In 1982 Charles P. Kindleberger and Guido Di Tella edited a three-volume Festschrift in Rostow's honour. A reviewer, Mancur Olson (1985), noted a paradox: many of the contributors were critics, and in a Festschrift! He pondered over an interesting question: how can so many distinguished critics also be admirers? Henry Rosovsky (1965) probably had the right explanation in an earlier comment: ‘I invariably learn more by disagreeing with Professor Rostow than I do by agreeing with most other writers.’

Among economists with roots in the 1960s, Rostow's visible positions in the US government made him the most influential. He helped to form the Alliance for Progress and was President John F. Kennedy's representative on it. As an architect of the Vietnam War and President Johnson's National Security Advisor, he became controversial in the political arena. He knew many of the world's leaders and was known by most of them. Through his public service, he became the Keynes of his day.

He continued to write books on important issues such as East–West relations, verification of nuclear arsenals, foreign aid and world population problems. He died in 2003 at age 87 just before his final book, Concept and Controversy (2003), was published. For many years, Rostow's ideas energized the field of economic development. That, even alone, is a major contribution to economics.

Rotating saving and credit associations (roscas) are the simplest form of collective financial institution. A rosca is a group of individuals who meet at regular intervals, each of whom contributes at each meeting a pre-determined amount to a collective ‘pot’ which is then given to one member. The latter is then excluded from receiving the pot in future meetings, while still being obliged to contribute to the pot. The meeting process repeats itself until each member has received the pot, thereby completing a cycle. Then the rosca can start a new cycle. From this description, the main virtues of rosca are clear: they do not require storage of funds, accounting and durations of obligations are transparent, and there are no complicated interest payments or debt management. Roscas are very popular in developing countries. For instance, average membership rates in Indonesia have been estimated at 40 per cent of the population (Armendariz de Aghion and Morduch, 2005), 20 per cent in Taiwan (Levenson and Besley, 1996) and 40 per cent in a Kenyan slum (Anderson and Baland, 2002). Although rosca do exist alongside more formal financial institutions, they are often the sole saving and credit institution in many rural areas.

Roscas vary widely in terms of the size of the contributions, the number of members and the frequency of meetings. Also, the process by which the pot is allocated can be a lottery (random rosca), or follow a fixed order imposed, for instance, by the leaders in the group (fixed rosca), or be determined by a bidding process (bidding rosca).

The literature identified four differing motives for individuals to save through rosca. First, rosca allow individuals to purchase indivisible goods earlier in expected terms than through the accumulation of individual savings (Besley, Coate and Loury, 1993). Roscas thus provide an implicit positive interest rate to those receiving the pot early. Second, as emphasized by Anderson and Baland (2002), rosca may be used by married women as a way to commit the household to higher saving rates than what can be done at home. Given the presence of social sanctions, husbands are then forced to comply with the...
Rotating savings and credit associations (ROSCAs): The New Palgrave Dictionary of Economics

...saving rate imposed by the rosca. Relatedly, Gugerty (2006) argues that people facing intertemporal inconsistency join rosacas to bind themselves to a particular saving pattern (see also Ardener, 1964; Ambec and Treich, 2007). Lastly, bidding rosacas provide some insurance to their members against short-term income shocks by providing implicit short-run credit to those willing to pay the highest bid.

The most common problem of rosacas has to do with enforcement. Indeed, the first members to receive the pot are de facto borrowers from the other members and, absent social sanctions, are better off not repaying their debts. Given that the size of the pot is fixed, they can always replicate (and also do better than) the best that the rosca can offer them by saving on their own. Social sanctions are then necessary to discipline members. Also, as argued in Anderson, Baland and Moene (2003), the rule for allocating the pot can be chosen to partially address this issue. Selection of members is another issue faced by rosacas, particularly bidding rosacas, where higher bidders may be exposed to more intrinsic risks than others (see Eeckhoudt and Munshi, 2005; Klonner and Rai, 2006).

Murray Rothbard was influential in continuing the tradition of the Austrian school of economics in America. In more than two dozen books and hundreds of articles, his work spanned economics, history, philosophy and political science. He earned his Ph.D. from Columbia University, but was influenced mainly by Ludwig Von Mises' seminar at New York University. Rothbard was a strong believer in apriorism, the idea that economic laws could be discovered using logical reasoning (as opposed to empirical testing), and he attempted to build on and extend the economic logic of Mises and others in that tradition. Rothbard's treatise, *Man, Economy, and State* (1962), analysed the economics of market exchange, while his follow-up volume, *Power and Market* (1970), analysed the economics of government intervention. An underlying theme of his work is that the market is the realm of mutually beneficial exchange, whereas the government is the realm of coercion where some gain at the expense of others.

Rothbard considered economics to be a value-free science, but he believed economic reasoning can be used to determine whether normative views are internally consistent. He was strongly critical of government intervention in the economy, arguing against those who believe that government policies can be Pareto-superior and make all people better off. For example, Rothbard was one of the only economists writing in the 1950s and 1960s to argue against all antitrust laws. He thought that perfect competition was an unattainable ideal, and he said that monopolies or cartels do not pose problems on the free market. He believed that the only monopolies that warrant concern are those sanctioned by government. Rothbard was critical of arguments about market failure in general, insisting that mainstream notions of economic efficiency were unrealistic. He criticized the welfare economics of his
day on the grounds that it rests on unscientific interpersonal comparisons of utility.

In addition, Rothbard wrote a great deal on economic history, often documenting government getting in the way of markets. For example, his 1963 book *America's Great Depression* argued that government caused and lengthened the Great Depression through distortionary monetary and regulatory policies. Rothbard also devoted much of his writing to political philosophy, and here too he was unabashedly libertarian. Rothbard's contribution is particularly noteworthy because he was one of the first economists to argue that markets do not depend on the existence of government. Before him, even the most free-market theorists, such as Ludwig von Mises, Henry Hazlitt, Ayn Rand, and Friedrich Hayek, had simply assumed that services like law enforcement must be provided collectively by the state. But in *Power and Market* and *For a New Liberty* (1973) Rothbard maintained that public goods such as law enforcement must be analysed in terms of marginal units and, as with other goods, those marginal units can be provided privately. He pointed to historical examples of private law enforcement and speculated how a purely private system might function. Rothbard's ideas advancing private property anarchism were radical, but they influenced many economists who now write about alternatives to government law (Stringham, 2006). Rothbard's thorough libertarian views pushed free-market thinking to become more free market.

rotten kid theorem

Theodore C. Bergstrom
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The rotten kid theorem states that, if a household head is sufficiently rich and benevolent towards other household members, then it is in the self-interest of other household members to take those actions that maximize the total income of the household, even at a cost to their own private income. This theorem holds under certain restrictive assumptions, but the assumptions needed for it to be true are not satisfied in many common family decision-making environments.

Keywords

Becker, G.; conditional transferable utility; Dawkins, R.; family economics; kin selection; leisure; normal goods; rotten kid theorem

Article

\[ u_i(x_i) = x_i, \] and the utility function of the household head, \( u(x_0, \ldots, x_n) \), is strictly increasing in all the \( x_i \)'s. Every household member earns some personal income, the amount of which depends on her own actions \( a_i \), but possibly also on the actions of other household members. Let \( a \) be the vector of actions chosen by household members, let \( m_i(a) \) be \( i \)'s personal income, and let \( m(a) = \sum m_i(a) \). Feasible allocations must satisfy the household budget constraint, \( \sum i x_i = m(a) \). For any income \( y \), define \( (x_0(y), \ldots, x_n(y)) \) as the allocation that maximizes \( u(x_0, \ldots, x_n) \) subject to \( \sum i x_i = y \). Assume that consumption for each \( i \) is a normal good so that \( x_i(y) \) is a strictly increasing function of \( y \). Finally, assume that the household head has personal income large enough so that in equilibrium he chooses to donate money to all other persons in the household. This means that, for all feasible \( a \) and for each kid, \( i, x_i(m(a)) > m_i(a) \). Consider the following two-stage game. In the first stage, household members choose their actions and thus determine total family income \( m(a) \). In the second stage the household head finds the allocation \( x(m(a)) \) that maximizes \( u(x_1, \ldots, x_n) \) subject to \( \sum i x_i = m(a) \) and donates...
rotten kid theorem : The New Palgrave Dictionary of Economics
rootten kid theorem

In the first stage of the game, each kid realizes that, after the head has redistributed income, her own consumption will be $x_i(m(a))$. The normal goods assumption implies that $x_i(m(a))$ is an increasing function of $m(a)$. Therefore, the self-interest of each kid coincides with maximizing total family income, $m(a)$. (To ensure that a maximum exists, assume that each $m_i$ is continuous and that each $a_i$ must be chosen from a closed bounded set.)

The trouble with the rotten kid theorem is that it fails to hold in models that make slight concessions toward realism. Bergstrom (1989) shows that, in general, the rotten kid theorem fails if kids care about their activities as well as about consumption. For example, if leisure is a complement to consumption, a child can manipulate the parents' transfer in his or her favour by taking too much leisure. Lindbeck and Weibull (1988) and Bruce and Waldman (1990) show that the rotten kid theorem fails when individuals can choose between current and future consumption. Lundberg and Pollak (2003) show a dramatic failure of the rotten kid theorem when families choose between discrete options like whether to move house or whether to have a child.

Bergstrom (1989) explored the most general conditions under which a rotten kid theorem can be proved. He showed that, in general, a necessary and sufficient condition for the conclusion of the rotten kid theorem to be satisfied is that there is 'conditional transferable utility'. This means that the utility possibility sets corresponding to all possible activity choices are nested and are bounded above by parallel straight line segments. For example, there is conditional transferable utility if kids care only about their consumption, so that $u_i(x_i, a) = x_i$ and if total family income is $m(a)$. Then the utility possibility frontier conditional on $a$ is the simplex $\{(u_1, \ldots, u_n) | \sum_1^n u_i \leq m(a) \text{ and } u_i \geq 0 \text{ for all } i\}$. In general, however, if the kids' utilities depend on their actions, kids will be able to influence the 'slope' of the utility possibility frontier by their choice of actions, $a$. For example, a selfish kid may benefit by choosing an action that reduces family income but makes it 'cheaper' for the parent to invest in her utility rather than that of her sibling. Bergstrom shows that the most general class of environments for which there is conditional transferable utility requires that each kid $i$ has a utility function of the form $u(x_i, a) = \lambda(a) x_i + B_i(a)$ where $x_i$ is $i$'s expenditure on consumer goods and $a$ is the vector of family members' activities. This allows the possibility that activities $a_i$ generate externalities in consumption as well as in income-earning. (Bergstrom and Cornes, 1983, show that in a public goods economy the efficient quantity of public goods is independent of income distribution if and only if preferences can be represented in this form, which is dual to the Gorman polar form for public goods.) Then, for any $a$, the upper boundary of the utility possibility set is $\{u | \sum u_j = \lambda(a) m(a) + \sum B_i(a)\}$. If utilities of kids are normal goods for the head, then each kid will maximize her utility by maximizing $F(a) = \lambda(a) m(a) + \sum B_i(a)$. Thus selfish kids would act in the family interest, as the rotten kid theorem asserts.

An interesting debate in evolutionary biology parallels the economists' rotten kid theorem. Alexander (1974) maintained that natural selection favours genetic lines in which offspring act so as to maximize family reproductive success. Dawkins (1976) disputed Alexander's argument, citing Hamilton's theory of kin selection (1964), which implies that in sexual diploid species offspring value the reproductive success of their siblings at only half of their own. Alexander (1979) conceded Dawkins's point, but offered an additional reason that offspring would act in the interest of their parents, namely, that 'the
rotten kid theorem: The New Palgrave Dictionary of Economics

parent is bigger and stronger than the offspring, hence in a better position to pose its will'. Bergstrom and Bergstrom (1999) propose an evolutionary model that could support the Becker–Alexander conclusion that children will act in the family interest. They construct a two-locus genetic model, where a gene at one locus controls an animal's behaviour when the animal is a juvenile and a gene at the other controls its behaviour when it is a parent. Then the frequency of recombination between genes at these two loci determines the evolutionary outcome of parent–offspring conflict. If recombination between these genes is rare, offspring will tend to act in the genetic interest of their parent. If recombination is frequent, there can be an equilibrium where some offspring successfully ‘blackmail’ their parents into giving them more resources than is optimal for the family's reproduction.

Roy model

James J. Heckman and Christopher Taber
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The Roy (1951) model of self-selection on outcomes is one of the most important models in economics. It is a framework for analysing comparative advantage. The original model analysed occupational choice with heterogeneous skill levels and has subsequently been applied in many other contexts. This article presents the model, discusses its identification, and describes some empirical applications based on the model.

Keywords

comparative advantage; discrete choice; estimation; identification; occupational choice; Roy model; selection bias; self-selection; separability

Article

The Roy (1951) model of self-selection on outcomes is one of the most important models in economics. It is a framework for analysing comparative advantage. The original model analysed occupational choice with heterogeneous skill levels and has subsequently been applied in many other contexts. We first discuss the model. We then summarize what is known about identification of the model. We end by describing some applications based on the model and its extensions.

Basic models

In the original Roy (1951) model, agents can pursue one of two possible occupations: hunting and fishing. They cannot pursue both at the same time. There is no interaction among agents so the choice of one agent does not affect the choice of another agent either through prices or through external effects. Let $\pi_f$ and $\pi_r$ be the price of fish and rabbits respectively in the village. Let $F_i$ denote the number of fish that individual $i$ would catch if he chooses to fish. Similarly let $R_i$ denote the number rabbits he would catch. Then individual $i$'s wage is

$$W_f = \pi_f F_i$$

if he fishes and

$$W_r = \pi_r R_i$$

if he hunts. The income that worker $i$ receives for working in sector $j$ is thus proportional to $\pi_j$ (where $j \in \{f, r\}$). If workers are pure income maximizers, they will choose the occupation with higher income. Thus a worker chooses to fish if $W_f > W_r$. If $F_i$ and $R_i$ are continuous random variables, $\Pr(F_i = R_i = 0) = 0$, so the indifference set is negligible. A fundamental aspect of the Roy model is that it allows for heterogeneity in $(F_i, R_i)$. This heterogeneity can arise from inherent ability differences or human capital investment.

A important issue is self-selection. Under what conditions will the best workers self-select into an occupation? Will people who self-select be above average? For example, for fishing, under what conditions is the average productivity of people working in the fishing sector above the population mean productivity:

$$E[\log(F_i) | \pi_f, \pi_r, \pi_f F_i > \pi_r R_i] > E[\log(F_i)] ?$$
Assume, as did Roy (1951), that log skills are jointly normally distributed

\[
\log \left( \frac{F_i}{R_i} \right) \sim \mathcal{N} \left( \left[ \begin{array}{c} \mu_f \\ \mu_r \end{array} \right], \left[ \begin{array}{cc} \sigma_f^2 & \sigma_{fr} \\ \sigma_{fr} & \sigma_r^2 \end{array} \right] \right)
\]

Then it is straightforward to show that

\[
E[\log (F_i) | \pi_f > \pi_r] = \lambda \left( \frac{\log (\pi_f) - \log (\pi_r) + \mu_f - \mu_r}{\sigma} \right)
\]

where \( \sigma^2 \) is the variance of \( \log(F_i/R_i) \) and \( \lambda(\cdot) \) is the inverse Mills ratio. (See selection bias and self-selection.)

The function \( \lambda \) is positive but decreasing in its arguments with \( \lim_{x \to \infty} \lambda(x) = 0 \). The selection effect is the second term on the right-hand side of this expression. There is a parallel expression for \( \log(R_i) \) with the subscripts \( f \) and \( r \) interchanged.

Recall that \( \pi_f \) and \( \sigma \) must both be positive. Therefore, the question of whether there is positive selection into fishing depends only upon the sign of \( \sigma_f - \sigma_r \). It does not depend on skill prices.

Moreover, since

\[
\sigma^2 = (\sigma_f - \sigma_r) + (\sigma_r - \sigma_r) > 0,
\]

at least one of \( (\sigma_f - \sigma_r) \) and \( (\sigma_r - \sigma_r) \) must be positive. Thus, there must be positive selection into one of the occupations, and there can be positive selection into both.

If, however, there is positive selection into only one occupation, the question arises as to which occupation is most likely to have positive selection. Roy argues that relatively simple tasks (setting traps for rabbits in his case) can be described by a small standard deviation of skill. For more difficult skills (fishing in his example) the standard deviation will be relatively higher as there is a bigger difference between the most skilled and the least skilled.

Thus, if fishing is the more difficult task, \( \sigma_f > \sigma_r \), there must be positive selection into fishing (that is, \( E(\log(F_i) | \pi_f > \pi_r) > E(\log(F_i)) \)).

Whether there is positive selection into hunting depends on the value of \( \sigma_r \) relative to \( \sigma_f \). When \( \sigma_r < 0 \), we will see positive selection into hunting. At the other extreme, if hunting and fishing are perfectly correlated, then \( \sigma_f = \sigma_r \), there is no selection into either occupation. Intuitively, since \( F \) and \( R \) are perfectly positively correlated, and \( F \) is more dispersed, persons with high values of \( F \) can avoid low incomes by using their value of \( R \). Persons with low values of \( F \) (and \( R \)) should fish because the upper tail of \( F \) is more dispersed.

For cases in between, either positive or negative selection is possible depending on the sign of \( \sigma_f - \sigma_r \). Heckman and Honoré (1990) generalize this result to a broader class of distribution functions.

This model has been generalized in a number of ways. There can be more than two occupational choices. Following Heckman and Sedlacek (1985), one can assume that individuals possess a vector of skills \( S_i \) and that different tasks use the different skills according to the function \( T_j(S_i) \). We still let \( \pi_j \) denote task prices so that we can write an individual's wage at task \( j \) as

\[
w_{ij} = \pi_j T_j(S_i).
\]

Another extension of the model allows individuals to care about aspects of the job other than just their wages (see Heckman and Sedlacek, 1985). Let \( U_j(w_i) \) be the utility that individual \( i \) would receive from performing task \( j \) under wage level \( w_i \). This allows for some tasks (such as playing basketball) to be generally preferred to more unpleasant tasks (such as cleaning bathrooms). Individuals then choose the occupation that yields the highest level of utility for them \( U_j(w_i) \). This is the generalized Roy model in which the generalization comes in the agent decision rules.

The generalized Roy model can be trivially extended to a model of labour force participation by allowing non-market work to be one of the tasks. To see this, let \( j=0 \) denote the home sector as in Gronau (1974) and Heckman (1974). Of course, in general, there will not be a market price for home-produced goods, but one can interpret \( T_j(S_i) \) as the value of goods produced at home. One could also assume that staying at home is pure leisure in which \( T_0(S_j) = 0 \), but people enjoy staying at home \( U_0(0) > U_j(0) \) for \( j > 0 \). The Roy model has been generalized to allow for uncertainty in agent decision making in Cunha, Heckman and Navarro (2005). See the reviews in Heckman, Lochner and Todd (2006) and Cunha and Heckman (2007).
Identification

The economics of these models is simple, but identification and estimation are considerably more difficult. Heckman and Honoré (1990) consider identification of the basic Roy model with two occupations and income maximization. They consider two different cases: (a) the standard Roy model, in which the two occupations represent two different sectors of the economy and the econometrician has data on wages in both sectors; and (b) a case motivated by labour supply in which the econometrician has wage data from one sector (the market sector) but not from the other (the home sector). It is important to keep in mind that the comparative advantage decision at the heart of the Roy Model is just one factor that can lead to selection bias. Selection bias and self-selection discusses the more general framework for thinking about sample selection and also discusses in some detail how the Roy model fits into this framework.

Heckman and Honoré (1990) consider identification from a single cross section. When one can observe wages in both sectors, under log normality, the Roy model is identified even without any regressors in the model. However, when one relaxes the log normality assumption, without regressors in the outcome equation the model is no longer identified. This is true despite the strong assumption of agent income maximization. Heckman and Honoré (1990) provide conditions under which one can identify these models using variation across markets, or by using variation in observables within a market. To see the intuition behind the latter case, consider the model in which

$$\log (F) = g_f(Z_f, X_f) + \epsilon_f$$

and $$g_r(Z_r, X_r) + \epsilon_r$$

and prices are normalized to 1. In this context, it is helpful for identification to have an exclusion restriction – that is, a variable $$Z_f$$ that varies separately from $$(X_f, Z_r)$$ and a variable $$Z_r$$ that varies separately from $$(X_r, Z_f)$$. As long as there is sufficient variation in the excluded variables, Heckman and Honoré (1990) show that with a location normalization the full model is identified provided that $$(\epsilon_f, \epsilon_r)$$ are independent of $$(Z_f, Z_r, X_f)$$, that is, they identify $$g_f, g_r$$ and the joint distribution of $$(\epsilon_f, \epsilon_r)$$. (They also establish identification when only one sector’s output is observed.)

To see the intuition for why the model is identified, consider an ‘identification at infinity’ argument. For convenience, take the location normalization to be

$$E(\epsilon_f) = E(\epsilon_r) = 0.$$

Suppose that $$g_r$$ is such that for any $$x$$, say $$x_0$$,

$$\lim_{Z_r \to -\infty} g_r(Z_r, x_0) = -\infty.$$

Let $$I \in \{f, r\}$$ be an indicator of the occupation that was chosen by individual $$i$$. Then

$$\lim_{Z_r \to -\infty} E(\log (F) | I = f, X_i = x, Z_f = Z_r, Z_r = Z_f) = g_f(Z_f, x) + \lim_{Z_r \to -\infty} E(\epsilon_f g_f(Z_f, x) + \epsilon_f > g_r(Z_r, x)) + \epsilon_r X_i = y, Z_f = Z_r, Z_r = Z_f = g_f(Z_r, x).$$

By varying $$(z_f, x)$$ one can trace out $$g_f$$. This occurs because conditioning on the event

$$g_f(Z_f, x) + \epsilon_f > g_r(Z_r, x) + \epsilon_r$$

becomes irrelevant as $$z_f$$ becomes arbitrarily small. Identification of $$g_r$$ is analogous using variation in $$z_r$$.

To identify the joint distribution of $$(\epsilon_f, \epsilon_r)$$ note that from the data one can observe

$$\Pr(I = f, \log (F) < \phi(N - x, Z_f = z_r, Z_f = z_r) - \Pr(g_f(Z_f, x) + \epsilon_f > g_r(Z_r, x) + \epsilon_r \phi(N - x, Z_f = z_r, Z_f = z_r - z_r)) - \Pr(\epsilon_f - \epsilon_r < g_f(Z_f, x) - g_f(Z_r, x), \epsilon_f < \epsilon_r < g_f(Z_f, x), N - x, Z_f = z_r, Z_f = z_r - z_r)$$

http://www.dictionaryofeconomics.com/proxylibrary.cs.cuny.edu/article?id=oids000_R002079&gpo=4&result_number=1488&n=62&n=2009-1-3-10:25:42
which is the cumulative distribution function of $(\xi - \epsilon y \in \phi)$ evaluated at the point $(\bar{g}\bar{r}Z_{r}, X_{i}) - \bar{g}\bar{r}Z_{r}, X_{i})$. By varying the point of evaluation one can identify the joint distribution of $(\xi - \epsilon y \in \phi)$ from which one can derive the joint distribution of $(\xi \in \phi)$. Thus the model is identified. Heckman and Honore (1989) also present conditions for identification of a competing risk version of a Roy model when there are no exclusion restrictions $(Z_{r} - X_{i} - \bar{r})$ but $g_{y}$ and $g_{t}$ can be independently varied. Buera (2006) makes stronger differentiability assumptions and relaxes the separability assumption in the choice equation. He also identifies a Roy model without exclusion restrictions.

Identifying the more general model where individuals choose fishing when

$$U_{y}(w_{y}) > U_{t}(w_{t})$$

is possible under a variety of assumptions. Consider the separable case in which

$$U_{y}(w_{y}) - U_{t}(w_{t}) = h(Q_{y}, Z_{y}, X_{y}) + \nu_{y}$$

where $Q_{y}$ is an additional variable that might affect the relative utilities of the two options. The function $h$ is identified up to a normalization (see, for example, Matzkin, 1992).

Identification of parts of the model follows from the preceding reasoning. If there is a variable that affects sectoral choice, but not wages as a fisherman, we can identify $g_{y}$. Note that this exclusion restriction could be in the form of either $Q_{y}$ or $Z_{y}$. We can then identify the joint distribution of $(\nu_{y}, E_{y})$ using an argument analogous to the above. Using the same argument we can identify $g_{t}$ and the joint distribution of $(\nu_{t}, E_{t})$. A formalization of this argument can be found in Heckman (1990) for the case in which $h$ is linear and is extended in Heckman and Smith (1998), Carneiro, Hansen and Heckman (2003) and Heckman and Navarro (2007). One cannot, without further assumptions, identify the joint distribution of $(\nu_{y}, E_{y})$. (Abbring and Heckman, 2007, present conditions for identification of the joint distribution by restricting dependence relations. See also Aakvik, Heckman and Vytlacil, 2005.)

If one is interested in evaluating policies in which wages can change, this reduced form model is not enough since there is no separation of wage effects from non-wage effects in the choice model. Assume further that we can

$$h(Q_{y}, Z_{y}, X_{y}) + \nu_{y} = \alpha_{1}h_{1}(Q_{y}, Z_{y}, X_{y}) + \alpha_{2}g_{y}(Z_{y}, X_{y}) + \nu_{y}$$

Identification of this model is possible if there are exclusion restrictions in $Z_{y}$ and $Z_{t}$ that is, if there are components of $Z_{y}$ and $Z_{t}$ that do not affect $h$. Under sufficient variation of these variables and imposing a normalization, the model is identified. An interesting special case of the model is when $Q_{y} = Q_{t}$. In this case one needs a somewhat weaker exclusion restriction in that one could use variation in $X_{y}$.

Empirical models

There are many examples that build on the Roy model, but in labour economics three stand out. The earliest empirical application of this model is to the labour supply decision (Heckman, 1974; Gronau, 1974). We refer interested readers to labour supply rather than discuss these models explicitly. The second application is to occupational choice, which is most closely linked to the original Roy model. The third, and perhaps most well known, application is to education.

We start by describing the empirical applications of the model to education. Willis and Rosen (1979) consider a model in which students decide whether to attend college. Students may have a comparative advantage in either the college sector or the high school sector. Their model assumes that decisions about schooling are made in an environment of perfect certainty on the principle of income maximization. They assume access to outcome measures in two periods. The decision to attend college depends on interest rates which are not observable to the econometrician. (One could reinterpret their model as a generalized Roy model if one interprets the interest rate as representing utility differences rather than interest rates.) Semiparametric identification requires two types of exclusion restrictions: a variable that influences the decision to attend college but not directly wages, and a variable that influences wages but not the decision to attend college directly. For the former type of exclusion restriction, Willis and Rosen (1979) use family background variables, arguing that they will be correlated with interest rates but uncorrelated with wages. For the latter type they use test scores, arguing that they are related to skill as in the Roy model, but unrelated to the interest rate.

Although they discuss comparative advantage in the labour market, as did Roy, they do not present direct empirical evidence on this question because they cannot estimate the joint distribution of schooling outcomes across both sectors. They present some indirect evidence on the importance of comparative advantage in the labour market because they can identify the counterfactual means of what college students would earn if they had been high school students and what high school students would earn had they been college students.

There are many extensions of this model, including Taber (2000), Cameron and Taber (2004) and Heckman, Lochner and Todd (2006). Cunha, Heckman and Navarro (2005) and Cunha and Heckman (2007) extend the model to allow for uncertainty, to identify agent information and to directly test for comparative advantage in the labour market by identifying the joint distribution of outcomes for the two counterfactual states (college and high school).
In a series of papers, Heckman, Lochner and Taber (1998a; 1998b; 1998c) estimate a general equilibrium version of this model. They allow the skill prices $\pi_j$ to be endogenous. They show that accounting for equilibrium effects is essential for estimating the impact of policy on earnings inequality. In particular, Heckman, Lochner and Taber (1998b) show that ignoring equilibrium effects overstates the impact of a tuition subsidy on college enrolment by an order of magnitude. They also decompose the policy effect on earnings inequality into its various components.

Other papers estimate a Roy model of occupational choice. Most notably, Heckman and Sedlacek (1985; 1990) estimate models in which workers choose between industrial sectors. In some cases they allow for non-market work. They show how to estimate the model, but reject a pure Roy model. They show instead that a more general model with utility maximization and non-participation can fit the data well. Gould (2002) extends this framework to address the changing wage structure. He shows that workers choose sectors to maximize their comparative advantage and that this activity tends to decrease earnings inequality. However, he shows that the importance of this effect decreases over time as sectors increasingly value more similar skill sets.

Article

René Roy was born in Paris on 21 May 1894. He entered the Ecole Polytechnique in 1914, and joined the army on 15 August 1914. He was seriously wounded on 14 April 1917 at the Chemin des Dames, as a result of which he was blinded at the early age of 23. This tragedy, which meant the collapse of all his youthful hope and dreams, brought him to the slough of despond, and exceptional spiritual strength alone enabled him eventually to accept the unacceptable with serenity and to undertake a double career as an engineer and economist that was to last 60 years.

He studied at the Ecole Polytechnique (from 1918 to 1920) graduating first in his year, and then at the Ecole Nationale des Ponts et Chaussées (1920–2). He entered the Ministry of Public Works and Transport as a state engineer in 1922, specializing in problems of local railway networks and urban transport until his retirement in 1964. He died in Paris in 1977.

In parallel with this activity, he became Professor of General Political Economy and Social Economy at the Ecole des Ponts et Chaussées in 1929, and Professor of Econometrics at the Statistical Institute of the University of Paris in 1931. In 1949 he taught econometrics at the Ecole d’Application de l’Institut National de la Statistique et des Etudes Economiques (School of Instruction of the National Institute of Statistics and Economic Studies). From 1947 he was in charge of an Econometrics Seminar at the National Centre of Scientific Research.

He was elected President of the Paris Statistical Society in 1949 and of the International Econometrics Society in 1953. He was also a fellow of the International Statistical Society (1949), a member of the Academy of Moral and Political Science (1951), and an honorary fellow of the Royal Statistical Society (1957). He received the degree of Doctor Honoris Causa from the University of Geneva in 1964.

René Roy's research was focused mainly on transport, demand functions, economic indices, fields of choice and their respective relationships. His main published works are Le régime économique des voies ferrées d'intérêt local (1925), his doctoral thesis; La demande de biens de consommation directe (1935);
De l'utilité – contribution à la théorie des choix (1942); ‘Les nombres indices’ (Journal de la Société de Statistique de Paris, 1949); and Eléments d'économétrie (1970). In addition, in collaboration with François Divisia and Jean Dupin, he published in 1953–4 A la recherche du franc perdu, whose three volumes cover the movement of prices, production and wealth respectively in France from 1914 to 1950. Roy's analysis of the basic relationships of demand functions and price and quantity index numbers are contained in his 1949 publication.

René Roy's ability to analyse very difficult questions and constantly stay abreast of the main publications of his era was a truly remarkable achievement for a totally sightless person. He showed that accomplishment is possible in the face of an irremediable adversity by dint of unremitting energy associated with remarkable intelligence. His book Vers la lumière (1930) gives us his message as a blind man.

How to cite this article

Originally founded in 1890 as the British Economic Association (BEA), the Royal Economic Society (RES) assumed its current title in 1902 when it obtained a Privy Council charter and royal patronage. The RES is now unquestionably the leading organization of professional economists in Britain, with its flagship publication the *Economic Journal (EJ)*, a world-class general journal for theoretical and applied research (having in 2004 an International Statistical Institute, ISI, journal citation ranking of 15/172 and 1.723 impact factor). Such dominance, however, has not always been the case and was not easily achieved, with the RES's fortunes, like those of many other long-established economics associations, subject to a changing complex of pressures, including at times competitors. The RES was the eventual institutional result of the long process whereby political economy was transformed into economics as the ‘sciences of the social’ were dissolved and reconstructed into the modern social sciences in the second half of the 19th century. The establishment of the BEA followed a long period of consultations over whether a new learned society was required to propagate what has come to be known in the modern literature as Marshall's mission for the professionalization of economics (Middleton, 1998), or whether the Royal Statistical Society (established 1834) and/or Section F (Economics and Statistics, established 1835) of the British Association for the Advancement of Science, were sufficient vehicles. The year 1890 witnessed also the publication of Marshall's *Principles of Economics* and the completion of the first instalment of the first Palgrave dictionary, which was published the following year, as was the first issue of the *EJ*. For Keynes (1940, p. 409), these happy concurrences made this the beginnings of the ‘modern age of British economics’. This now looks somewhat questionable: the BEA and *EJ* were part of a pre-professionalization trend towards ‘clearer demarcation and definition of the field of
scholarly endeavour’ (Kadish and Freeman, 1990, p. 23) and the achievements of the professionalization agenda were as yet limited. That this was the case is apparent from what was one of the central issues of the debate preceding the BEA’s formation: would it be a closed society of professional economists (at this time, it was still not true that a majority of these consisted of academics) or would it be open to all, however imperfect their claim to be called an economist? Mindful of the contemporaneous example of the American Economic Association (AEA), where many of its leading figures had been deeply involved in methodological and policy disputations which had been unhelpful to the professionalization agenda, the BEA’s founders resolved to follow a more cautious and restricted policy than its transatlantic counterpart: membership was not open but dependent upon a candidate’s approval by Council (with the chosen designated as Fellows from 1902 to 1964 under the Royal Charter); the BEA was to refrain from organizing discussions and conferences, partly for fear of exposing the substantial differences of opinion within their ranks; and, in its early years, the Council routinely chose a prominent public figure rather than an academic as its president, beginning with the then Chancellor of the Exchequer, G. J. Goschen. While the early years of the BEA were often difficult, the *EJ* was an undoubted success, and this notwithstanding the rival Oxford publication, the *Economic Review*, which had been launched a few months earlier (and survived until 1914). The *EJ* was not conceived as a specialist publication for an exclusively academic or quasi-academic economics audience, but instead as a ‘means of disseminating economic truth amongst readers from all walks of life, while setting new standards of economic investigation’ (Kadish and Freeman, 1990, pp. 36–7). This general informational role was to endure strongly until the 1970s and was still be present in the 1990s when, as the journal became increasingly internationalized, it almost exclusively focused on scholarly papers and its policy forum, with less emphasis on book reviews and with reports on its learned society activities hived off to the website (http://www.res.org.uk).

The *EJ*’s initial editor was F. Y. Edgeworth, followed by Keynes (singularly and jointly, 1912–45) and then R. F. Harrod (1945–61), during which time the *EJ* consolidated its status as the leading British economic journal, despite the appearance of several rivals. Cambridge, Oxford and London economists initially dominated, but from the 1970s onwards, as the balance of professional influence and authority shifted away from the older centres, the Council had to respond to pressures to make the RES a more democratic organization. Concurrently, the *EJ* editors found that the ever-increasing scale, scope and technical nature of the discipline necessitated increased personnel to provide expert opinion on journal submissions. An editorial board was established in 1971 and has since evolved; most importantly, it now has more foreign (largely, but not exclusively, US) than British economists. RES membership is now over 3,300 individuals, of whom 60 per cent are not British residents, and there are a further 2,400 institutional subscribers to the *EJ* and the *Econometrics Journal* (established 1998). Notwithstanding the internationalization of the *EJ*, the RES mission statement remains essentially British: to be the ‘professional association which promotes the encouragement of the study of economic science in academic life, government service, banking, industry and public affairs’. Increasingly an umbrella organization for a large number of activities, mainly but not exclusively to do with university economics, the RES maintains also its activities as a major publisher of scholarly editions, of which the 30-volume collected writings of Keynes is one of its major achievements, even if it did nearly bankrupt the Society. It has also finally resolved one of the issues of disagreement at its creation: since 1990 the RES has operated an annual conference, selected papers from which appear in a special issue of the *EJ*, itself now enlarged for its second century from a quarterly to a bimonthly publication.

Rubin causal model

Guido W. Imbens and Donald B. Rubin

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The Rubin Causal Model (RCM), a framework for causal inference, has three distinctive features. First, it uses ‘potential outcomes’ to define causal effects at the unit level, first introduced by Neyman in the context of randomized experiments and randomization-based inference, but not used formally in non-randomized studies or with other modes of inference until Rubin (1974; 1975). Second is its formal use of a probabilistic assignment mechanism, which mathematically describes how treatments are given to units, with possible dependence on background variables and the potential outcomes themselves. Third is an optional probability distribution on all variables, including the potential outcomes, which thereby unifies frequentist and model-based forms of statistical inference for causal effects within one framework.

Article

The Rubin Causal Model (RCM) is a formal mathematical framework for causal inference, first given that name by Holland (1986) for a series of previous articles developing the perspective (Rubin, 1974; 1975; 1976; 1977; 1978; 1979; 1980). There are two essential parts to the RCM, and a third optional one. The first part is the use of ‘potential outcomes’ to define causal effects in all situations – this part defines ‘the science’, which is the object of inference, and it requires the explicit consideration of the
Rubin causal model: The New Palgrave Dictionary of Economics

manipulations that define the treatments whose causal effects we wish to estimate. The second part is an explicit probabilistic model for the assignment of ‘treatments’ to ‘units’ as a function of all quantities that could be observed, including all potential outcomes; this model is called the ‘assignment mechanism’, and defines the structure of experiments designed to learn about the science from observed data or the acts of nature that lead to the observed data. The third possible part of the RCM framework is an optional distribution on the quantities being conditioned on in the assignment mechanism, including the potential outcomes, thereby allowing model-based Bayesian ‘posterior predictive’ (causal) inference. This part of the RCM focuses on the model-based analysis of observed data to draw inferences for causal effects, where the observed data are revealed by applying the assignment mechanism to the science. A full-length text that discusses estimation and inference for causal effects from this perspective is Imbens and Rubin (2006).

Implications of the RCM for research design

Before defining each of these three parts of the RCM, it is helpful to consider the implications of this structure for applied research about causal effects. The first part implies that we should always start by carefully defining all causal estimands (quantities to be estimated) in terms of potential outcomes, which are all values that could be observed in some real or hypothetical experiment that compares the results under an active treatment with the results under a control treatment. That is, causal effects are defined by a comparison of (a) the values that would be observed if the active treatment were applied and (b) the values that would be observed if, instead, the control treatment were applied. This step contrasts with the common practice of defining causal effects in terms of parameters in some model, where the manipulations defining the active versus control treatments are often left implicit and ill-defined, with the resulting causal inferences correspondingly weak and ill-defined. This first part can be completely abstract and can take place before any data are observed or even collected. In the RCM, however, there is ‘no causation without manipulation’ (Rubin, 1975, p. 238), where the manipulation (that is, the treatment) could be real or hypothetical. The collection of potential outcomes with and without this manipulation defines the scientific objective of causal inference in all studies, whether randomized, observational or entirely hypothetical.

The second part of the RCM, the assignment mechanism, implies that, given the defined science, we should continue by explicating the design of the real or hypothetical study being used to estimate that science. The assignment mechanism describes why some study units will be (or were) exposed to the active treatment and why other study units will be (or were) exposed to the control treatment, and the reasons are formalized by the mathematical statement of the assignment mechanism. When the study is a true experiment, the assignment mechanism may involve the consideration of background (that is, pretreatment assignment) variables for the purpose of creating strata of similar units to be randomized into treatment and control, thereby improving the balance of treatment and control groups with respect to these background variables (that is, covariates). A true experiment automatically cannot use any outcome (post-treatment) variables to influence design because they are not yet observed. If the observed data were not generated by a true experiment, but rather by non-randomized observational data, there still should be an explicit design phase. That is, in an observational study, the same guidelines as in an experiment should be followed.

More explicitly, the design step in the analysis of an observational data set for causal inference should
Rubin causal model: The New Palgrave Dictionary of Economics

structure the data to approximate (or reconstruct or replicate) a true randomized experiment as closely as possible. In this design step, the researcher never uses or even examines any outcome data but rather identifies subsets of units such that the treatments can be thought of as being randomly assigned within the subsets. This assumed randomness of treatment assignment is assessed by examining, within these subsets of units, the similarity of the distributions of the covariates in the treatment group and in the control group. Because this design step is focused on creating these subsets of units with balanced distributions of covariates between treatment and control groups, and never uses outcome data, the researcher cannot select a design to produce a desired answer, even unconsciously.

The third part of the RCM is optional; it derives inferences for causal effects from the observed data by conceptualizing the problem as one of imputing the missing potential outcomes. That is, once outcome data are available (that is, observations of the potential outcomes corresponding to the treatments actually received by the various units), then the modelling of the outcome data given the covariates should be structured to derive predictions of those potential outcomes that would have been observed if the treatment assignments had been different. This modelling will generate stochastic predictions (that is, imputations) for all missing potential outcomes in the study, which, when combined with the actually observed potential outcomes, will allow the calculation of any causal-effect estimand. Because the imputations of the missing potential outcomes are stochastic, repeating the process results in different values for the causal-effect estimand. This variation across the multiple imputations (Rubin, 1987; 2004a) generates interval estimates and tests for the causal estimands. Typically, in practice this third part is implemented using simulation-based methods, such as Markov chain Monte Carlo computation applied to Bayesian models.

The conceptual clarity in the first two steps of the RCM often allows previously difficult causal inference situations to be easily formulated and handled. The optional third part often extends this success by relying on modern computational power to handle analytically intractable problems. With this overview in place, we consider features of the RCM in more detail.

Potential outcomes and causal effects

For defining causal effects, there are three basic primitives – concepts that are fundamental and on which we must build: units, treatments and potential outcomes. A unit is a physical object, for example a person, at a particular point in time. A treatment is an action that can be applied or withheld from a unit. We focus on the case of two treatments, although the extension to more than two treatments is simple in principle although not necessarily so with real data. Associated with each unit are two potential outcomes: the value of an outcome variable $Y$ at a future point in time if the active treatment is applied, and the value of $Y$ at the same future point in time if instead the control treatment is applied. The objective is to learn about the causal effect of the application of the active treatment relative to the control on $Y$, where, by definition, the causal effect is a comparison of the two potential outcomes. For example, the unit could be a person ‘now’ without a job, the active treatment could be participating in a job training programme, and the control could be not participating. The outcome $Y$ could be the total income over the next three years, with the two potential outcomes being the total income with and without job training; the causal effect of being trained versus not being trained is the comparison of the person's three-year total income with and without the training.

Notationally, let $W$ indicate which treatment the unit receives: $W = 1$ the active treatment, and $W = 0$ the
Rubin causal model: The New Palgrave Dictionary of Economics

control treatment. Also let \( Y(1) \) be the value of the potential outcome if the unit received the active version, and \( Y(0) \) the value if the unit received the control version. The causal effect of the active treatment relative to the control is the comparison of \( Y(1) \) and \( Y(0) \) – typically the difference, 
\( Y(1) - Y(0) \), or perhaps the difference in logs, \( \log [Y(1)] - \log [Y(0)] \), or some other comparison, possibly the ratio. We can observe only one or the other of \( Y(1) \) and \( Y(0) \) as indicated by \( W \). Y_{obs} = WY(1) + (1 - W)Y(0) . The ‘fundamental problem facing inference for causal effects’ (Rubin, 1978, p. 38) is that, for any individual unit, we observe the value of the potential outcome for this unit under only one of the possible treatments, namely, the treatment actually assigned, and the potential outcome under the other treatment is missing. Thus, inference for causal effects is a missing-data problem – the ‘other’ value is missing, so the nature of causal inference is that at least 50 per cent of the values of the potential outcomes are missing. Covariates have values that are unaffected by the treatments, such as age or sex of the unit in the job training example, and are denoted by \( X \). Even when \( X \) represents a lagged \( Y \), such as total income last year, \( Y(1) - X \) is not the causal effect of training unless \( Y(0) = X \), but rather a change of income across time.

To clarify the RCM set-up with potential outcomes, consider a specific difficult case: what is the causal effect of race on hiring practices? To consider this explicitly causal question in the RCM, we must consider the manipulations that define the active and control treatments. Literally changing one's race is presumably impossible given current medical technology, but one can conceptualize experiments that can plausibly capture what researchers want to know, that is, how employers react to race when all else is constant. For example, suppose that résumés are submitted by mail to groups of employers, where the treatment to be applied to each résumé (that is, each unit) is the name attached to it (see, for example, Bertrand and Mullainathan, 2004). Here, the active treatment is the use of a distinctive African-American name on the résumé, and the control treatment is the use of a traditional name. In this case, the explication of what is meant by ‘the causal effect race’ is through the description of the manipulations, and the causal effect to be estimated is thereby well-defined: the causal effect of having a résumé with an African-American name compared with a traditional name on the resultant hiring outcome. Whether that effect corresponds to what the investigator wants to estimate or to what others believe is relevant to policy is another issue, but the causal nature of the comparison is clear. If it is not the desired quantity estimand or is deemed not relevant, then other more appropriate manipulations should be described.

Suppose, now that there are \( N \) units rather than only one. To make the representation with only two potential outcomes for each unit adequate, must accept an assumption, the stable unit treatment value assumption (SUTVA; Rubin, 1980), which rules out interference between units (Cox, 1958) and rules out different versions of the treatments for the units (for example, no ‘technical errors’; Neyman, 1935; Rubin, 1990b). SUTVA can be weakened, but still some such assumption regarding the full set of potential outcomes is required. Often, in practice, SUTVA is made more plausible by aggregating the units. For example, training some of the unemployed in a local labour market may affect job opportunities for others in that local market. Therefore changing the unit of analysis to be the local labour market in a study with many geographically separated local labour markets may make it more plausible that there is no effect of the exposure of one unit to the treatment on other units.

Under SUTVA, all causal estimands (quantities to be estimated) can be defined from the matrix of values with \( i \)th row: \( (X_i, Y_i(0), Y_i(1)), i = 1, ..., N \). A causal estimand involves a comparison of \( Y_i(0) \) and \( Y_i(1) \) on all \( N \) units, or on a common subset of units; for example, the average causal effect across all
units that are female as indicated by their $X_i$, or the median $Y_i(1)$ minus the median $Y_i(0)$ for the set of units with $X_i$ indicating male and $Y_i(0)$ indicating no income. By definition, all relevant scientific information that is recorded is encoded in this matrix, and so the labelling of its rows is a random permutation of 1, ..., $N$; that is, the $N$-row matrix \{X, Y(0), Y(1)\} is row exchangeable. For convenience, we refer to this array of values as the ‘science’, functions of which we wish to estimate.

Brief history of potential outcomes to define causal effects

The basic idea that causal effects are the comparisons of potential outcomes on a common set of units seems so direct that it must have ancient roots, and we can find elements of this definition of causal effects among both philosophers (for example, Mill, 1843, p. 327) and experimenters (for example, Fisher, 1918, p. 214). But apparently there was no formal notation for potential outcomes until Neyman (1923), which appears to have been the first place where a mathematical analysis is written for a randomized experiment. This notation became standard for work in randomized experiments with randomization-based inference, and was a major advance. Independently and nearly simultaneously, Fisher (1925) recommended physically randomizing treatments to units in experiments, as well as a different, but compatible, method of randomization-based inference, although Fisher apparently never used the potential outcomes notation. But despite the almost immediate acceptance in the late 1920s of Fisher's proposal for randomized experiments, and of Neyman's notation for potential outcomes in randomized experiments, and of both men's proposals for randomization-based inference, this potential outcome notation was not used for causal inference more generally for a half century thereafter, apparently not until introduced by Rubin (1974). As a result, the insights into causal inference that accompanied the use of the potential outcomes notation were entirely limited to the relatively simple setting of randomization-based inference in randomized experiments.

The approach used in nonrandomized settings, during the half-century following the introduction of Neyman's seminal notation for randomized experiments, was based on mathematical models (for example, regression models) relating the observed value of the outcome variable $Y_{obs,i}$ to $X_i$ and $W_i$, and then defining causal effects as parameters (for example, regression coefficients) of these models. This was the standard approach in medical and social science, including economics, and led to substantial confusion – the role of randomization cannot even be directly stated mathematically using the observed outcome notation. Of course, there were seeds of this first part of the RCM in social science before 1974, in particular in economics, in Tinbergen (1930), Haavelmo (1944) and Hurwicz (1962), but we can find no previous use of explicit notation like Neyman's to define causal effects. The use of the idea of potential outcomes certainly did appear in discussions in economic theory, for example, in the context of supply and demand functions (for example, Haavelmo, 1944) or the Roy (1951) model, but these discussions did not lead to inference in terms of potential outcomes. Instead, inference took place in terms of the specification of simultaneous equations using observed quantities and distributional properties of error terms (for example, Heckman and Robb, 1984, in the context of program evaluation models).

Nevertheless, the potential outcome part of the RCM framework for defining causal effects, namely, a generalization of Neyman's notation to allow non-randomized data, seems to have been basically...
Rubin causal model: The New Palgrave Dictionary of Economics

accepted and adopted by most researchers by the end of the 20th century; compare, for example, Imbens and Angrist (1994) and Heckman, Ichimura and Todd (1998) with the earlier formulation in Heckman and Robb (1984). An article exploring whether the full potential outcomes framework can be avoided when conducting causal inference is Dawid (2000), which included discussion by others that was largely supportive of the propriety of potential outcomes for causal inference.

The assignment mechanism and assignment-based causal inference

The second part of the RCM framework is the specification of an ‘assignment mechanism’: a probabilistic model for how some units received the active treatment and how other units received the control – how we conceptualize the design for how some potential outcomes were revealed and others remained hidden (that is, missing). The assignment mechanism is fundamental to causal inference. It specifies the conditional probability of each vector of assignments $W = (W_1, \ldots, W_N)^T$ given the matrix of all covariates and potential outcomes:

$$
\Pr(W|X, \gamma(0), \gamma(1)).
$$

(1)

It appears that Rubin (1975) was the first place that expressed the possible dependence of the assignment vector on the potential outcomes in this direct way, which allows the statement of what makes randomized experiments special, and more generally, generates a classification of assignment mechanisms. Again, economic theory sometimes implied a specific assignment mechanism, but this theory was never explicitly stated as in the general form of (1). For example, individuals may choose the occupation that maximizes their earnings, as in the Roy model, which would lead to $W_j = \arg\max W(\gamma_j(W))$, or more generally individuals may optimize an objective function that involves expectations over the unknown components of the potential outcomes. Imbens and Rubin (2006) provide details of such examples.

Randomized experiments are special in that they have ‘unconfounded’ and ‘probabilistic’ assignment mechanisms. Unconfounded assignment mechanisms (Rubin, 1990a) are free of dependence on either $Y(0)$ or $Y(1)$:

$$
\Pr(W|X, \gamma(0), \gamma(1)) = \Pr(W|X).
$$

(2)

Assignment mechanisms are ‘probabilistic’ (or ‘probability’ as in Rubin, 1990a) if each unit has a positive probability of receiving either treatment:
Rubin causal model: The New Palgrave Dictionary of Economics

\[ 0 < \Pr(W_i = 1|X, \gamma(0), \gamma(1)) < 1. \]  
(3)

'Strongly ignorable' assignment mechanisms (Rosenbaum and Rubin, 1983a) satisfy (2) and (3), and thus have unit level probabilities, or 'propensity scores', \( \Pr(W_i = 1|X) \), that are strictly between 0 and 1, and are free of all potential outcomes.

Ignorable assignment mechanisms (Rubin, 1978), are free from dependence on missing potential outcomes but may depend on observed potential outcomes \( \gamma_{obs} = \{\gamma_{obs,i}\} \)

\[ \Pr(W|X, \gamma(0), \gamma(1)) = \Pr(W|X, \gamma_{obs}). \]  
(4)

Ignorable but confounded assignment mechanisms arise in practice, especially in sequential experiments. All strongly ignorable assignment mechanisms are unconfounded, and all unconfounded assignment mechanisms are ignorable, but not the other way. Strongly ignorable assignment mechanisms allow particularly straightforward estimation of causal effects, and are the basic template for the analysis of observational studies. More generally, observational studies have possibly confounded, non-ignorable, assignment mechanisms. A confounded assignment mechanism is one that depends on the potential outcomes, and so does not satisfy (2); a non-ignorable assignment mechanism does not even satisfy (4), and thus allows treatment assignment (or, to use common economics terminology, 'selection') to depend on unobserved values, that is, the missing potential outcomes, \( \gamma_{mis} = \{\gamma_{mis,i}\}, \gamma = \{\gamma_{obs}, \gamma_{mis}\} \).

When the assignment is strongly ignorable, it can generally be represented as a 'regular' assignment mechanism, which is proportional to the product of the propensity scores:

\[ \Pr(W|X, \gamma(0), \gamma(1)) \propto \prod_{i=1}^{N} \Pr(W_i = 1|X_i). \]  
(5)

Regular assignment mechanisms are the basic template in the RCM for the analysis of observational data, because two units with the same propensity score but different treatments are essentially randomized into the two treatment conditions. Therefore, with regular assignment mechanisms, matching on the propensity score (for example, as in Rosenbaum and Rubin, 1984), or subclassifying on
Rubin causal model: The New Palgrave Dictionary of Economics

it (for example, as in Rosenbaum and Rubin, 1985), restores the assumed underlying experimental design, and inference is straightforward based only on the assignment mechanism. These assignment-based methods of inference are due to Neyman (1923) and Fisher (1925), and they involve the calculation of large-sample confidence intervals and exact significance tests for null hypotheses, respectively; both are discussed in Rubin (1990a; 1990b; 1991). For the validity of either Fisher's or Neyman's approach, the analysis must formally be defined a priori, as part of the design. But the existence of these assignment-based modes of inference helps justify the view in the RCM that the model for the assignment mechanism is more fundamental for causal inference than the model for the science, which is not needed for randomization-based inference.

Thus, in the RCM an observational study should be designed as if its data arose from a ‘broken’ randomized experiment, where the unknown propensity scores must be reconstructed on the basis of the covariates \( X \) prior to ever observing any potential outcomes. In such settings, it is often quite advantageous to use estimated propensity scores (for example, as in Rosenbaum and Rubin, 1984; Rubin and Thomas, 1992a; 1992b; 1996; 2000; Hirano, Imbens and Ridder, 2003). When estimated propensity scores for some units are so low that they have essentially no chance of being treated, then those units should be discarded from further consideration when estimating the treatment effect in the treated (see, for example, Peters, 1941; Belson, 1956; Cochran and Rubin, 1973; Rubin, 1973a; 1973b; 1977; Rosenbaum and Rubin, 1985; Dehijia and Wahba, 1999; Crump et al., 2005). The result of the design phase should be treatment and control groups with very similar distributions of observed \( X \)s, because of either matching or subclassification. If a data-set does not permit similar \( X \) distributions to be constructed in treatment and control groups, it cannot be used to support causal inferences without extraneous assumptions justifying extrapolations. Rubin (2002) offers an example of such matching and subclassification in the context of the US tobacco litigation, and Rubin (2006a) is a book devoted to matched sampling.

A striking example of the applied success of the above approach to inference in observational studies is Dehijia and Wahba (1999), which reanalysed the classic Lalonde (1986) data on job-training experiments but using the assignment-based approach of the RCM. In contrast to the wild variety of contradictory, but highly significant, answers found by the traditional econometric methods, Dehijia and Wahba used matching on the propensity score to arrive at inferences that tracked those from the underlying randomized experiment in the overall sample and in a variety of subsamples (see also Abadie and Imbens, 2006).

**Posterior predictive, or model-based, causal inference**

The third part of the RCM involves an optional distribution on the \( N \)-row array of science, \( \Pr(X,Y(0),Y(1)) \), thereby allowing Bayesian, or model-based, inference as well as assignment-based inference. An important virtue of the RCM framework is that it distinctly separates the science – its definition in the first part (and a possible model for it in the third part) from the design of what is revealed about the science – the assignment mechanism in the second part, which can also involve some scientific insights as when it is assumed to be generated by equilibrium conditions, as in supply and demand models, or by optimizing behaviour, and so on.
Bayesian inference for causal effects directly and explicitly confronts the missing potential outcomes, $Y_{\text{mis}}$, by using the specification for the assignment mechanism and the specification for the underlying data to derive the posterior predictive distribution of $Y_{\text{mis}}$, that is, the distribution of $Y_{\text{mis}}$ given all observed values:

$$\Pr(Y_{\text{mis}} | X, Y_{\text{obs}}, W).$$

This distribution is posterior because it conditions on all observed values ($X, Y_{\text{obs}}, W$) and is predictive because it predicts (stochastically) the missing potential outcomes. From this distribution and all of the observed values (the observed potential outcomes, $Y_{\text{obs}}$; the observed assignments, $W$; and observed covariates, $X$), the posterior distribution of any causal effect can, in principle, be calculated. This conclusion is immediate if we view the posterior predictive distribution as specifying how to take a random draw of $Y_{\text{mis}}$. Once a value of $Y_{\text{mis}}$ is drawn, any causal effect can be directly calculated from the drawn value of $Y_{\text{mis}}$ and the observed values of $X$ and $Y_{\text{obs}}$, for example, the median causal effect for males: $\text{med}\{Y_i(1) - Y_i(0)|X_i\text{ indicate males}\}$. Repeatedly drawing values of $Y_{\text{mis}}$ and calculating the causal effect for each draw generates the posterior distribution of the desired causal effect. Thus, we can view causal inference entirely as a missing data problem, where we multiply-impute (Rubin, 1987; 2004a) the missing potential outcomes to generate a posterior distribution for the causal effects.

For example, the treated units have $Y_i(1)$ observed and $Y_i(0)$ missing. Under ignorability, the regression of $Y_i(0)$ on $X_i$ among treated units, for which there is no direct evidence, can be shown to be the same as the regression of $Y_i(0)$ on $X_i$ among controls, for which we have data. Thus, this third part of the RCM tells us to build a realistic model of $Y_i(0)$ given $X_i$ among control subjects, and use it to impute the missing $Y_i(0)$ among the treated from their $X_i$ values, while being wary of issues of extrapolation beyond the observed range of $X_i$ control values. Analogously, build a model of $Y_i(1)$ given $X_i$ among the treated, and use it to impute the missing $Y_i(1)$ among controls. The general structure is outlined in Rubin (1978), and is developed in detail in Imbens and Rubin (2006); a chapter-length summary appears in Rubin (2007).

**Advantages of the RCM**

Because of the flexibility in the RCM for (a) formulating causal estimands, and (b) positing assignment mechanisms, it can handle difficult cases in principled ways. With observational studies, estimated propensity scores play a key role, because the initial analysis proceeds as if the assignment mechanism were unconfounded. To assess the consequences of this assumption, sensitivity analyses can be conducted under various hypothetical situations, typically with fully missing covariates, $U$, such that treatment assignment is unconfounded given $U$ but not given the observed data. Assumed relationships (given $X$) between $U$ and $W$, and between $U$, $Y(0)$ and $Y(1)$, are then varied, for example, as in...
Rubin causal model: The New Palgrave Dictionary of Economics

Rosenbaum and Rubin (1983b), utilizing the third part of the RCM. Ideally, this speculation occurs at the design stage. Extreme versions of sensitivity analyses lead to large-sample bounds (for example, Manski, 2003).

A complication, common when the units are people, is non-compliance with assigned treatment. Early work related to this issue can be found in economics using the terminology of instrumental variables, and the bridge from this terminology to the basic RCM is developed in Imbens and Angrist (1994) and in Angrist, Imbens and Rubin (1996), and the connection to the full RCM approach is presented in Imbens and Rubin (1997) and in Hirano et al. (2000). Another complication is censoring due to death, where units may ‘die’ before the final outcome can be measured. This problem is formulated from the RCM perspective in Rubin (2006b), with bounds given in Zhang and Rubin (2003); see Zhang, Rubin and Mealli (2007) for application to the evaluation of job-training programmes. This topic is also related to ‘direct’ and ‘indirect’ causal effects (Rubin, 2004b; 2005). Combinations of such complications are considered in Barnard et al. (2003) in the context of a school choice example, as well as in Mealli and Rubin (2002; 2003), Jin and Rubin (2007) and Frangakis and Rubin (1999; 2001) in other contexts. The above examples can all be viewed as special cases of ‘principal stratification’ (Frangakis and Rubin, 2002).

The references in the preceding paragraph are clearly idiosyncratic in the sense of their being specific applications of the RCM in which the authors of this article have been participants, and are not representative, but we hope they provide indications of the breadth of recent applications of the RCM.

Article

Richard Ruggles and his wife, Nancy Ruggles, with whom he co-authored almost all of his work, did pioneering work in the field of national economic accounting. Mr Ruggles attended Harvard for both undergraduate and graduate study, earning his BA in 1939, an MA in 1941 and his Ph.D. in 1942. After earning his doctorate, Richard Ruggles joined the Office of Strategic Services as an economist during the Second World War. He worked for the office in London, where he estimated the production rates of tanks at German factories using photographs of the serial numbers from captured or destroyed tanks. In 1945–6 he was with the US Strategic Bombing Survey in Tokyo and Washington. Mr Ruggles returned briefly to Harvard as an instructor in 1946 before joining the Yale faculty a year later as an assistant professor of economics. He was named an associate professor in 1949 and a full professor in 1954. He was appointed the Stanley Resor Professor of Economics in 1954. He chaired the department of economics from 1959 to 1962. He also conducted research for numerous government agencies and bodies, including the United Nations, the Organization of American States, the Federal Reserve Board, the Bureau of the Census and the National Bureau of Economic Research, as well as the Ford Foundation.

Three principal themes emerge in the work of the Ruggles. The first is the reconciliation of macrodata with microdata. National accounts were developed during the 1930s and 1940s by Simon Kuznets, Richard Stone and Richard Ruggles, among others. The 1950s saw the development of microdata such as the Current Population Survey (CPS) in the United States. In principle, the data contained in microdata sources such as income should be consistent with the corresponding entries in the national accounts. In practice, however, this was seldom the case. Several requirements are put forward by Nancy and Richard Ruggles to fully integrate the two sources. First, the definition of sectors should be the same. For example, while household microdata include only households, the macro ‘household’...
accounts often include non-profits and group quarter residents, such as those living in college dormitories, nursing homes and prisons. Second, definitions and imputations, such as the treatment of pensions and imputed rent, should be consistent between the two sources. Third, alignment of macro and microdata should not rely exclusively on macro totals. For example, in national accounts personal interest is computed as a residual whereas in microdata the household provides a direct estimate.

The second theme is the synthesis of microdata from several sources. Since household surveys can ask only a limited number of questions, different surveys concentrate on different characteristics. The CPS focuses on demographics and income, while the Consumer Expenditure Survey is very strong on expenditures and the Survey of Consumer Finances concentrates on assets and liabilities. Another problem is that different microdata focus on different parts of the income distribution. The CPS focuses mainly on the middle classes but its income data are weak for the lower and upper tails while the Internal Revenue Service Tax Model, a sample of tax returns, contains detailed income data on the upper tail but limited information on the bottom tail since these families do not file tax returns.

The solution proposed by the Ruggles is a statistical match of microdata. The idea is to merge microdata files which are complementary in terms of the variables they contain or the parts of the distribution that they cover. One such successful match described in their work was between the 1970 Census of Population and the 1969 Tax Model.

A third theme is the importance of institutional sectoring for the analysis of economic behaviour. In several papers, the Ruggles focus on the measurement of savings. Though most theories of savings, such as the life-cycle model, implicitly assume that all savings is done by households, Nancy and Richard Ruggles argue that savings is done by different institutions. In their accounting scheme, they develop separate current and capital accounts for the household, enterprise, and government sectors. They find that the household and the enterprise sectors are each self-financing. On net, the household sector channels almost no financial savings to the enterprise sector, and almost all investment done by enterprises is financed through enterprise savings. These results have wide-ranging implications for theories of savings and investment.

Saint-Simon, Claude-Henri (1760–1825)

K. Tribe

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

industrial society; Saint-Simon, C.-H. de Rouvroy; science of production

Article

Born in 1760 into a noble family, Saint-Simon spent the first 40 years of his life as a soldier and speculator before devoting himself to the study of science and society. Commissioned in 1778, he served with the French forces in the Caribbean and in America, taking part in the Battle of Yorktown (1781). In 1787 he left the army and became associated with a Spanish project for a canal linking Madrid to the Atlantic, in which project he intended to direct the workforce of 6,000 men. The outbreak of the French Revolution prompted his return to France, where he became President of the Municipal Assembly in Falvy, near Péronne. His ambitions for social improvement led him into the purchase of aristocratic and church property from the government, and a financial partnership he formed to this end met with great success. A period of imprisonment in 1793–4 ended with the fall of Robespierre, and in the ensuing period his business interests expanded rapidly. On the proceeds of his financial successes he founded a salon and became a patron of the sciences. During the peace of 1801–2 he travelled to England, and then to Geneva to visit Madame de Stâel. While in Geneva he published his first text of any significance on the reform of society, Lettre d’un habitant de Genève à l’humanité (1802). Returning to Paris via Germany, he published further pieces on social reorganization, though his writing was interrupted by the collapse of his personal fortune in 1806. With the support of a former servant, Saint-Simon found time for full-time study and in 1807 was able to publish an introduction to the scientific tasks of the 19th century. In 1814 he was joined in his work by the historian Augustin Thierry, and with his aid assumed the role of a leading publicist for liberal interests. This found its most direct expression in the editing of a series of journals: L’Industrie (1816–18); Le Politique (1819); and L’Organisateur (1819–20). This last brought him some recognition in France and abroad, and led him to the publication of a series of pieces in 1821 under the title Du Système industriel, one of his most important works. Despite this success, he felt that his work failed to gain appropriate recognition, and he attempted suicide in 1823. Nursed back to health by a loyal band of followers, he continued writing and studying, his final years being marked...
increasingly by his interest in religious sentiment as a means of social change. He died in May 1825.

The work of Saint-Simon has been variously described as corporatist, totalitarian and even anarchist. Some care is needed in such characterizations, for the work of Saint-Simon must be distinguished from that of his followers like Comte or Halévy who contributed to the formation of ‘Saint-Simonianism’; and it is also necessary to treat with care the accounts of Saint-Simon to be found in the work of those heavily influenced by him, such as Proudhon or Durkheim. Saint-Simon's own writing was not presented in a systematic manner, nor did he pay much regard to scholarly niceties when developing his ideas. Nevertheless, his name is associated with a number of important ideas which have marked the development of social thought.

Saint-Simon believed that the study of society should be conducted on a scientific basis; that a positive, empirical science of society was both necessary and possible. Society, he argued, was like an organism governed by natural laws; and a ‘healthy’ society was one which is well-organized. Proper recognition of this fact would make possible the reconstruction of society on sound foundations – utopia would become constructible through the application of science to society.

Future society would be industrial society, in which ‘general directors’ would ensure that useful work was unhindered and government would therefore administer things, not people. Politics would become the ‘science of production’ – the link to 19th-century socialist thought is here quite evident. ‘Industry’ embraced all kinds of productive activity, and so ‘industrial society’ is one of productive activity in general, not a vision of a technological or manufacturing future. Accordingly, society is primarily arranged into ‘industrious’ and ‘idle’ classes. The future society was not to be a classless one: differences between groups would continue to exist, but would not be a source of social antagonism.

In later life the teachings of Saint-Simon assumed an ever more spiritual cast, a development that was promoted after his death by the group of followers that he had gathered. In the early 1830s the sect had a large number of influential adherents, although a formal organization in the shape of a ‘Church’ soon collapsed. Napoleon III was an open admirer of Saint-Simon’s ideas, and the creation of the Crédit Mobilier investment bank, a model commercial bank involved in economic and financial developments, owed much to Saint-Simon's ideas.

Paul Anthony Samuelson (born in Gary, Indiana, in 1915) has made fundamental contributions to nearly all branches of economic theory. Besides the specific analytic contributions, Samuelson more than anyone else brought economics from its pre-1930s verbal and diagrammatic mode of analysis to the quantitative mathematical style and methods of reasoning that have dominated for the last three decades. Beyond that, his *Economics* (McGraw Hill, first edition, 1948, now in its twelfth edition, the first with a co-author, William D. Nordhaus) has educated millions of students, teaching that economics, however dismal, need not be dull.

Ten eminent economists describe and evaluate his work in their respective fields in Brown and Solow (1983). Arrow (1967) and Lindbeck (1970) provide useful overall reviews. (See also the papers in Feiwel, 1982.)

Bliss in his 1967 review of the first two volumes of the *Collected Scientific Papers* comments on the impossibility for anyone other than Samuelson of reviewing his work. The task has not been made any easier by the publication of another two volumes of collected papers, and by the 144-page summary of developments in economic theory since the *Foundations* in the 1983 enlarged edition. Rather than try to be comprehensive, I will describe the major analytic contributions in several areas, ending with macroeconomics where I also discuss Samuelson's views and advice on economic policy. I conclude with a description of his role at and through MIT.

Although the topic-by-topic approach is unavoidable, the man and the economist is more than the sum of his contributions in several areas. The verve and sparkle of his style, the breadth of his economic and general knowledge, the mastery of the historical setting and the generosity of his hyphenated freight-train allusions to predecessors, are unique. Samuelson's presidential address to the American Economic Association (1961: II, ch. 113) is a good sampler. (References to the *Collected Scientific Papers* (CSP)
I Background

Samuelson has provided fragments of his autobiography in ‘Economics in a Golden Age: A Personal Memoir’ (1972: IV, ch. 278), and in biographical articles on contemporaries and teachers. He attended 14 schools, in Gary, Indiana, on the North Side of Chicago, in Florida, and then at Hyde Park High in Chicago. From Hyde Park High he entered the University of Chicago in January 1932, taking his first economics course from Aaron Director. ‘It was as if I was made for economics’ (1972: IV, p. 885). Milton Friedman and George Stigler were Chicago graduate students at the time. Jacob Viner's famous course in economic theory provided the sound non-mathematical microeconomics that any economist needs to truly understand the field (1972: IV, ch. 282; see also Bronfenbrenner, 1982).

In 1935 he moved to graduate school at Harvard, propelled by a fellowship that required him to leave Chicago and attracted, he claims, by the ivy and the monopolistic competition revolution. Samuelson spent five years at Harvard, the last three as a Junior Fellow. It was the time of both the Keynesian and monopolistic competition revolutions, and ‘Harvard was precisely the right place to be’ (1972: IV, p. 889). The teachers he mentions most are Hansen, Leontief, Schumpeter and E.B. Wilson, the mathematical physicist and mathematical economist.

His fellow students make up the larger part of the honour roll of early post-Second World War United States economics (1972: IV, p. 889). Among them was his wife of 40 years, Marion Crawford (1915–78), author of a well-known 1939 article on the tariff. Abram Bergson (particularly his 1938 article on the social welfare function) and Lloyd Metzler are most mentioned among his other fellow students. Samuelson was the dominant presence among the students: Cary Brown in conversation describes the excitement as his papers were analysed and absorbed by the graduate students; James Tobin in correspondence says that the students loved the seminars, where Samuelson could be counted on to put down his seniors with brash brilliance.

The Keynesian revolution and Alvin Hansen had a greater impact on Samuelson's work and attitudes than the monopolistic competition revolution and Chamberlin. Chamberlin is barely mentioned in his reminiscences of Harvard and his only monopolistic competition article appeared in 1967 in the Chamberlin festschrift (III, ch. 131). Much of Samuelson's work assumes perfect competition, but none of his macroeconomics or his policy advice gives any credence to the view that the macro-economy is better left alone than treated by active policy (except perhaps his views on flexible exchange rates).

His first published article ‘A Note on the Measurement of Utility’ (1937: I, ch. 20) appeared when he was a 21-year-old graduate student. By 1938 the flow was up to five articles a year, a rate of production that has been maintained with perturbations for half a century. And of course, since 1948 he has produced a new edition of Economics almost every three years.

Samuelson moved to MIT as an Assistant Professor in 1940 and has remained there since. Harvard's failure to match MIT's offer at that time has been the subject of much speculation. Samuelson himself has been eager to find excuses for Harvard (1972: IV, ch. 278, footnote 11, p. 896). His is not the best position from which to judge or to write freely; he has noted that academic life, and by implication the chairman of the Economics Department, Burbank, one of the few of whom Samuelson speaks harshly in print, were not innocent of anti-Semitism in that pre-Second World War era. Burbank was a political
power in the Department and University. His attitude to mathematical economics can be gauged by the fact that indifference curves were outlawed in the introductory course he supervised. It is hard to believe that even the Harvard of 1940 would have been unable to find room for an economist of Samuelson's already recognized stature unless a non-academic reason or reasons stood in the way. Among those reasons were anti-Semitism, his then brashness, and his brilliance: indeed Schumpeter is rumoured to have told his colleagues that it would have been easier to forgive their vote if it had been based on anti-Semitism rather than on the fact that Samuelson was smarter than they were. Samuelson has been at MIT since 1940, virtually without a break. Except for a few months away on a Guggenheim, he has taken time off only in Cambridge, Mass. He proudly claims that he has never been in Washington for as long as a week – though he was a major adviser to President Kennedy. His only departure from academic economics came in 1944–5, when he worked at MIT's Radiation Laboratory. He became one of 12 MIT Institute Professors in 1966. He has gathered all the honours the profession can offer: the first John Bates Clark medal (1947); the second Nobel Memorial Prize in Economics (1970); he has been President of the American Economic Association (1961), the Econometric Society (1951), and the International Economic Association (1965–8); and he has been awarded numerous other prizes and honorary degrees. Although many graduate students have passed through his classes and been profoundly affected by him, there is no Samuelson school of economics, no overarching grand design for either economics or the world that is uniquely his. It is for that reason that his contributions have to be discussed field by field. The nearest that he has come to proclaiming a vision is in the Foundations.

II Foundations of Economic Analysis

Foundations, published in 1947, is based on Samuelson's 1941 David Wells prize-winning dissertation, Foundations of Analytic Economics, subtitled ‘The Observational Significance of Economic Theory’. Its themes are partially described by the subtitle and by the motto from J. Willard Gibbs, ‘Mathematics is a language’. The thesis, dated 1940, is very close in content to the Foundations. The Foundations in places claims to be an attempt to derive empirically meaningful comparative equilibrium results from two general principles, that of maximization, and Samuelson's correspondence principle. The correspondence principle states that the hypothesis of dynamic stability of a system yields restrictions that make it possible to answer comparative equilibrium questions. The maximizing theme recurs in Samuelson's 1970 Nobel Prize lecture, ‘Maximum Principles in Analytic Economics’ (III, ch. 130). The point is not the now common view that only models in which everyone is relentlessly maximizing are worth considering. Rather it is that the properties of the maximum (for instance, second-order conditions) usually imply the comparative static properties of the system. Samuelson also invokes the generalized Le Chatelier principle, which loosely interpreted states that elasticities are larger the fewer constraints are imposed on a system. Analogies from physics (and biology) figure prominently in Samuelson's analytic methods and explanations of his results. The correspondence principle was intended to do for market or macroeconomic comparative statics what maximization did for the comparative statics of the individual or firm. The principle can be useful when the analyst knows something about the dynamic behaviour of a system, but as noted by Tobin (1983), is ambiguous in that different dynamics may be consistent with the same steady-state behaviour. The simplest example of the ambiguity can be seen in a demand–supply diagram where the supply curve
is negatively sloped. Whether a tax on the good will increase or reduce price depends on which curve is more steeply sloped. Whether the market is stable or not depends on the same fact and whether quantity or price rises in response to excess demand – that is, whether dynamics are Marshallian or Walrasian.

In the introduction to the 1983 enlarged edition, Samuelson records correctly that the *Foundations* was better off for not sticking to its narrow themes. Substance keeps breaking in on the methodology. The treatment of the theory of the consumer and firm, developed in detail, does not differ in essence from that of Hicks in *Value and Capital*. But where Hicks hides the mathematics in appendices, Samuelson flaunts his in the text. Nonetheless Samuelson takes pains to provide economic insight, including interpretations of Lagrange multipliers as shadow prices. These portions of the *Foundations* apparently existed in 1937–8 and were written independently of *Value and Capital* (Bronfenbrenner, 1982, p. 349), though not of course of Hicks and Allen (I, ch. 1, p. 4).

The theory of revealed preference (see below) receives prominence, as do two chapters on welfare economics, and in Part II chapters on the stability of general equilibrium. A few pages on money in the utility function (pp. 117–24) remain authoritative. The mathematical appendices on maximization and difference equations have been useful despite an elliptical style that leaves many steps to be filled in by the user.

Samuelson's thesis is dated 1940: *Foundations* is the work of a 25-year-old. There are signs of youth in the eagerness to proselytize for the new mathematical faith and its overreaching in trying to impose an entirely coherent theme on the material. But the book bears the unmistakable mark of the master, in command of the economics of his material, at home with technique, and most remarkably for a young man in a hurry, thoroughly familiar and patient with the literature. It is, as Schumpeter no doubt remarked, a remarkable performance.

### III Consumer theory and welfare economics

Samuelson's first published paper (1937: I, ch. 20) set up a finite horizon continuous time intertemporal optimization model of a consumer with additively separable utility function and exponential discounting, and derived the result that the profile of consumption is determined by the relation between the interest rate and rate of time preference. The focus is however the measurability of utility.

The theory of revealed preference, his major achievement in consumer theory, made its unnamed appearance in 1938 in ‘A note on the pure theory of consumer's behaviour’ in *Economica* (I, ch. 1; see also Houthakker, 1983, and Mas-Colell, 1982, for exceptionally lucid accounts). The purpose was to develop the entire theory of the consumer free of ‘any vestigial traces of the utility concept’ (I, p. 13). Rather than postulate a utility function or, as Hicks and Allen had done, a preference ordering, Samuelson imposed conditions directly on the choices made by individuals – their preferences as revealed by their choices. The key condition was the weak axiom of revealed preference, applying to choices made in two situations, say zero and one. With prices and quantities of goods \( j, j=1, \ldots, n \) in situation \( i \) given by \( p^i_j \) and \( x^i_j \), the axiom is

\[
\sum_j p^0_j \left( x^1_j - x^0_j \right) \leq 0 \text{ implies } \sum_j p^1_j \left( x^1_j - x^0_j \right) \leq 0
\]
In words, if the individual chooses consumption bundle zero when he could have chosen the bundle one, he will not choose one when zero is available.

This minimal condition of consistency is shown to imply most of the conditions on demand implied by utility theory. But the symmetry and negative definitiveness of the Slutsky matrix could not be established using the weak axiom. Equivalently, the issue was the so-called integrability of demand functions, with the question being whether the preference map could be recovered given enough observations on the individual's choices. Houthakker (1950) solved the problem, by proposing the strong axiom of revealed preference, namely that for any finite string of choices in which B is revealed preferred to A, C is revealed preferred to B, ..., and Z is revealed preferred to Y, then A is not revealed preferred to Z. In this case, and given appropriate continuity conditions on demand, the demand functions are integrable and an entire preference map, satisfying the Slutsky conditions, can be recovered from the individual's choices.

The full equivalence between the properties of the demand functions of an individual and the preference ordering is the leading example of Samuelson's definition of the operational or observational significance of economic theory. Samuelson regards a theory as meaningful if it is potentially refutable by data. A single consumer could make a succession of choices that contradict the strong axiom. But the theory is not operational in the sense that a modern econometrician would want it to be: it does not apply to aggregate data, nor, in the form in which Samuelson left it, does it apply to choices that are made in chronological time.

Revealed preference links the theory of demand, index numbers, and parts of welfare economics. The link between demand and index number theory comes in the Foundations' (pp. 147–8) recognition that the fundamental index number problem is to deduce from price and quantity information alone whether an individual is better off. Using the weak axiom, Samuelson demonstrates the conditions under which, in a comparison of two situations, it is possible to say whether an individual is better off in one (Foundations, pp. 156–63). He argues that index numbers add no information on the essential question and indeed may be positively misleading in tempting the observer to attach significance to the numerical scale of measurement.

A similar concern no doubt motivates Samuelson's long-standing hostility to the use of consumer surplus measures. He has frequently argued that there is no need for the concept. He asserts in Foundations (p. 197) that there is no need for consumer's surplus in answering, for example, the question of whether Robinson Crusoe, a socialist state, or a capitalist one, should build a particular bridge. That view may have been moderated over the decades: the 1985 Samuelson–Nordhaus Economics (p. 418) states that the concept 'is extremely useful in making many decisions about public goods – it has been employed in decisions about airports, roads, dams, subways, and parks' (bridges are conspicuously absent).

The revealed preference axiom comes into play too in Samuelson's 'Evaluation of Real National Income' (1950: II, ch. 77), a largely negative report on the then new welfare economics that attempted to deduce from aggregate data criteria that would make it possible to say whether society was better off in one situation than another. Taking, as he has since 1938, the viewpoint that a Bergsonian social welfare function is the best way of understanding social welfare issues, Samuelson showed that no index-number type national income comparison between situations A and B could reveal whether society's feasible utility possibility frontier (a useful Samuelson innovation, apparently simultaneously invented by Allais)
in A lies uniformly outside that of B. And, he argued, we could claim situation A is better than B only if that is the case.

In the *Foundations* (chapter 8) Samuelson draws extensively on the Bergsonian social welfare function to elucidate definitively the notion of Pareto optimality and the ‘germ of truth in Adam Smith's doctrine of the Invisible Hand’ (*Foundations*, 1983 edn, p. xxiv). Arrow (1967) is critical of Samuelson's failure to look behind the social welfare function, and of his failure to link it to actual policy decisions. Similar sentiments are conveyed along with a more complete evaluation of Samuelson's welfare economics in Arrow (1983). Samuelson (1967: III, ch. 167) asserts that the Bergson Social Welfare Function and the Arrow Constitution Function are distinct concepts, though the argument is difficult to follow. The expected utility theorem shows Samuelson wrestling for decades with his doubts over the independence axiom (I: ch. 12, 1950; ch. 13, 1952; ch. 14, 1952; *Foundations*, 1983, pp. 503–18). Despite his tentative 1983 acceptance of the expected utility formulation, he notes with approval Machina's (1982) development of expected utility without the independence axiom. Of course, these doubts have not kept him from making creative use of the expected utility approach in models of portfolio choice and finance.

### IV Capital theory

The theory of capital and growth sections of the first four volumes of *CSP* account for 38 papers, the largest single category. Although capital theory is the branch of economics most vulnerable to Samuelson's comparative technical advantage, and although both his earliest papers are placed in that category in *CSP* (1937: I, ch. 17, ch. 20) the output in this area is concentrated in *CSP* III, covering the years from 1965 to 1970. Solow (1983) provides a fine review of this part of Samuelson's research, some of which he co-authored.

Among the early papers, the 1943 Schumpeter *festschrift* contribution ‘Dynamics, Statics, and the Stationary State’ (I, ch. 19) discusses the economics of the steady state and the possibility of a zero interest rate. Samuelson argues that a steady state with a zero real interest rate is possible if the rate of time preference of the infinitely lived individuals is zero; he has in mind a situation in which the marginal product of capital can be driven to zero. In this article (I, p. 210), as in his first paper (I, p. 216), Samuelson makes highly favourable reference to Ramsey, in contrast to the famous unflattering 1946 remark (II, p. 1528). The well-known argument that a zero rate of interest is impossible because income generating assets would have an infinite value is rejected, on the ground that an infinite value is not a problem since assets could trade against each other at finite price ratios. Some second thoughts are presented in a 1971 paper (IV, ch. 217); curiously, Samuelson discusses the Schumpeter issue entirely in a model with infinite horizon maximizers rather than in an overlapping generations framework.

The modern contributions in *CSP* I include the famous 1958 consumption loans model, which will be examined in the macroeconomics section, and the surrogate production function (1962: I, ch. 28). As Solow (1983) notes, much of the capital theory in *CSP* is related to developments in Dorfman, Samuelson and Solow (1958), which itself grew out of a 1949 Samuelson three-part memorandum for the Rand Corporation.

Notable among the contributions is a variety of turnpike theorems. A turnpike theorem is conjectured in the 1949 Samuelson memorandum, and fully worked out in the 1958 volume. The theorem states that for
any accumulation programme, starting from an initial vector of capital goods, and with specified
terminal conditions, as the horizon lengthens the optimal programme spends an increasing proportion of
its time near the von Neumann ray; more generally in problems with intermediate consumption, the
economy spends time near the modified golden rule. Several of the papers in the capital and growth
section of CSP III contain turnpike theorems. A periodic turnpike result is reported in 1976 (IV, ch. 224).
The surrogate production function was an attempt to justify the aggregate production function as being
consistent with an underlying model with heterogeneous capital goods and production techniques, and
one type of labour. The article names and uses the factor price frontier, noting that it had been used
earlier by others, including himself (in 1957: I, ch. 29). Samuelson shows that a downward sloping
factor price frontier is traced out in a competitive multi-capital goods multi-technique economy, with
higher steady state wages accompanying a lower steady state interest rate. Further, this frontier has the
same properties as in the one-sector model, with the slope of the factor price frontier equal to the capital
labour ratio. The theorem is correct, but as noted by Solow (1983), the conditions for it to obtain are
special.
Under more general conditions, the famous reswitching result may occur in which a given technique of
production that had been used at a low interest rate comes back into use again at a high interest rate (see
the November 1966 Quarterly Journal of Economics). Reswitching implies that the one-sector
neoclassical production function cannot be viewed as a general ‘as if’ construct that describes the
behaviour of economies with several techniques of production. Cambridge (England) critics of
neoclassical capital theory viewed reswitching as a confirmation of the view that marginal productivity
had nothing to do with distribution, since the same techniques of production might be used with two (or
many) different distributions of income. Various criticisms are offered by Robinson (1975) and
responded to with forebearance in CSP (1975: IV, ch. 216).
Samuelson started the surrogate production function article by denying the need for any concept of
aggregate capital. That position would be strengthened by the reswitching result. However, as with so
many useful constructs in economics, the concept of aggregate capital has survived the demonstration
that its validity may be limited. Neither Samuelson nor other neoclassics have been constrained by
reswitching from using one-sector production functions or marginal productivity factor-pricing
conditions.
The property that the slope of the factor price frontier is equal to the capital–labour ratio is one example of
the duality between price and quantity that Samuelson began to emphasize in the Foundations and has
used repeatedly since. Foundations (p. 68) contains the Roy’s Identity envelope condition that the
derivative of the minimized cost function of the firm with respect to the wage of factor \(i\) is the demand
for factor \(i\). It also provides shadow price interpretations of Lagrange multipliers. Samuelson has used
duality in optimal growth and linear programming problems (‘Market mechanisms and maximization’,
1949: I, ch. 33, is a gem) and in CSP (1965: III, ch. 134).

V Dynamics and general equilibrium

Chapters IX through XI of Foundations cover stability analysis and dynamics, in both individual
markets and the economy at large. The basic assumption of this dynamics is the ‘law of supply and
demand’ that price rises in response to excess demand.
The impetus for the multi-market analysis came partly from Hicks's Value and Capital (1939) discussion
of stability, in which there is no explicit dynamical system. The Samuelson approach is general equilibrium, though it does not start from the primitives of endowments. As Hahn (1983) notes, the underlying microeconomics is not specified. Samuelson nonetheless set the agenda of the next 15 years for the study of dynamics in a more explicitly general equilibrium framework, and most important, in a framework in which the issue of stability is precisely posed.

Explicit use of the law of supply and demand in theoretical work has fallen out of favour, though the Phillips curve can be interpreted as using that approach. The monopolistic competition wing of macroeconomics prefers to model price setting by firms and workers explicitly rather than rely on an auctioneer, and the equilibrium approach assumes prices are continuously at market-clearing levels. The older approach is used in disequilibrium macroeconomics, but is typically regarded as suspect.

Samuelson has not been a general equilibrium theorist in the sense of one striving for maximum generality. He has been general equilibrium in the sense opposed to partial equilibrium: he frequently works with models of the whole economy, in growth and capital theory, in trade and macroeconomics, and in his excursions into the history of thought.

The most micro-oriented of these general equilibrium contributions are the non-substitution theorem (1951: I, ch. 36) and factor–price equalization. The non-substitution theorem was presented at a 1949 conference, and was obtained independently by Samuelson and Georgescu-Roegen (I, p. 521). Consider an economy where labour is the only primary factor, and where goods are used either for consumption or as input into the production of other goods. Suppose the production function for each good is neoclassical, permitting substitution among factors of production, but there is no joint production. The theorem is that relative prices in this economy are independent of demand, that is, are determined on the supply side alone. There is a single least cost way of producing each good, where cost is determined by direct and indirect labour requirements. Hahn (1983) provides a clear account of the theorem, and generalizations to dynamic systems with capital (1961: I, ch. 37). The question in the system with capital is whether, given the interest rate, the relative price structure is unique. Conditions for uniqueness are discussed in Hahn. The link with the surrogate production function, published at about the same time, is clear. The nonsubstitution theorem is used also in Samuelson's discussions of Ricardo (1959: I, chs 31, 32).

VI International trade

‘Our subject puts its best foot forward when it speaks out on international trade’ (1969: III, p. 683), and some of Samuelson's best-known contributions are undoubtedly in this field. Jones's 1983 article describes Samuelson's considerable impact on trade theory: on the gains from trade; the transfer problem; the Ricardian model; the Heckscher–Ohlin–Samuelson model; and the Viner–Ricardo model. Earliest among the well-known contributions is the 1941 Stolper–Samuelson result (II, ch. 66), which uses the two-sector, two-country Heckscher–Ohlin model with identical production functions in the two countries to analyse the effects of the opening of trade, or the imposition of a tariff, on the wage. The result is that protection will benefit the factor that is relatively (to the other country) scarce. Or, the opening of trade benefits the relatively plentiful factor. But the paper contains more than that result. As Jones (1983) notes, it introduces the basic elements of Heckscher–Ohlin theory for small-scale trade models – and those models were the analytic core of real trade theory for decades.

Stolper–Samuelson flags the issue of factor–price equalization, the question of whether trade in goods
alone can produce the factor price equalization that would obtain if factors were freely mobile. Ohlin claimed that trade would cause a necessarily incomplete tendency to equalization. Samuelson (1948 and 1949: II, ch. 67; 68) showed in the Heckscher–Ohlin context conditions under which equalization would be complete: identical production functions in the two countries, no factor-intensity reversals, and similarity of the ratio of endowments (so that countries are not specialized in production). The paper was remarkable and surprising, and did not suffer from the happy coincidence that a 1933 Abba Lerner contribution rediscovered by Lionel Robbins had independently reached the same conclusions in a similar model.

Factor price equalization in more generality is considered in the famous 1953 paper ‘Prices of factors and goods in general equilibrium’ (II, ch. 70), which caused a substantial literature including Gale–Nikaido (1965). It is striking that many of Samuelson's famous papers led to prolonged discussion of the exact conditions needed for his particular results to obtain: he opened more doors in economics than he closed.

The transfer problem is an old issue in the literature that arose in the 1920s, after Second World War, and arises again in contemplation of the world debt crisis. Samuelson's 1952 and 1954 papers (II, chs 74, 75) are classics in this extensive literature, on the issue of whether a transfer from one country to another (such as German reparations) is likely also to worsen the terms of trade of the country making the transfer, which Samuelson describes as the orthodox presumption. In the modern context the orthodox presumption would be that the developing countries will have to suffer a terms of trade loss to run current account surpluses to reduce their indebtedness. Samuelson typically argues that there is no presumption about the terms of trade shift, though the orthodox presumption is more likely to hold where there are non-traded goods or impediments to trade (1971: III, ch. 163).

Samuelson's contributions to trade theory are classics: the contributions are basic, the models are tractable and fecund, the problems come from the real world as well as the literature, the articles continue to reward the reader. And they continue to be read.

VII Finance

Despite his long-time personal interest in capital markets, Samuelson's contributions to finance theory started only as he turned 50. These papers are concentrated in CSP III and IV; the earlier ones are self-reviewed in ‘Mathematics of speculative price’ (1972: IV, ch. 240). Merton (1983) describes and evaluates six of Samuelson's favourite papers in finance, broadly defined to include his 1952 paper on expected utility and the independence axiom (I, ch. 14).

The two most important papers are ‘Proof that properly anticipated prices fluctuate randomly’ (1965: III, ch. 198) and ‘Rational theory of warrant pricing’ (1965: III, ch. 199). ‘Proof …’ provides a first precise formulation of the consequences for speculative prices of market efficiency. The theorem describes the behaviour of the current price of a commodity for delivery at a given future date, for example June 1990 wheat. Assuming that speculators do not have to put up any money to enter the contract, the result is that the market price should be the expectation at each date of the June 1990 wheat price. Given rational expectations, there is no serial correlation in the changes in price. Hence ‘properly anticipated prices fluctuate randomly’.

Samuelson says of this theorem, which is now entirely basic: ‘This theorem is so general that I must
confess to having oscillated over the years between regarding it as trivially obvious (and almost trivially vacuous) and regarding it as remarkably sweeping. Such perhaps is characteristic of basic results’ (III, p. 186).

Note what the theorem does not say, using the exchange rate as the example. The theorem is not that the exchange rate fluctuates randomly; predictable inflation or predictable business cycle fluctuations can cause predictable movements in the exchange rate. Rather it is the current price of foreign exchange at a given future date that fluctuates randomly. The notion that efficiency produces random motion is itself fascinating. But far more important is the restriction on empirical behaviour implied by efficiency that Samuelson derives in a well-defined context. Testing for efficiency of speculative markets has become a major industry.

‘Rational theory of warrant pricing’ missed its target, but it is as Merton (1983) remarks, a near miss. Samuelson had pursued option pricing for well over a decade. He supervised Kruizenga's 1956 MIT dissertation on the topic, and was familiar with Bachelier's 1900 continuous time stochastic calculus calculation of rational option prices. Samuelson derived a partial differential equation for the option price that depends, among other variables, on the expected return on the stock and the required return on the option. The remarkable feature of the Black–Scholes solution to the problem is that the rational price of the warrant does not depend on the expected return on the stock, but rather on the risk-free rate. Nonetheless, the Samuelson differential equation can be specialized to the correct Black–Scholes equation.

Other contributions to finance theory include papers on diversification (1967: III, ch. 201), and on conditions under which mean-variance analysis can be justified (1970: III, ch. 203) – with continuous time models providing the best argument for the procedure.

VIII Macroeconomics

All the Samuelson contributions described to this point are firmly neoclassical. His work in macroeconomics presents a more mixed picture. I take up in turn the early multiplier–accelerator model, which is not at all price-theory oriented, the neoclassical synthesis, Samuelson the policy adviser and commentator, and the entirely neoclassical consumption loans model.

The multiplier–accelerator model

In a 1959 note (II, ch. 84) on the multiplier–accelerator model, Samuelson describes his contribution as being the algebraic generalization of a numerical example of Alvin Hansen's. The model (1939: II, ch 82, 83) is a simple one in which current consumption is proportional to lagged output and investment is determined by the difference between current and lagged consumption (the accelerator). This implies a second-order difference equation, which can generate asymptotic or oscillatory damped approaches to equilibrium, or oscillatory or non-oscillatory explosive paths for output. Although Frisch and Slutsky had already written on the ability of stochastic difference equations to mimic cycle-like behaviour, Samuelson does not – except for a quotation from J.M. Clark that receives little emphasis – link his second-order equation with a stochastic forcing term.

Samuelson (1939: II, p. 1111), while emphasizing the simplicity of the algebraic analysis, argues for the
empirical importance of the accelerator. This judgment has held up over time as flexible accelerator effects continue to feature strongly in modern estimated investment functions. From the theoretical point of view, the multiplier–accelerator model is interesting for the lack of concern over microfoundations. Where a 1980s macroeconomist might agonize over the microfoundations of the consumption function, over the accelerator, or over the impact of rational expectations of future output on investment, Samuelson proceeds constructively with a simple implicitly fix-price model. The famous 45-degree diagram popularized in *Economics* – and for several editions on the cover – forcefully emphasizes Samuelson's view that aggregate demand is the key determinant of output.

In the 1940 ‘Theory of pump-priming reexamined’ (II, ch. 85) he stipulates the basic features of the private economy forming the environment within which governmental action must take place … – (1) The economic system is not perfect and frictionless so that there exists the possibility of unemployment and under-utilization of productive resources …

This view pervades Samuelson's macroeconomics. Indeed, when asked recently his view of the causes of wage and price stickiness, he replied that he decided 40 years ago that wages and prices were sticky, that he could understand the behaviour of the economy and give policy advice on that basis, that he had seen nothing since then to lead him to change his view on the issue – and that he had not seen a payoff to researching the question.

He was of course aware of the issues. An abstract of a paper presented at the 1940 meetings of the Econometric Society (II, ch. 88) describes a totally modern discussion of the question of whether general involuntary unemployment is impossible in a world of price flexibility. His penetrating 1941 review of Pigou's *Employment and Equilibrium* (II, ch. 89) outlines a simple classical model in which price flexibility through its effects on aggregate demand produces full employment even with a constant real wage. This is not however Pigou's model; according to Samuelson, Pigou adopts a model in which money wage flexibility is an alternative to active monetary policy. Samuelson never regarded the Pigou effect as being of real world significance (1963: II, ch. 115).

The neoclassical synthesis

Tobin (1983, p. 197) describes the neoclassical synthesis as Samuelson's greatest contribution to macroeconomics. The synthesis is outlined in articles in the early 1950s (1951: II, ch. 98; 1953: II, ch. 99; 1955: II, ch. 100) and developed in successive editions of *Economics*. It argues that monetary and fiscal policy can be used to keep the economy close to full employment, and the monetary–fiscal mix can be used to determine the rate of investment.

The synthesis represents the views of mainstream macroeconomics in the 1950s and 1960s, and perhaps in the 1970s and even the 1980s. Its activist spirit was evident in the Kennedy administration. Its acceptance must have been helped by the widespread use of Samuelson's *Economics* and by the many clones that preached its message.

Perhaps the most notorious component of the neoclassical synthesis is the 1960 Samuelson–Solow ‘Analytic aspects of anti-inflation policy’ (II, ch. 102), which presents a United States Phillips curve. This article is frequently cited as containing the view that the Phillips curve presents society's long-run
tradeoffs between inflation and unemployment. It does not. The paper starts by discussing the difficulties of distinguishing cost–push from demand–pull inflation. Samuelson and Solow then plot the scatter of percentage changes in average hourly earnings in manufacturing against the unemployment rate (the years plotted are not specified, but include the 1930s). The discussion that follows considers alternative points on the Phillips curve as policy choices for the next few years. But the authors warn explicitly that the discussion is short-term, and that it would be wrong to think that the menu of choices represented by the Phillips curve ‘will maintain its same shape in the longer run … [I]t might be that … low-pressure demand would so act upon wage and other expectations as to shift the curve downward in the longer run …’ (II, p. 1352). This is though hardly a clear demonstration of the vertical long-run Phillips curve – for Samuelson–Solow suggest that low demand might also cause the Phillips curve to shift up (a notion that many in Europe now find entirely believable) – but it is clear evidence that the authors were not guilty of believing the Phillips curve would stay put no matter what. In conversation, Samuelson has said that he was always the Kennedy administration pessimist about the long-run Phillips curve tradeoff.

The policy adviser and commentator

Samuelson has long taken an active part in economic policy debates, through Congressional testimony, as consultant to the Treasury and the Fed, in his Newsweek column that ran every three weeks from 1966 to 1981, in other newspaper columns, public addresses, advice to candidates and Presidents, and in contributions at academic conferences and in symposia. His views reflect the neoclassical synthesis, a disdain for rules rather than discretion in determining policy, and an almost shameless eclecticism. He knows the macroeconomic numbers and can speak the language of policy discussions. He is a cautious forecaster, rarely committing numbers to print, preferring to decide on which side of the consensus to place his bets. His 1941 consumption function remains his only econometric work (II, ch. 87); he has said that the major disappointment in economics in the last 40 years has been the failure of econometric evidence to settle disputes. Macroeconomics is Samuelson's primary applied economics field, with finance the second. He keeps up with the current state of the macroeconomy, drawing on forecasts and empirical work of others. He is sceptical of individual forecasts though a law of averages permits him to put some trust in the mean or median forecast. His eclecticism makes his policy views less exciting than those of economists with a strong view of the way the world works – but he has never sought to be interesting rather than right. (This despite his 1962: II, ch. 113, p. 1509) comment on John Stuart Mill: ‘It is almost fatal to be flexible, eclectic, and prolific if you want your name to go down in the history books …’.)

Nonetheless, Samuelson's implied attitude to the applications of economics gives pause. As Arrow (1967) notes, his work reveals ambivalence about the relevance of neoclassical price theory. He shows no great faith that his microeconomics can be applied to the real world. No doubt comparative advantage plays a role in that attitude. But the theoretical sophistication he brings from microeconomics does not distinguish his macroeconomic policy advice and forecasting from that of the pack; his neoclassical training is not seriously used in Samuelson's applied macroeconomics. Economics may be evidence however that he values simple microeconomics.

The consumption loans model
In the classroom Samuelson has confessed that among his many offspring the consumption loans model (I, ch. 21) is his favourite. The affection is amply rewarded: within macroeconomics the two-period lived overlapping generations structure of the model has been used in countless papers in which a tractable framework with an explicit time structure is needed. The original consumption loans model examined the role of money or bonds as institutions for making Pareto-improving trades feasible; the structure has been used subsequently to examine the dynamics of capital accumulation, the burden of the debt, Ricardian equivalence, social security, the role of money, the effects of open market operations, intertemporal substitution of leisure, labour contracts, government financial intermediation, and more. The set-up for the original model is one in which people live two periods, with utility functions defined over consumption in the two periods. Each young person receives an endowment of one nonstorable chocolate in period 1. In the absence of trade each person could consume only in period 1. Trades are possible in which the current young give part of their chocolate to the current old in return for chocolate to be received next period from the then young. But there is no double coincidence of wants, no direct way of making the bilateral trades.

Now comes the ostensible point of the model: the social contrivance of money makes trade possible, and its introduction is a Pareto-improving change given the pattern of endowments. The consumption loans model has been much criticized as a model of money, because it implies the velocity of circulation is one per generation. Equivalently, the criticism is that the model describes money as effectuating integenerational transactions whereas in practice other assets, such as bonds, serve that role. (Patinkin 1983 discusses the consumption loans model as a basis for monetary theory and also Samuelson's excursions into the history of monetary thought.)

This is certainly correct. But the significance of the consumption loans model is not its rationale for the existence of money. Rather the model has been so influential and popular because it provides a simple tractable general equilibrium structure for modelling intertemporal problems with life-cycle maximizing individuals. The earlier examples prove how easily the general structure can be adapted. It can also be adapted to more periods of life (in the original article Samuelson extended lifetimes to three periods), with 50 period lifetime models being easily solvable on computers. Its strength lies in the elegance and robustness with which it captures the essential point that finite lived individuals exist in an infinitely lived economy (we are each but not all dead in the long run).

Nearly 30 years after the consumption loans model was first published, Malinvaud (1987) drew attention to the little-noticed earlier discovery and extended development of the overlapping generations model by Allais (1947). No doubt Samuelson's eminence and location in the United States, as well as publication in *Journal of Political Economy* rather than a book, had much to do with his independent discovery providing the impetus for the exploitation of this extraordinarily useful model – though even so, it took several years before the overlapping generations structure found its way into common use.

IX Samuelson and MIT

MIT had famous economists before Samuelson: Francis A. Walker, third president of MIT (1881–99) and first president of the American Economic Association (1886–92), and Davis R. Dewey, president of the AEA (1909) and editor of the *American Economic Review* (1911–40). But the modern era, in which
the Department of Economics has risen to worldwide prominence within the profession begins with the arrival of Samuelson in 1940. Brown and Solow (1983) describe the MIT Department of the 1930s, and the transformation that nearly began in 1941 after Samuelson arrived and the first Ph.D. class, including Lawrence Klein and George P. Shultz, was about to get under way. Second World War intervened, and it was only in the late 1940s and early 1950s that the faculty and the Ph.D. programme reached full strength.

The MIT department and Ph.D. programme have been consistently among the best in the world since the early 1960s. The names of the faculty members are well known. Equally remarkable is the collection of eminent economists who are MIT Ph.Ds, whose names are legion but whom it would only be invidious to begin to list.

Samuelson's role in this success was pivotal but not domineering. His research habits (including sheer hard work), the open-door policy for students (a lesser burden for someone of whom the students were in awe than for others) and fellow faculty, his absolute refusal to use authority instead of reason in faculty meetings, his zest for conversation about economics, economists, and all else, made him a role model for a department where cooperation and friendliness have been extraordinary. He helped shape the department but he did not dictate its shape; he told one of his young co-authors that as a young man he decided that at age 40 he would stop taking initiatives in the department, at 50 he would venture an opinion only when asked, and at 60 would stop attending faculty meetings. Within the margin of error allowed to economists, he held to that resolution.

Samuelson the teacher played a lesser role. His world-wide fame (and that of other faculty members) doubtless was a major reason many of the outstanding students were there. But, at least in the last two decades, he supervised relatively few theses. His method of supervision was ideally suited to better students, for he would ask broad questions and give general guidance rather than involve himself in details.

His classroom lectures in the period 1966–9 when I heard them were not a model of organization. His advanced theory lectures were given in the first class of the day and it was always possible to tell whether the traffic had been bad that day by whether his hand-written mimeographed lecture notes were available at the beginning of the lecture or only later. The time until the notes arrived was taken up by stories setting the historical background for the problem, and anecdotes about the protagonists. The day he lectured en route to deliver his contribution to the Irving Fisher *festschrift* (1967: III, ch. 184) was especially memorable, though word filtered back from New Haven that his Yale audience was less than enchanted by the stories. His students were not surprised to find in his Nobel lecture (1970: III, ch. 130) both that he had been warned that the lecture was to be serious, and that he started a less than serious story with that warning.

His lectures were simply not designed for the novice. But they were superb for those with some background. He explained finer points, threw out open questions, made unexpected connections between topics, and communicated the zest with which he approaches economics.

**X Concluding comments**

Among the missing from this list of Samuelson's contributions are his work in the history of thought (where he has been more interested in clarifying analysis than in evaluating contributions), his methodological articles, the famous public goods theorem, the recent work on mathematical biology, the
informative and entertaining biographies of contemporaries, the frank self-evaluations, and *Economics*. The extraordinary success of *Economics* is something of a mystery, for the book is not easy – as witness the fact that simpler texts that follow Samuelson's structure have found a large market. *Economics* is a multi-level book that in its appendices, footnotes and allusions goes far beyond elementary economics. Depending on what students retain from their economics courses, *Economics* may have done much to raise the level of public discourse about economic policy.

Samuelson's self-evaluations, as in ‘Economics in a Golden Age’ (1972: IV, ch. 278), must have shocked many readers. The typical self-effacing scientist does not include stories of Newton and Gauss in his intellectual autobiography. Reflection leads to a different perspective: it would have been easy for Samuelson not to ‘tell the truth and shame the devil’ (1972: IV, p. 881). But how much more interesting it is to have the account of how Samuelson views his own achievements.

Samuelson was described in 1967 as ‘knocking on the door … of the pantheon of the greats …’ (Seligman, p. 160). He may have been let in by now. But the final word has to be left to Franco Modigliani, who, after the speeches at the 1983 party at which Samuelson was presented with the Brown–Solow *festschrift*, walked over to the seated Samuelson, wagged his finger at him, and said ‘You’, and after a pause ‘You have enriched our lives.’

Sargan, John Denis 1924–1996

David F. Hendry and Peter C.B. Phillips
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Denis Sargan was the leading British econometrician of his generation, playing a central role in establishing the technical basis for modern time-series econometric analysis. In a distinguished 40-year career as teacher, researcher, and practitioner Sargan transformed the role of econometrics in the analysis of macroeconomic time series and the teaching of econometrics. His research spanned exact finite-sample, approximate and asymptotic distribution theory for econometric estimators and tests, systems and single equation methods of modelling time-series and panel data, and problems of identification, together with applications, numerical analysis and simulation methods. Much of this foundational research remains relevant to current work.

Keywords

asymptotic theory; bootstrap; cointegration; computation; data mining; distribution of wealth; Durbin–Watson statistic; dynamic simplification; dynamic specification; Econometric Society; econometrics; Edgeworth expansions; equilibrium-correction mechanisms; estimation; finite-sample theory; full information maximum likelihood; Gaussian random walks; inference; inflationary expectations; instrumental variables; Leontieff, W.; limited information maximum likelihood; maximum likelihood; measurement error; moment approximations; Monte Carlo methods; Phillips curve; Phillips, A. W. H.; Sargan, J. D.; simplification; simulation-based methods; simultaneous equations; statistical methods; structural estimation; subjective probability; testing; three-stage least squares; unit root theory; weak instrumentation

Article

J.D. Sargan was born on 23 August 1924, in Doncaster, Yorkshire, where he spent his childhood. He was Emeritus Professor of Econometrics at the London School of Economics when he died at his home in Theydon Bois, Essex, on Saturday 13 April 1996. He received his secondary education at Doncaster
Grammar School and, at the age of 17, gained a State Scholarship for entrance to St Johns College, Cambridge, where he took a first in mathematics and was Senior Wrangler. Immediately after obtaining his degree, he was drafted into war work as a junior scientific officer attached to the RAF in Haverfordwest, where he provided basic statistical advice on the testing of new weapons systems. Like many of his generation Sargan's enthusiasm for economics was aroused by Keynes's *General Theory of Employment, Interest and Money*, and he decided to use his knowledge of mathematics and statistics to help tackle some of the pressing economic problems that faced society in the post-war years. Accordingly, in 1946 he returned to Cambridge to do more statistics, particularly time series, and to read economics, taking advantage of regulations that enabled him to complete a BA degree in economics in a year. More detailed biographical information is given in Hendry and Phillips (2003), on which much of the following discussion draws.

Starting his professional career as a lecturer in economics at Leeds University in 1948, Sargan went on to become the leading British econometrician of his generation, playing a central role in establishing the technical basis for modern time-series econometric analysis. In a distinguished career spanning more than 40 years as a teacher, researcher and practitioner, particularly during the period that he was Professor of Econometrics at the LSE, Sargan transformed both the role of econometrics in the analysis of macroeconomic time series and the teaching of econometrics. His influence on British econometrics was profound and continues today in the traditions he established.

**Early research**

Much of Sargan's research in the first decade of his career at Leeds University over 1948–58 was devoted to economic issues associated with the distribution of wealth, duopoly, production and growth. His paper (1957a) on the distribution of wealth is recognized to this day as the most general analytic treatment of the determination of the wealth distribution. His work (1958a; 1961a) on the instability of Leontieff's dynamic input–output model also attracted attention, showing that the Leontief model is not well adapted to explaining the behaviour of a decentralized economy. In addition to these researches on economic issues, he also published an early paper (1953a) on subjective probability and Bayesian thinking in economics, and another paper (1953b) on some of the statistical properties of the covariogram and periodogram.

Sargan's first foray into econometric methodology began with his paper (1957b) on ‘The Dangers of Oversimplification’, a discussion of the path-breaking analysis of the Oxford Savings Survey by Malcolm Fisher. Sargan's comments revealed a concern with three issues that recurred in his later research on econometric methodology: the abstract and constrained form of economic-theory models relative to the complexities of the data under analysis; the oversimplified nature of many estimated regression equations, excluding effects that were likely to be important in practice; and the problems of interpreting tests of large numbers of hypotheses. The first two concerns may have led to his subsequent interest in estimating relatively general and unrestricted models, and the third to his ideas about ‘data mining’ and model selection which became manifest in later research that was published posthumously in Sargan (2001a; 2001b). This discourse on oversimplification was closely followed by two major papers in econometrics that developed a theory of instrumental variable (IV) estimation, published in *Econometrica* in 1958 and the *Journal of the Royal Statistical Society* (JRSS) in 1959.
Instrumental variables

The two IV papers broke new ground, taking several large steps forward in the analytical treatment of simultaneous equations and the econometric methodology of estimation and inference. They quickly established Sargan as a technically accomplished new thinker in the econometrics arena, and they remain of lasting significance. The *Econometrica* paper laid out the methodology of IV estimation as we presently know it, provided asymptotics, related the approach to canonical correlation analysis and limited information maximum likelihood, gave tests for overidentification and under-identification, developed significance tests and confidence intervals, suggested instruments for use in practical work, and discussed the accuracy of the asymptotic theory. In the course of the latter discussion, Sargan pointed out that biases in estimation are likely to be large when the structural equation is almost unidentified, thereby foreshadowing some concerns over the effects of weak instrumentation that have occupied professional interest in recent years, following their explicit treatment in P. Phillips (1989), Nelson and Startz (1990) and Staiger and Stock (1997).

The *JRSS* paper advanced the analysis of IV estimation by considering the more general case where the structural coefficients $\alpha = \alpha(\Theta)$ satisfied some analytic constraints and could be functionalized on a vector of fundamental parameters $\Theta$, applying the theory to the case of structural models with autoregressive errors, constructing statistical tests and confidence intervals, and again looking at overidentified and unidentified cases. The framework of this paper made it possible to consider problems of dynamic specification in a rigorous manner by means of statistical testing in a nonlinear in parameters context, thereby laying a foundation for much subsequent research in econometric methodology including Sargan's own later work (1980) on dynamic simplification.

Focus on econometric theory

Sargan took up a Fulbright scholarship in the United States for two years from 1958, spending the first academic year at the University of Minnesota, teaching summer school at Stanford University, moving to the University of Chicago for 1959–60 and visiting the Cowles Foundation at Yale in 1960. These visits firmly focused his growing interest on the econometric theory of estimating structural economic models from time-series data and, together with the publication of his two papers on IV estimation, brought his work in econometrics to the attention of the North American academic community. From this point forward, Sargan's career fell under the spell of a deep fascination with the design of statistical methods suitable for studying empirical economic problems and the intellectual problems involved in working out their finite sample and asymptotic properties.

In July 1960, Sargan returned to Leeds University to take up a readership, and his growing reputation for insightful, rigorous and powerful analyses led to his election to a fellowship of the Econometric Society in 1963. In the same year, he was recruited by the London School of Economics as a Reader in Statistics, in the same department as Jim Durbin, before joining A.W.H. (Bill) Phillips (already famous for the Phillips machine and the Phillips curve) in the economics department as Professor of Econometrics in 1965.

The period of the early 1960s saw the publication of some of Sargan's most influential papers and the formation of fundamental ideas that would play a major role in his later research. Two articles in
Econometrica (1961b; 1964b) studied maximum likelihood estimation of structural systems. The first set up a framework that enabled structural estimation in the presence of autoregressive errors, thereby accomplishing a marriage of two earlier theories. The second elegantly established the asymptotic equivalence of full information maximum likelihood (FIML) and three-stage least squares (3SLS), thereby confirming the asymptotic efficiency of the latter. A third paper, presented at the Copenhagen meetings of the Econometric Society in 1963 and later abstracted in Econometrica (1964b), conceived the notion of approximating the distributions of econometric estimators by means of Edgeworth expansions. This paper was never published, but it gradually evolved into a major research programme concerned with the theory and application of Edgeworth expansions, formally beginning nearly a decade later with the publication of Sargan and Mikhail (1971).

The ‘Colston paper’

A fourth paper was prepared for the Colston Society conference on National Economic Planning held at Bristol University in 1963 and was published in 1964. This ‘Colston paper’ (1964a), as it has become known, is possibly Sargan's most famous paper and is certainly his most important contribution to empirical econometric methodology. The paper laid out the conceptual basis of the so-called ‘LSE approach’ to econometric modelling, so Sargan is justly credited with the foundation of that approach. The main characteristics of the ‘LSE approach to econometric modelling’ (which in fact draws on work from many other institutions) are blending prior economic theory ideas with thorough data analysis to develop empirical models consistent with both sources of information, but with neither having precedence. In the context of time series, this led to an emphasis on commencing empirical modelling from relatively general dynamic equations capable of capturing the properties of the data while representing the relevant economic theories, rather than estimating stochastic implementations of theory models. Few papers can have contained so many novel ideas, each of which really deserved a separate article.

The paper is characteristically self-effacing and modest about its many practical contributions, though technically brilliant and economical in its execution. First, as a framework for constructing models, Sargan considered the use of ‘long-run’ economic analysis to specify the equilibrium of a model and introduced ‘equilibrium-correction’ mechanisms as a behavioural dynamic, following some earlier work (particularly A. Phillips, 1954) on trade cycle adjustment mechanisms. In doing so, Sargan established what is now perhaps the most widely used form of time-series econometric equation in empirical work. Second, Sargan viewed the presence of autoregressive errors in time-series models as a simplification (by virtue of the implicit factorization) of more general system dynamic reactions, and he constructed mis-specification tests that were valid even after estimating dynamic equations. This work translated into Sargan's later concern (1980) for direct tests of dynamic specification and simplification strategies in inference. To address another practical problem of empirical research, the Colston paper formulated a procedure for comparing linear against logarithmic specifications, and investigated the impact of data transformations on the selection of models. The paper further proposed a nonlinear in parameters IV estimator for models where the data were subject to measurement errors, devised and implemented operational computer programs for the new econometric methods, and included a proof that the required iterative computations would converge. Finally, the paper illustrated the methodology by matching the econometric theory to the specific, topical and difficult empirical problem of wage and price
determination in the United Kingdom. Previous models had related the changes in the variables, namely, wage inflation and price inflation. Such formulations precluded any relationship between the levels of wages and prices, which could therefore drift apart over time. Sargan argued that economic agents are concerned about the level of real wages, not just price inflation, so he formulated a model with a long-run equilibrium and incorporated real wages in the wage equation, thereby distinguishing the equation from many other models, including the Phillips curve. The paper also included a data-based proxy for ‘inflation expectations’, which was called ‘an extrapolation of past price movements into the future’ and the disequilibrium of real wages from its target depended on unemployment, productivity and political factors. In modern parlance, the levels variables were integrated whereas the differences and the equilibrium errors were not, so the equation implicitly required cointegration between the levels.

Sargan's analysis highlighted the role of real-wage resistance in wage bargains, interpreting the equilibrium correction – the deviation of real wages from a productivity trend – as a ‘catch-up’ mechanism for recouping losses incurred from unanticipated inflation. As the 1960s proceeded, this real-wage resistance proved to be an insuperable barrier to the successful implementation of incomes policy in the UK. The Colston paper also included a policy discussion in which permanent and transitory effects were distinguished to ascertain which changes would persist and which fade out (such as devaluations).

Prior to Sargan's Colston paper, it was common in empirical econometric practice to test for residual autocorrelation (for example, by the Durbin–Watson statistic), and if it were shown to be present, estimate a ‘generalized’ model that allowed for an autoregressive-error process. Sargan reversed this convention, interpreting autoregressive errors as a restriction on the dynamic specification of a model that, when valid, permitted the adoption of a more parsimonious representation. He also stressed that empirical specifications should be stringently evaluated, and formulated tests for the validity of the instrumental variables used in estimation and for higher-order autoregressive errors based on the residuals from the estimated equations. Despite the existence of this test, which was valid in dynamic equations, the Durbin–Watson test continued to be widely and invalidly used for many years in dynamic systems. Regarding computation, the paper carefully addressed the logic of the calculations both to embed all of the estimators in a common framework and to ensure as efficient an iterative procedure as possible, including good selections of the initial values and step lengths, and checks for multiple optima. Sargan's demonstration that the step-wise iterative computations converged to a local optimum was the first of its kind in econometrics and reflected his keen interest in numerical analysis.

Thus, in matters of econometric theory, empirical methodology, numerical computation, empirical application and the integration of economic ideas and econometric technique, the Colston paper was a watershed of new ideas and stands as one of the classic works of econometrics. Many new avenues of research were opened up, leading through equilibrium correction to cointegration analysis, encompassing, general-to-specific modelling, and a greater emphasis on model evaluation (Hendry, 1995, provides an overview).

Advanced theory

While the Colston paper constituted Sargan's most influential work from the perspective of empirical practice, the challenges that fired his intellectual passion principally lay elsewhere – in advanced theory. His greatest theoretical interest was in developing a finite sample distribution theory of estimation and...
inference, perhaps the most technically demanding field of econometric analysis. His main contributions in this area began with the publication of Sargan and Mikhail (1971), continued throughout the 1970s and 1980s, and covered all approaches – exact analytical derivation, asymptotic series approximations of both distributions and moments, and simulation-based methods. Despite the near-intractable nature of the manifold problems in this field, Sargan devoted a huge effort to produce solutions, pushing the frontiers of knowledge forward in remarkable ways in each of the main approaches.

Since economic systems are typically dynamic and/or simultaneous, the finite sample distributions of most econometric estimators and tests are extremely complicated, and the exact derivation of these distributions is a technically daunting task in all but the most trivial cases. Even when an exact theory is developed, the final results are often of limited applicability, rely on strong distributional assumptions and do not extend to dynamic settings because of formidable mathematical complexity. Sargan (1976a, Appendix A) provided the first general exact results for the distribution of the IV estimator in a structural equation, but he was able to resolve the distribution in closed form (as distinct from integral form) only in the just identified case. The general overidentified case was resolved subsequently in P. Phillips (1980).

Even in cases where the exact distribution itself is unattainable, certain interesting features of the distribution may be established, such as the existence or non-existence of moments. In this regard, Sargan (1970) gave an elegant demonstration of the fact that structural form FIML estimators, for instance, have no finite integral-order moments (mean, variance, and so on), thereby establishing that these distributions typically have thick tails. By contrast, IV estimators generally have finite moments up to an order that is determined by the degree of overidentification of the structural equation and, on this topic, Sargan (1978) provided a definitive analysis of moment existence for the 3SLS estimator. In related work that was eventually published in his collected papers, Sargan (1975b) examined the tail behaviour of reduced form estimators and here showed that FIML estimators have finite moments to a certain order (determined by the sample size) whereas IV estimators like 3SLS typically have no finite reduced form moments in overidentified cases. These exact results reveal that FIML procedures can offer some advantages, in terms of reduced outlier activity, when the fitted reduced form is used, for example in prediction.

More general results can be obtained using series expansion and other approximations. Indeed, Sargan hoped that general approximation formulae using Edgeworth asymptotic series could be developed and incorporated into regression software, possibly with the use of computerized algebra, and then used to adjust critical values and improve inference. That goal has not yet been realized and, even with the advent of more recent bootstrap technology, continues to be elusive, partly because available approximations are rarely accurate enough and partly because major difficulties are encountered with all approaches in time-series models as the zone of non-stationarity is approached.

In terms of computer-intensive methods, Sargan helped at an early stage in the development and implementation of ideas (such as the use of antithetic and control variates) that made simulation methods viable and computationally efficient (Sargan, 1976a, Appendix D). He also made important headway in validating approaches based on moment approximations (Sargan, 1974a), and even considered the complex case where Monte Carlo estimates and moment approximations are developed in cases where the actual moments fail to exist (Sargan, 1982), so that the approximations characterize pseudo-moments (or moments of suitable approximating distributions). Pseudo-moment expansions of this type provide an intriguing way of interpreting the descriptive moment statistics conventionally reported in Monte Carlo studies.
When the moments of the underlying distribution are infinite, Sargan's results reveal that such simulation-based moment statistics can be validly interpreted as estimates of the actual moments of the Edgeworth approximating distributions up to a certain order, depending on the sample size and the number of replications. This work resolved a major potential concern in the reporting of simulation-based research, since many simulation experiments are conducted in settings where the existence of moments has not been established.

Sargan's work on asymptotic expansions of the finite sample distributions of econometric estimators and test statistics was extraordinary in its coverage and its generality, dealing with IV estimators (Sargan and Mikhail, 1971), full information maximum likelihood (Sargan, 1970), k-class estimators (Sargan, 1975a), asymptotic chi-squared criteria (Sargan, 1980), and the theory of validity of the expansions in econometric contexts (Sargan and Satchell, 1986) together with formulae and algorithms for implementation of the approach (Sargan, 1976a). The final reference in this list is Sargan's famous Walras–Bowley lecture, which was presented at the 1974 San Francisco meetings of the Econometric Society and contained a multifaceted analytical development of the subject complete with four long technical appendices dealing with different approaches and detailing formulae that must have been obtained over many years of research. In a lucid discussion of density expansions in a general setting, this paper gave explicit formulae for the components of the Edgeworth expansion for a general form of econometric statistic and revealed the dependence of the correction terms on the form of the statistic and the cumulants of the sample moments on which the statistic depended. Importantly, given subsequent research, the paper also supplemented the idea of analytic expansions with a simulation-based approach (originally due to George Barnard) that is now recognized as a version of the modern parametric bootstrap.

Sargan's Walras–Bowley lecture and several of his other papers in this demanding field are filled with technical innovations and show little sign of aging even after decades of subsequent research. Although asymptotic expansions have been found an unreliable means of improving inferential accuracy, Sargan's theoretical contributions helped blaze the trail of finite-sample theory in the 1970s and early 1980s, and they furnish a substantial body of results that have improved our understanding of the properties of econometric estimators and tests. Edgeworth expansions of the sort Sargan sought to validate and implement are now routinely used (for example, Hall, 1992; Horowitz, 2001) to validate the improvements delivered by bootstrap methods in practical econometric applications.

Other contributions

In addition to the main themes of his research outlined above, Sargan made several other intriguing contributions to econometric theory. His work (1975a) on ‘large models’, for instance, still stands as a lone pioneering piece of technical analysis of the consequences of having a system whose size is large relative to the available database, and was strangely unlike any of the other papers published in the symposium on large macroeconometric models in which it appeared. Instead, as Robinson (2003) has argued, Sargan's ideas on large simultaneous systems are more relevant to the semiparametric methods that are now commonplace in econometrics.

Sargan's (1974a) work on continuous time stochastic models represents another major contribution, again in a very different field. This paper provided the first formal asymptotic study of the effects of approximating open-loop linear differential equation systems with discrete time simultaneous equations.
Such discrete approximations were in use in practical work, and later have become more popular through the use of Euler approximations of differential equations in financial econometrics. Sargan's work built on an earlier study by Bergstrom (1966) and analysed the order of magnitude, in terms of the sampling interval, of the inconsistency in various IV and FIML econometric estimates of the coefficients in the continuous system. The paper also examined more applied issues such as the impact of this bias on forecasting.

Research on identification

In other important research, Sargan (1980) addressed the thorny issue of the effects of near non-identification on modelling and inference. Early researchers on simultaneous equations methodology had recognized the importance of, but practical difficulties in assessing, identification. Tests for under-identification (such as those in Sargan, 1958b) were a manifestation of this concern. In practical work, however, these tests are seldom used, and most empirical research proceeds by assuming an equation is identified by order conditions. Sargan recognized that, in the event of near lack of identification, the asymptotic properties of econometric estimators and tests would be affected – in fact, in an early discussion, Sargan (1959, section 6) hints at some of the possibilities, including slower rates of convergence than the usual $\sqrt{n}$ rate for a sample of size $n$. Subsequently, Sargan (1975b) explored the relationship between identification and consistent estimability in systems of simultaneous stochastic equations. Then, in his presidential address to the Econometric Society in 1980, he considered nonlinear-in-parameter models that were ‘nearly unidentified’, in the sense that the first-order rank condition for local identification failed, but higher-order defining shape conditions held so that there was still identification. In singular cases like these, which followed the earlier discussion in the 1959 paper, Sargan found that the conventional asymptotic theory for IV estimation broke down, with slower rates of convergence and a non-normal limit theory applying. Sargan (1983b) later showed that similar problems of singularity occur in dynamic models with autoregressive errors. This work on near lack of identification anticipated future research, and its arena of application has proved to be far wider than may originally have been envisaged. It is especially relevant, for instance, in micro-econometric applications where the relevance condition is weak and the IVs are sometimes barely correlated with the regressors. A prominent example in this field has been the study of the impact of schooling on earnings, where intrinsic ability affects both, is unmeasured and therefore contaminates the equation error. In such cases, the search for an instrumental variable that satisfies orthogonality with the error can lead to some arcane choices that end up being only weakly correlated with the regressors they service (Angrist and Krueger, 1991). The impact of such weak (or nearly irrelevant) instruments in applied econometric work is now an intensive area of research – see Andrews and Stock (2005) for an overview.

More time-series analysis

While Sargan retired before unit root and cointegration theory revolutionized time-series econometrics in the 1980s, he had studied Gaussian random walks, presenting an early paper on the subject at the UK econometric study group held at LSE in 1973, some results of which later appeared in joint work with Bhargava (1983c) in *Econometrica*. In further work, Sargan and Bhargava (1983d) showed that in
regression models with moving average errors where there is a root on or near the unity circle, the
likelihood function can have a local maximum at unity with reasonably high probability and that the
limit theory is nonnormal in the unit root case, invalidating conventional tests. Accordingly, their paper
argued against the empirical practice of checking for overdifferencing and in support of a most powerful
invariant test of independence based on the Berenblut–Webb (1973) statistic. This approach has
subsequently received much attention in the unit root testing context.
This brief summary of Sargan's theoretical contributions to econometrics shows the enormous range of
his research interests. While almost all of the econometric theory he developed related to time series
models fitted by time-domain methods, he also worked on adapting frequency-domain methods to
simultaneous equations models in econometrics (Espasa and Sargan, 1977), missing data (Sargan and
Drettakis, 1974b) and took some interest in panel data problems (Sargan and Bhargava, 1983e). By the
time he retired in 1984, he had worked on most of the important problems and research areas in
econometrics of his generation.

Overview

Sargan's appointment at the LSE in 1965 took its econometrics group to the technical forefront in
research. He can be credited with the creation of a generation of econometricians in the UK who were
trained to high technical levels in all aspects of quantitative economics but who were especially strong in
econometric theory and methodology. His devotion to teaching and research training was exemplary. In
total he supervised 36 successful doctorates in a host of fields covering much of the discipline of
econometric method and many of its applications. Sargan held a ‘modern’ view of dissertation research
as a process by which students learnt the practice of research by means of intimate involvement on the
part of a supervisor. In this regard, his generosity to his students and colleagues was famous at the LSE
and beyond, and undoubtedly played a major role in attracting doctoral students in econometrics. A full
listing of his graduate students and their dissertation titles is contained in Sargan (1988a).

Sargan's contributions earned him international distinction and honours. In 1980 he served as President
of the Econometric Society, presiding over the World Congress of the Society at Aix-en-Provence. He
was made a Fellow of the British Academy in 1981 and assumed the Tooke Professorship of Economic
Science and Statistics at the LSE in 1982. On retirement in 1984, he became Emeritus Professor of
Economic Science and Statistics at the University of London, and an international conference was held
in his honour at Oxford University. He became an honorary foreign member of the American Academy
of Arts and Sciences in 1987, was awarded a fellowship of the LSE in 1990, and received an honorary
doctorate from the University of Carlos III, Madrid in 1993, where a further celebratory conference was
held for him.
The wide range of Sargan's research is celebrated by the topics addressed in the volume edited by
Hendry and Wallis (1984), which commemorated his 60th birthday. He was interviewed for the journal
(1988a), which, together with his advanced econometrics lecture notes edited by Desai (Sargan, 1988b)
well illustrate his analytic rigour and intellect. Three issues of econometrics journals have appeared in
his memory: one in Journal of Applied Econometrics, 2001, which was on empirical macro-
econometrics; another in Econometric Reviews, 2001, gave a biographical history of Sargan's career and
Sargan had an enormous intellectual influence within the UK, both on the training of econometric theorists and on econometric practice. Outside the UK, his influence has not been as strong and, particularly in North America, different traditions and interests have prevailed. The Colston volume was an obscure source for economists and this undoubtedly limited the impact of his work on econometric methodology; and his choice of problems in econometric theory also did not always relate well to the immediate concerns of empirical researchers or other econometricians – he had his own vision of what the subject needed, and he pursued that vision with determination. Yet, when the history of econometrics in the second half of the 20th century is written, Sargan's place among the leaders of the econometric profession in that era is assured. The research agenda that he initiated has proved to be of tremendous scope, affecting almost every major area of the discipline. His scientific works show a remarkable durability, some of them (like the Colston paper and Walras–Bowley lecture) having the status of enduring classics. The world of econometric theory and its applications has moved on, but the themes of Sargan's research program persist in ongoing work, and his technical accomplishments remain part of the edifice of theory, technique and methodology that we collectively call econometrics.

satisficing

Herbert A. Simon
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

‘Satisficing’ (choosing an option that meets or exceeds specified criteria but is not necessarily either unique or the best) is an alternative conception of rational behaviour to optimizing. It is an attractive alternative when genuine optima could be computed only with infeasible levels of effort, or when goals are incommensurable. The standards that determine ‘satisfactory’ may be determined by the adjustment of aspiration levels in response to experience. Satisficing may provide an improved representation of actual choice behaviour, but at the cost of less predictive power than optimizing theory.

Keywords

computation; convexity; incommensurability; linear programming; operations research; optimization; satisficing; search costs; Stigler, G.

Article

A decision maker who chooses the best available alternative according to some criterion is said to optimize; one who chooses an alternative that meets or exceeds specified criteria, but that is not guaranteed to be either unique or in any sense the best, is said to satisfice. The term ‘satisfice’, which appears in the Oxford English Dictionary as a Northumbrian synonym for ‘satisfy’, was borrowed for this new use by H.A. Simon (1956), in ‘Rational Choice and the Structure of the Environment’.

Optimization and its problems

In the literature of economics and statistical decision theory, rationality has usually been defined in such a way as to imply some form of optimization, for example, maximization of utility subject to budget constraints. In simple situations, like the illustrative examples used in economics textbooks, computing a maximum may be a simple process, requiring, perhaps, nothing more onerous than taking a first
derivative and setting it equal to zero. Even in much more complex situations, involving thousands of linear equalities and inequalities but also a linear criterion function, the powerful methods of linear programming often permit optimal choices to be found with tolerable amounts of computing effort. In many (most?) real-world situations, however, genuine optima (maxima or minima) are simply not computable within feasible limits of effort (see rationality, bounded). This is especially true when decisions must be made without benefit of computer, but it is frequently true even when powerful computing facilities are available. The complexity of the world is not limited to thousands or even tens of thousands of variables and constraints, nor does it always preserve the linearities and convexities that facilitate computation.

The satisficing alternative

Faced with a choice situation where it is impossible to optimize, or where the computational cost of doing so seems burdensome, the decision maker may look for a satisfactory, rather than an optimal alternative. Frequently, a course of action satisfying a number of constraints, even a sizeable number, is far easier to discover than a course of action maximizing some function. The example has been given of searching for a needle in a haystack. Given a probability density distribution of needles of varying degrees of sharpness throughout the haystack, searching for the sharpest needle may require effort proportional to the size of the haystack. The task of searching for a needle sharp enough to sew with requires an effort that depends only on the density of needles of the requisite sharpness, and not at all on the size of the stack. The attractiveness of the satisficing criterion derives from this independence of search cost from the size and complexity of the choice situation. In a formal sense, a process of satisficing could always be converted into a process of optimizing by taking into account the cost of search, and only searching up to the point where the expected gain derivable from another minute of search is just equal to the opportunity cost of that minute (Simon, 1955; Stigler, 1961). However, this conversion imposes a new, possibly heavy, informational and computational burden upon the chooser: the burden of estimating the expected marginal return of search and the opportunity cost. Solving these estimation problems may be as difficult as making the original choice, or even more difficult. An alternative is to search until a satisfactory alternative is found. Conversely, most of the so-called optimization models of operations research and management science can more profitably be viewed as satisficing models. In the application of OR optimization techniques, some highly simplified approximation to a real-world situation is reduced to a formal model (for example, a linear programming or integer programming model), and an optimum is then calculated for this approximation with respect to a similarly approximate criterion function. The resulting ‘optimal’ decision will often provide a satisfactory decision for the real-world situation, but without guarantee that it will be better than a decision arrived at by some alternative satisficing technique. How may the satisficer set the level of the criteria that define ‘satisfactory’? Psychology proposes the mechanism of aspiration levels: if it turns out to be very easy to find alternatives that meet the criteria, the standards are gradually raised; if search continues for a long while without finding satisfactory alternatives, the standards are gradually lowered. Thus, by a kind of feedback mechanism, or ‘tâtonnement’, the decision maker converges toward a set of criteria that are attainable, but not without effort. The difference between the aspiration level mechanism and the optimization procedure is that the
Satisficing: The New Palgrave Dictionary of Economics

former calls for much simpler computations than the latter. It is somewhat analogous to the difference between adaptive and rational expectations, respectively, in the theory of choice under uncertainty.

Incommensurability of goals and outcomes

Satisficing can also provide another kind of computational advantage over optimizing. Human decision makers often find it very difficult to make trade-offs among aspects or dimensions of value that seem to them incommensurable. Of course, it is the function of the utility function to insure commensurability in all cases, but we may not wish to postulate in advance that such a function exists, or may not know how to characterize it. Three classes of situations into which incommensurability is especially likely to intrude are: (1) cases of uncertainty, where, for each alternative, a bad outcome under one contingency must be balanced against a good outcome under another; (2) cases of multiperson choice, where one person's gain is another's loss; and (3) cases where each choice involves gain along one dimension of value and loss along another very different one.

It has been observed empirically that in circumstances of these kinds, and especially when each outcome entails unpleasant as well as pleasant consequences, decision makers do not proceed promptly to a choice, but instead seek to avoid the necessity for comparison. One common reaction, for example, is to refuse to choose among the given set of alternatives, and instead, to initiate a search for a new alternative that: in case (1), will ensure at least a minimally satisfactory outcome under all contingencies; in case (2), will ensure all participants a satisfactory outcome; and in case (3), will ensure an outcome that is at least minimally satisfactory along all dimensions. The acceptance of such alternatives comes within our definition of satisficing (Hogarth, 1980).

Consequences for economic theory

It is easier to reconcile a satisficing than an optimizing theory of economic decision making with what is known empirically of actual choice behaviour and of the computational limits of the human mind. On the other hand, a great deal is given up by the substitution of the former for the latter – given up in terms of the strength and variety of theorems that can be derived from the postulate of rationality in the two cases. To make predictions about behaviour on the basis of a satisficing theory requires much more empirical data about, for example, aspiration levels and their adaptivity, than does prediction on the basis of the optimizing theory. The magnitude of the difference becomes less, however, when we recognize that the optimizing theory says nothing about the shape or content of the utility function. It simply postulates a consistency of behaviour over time that may not be found if the decision maker is satisficing instead of optimizing.

In the last analysis, a choice between the two kinds of postulates will have to be made in terms of their relative effectiveness and accuracy in predicting and explaining economic behaviour, at both micro and macro levels. There is still little consensus in the economics profession as to the circumstances under which one postulate or the other will be the more advantageous.

Sauvy was born 31 October 1898, in Villeneuve-de-la-Raho, France. He graduated from the Ecole Polytechnique, and is known as a demographer, economist, statistician and sociologist. He was an adviser to Jean Monnet and Paul Reynaud 1938–1940, a member of the Population Commission of the United Nations from 1947 to 1974, and he occupied a chair in social demography at the College of France from 1959 to 1969. He founded the Institut National d'Etudes Démographiques, one of the world's leading centres of demographic research, which he directed from 1945 to 1962. He was president of the International Union for the Scientific Study of Population from 1961 to 1963. A prolific author, his works include 45 books and many articles, on a broad range of topics from French economic history since the First World War to the effect of technological change on employment and the history of thought in demography. But he is best known among demographers and economists for his two-volume treatise *Théorie générale de la population* (1966), published in English in 1969 as *The General Theory of Population*.  

*The General Theory of Population* attempts both theoretical and substantive generality and is largely independent of the English-language literature on the subject. Thus one finds no references to or integration of the English literature on the economics of fertility or the consequences of population change or optimum population theory. Rather, the treatise presents a highly individual view of the subject. The book is full of briefly presented but penetrating insights on a wide variety of topics, often illustrated with descriptive data. For an economist, however, the main interest of the book is in its more rigorous development and extension of the concepts of economic–demographic equilibrium, and of maximum, minimum and optimum population. The analysis is entirely comparative statics, based on the assumption of first increasing, then decreasing returns to labour and population. At the minimum population and again at the maximum, the average product of labour equals the subsistence level; in
between these population sizes there remains an economic surplus after subsistence needs are met. Per capita product is of course maximized when the marginal product equals the average; more interestingly, total surplus is maximized when the marginal product of labour equals subsistence, at what is termed the ‘power optimum’ population – with the notion that a costly collective social goal can best be met at this size. The military optimum will be at a point between the power optimum and the maximum, since it requires both soldiers and surplus output. The implications of inequalities in income distribution are also discussed; the labour intensity of the consumption goods demanded by the rich will influence the size of the equilibrium population. Sauvy's theories, particularly of the determinants of the equilibrium population, have had an important influence on the thinking of economic demographers and social historians on the subject of homeostasis in human populations.

Savage, Leonard J. (Jimmie) (1917–1971)

I. Richard Savage

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Bayesian statistics; De Finetti, B.; expected utility; likelihood; probability; Ramsey, F. P.; Savage, L. J.; stable estimation

Article

L.J. (Jimmie) Savage, né Leonard Ogashevitz, was born in Detroit on 20 November 1917 and died in New Haven on 1 November 1971. His interests were encyclopedic: as a youth he immersed himself in the Book of Knowledge, and at the time of his death he was preparing for the Peabody Museum a demonstration-exhibit on animal odorants. The dominant theme of Savage's professional work was the mathematical analysis of normative behaviour.

He received a BS (1938) and Ph.D. (1941) from the University of Michigan. In the early 1940s he obtained a broad postdoctoral exposure to pure and applied mathematics at the Institute for Advanced Study in Princeton, at Cornell, Brown, the Statistical Research Group of Columbia, the Courant Institute at New York University, and at Woods Hole Marine Biological Laboratory. From 1946 to 1960 he was at the University of Chicago, where he was central to the development of the statistics programme. Subsequently, he held professorships at Michigan and at Yale. Always, he was intellectually generous with students, colleagues, visitors and correspondents.

Savage's basic views and results on normative behaviour appear in his Foundations (1954). His essential theme, still being elaborated, is the relation between a person's probability for an event and his utility for the event. In particular, his probabilities and utilities must be consistent with the principle of maximizing his expected utility. These results flow from compelling axioms of coherent behaviour and they recommend specific strategies for applied statistics, such as the use of Bayesian statistics and the likelihood principle.

Savage's axioms imply that all probabilities reflect individual experience so that there is no reason for two people to have the same probability for a particular event. His theory conflicts with traditional views that hold probabilities to be basic constants of nature. At first Savage thought this conflict would not be significant in applying statistical theory but he remarked in the preface to the second edition of the
Foundations (1972) that he was not successful in bringing the theories of statistics together at the applied level. He recognized the long process from elegant theory to serious applications. His paper on elicitation of probabilities (1971) develops methods to implement his theory of personal probability. And Savage (1977) warns against holding theoretical foundations as adequate to cover all aspects of applied statistics.

Savage's work on the foundations of statistics had major antecedents in Frank Ramsey and B. De Finetti, whose work was developed, polished and taught to a generation of scholars by Savage himself. Hewitt and Savage (1955) is both elegant mathematics and an extension of a basic result of de Finetti in the foundations of statistics. Dubins and Savage (1965) stems from a normative problem and bears mathematical fruit. Exposition of the basic ideas of applied Bayesian statistics combined with the new theory of stable estimation appears in Edwards, Lindman and Savage (1963). Additional biographical and critical analysis as well as most of Savage's published papers appear in the selection prepared by Ericson et al. (1981).

Savage's subjective expected utility model

Edi Karni

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article reviews Savage's subjective expected utility theory and takes a critical view of the corresponding concept of subjective probabilities as a representation of decision makers’ beliefs.

Keywords

Bayesian statistics; Bernoulli, D.; de Finetti, B.; decisions under uncertainty; expected utility hypothesis; monotonicity; objective probability; probability; Ramsey, F. P.; Savage, L. J.; St Petersburg paradox; state-dependent preferences; subjective probability; sure thing principle; utility; utility-maximizing behaviour

Article

In his seminal book *The Foundations of Statistics*, Savage (1954) advanced a theory of decision making under uncertainty and used that theory to define choice-based subjective probabilities. He intended these probabilities to express the decision maker's beliefs, thereby furnishing Bayesian statistics with a behavioural foundations.

The interpretation of probability as a numerical expression of beliefs is as old as the idea of probability itself. According to Hacking (1984), the notion of probability emerged in the 1650s with a dual meaning: (a) the relative frequency of a random outcome in repeated trials and (b) a measure of a decision maker's degree of belief in the truth of propositions or the likely realization of events. Both the ‘objective’ and the ‘subjective’ probabilities, as these inputs are now called, played important roles in the developments that lead to the formulation of Savage's subjective utility model.

In the early stages of their respective evolutions, the notion of utility was predicated on the existence of objective probabilities, and the notion of subjective probabilities presumed the existence of some form of utility. The ideas of utility and expected utility-maximizing behaviour were originally introduced by Bernoulli (1738). Bernoulli's preoccupation with resolving the famous St Petersburg paradox justifies
Savage's subjective expected utility model: The New Palgrave Dictionary of Economics

his taking for granted the existence of probabilities in the sense of relative frequencies. In the same vein, von Neumann and Morgenstern's (1944) axiomatic characterization of expected utility-maximizing players facing opponents who may employ a randomizing device to determine the choice of a pure strategy assumes that probabilities of these strategies are relative frequencies.

In the late 1920s and 1930s, Ramsey and de Finetti formalized the concept of choice-based subjective probability assuming that individuals seek to maximize expected utility when betting on the truth of propositions. In the behaviourist tradition, they explored the possibility of inferring the degree of confidence a decision maker has in the truth of a proposition from his betting behaviour and quantifying the degree of confidence, or belief, by probability. Invoking the axiomatic approach and taking the existence of utilities as given, Ramsey (1931) sketched a proof of the existence of subjective probabilities. De Finetti (1937) proposed a definition of subjective probabilities assuming linear utility and no arbitrage opportunities.

These developments culminated in the work of Savage. While synthesizing the ideas of de Finetti and von Neumann and Morgenstern, Savage introduced a new analytical framework and conditions that are necessary and sufficient for the existence and joint uniqueness of utility and probability, and the characterization of individual choice as expected utility-maximizing behaviour.

**Savage's analytical framework**

Decision making under uncertainty pertains to situations in which a choice of a course of action, by itself, does not determine a unique outcome. To formalize this notion Savage (1954) introduced an analytical framework consisting of a set $S$, whose elements are *states of the world* (or states, for brevity); an arbitrary set $C$, of *consequences*; and the set $F$, of *acts* (that is, functions from the set of states to the set of consequences). Acts correspond to courses of action, consequences describe anything that may happen to a person, and states are possible resolutions of uncertainty, that is, ‘a description of the world so complete that, if true and known, the consequences of every action would be known’ (Arrow, 1971, p. 45). Implicit in this definition is the notion that there is a unique true state. Events are subsets of the set of states. An event is said to obtain if it includes the true state.

A decision maker is characterized by a preference relation, $\succeq$, on $F$. The statement $f \succ f'$ has the interpretation ‘the course of action $f$ is at least as desirable as the course of action $f'$. Given $\succeq$, the strict preference relation $\succ$ and the indifference relation $\sim$ are defined as follows: $f \succ f'$ if $f \succeq f'$ and not $f' \succ f$; $f \sim f'$ if $f \succ f'$ and $f' \succ f$.

**The preference structure**

The evaluation of a course of action in the face of uncertainty involves the decision maker's taste for the possible consequences and his beliefs regarding their likely realization. Savage's subjective expected utility theory postulates a preference structure, depicted axiomatically, permitting the numerical expression of the decision maker's valuation of the consequences by a utility function, that of his beliefs by a (subjective) probability measure on the set of all events, and the evaluation of acts by the mathematical expectations of the utility with respect to the subjective probability.
To state Savage's postulates, I employ the following notation and definitions. Given an event \( E \) and acts \( f \) and \( h \), let \( f_E h \) be the act such that \(( f_E h)(s) = f(s)\) if \( s \in E \), and \(( f_E h)(s) = h(s)\) otherwise. An event \( E \) is null if \( f_E h \sim f' E h' \) for all acts \( f \) and \( f' \), otherwise it is non-null. A constant act is an act that assigns the same consequence to all the states. To simplify the exposition, I denote the constant acts by their values (that is, if \( f(s) = x \) for all \( s \), I denote the act \( f \) by \( x \)).

The first postulate asserts that the preference relation is transitive and that all acts are comparable.

**P.1:** A preference relation is a transitive and complete binary relation on \( F \).

The second postulate, also known as the sure thing principle, requires that the preference between acts depend solely on the consequences in states in which the payoffs of the two acts being compared are distinct. This implies that the valuation of the consequences of an act in one event is independent of the payoffs of the same act in the complementary event.

**P.2:** For all acts, \( f, f', h, h' \) and every event \( E \), \( f E h \succ f' E h' \) if and only if \( f E h' \succ f' E h' \).

The sure thing principle makes it possible to define conditional preferences as follows. For every event \( E' \), \( f \succ E f' \) if \( f \succ f' \) and for every \( s \) not in \( E \), \( f(s) = f'(s) \).

The third postulate asserts that the ordinal ranking of consequences is independent of the event and the act that yield them.

**P.3:** For every non-null event \( E \) and all constant acts, \( x \) and \( y \), \( x \succ y \) if and only if \( x E f \succ y E f \) for every act \( f \).

In view of P.3, it is natural to refer to an act that assigns to an event \( E \) a consequence that ranks higher than the consequence it assigns to the complement of \( E \) as a bet on \( E \). Ramsey (1931) was the first to suggest that a decision maker's belief that an event \( E \) is at least as likely to obtain as another event \( E' \) should manifest itself through preference for a bet on \( E \) over the same bet on \( E' \).

The fourth postulate, which requires that the betting preferences be independent of the specific consequences that define the bets, formalizes this idea.

**P.4:** For all events \( E \) and \( E' \) and constant acts \( x \), \( y \), \( x' \) and \( y' \) such that \( x \succ y \) and \( x' \succ y' \), \( x E y \succ x' E y' \) if and only if \( x E y \succ x' E y' \).

Postulates P.1–P.4 imply the existence of a transitive and complete relation on the set of events that has the interpretation ‘at least as likely to obtain as’ representing the decision maker's beliefs as qualitative probabilities. They also imply that the decision maker's risk attitudes are event-independent.

The fifth postulate renders the decision making problem and the qualitative probabilities non-trivial by ruling out that the decision maker is indifferent among all acts.

**P.5:** For some constant acts \( x \) and \( x' \).

The sixth postulate introduces a form of continuity of the preference relation. It asserts that no consequence is either infinitely better or infinitely worse than any other consequence. Put differently, the next postulate requires that there be no consequence that, if it were to replace the payoff of an act on a non-null even, no matter how unlikely, will reverse a strict preference ordering of two acts.

**P.6:** For all acts \( f, g \), and \( h \) satisfying \( f \succ g \), there is a finite partition \( \{ E_i \}_{i=1}^n \) of the set of states such that, for all \( i \), \( f \succ g E_i h \) and \( h E_i f \succ g \).

A probability measure is non-atomic if every non-null event may be partitioned into two non-null sub-events. Formally, \( \pi \) is a non-atomic probability measure on the set of states if for every event \( E \) and
number \(0 < \alpha < 1\) there is an event \(E' \subset E\) such that \(\pi(E') = \alpha \pi(E)\). Postulate P.6 implies that there are infinitely many states of the world and that, if there exists a probability measure representing the decision maker's beliefs, it must be non-atomic. Moreover, the probability measure is defined on the set of all events, hence it is finitely additive (that is, for every event \(E\), \(0 \leq \pi(E) \leq 1\), \(\pi(S) = 1\) and for any two disjoint events, \(E\) and \(E'\), \(\pi(E \cup E') = \pi(E) + \pi(E')\).

The seventh postulate is a monotonicity requirement asserting that, if the decision maker considers an act strictly better (worse) than each of the payoffs of another act on a given non-null event, then the former act is conditionally strictly preferred (less preferred) than the latter.

\[\text{P.7: For every event } E \text{ and all acts } f \text{ and } f', \text{ if } f \succ E f'(s) \text{ for all } s \in E \text{ then } f \succ E f' \text{ and if } f'(s) \succ E f \text{ for all } s \in E \text{ then } f' \succ E f.\]

Representation

Savage's theorem establishes an equivalence between a preference relation having the properties described by the seven postulates and a preference relation induced by the maximization of the expectations of a utility function on the set of consequences with respect to a probability measure on the set of all events. The utility function is unique up to a positive affine transformation and the probability measure is unique.

\[\text{Savage's theorem: } \Rightarrow \text{ be a preference relation on } F. \text{ Then the following two conditions are equivalent:}\]

1. (a) \(\Rightarrow\) satisfies postulates P.1–P.7.

Interpretation and criticism

In Savage's theory, consequences are assigned utilities that are independent of the underlying state of the world, and events are assigned probabilities that are independent of acts. These assignments, however, are not implied by the postulates. This observation merits elaboration.

The structure of the preference relation, in particular postulates P.3 and P.4, implies that the preference relation is state independent. In other words, the ordinal rankings of both consequences and bets are independent of the underlying events. This implies event-independent risk attitudes but does not, by itself, rule out the possibility that the states affect the decision maker's well-being, or that the utility of the consequences is state dependent. Put differently, Savage's model implies state-independent preferences but not a state-independent utility function. The utility and probability that figure in the representation of the preferences in Savage's theorem are unique as a pair, that is, the probability is unique given the utility and the utility is unique (up to a positive affine transformation) given the probability. It is possible, therefore, to define new probability measures and state-dependent utility functions – and thereby to obtain a new subjective expected utility representation – without violating any of Savage's postulates. For instance, let \(\gamma\) be a bounded, positive, non-constant, real-valued function on \(S\), and let \(\Gamma = \int_S \gamma(s) \, d\pi(s)\). For every event \(E\), define \(\hat{\pi}(E) = \int_E \gamma(s) \, d\pi(s) / \Gamma\) and let \(\hat{u}(x, s) = \Gamma u(x) / \gamma(s)\) for all \(s \in S\) and \(x \in C\). Then, for every act \(f\),
Savage's subjective expected utility model: The New Palgrave Dictionary of Economics

Because $\gamma$ is arbitrary and non-constant, $\pi \neq \hat{\pi}$. This shows that the uniqueness of the probability in Savage's theory is predicated on the convention that the utility function is state independent (that is, constant acts are constant utility acts). This convention is not implied by the postulates, it has no choice manifestation, and its validity is not subject to refutation in the context of Savage's analytical framework. Moreover, the employment of this convention renders the definition of probability in Savage's model arbitrary and the claim that it represents the decision maker's beliefs scientifically untenable. That said, it is noteworthy that, in so far as the theory of decision making under uncertainty is concerned, because all the representations obtained using the procedure outlined above are equivalent, the failure to correctly quantify the decision maker's beliefs is not critical. In so far as providing choice-based foundations of Bayesian statistics is concerned, however, this failure is fatal. A somewhat related aspect of Savage's model that is similarly unsatisfactory concerns the interpretation of null events. Ideally, an event should be designated as null and be ascribed zero probability if and only if the decision maker believes it to be impossible. In Savage's model an event is null if the decision maker displays indifference among all acts that agree on the payoff on the complement of the said event. However, this definition does not make a distinction between an event that the decision maker perceives as impossible and one whose possible outcomes he perceives as equally desirable. It is possible, therefore, that events that the decision maker believes possible, or even likely, are defined as null and assigned zero probability. Consider this example: a passenger who is indifferent to the size of his estate in the event that he dies is about to board a flight. For such a passenger, a plane crash is a null event and is assigned zero probability, even though he may believe that the plane could crash. This problem renders the representation of beliefs by subjective probabilities dependent on the implicit and unverifiable assumption that in every event some outcomes are strictly more desirable than others. If this assumption is not warranted, the procedure may result in a misrepresentation of beliefs.

The requirement that the preferences be state independent imposes significant limitations on the range of applications of Savage's theory. Choosing a disability insurance policy, for example, is an act whose consequences - the indemnities - depend on the realization of the decision maker's state of health. In addition to affecting the decision maker's well-being, it is conceivable that alternative states of disability influence his risk attitudes. Disability may also alter the decision maker's ordinal ranking of the consequences, which is a violation of P.3. For instance, a leg injury may reverse a decision maker's preferences between going hiking and attending a concert. Similar observations apply to the choice of life and health insurance policies.

Savage presented his seven postulates as principles that a rational individual ought to follow rather than an hypothesis describing how individuals actually choose among courses of action in the face of uncertainty. Indeed, almost from the moment of its inception, the descriptive validity of Savage's model - in particular, the sure thing principle, which is responsible for the specific functional form of the representation and the separability and linearity in the probabilities - has been qsted. It has repeatedly been shown in experimental settings that the theory fails systematically to predict subjects' choice. The most severe and remarkable criticism in this regard is due to Ellsberg (1961), who demonstrated using simple thought experiments that individuals display choice patterns that are inconsistent with the existence of beliefs representable by a probability measure.

Sax was born in Jauernig (then, Austrian-Silesia; today, Javornik in Czechoslovakia). He studied in Vienna, where he became an university lecturer. After some practical activity (among other things in the railway organization), he became, in 1879, professor of political economy at the University of Prague. From 1879 to 1885 he was a member of the Vienna Chamber of Deputies. In 1893 he abandoned his Prague professorship and retired to Abbazia, Istria (then, Italy; today, Opatija in Yugoslavia), where he died in 1927.

Sax holds a peculiar place within the older Austrian school. He shared its basic idea according to which ‘value’ virtually opens the way to the explanation of all economic problems. However, in methodological matters, in the conception of economics, and in the interpretation of the value phenomenon itself, he went his own way. For Sax ‘value’ is not the rationally perceived significance of a commodity for the welfare of a person, but an emotional relationship between the person and the world of goods. His conception of economics is based on the distinction between individualism and collectivism. Behaviour is individualistic if it results (self-determined) from the individual personality; behaviour is collectivistic if the individual is motivated only as a member of a (larger and stable) group and in relation to this group. According to Sax, these two fundamental forces shape all economic and social phenomena in a characteristic way: the simple feeling of value becomes, individualistically, the exchangeable value; collectivistically, the complicated determination of value within a group. In relation to the social environment, these two fundamental forces can appear egoistic, altruistic and (as a mixture of both) mutualistic. Sax believed he had overcome the psychological one-sidedness of the classical school, and therefore he considered the findings of his theoretical work as exact results of inductive research.

According to Sax, the distinction between individualism and collectivism corresponds to the (value-based) theories of private and public economy. The absolute tax level (today called tax–GNP ratio) is determined by evaluations of such individuals in whom the fundamental force of collectivism is effective; they take care of the fact that the levels of the private and the public sphere are balanced. The relative tax level (today called tax apportionment to individuals) is deduced by Sax from the ‘equivalence of value’ of the individual tax liabilities; this results in the application of the equal sacrifice theory. For Sax, compulsion in taxation merely substitutes for a lack of correct insight. The

'stamemindedness of those governing' and the 'resistance of those governed' prevent the abuse of power. Besides fiscal theory problems, Sax paid particular attention to the then young science of transport economics. His statements on transport policy (1878–9) are founded on a theoretically analysed historical experience, although the theoretical sections do not reach up to the abstract (mathematical) level such as Launhardt's treatment of transport problems. Despite the fact that much of Sax's writings on transport economics has since become obsolete, the book remains an excellent piece of applied economics.

French statesman, financier and economist, born in Paris in 1826; died there on 22 April 1896. He was the son of Horace Emile Say, the grandson of Jean-Baptiste Say, the nephew of Louis Auguste Say and Charles Comte. Léon Say became one of the most prominent statesmen of the French Third Republic. He served as Finance Minister from 1872 to 1879, and again in 1882, overseeing the largest financial operation of the century – payment of war reparations in Germany. His financial policies were directed towards a decrease in public expenditures and the removal of barriers to internal trade. A brilliant speaker and debater, he railed against socialism from the left and protectionism from the right. With Gambetta and Freycinet, he launched the ambitious programme of public works that bears the latter's name. Upon leaving the Cabinet, Say returned to his seat in parliament, assuming the leadership of the free trade party. He was at one time considered for the presidency of the republic, but was gradually set apart from his constituency by a rising tide of radicalism.

As an economist, Say's talents fall somewhere between the modest gifts of his father and the more imposing skills of his grandfather. He left no large work nor did he create any school of thought. Like his father, he was faithful to the doctrines of his namesake, and was a competent editor of his grandfather's works. In his youth he associated briefly with Léon Walras in a scheme to promote cooperative associations of production. He later became a frequent contributor to the Journal des économistes, mostly on economic policy, and a lecturer at the Ecole des Sciences Politiques, which was the prototype of the London School of Economics and Political Science. Say had a broad knowledge of history and theory, and he was capable of sustained exposition at a high level. As an example, his Solutions dómocratiques de la question des impôts’ (1886) was directed against the idea of using taxation as a means of social equalization. He argued, instead, that the basis of taxation should always be real (based on property), never personal.

A curious parallel exists in the careers of Say and Turgot, whose name Say declared he could not even...
pronounce without emotion. They shared a body of ideas and a similar destiny. Both achieved eminence as finance ministers in the French government, only to be turned out upon losing public favour. Say however, helped to immortalize his predecessor by writing one of the earliest biographies of Turgot.

aggregate supply and demand; classical economics; labour theory of value; Malthus, T. R.; methodology of economics; Mill, J.; Ricardo, D.; Say's Law; Sismondi, J. C. L. S. de; Smith, A.; utility theory of value

Article

Although Jean-Baptiste Say is remembered primarily for Say's Law, one of the cornerstones of classical economics, he was also an early proponent of the utility theory of value, and was therefore very much at odds with his classical contemporaries, to whom labour was the source of value. Say's best-known work, his *Traité d’économie politique* (published in five editions, from 1803 to 1826) was intended as a shorter and more systematic presentation of economics than Adam Smith's *Wealth of Nations*. The success of this book made Say the best-known expositor of Smith in Europe and America, and he became in 1815 France's first professor of political economy. Translations of the *Traité* were used as textbooks at universities on both sides of the Atlantic.

Say was not, however, a mere uncritical expositor of Smith. The central importance of labour in Smith's discussions of value was replaced by Say's concern to show utility as the ultimate foundation of value. Production itself was defined as the production of utility, not of physical output. He noted in the first chapter of his *Traité* that this was subjective utility, which the economist must take as given data, however much moralists might attempt to change people's valuations. Businessmen also played a much more important and honourable role in Say than in Smith – Say having been a businessman himself and descended from a mercantile family. The *Traité d’économie politique* also went beyond Smith in developing what Say called ‘one of the most important truths of political economy’ – that supply creates its own demand, the doctrine ultimately named Say's Law.

Much controversy has surrounded the question of Say's originality in developing this principle, or rather, related series of principles. Claims have been made for James Mill as the real author of Say's Law. However, Mill's earliest published discussion of issues involving aggregate supply and demand came in an 1804 review in *The Literary Journal* of a book by Lauderdale – one year after the first edition of Say's *Traité* was published. While the chapter (‘Des Débouchés’) in which Say's Law was first set forth
was very brief in the first edition, there was further discussion of the same principle in that same edition, notably in Chapter 5 of the second volume. Later editions brought these scattered discussions together in an enlarged chapter on aggregate supply and demand, but much of the substance was there from the beginning. Mill was only the first of many to reformulate and elaborate what Say had done.

Say was concerned with the methodology as well as the substantive propositions of economics. He advocated systematic analysis rather than naive empiricism, but was also highly critical of the abstract deductive method of Ricardo and his followers. According to Say, Ricardo ‘pushes his reasonings to their remotest consequences, without comparing their results with those of actual experience’. During a friendly correspondence with Ricardo, Say pointed out that facts ‘are the masters of us all’. In the introduction to his *Traité d’économie politique*, Say also expressed his fear of ‘our always being misled in political economy, whenever we have subjected its phenomena to mathematical calculation’.

Say was in touch with the leading economists of his day, by mail and in person. He never resolved his differences with Ricardo as to whether value was based on labour or utility, but in attempting to clarify his position in 1822, Say spoke of ‘the last quantity of useful things’ as being crucial – a suggestion of the missing *marginal* concept essential to the utility theory of value. In his correspondence with Sismondi and Malthus, he came ultimately to reconcile Say's Law with their theories of aggregate disequilibrium. The fifth edition of his *Traité d’économie politique* in 1826 incorporated some of Sismondi's reasoning at the end of his chapter on Say's Law of markets (unfortunately, the English translation is from the previous edition) and called this to Malthus's attention as an admitted ‘restriction’ on this doctrine. A later textbook by Say, *Cours complet d’économie politique*, published in 1828–9, followed the chapter on Say's Law with one entitled ‘Limits of Production’, a phrase from Sismondi along with Sismondian analysis in the chapter.

Say was a policy-oriented economist rather than a model-builder like Ricardo. In his introduction to the new restrictions added to his chapter on the law of markets, Say remarked: ‘Now, we are studying practical political economy here.’ To Malthus he wrote: ‘It is better to stick to facts and their consequences than to syllogisms.’

### How to cite this article

Say's Law, the apparently simple proposition that supply creates its own demand, has had many different meanings, and many sets of reasoning underlying each meaning – not all of these by Jean-Baptiste Say. Historically, Say's Law emerged in the wake of the Industrial Revolution, when the two striking new economic phenomena of vastly increased output and the economy's cyclical inability to maintain sales and employment led some to fear that there was some inherent limit to the growth of production – some point beyond which there would be no means of purchasing it all. At the very least, some feared, there would not naturally or automatically be generated sufficient purchasing power to absorb the ever-growing output of the industrial economy, unless special policy arrangements were made to insure that income would be large enough to purchase output. Robert Owen and Karl Rodbertus exemplified these views, which were not those of any school of economists.

Say's Law attempted to answer such concerns by pointing out that the production of output tends of itself to generate purchasing power equal to the value of that output: supply creates its own demand. But Say's Law did not spring forth, full blown, like Minerva from the head of Zeus. It emerged piecemeal over a span of years, enveloped in controversies that ultimately involved nearly every noted economist of the early 19th century, and as its elaboration proceeded its definitions shifted under polemical stress. Moreover, the basic terms of discourse in economics were themselves in a process of evolution. The words ‘supply’ and ‘demand’ had different meanings for those economists like Sismondi and Malthus, groping towards the schedule or functional meanings of today, from those in the writings of David Ricardo or John Stuart Mill, who rigidly defined the terms as quantity supplied and quantity demanded. They repeatedly argued past each other.
The central meaning of Say's Law was implied by J.B. Say's rhetorical question, ‘how could it be possible that there should now be bought and sold in France five or six times as many commodities as in the miserable reign of Charles VI?’ This dramatized his main point, that there was no long-run limit to the growth of output, or of the demand for it. This did not deny that a short run derangement of the economy could take place, but Say described this as ‘an evil which can only be passing’. Moreover, he attributed these short-run phenomena to a wrong mixture of output, compared to consumer demand, rather than to aggregate overproduction. This was an ad hoc addendum, not logically implied by the principle of supply creating its own demand. Say thus created a subsidiary meaning of Say's Law – a denial that there was such a thing, even in the short run, as aggregate overproduction – which is to say, that there was no such thing as an equilibrium aggregate output. There could be a ‘partial glut’ of particular commodities produced in excess of demand but there could be no ‘general glut’ of commodities in the aggregate. It was this vulnerable subsidiary argument which Sismondi and Malthus attacked in the 19th century and Keynes in the 20th.

The first edition of Say's *Traité d'économie politique* in 1803 contained the crucial propositions of Say's Law, though not all in his chapter on markets (‘Des Débouchés’). The quantity of products demanded was ‘without a doubt’ determined by the quantity of products created, according to Say. ‘The demand for products in general is therefore always equal to the sum of the products’, he said. The distinction between secular stagnation and short-run downturns, and between partial and general gluts, was also present from the first edition of Say's *Traité*. These ideas all reappeared in James Mill's writings shortly afterward, but Say's priority is clear, both from the dates of the publications and from Mill's citation of Say in his own early writings, depriving him of even subjective originality.

The elder Mill did, however, make a significant contribution to the evolution of Say's Law. Where Say had asserted the inherent sufficiency of demand to purchase supply in terms of half the goods being essentially bartered for the other half, or in terms of saved money being spent as investment, Mill added the behavioural theory that people produced only because of, and only to the extent of, their demand for other goods. Each individual's supply equalled his demand *ex ante*; therefore society's supply must equal society's demand *ex ante*. Unfortunately, Mill also cited the *ex post* identity of supply and demand as evidence, as did J.R. McCulloch, Robert Torrens and John Stuart Mill.

While Say's priority over James Mill is readily established, the notion that in the long run aggregate demand ‘has no known limits’ was stated by the Physiocrat Mercier de la Rivière in the year of Say's birth. Nor was this a passing remark. His book, *L'Ordre naturel et essential des sociétés politique* (1767), especially Chapter 36, contained both the concept of a circular flow of money and of goods, and discussions of the conditions under which the existing level of aggregate output would be reproduced in subsequent time periods, as well as the conditions in which it would fall because receipts failed to cover the supply price of inputs. Yet it was not through Mercier de la Rivière but through Say that Say's Law entered the mainstream of economics. Ironically, both Say and Mill attacked Mercier de la Rivière. While his statement that aggregate demand is unlimited anticipated both of them, his concept of aggregate equilibrium and disequilibrium was anathema to the subsidiary version of Say's Law that was an integral part of the doctrine during the early 19th century.

Adam Smith also anticipated Say when he asserted in *The Wealth of Nations* (p. 407) that ‘a particular merchant’ could have a glut of goods but that a whole nation could not. Moreover, Smith's doctrine that savings rather than consumption promoted growth provided yet another dimension to Say's Law and the controversies surrounding it. One possible meaning of Smith's statement was that a shift in the savings

function – a willingness to save and invest more at a given rate of return – would tend to increase future output. But another interpretation, equally permissible in the absence of functional concepts, was that an increased quantity saved would promote future growth. Lord Lauderdale interpreted Smith in the latter sense, and attacked this proposition on grounds that there was some equilibrium level of savings and investment which, if exceeded, would reduce rates of return to a point that would cause the existing levels of savings to decline in subsequent time periods. In short, Lauderdale argued that there could be a general glut of capital, just one step from saying that there could be a general glut of aggregate output.

The leading critics of Say's Law during the classical era – Sismondi, Malthus and Lauderdale – all asserted short-run disequilibrium, not long-run stagnation, but the long-run comparative-statics approach of the Ricardians made it especially difficult for them to understand what the critics were saying in short-run dynamic terms. While Say himself ultimately came to understand – and reproduce in his later writings – the aggregate equilibrium theories which he now reconciled with the central meaning of Say's Law, more than 20 years later John Stuart Mill was still representing Lauderdale, Sismondi and Malthus as stagnationists. However, after completely misinterpreting their positions, J.S. Mill also set forth the most sophisticated analysis of the issues in classical economics in the second of his Essays on Some Unsettled Questions in Political Economy (1844).

After denouncing the ‘mistakes’, the ‘completely erroneous’ ideas and ‘palpable absurdities’ of those who emphasized the need for adequate aggregate demand, J.S. Mill nevertheless conceded that there could be ‘general excess’ in the sense that when money was not immediately respent, a seller ‘does not therefore necessarily add to the immediate demand for one commodity when he adds to the supply of another’. Thus there may be ‘a superabundance of all commodities relative to money’. Both the previous classical economists and such critics as Sismondi and Malthus had analysed the issue of aggregate output in essentially barter terms, despite incidental references to money. The theory of equilibrium aggregate output in Sismondi and Malthus was based on a balance of the utility of output and the disutility of the efforts required to produce it – a balance which could be temporarily unbalanced in their short-run dynamic models, though not in the long-run comparative statics model of James Mill.

John Stuart Mill's model, in which the role of money was important, was a different dimension, though not unique – Robert Torrens having expressed similar ideas more than two decades earlier. However, on the crucial issue of an aggregate equilibrium output in a non-monetary model, J.S. Mill remained adamant that there could be only internal disproportionality, not aggregate overproduction. Output, ‘if distributed without miscalculation among all kinds of produce in the proportion which private interest would dictate, creates, or rather constitutes, its own demand’. The issue remained to J.S. Mill one of internal ‘proportions’, not aggregate amounts.

Discussions of Say's Law virtually disappeared from economics for at least a generation after John Stuart Mill wrote on it in the 1840s. Even the sweeping challenges of neoclassical economics to classical orthodoxy, beginning in the 1870s, largely bypassed the issue of Say's Law. Isolated criticisms came from beyond the pale – from Marx, Hobson and assorted cranks. Within the economics profession, Say's Law was one of those things simply assumed and ignored. Early in the 20th century, Knut Wicksell explored the relationship between the quantity theory of money and Say's Law. The classical assumption that money is demanded only for transactions during the current period is incompatible with the price level being determined by the quantity of money, for a change in the price level requires that, at some point in the process, there must be either an excess or deficient money demand for goods in the aggregate, causing the general price level to go up or down in response. However, Wicksell's own
belated recognition by the English-speaking world meant that Say's Law did not become a major concern again until the appearance of John Maynard Keynes's *General Theory of Employment, Interest and Money* in 1936.

Modern, and especially Post Keynesian, discussions of Say's Law have revealed it to be not one, but a number of related, propositions. The most general of these propositions is that the aggregate value of goods supplied (including money) equals the aggregate value of goods demanded (including money). Thus an excess supply of goods is the same as an excess demand for money. This proposition has been christened 'Walras' Law'. Where there is assumed to be no excess demand for money, as in James Mill, for example, then aggregate supply is identically equal to aggregate demand. This proposition has been christened 'Say's Identity'. When the equality of aggregate supply and demand is stated as an equilibrium condition – a sense in which equilibrium output theorists like Sismondi and Malthus could subscribe to it – then it merely states that both equilibrium and disequilibrium levels of output may exist. This proposition has been christened 'Say's Equality'. This Ricardo, James Mill, and initially Say, all denied.

The Keynesian Revolution not only produced a more sophisticated theory of aggregate equilibrium, but also contributed to the distortion of Say's Law, which Keynes reduced to Say's Identity. According to Keynes, Say's Law 'is equivalent to the proposition that there is no obstacle to full employment'. Only the cruder statements of the Ricardians said that.

Say's Law has been an important proposition in many ways. By indicating that the possibility of purchasing output from the income generated during its production is ultimately not limited by the mere size of output, Say's Law exposed the fallacy of recurrent popular fears that economic growth must collide with some impassable limit. The modern Post Keynesian delineations of the different senses of Say's Law (Walras’ Law, Say's Identity, Say's Equality) more precisely specify the conditions of aggregate equilibrium and disequilibrium, and indicate the theories of economic behaviour behind them. Finally, the long history of controversies over Say's Law sheds light on the enormous difficulties involved when even intelligent thinkers with honesty and goodwill try to understand each other's theories without clearly defined terms and without a clear sense of the conceptual framework of the opposing views. In short, its implications reach beyond economics to intellectual history in general.

Scandinavia, economics in

Niels Kærgård, Bo Sandelin and Arild Sæther
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Scandinavia includes in a narrow sense Denmark, Norway and Sweden, which have similar languages and have strongly influenced one another. Danish economists made early contributions to neoclassical distribution theory, econometric analysis and multiplier theory. Like most economists from small-language communities they understood the major European languages but wrote in their domestic languages, which delayed international knowledge about their contributions. In Norway Ragnar Frisch revolutionized economics in the 1930s, but met opposition from colleagues. Swedish economics flourished in the early 20th century with Knut Wicksell and Gustav Cassel and later with the Stockholm School. In recent decades national traits have largely disappeared.

Scandinavia, economics in: The New Palgrave Dictionary of Economics

Denmark–Norway before 1814

Ludvig Holberg (1694–1754) was the first to forcefully advocate political economy as a science and academic discipline in the dual monarchy of Denmark–Norway. Today he is recognized as the Molière of northern Europe, but few know about his contribution to economics. Strongly influenced by the natural law philosopher Samuel Pufendorf (1632–94), but also by English and French Enlightenment philosophy, he studied economic phenomena and problems from the perspective of moral philosophy. His contributions cover a wide spectrum and include his literary authorship, his achievements at the University of Copenhagen, and his efforts in re-establishing Sorö Academy as a modern centre of higher education. The latter was made possible in 1747 when Holberg bequeathed his estates to Sorö Academy. The Academy placed modern sciences on its curriculum, and quickly became an alternative to the University of Copenhagen, which was marked by a strong theological influence. At the Academy students were taught ‘Political Economy, Commerce and Cameral Sciences’. This proved a great success. In the second half of the 18th century the Academy functioned as the academic home for social scientists and social critics. At Sorö Jens Schelderup Sneedorff (1724–64) was appointed the first professor of political economy and public law in 1751. He and his successor Andreas Schytte (1726–77) were influenced both by German cameralism and, like Holberg, by English and French philosophers. Schytte wrote the first textbooks in political economy in the local language.

At the university Ole Stockfleth Pihl (1729–65) was appointed the first professor in political economy in 1761. Before that he had been the editor and publisher of the monthly *Oeconomisk Journal*. As the position had no salary he resigned after two years. The next professor, Johan Christian Fabricius (1745–1808), was appointed in 1772. His salary was so small that after four years he accepted a chair in natural history, political economy and cameral sciences at University of Kiel, the second university in the dual monarchy. Here he created ‘an economic garden’ and wrote a widely used textbook in political economics.

Another important factor in the development of political economy as a science was the establishment of *Danmark og Norges Oeconomiske Magazin* in 1756. Its initiator and editor, the bishop of Bergen Erik Pontoppidan (1698–1764), was an enlightened mercantilist, whom the king had called on to carry out reforms at the university. His reforms were not successful, but the *Economic Magazin* became a sanctuary and a workshop for those who were engaged with economic questions in the middle of the 18th century. Otto Diderich Lütken (1713–88), its most important contributor, is considered the most original of economic thinkers in Denmark–Norway in the 17th century. He published several essays discussing theoretical as well as practical economic issues. In one article he claims, as Malthus did 40 years later, that there is a connection between population and available food, and that population would increase until a shortage of food put an end to further growth.

The influence of the *Economic Magazin* was considerable. People connected with this periodical and with Sorö Academy gained influence from the mid-18th century and far into the 19th century. Their thinking found expression in the agricultural and social reforms carried out towards the end of the 19th century, and is credited with giving impetus to a translation of Adam Smith’s *Wealth of Nations* in 1779, initiated by Norwegian tradesmen.

Denmark after 1814
Characteristics of Danish development

Unlike in many other countries, social development in Denmark has been characterized by its continuity. No political changes have been sufficiently radical to create a break in academic traditions. In 1849 the country changed from being an absolute monarchy to being a democracy, but A.F. Bergsøe was professor in political economy during the whole period 1845–54. In 1901, after decades of political struggle, a right-wing government was replaced by parliamentarism and a left-wing government, but H. W. Scharling, Minister of Finance in the right-wing government, was professor in political economy without interruption from 1869 to 1911. Furthermore, the economic systems in Denmark have not been subjected to disturbances great enough to leave traces in the science of economics. The Danish economy has been marked by relatively stable growth for 200 years.

Apart from continuity, a dominant fact is the small size of the country. Until 1936, the University of Copenhagen was the only institution offering university-level teaching in economics. Courses in economics were started in 1848, and from that time there were two chairs in political economy, one of them a chair in cameralism and public economics dating back to 1762. In 1886, Harald Westergaard was given a personal chair, bringing the number of professors to three. This number did not increase again until after the First World War, and not dramatically until after the Second World War. In the 1960s and 1970s, the number of professors begins to shoot up, with five universities and 14 full professors in economics in 1960, and eight universities and 34 chairs in 1995. These figures actually underestimate the growth; before 1960, there were scarcely any teachers who were not full professors, whereas the number of assistant and associated professors today is much greater than the number of professors.

International contacts

Perhaps the tiny domestic research environment made international contacts even more necessary than would have been the case in larger countries. An example of this can be seen in the marginal revolution at the beginning of the 1870s. When this revolution was started by Jevons, Menger and Walras, they had no contact with each other. Jevons died in 1882 without having heard of Menger (Howey, 1972). In Denmark, the publication of Walras's first volume was reviewed by Nationaløkonomisk Tidsskrift in 1875, and the reviewer (an institutional economist, A. Petersen) found, ‘surprisingly’, that Walras did not know Jevons's work (Kærgård, 1996).

Danish economists corresponded in French with Walras and in English with Jevons at a time when Danish economics was largely German-oriented. Contact with other Scandinavian economists was particularly close. From 1863 onwards, there were regular Scandinavian conferences on political economy, and a ‘Marstrand Meeting’ for Scandinavian economic researchers was arranged for most years between 1936 and 1985.

All this has changed in recent decades, when Danish economists have become an ordinary part of the general international research community. At the same time, the trend has been to move from publishing in books towards publishing in international journals, and from publishing in Danish to publishing in English.

Danish contributions
If we consider the contributions made by Danish economists, we find none who have come even close to an established position in the history of economics. Hutchinson's standard text *A Review of Economic Doctrine 1870–1929* mentions 359 names; these include six Swedes, one Norwegian and no Danes (Boserup, 1980).

Thus the history of Danish economics cannot until the most recent decades show internationally known names, but it is filled with overlooked precursors and with discoveries described in Danish, never known outside the domestic border. Mentioned can be Otto Ditlev Lütken, who wrote on population growth and scarcity of food before Malthus (Sæther, 1993); Bing and Julius Petersen, who wrote on neoclassical distribution theory in 1873 (Whitaker, 1982); Westergaard, who in the 1870s was the first to use mathematical maximization theory in economics (Creedy, 1980; Davidsen, 1986; and Kærgård and Davidsen, 1998); Mackeprang, whose thesis of 1906 was the first econometric analysis (Kærgård, 1984); Warming's description of the identification problem from 1906 (Kærgård, 1984, and Kærgård, Andersen and Topp, 1998); Wulf and Warming's development of the multiplier theory from 1896 to 1932 (Boserup, 1969; Topp, 1981); Frederik Zeuthen's discussion of monopolistic competition in the late 1920s (Brems, 1976); Jørgen Pedersen's description of fiscal policy in 1937 (Topp, 1988) and Gelting's derivation of the balanced budget multiplier in 1941 (Hansen, 1975). None of these discoveries were published in English, and were not made known internationally until after the theories had become widely known.

There are several possible explanations for the high number of unknown Danish contributions to economic theory. Brems (1986) suggests two barriers to the dissemination of economic theories: a linguistic barrier (Anglo-Saxons do not speak German and French) and a mathematical barrier. Unlike the economists in the larger European countries, those from the small-language communities such as Denmark understood all major languages, and were therefore better acquainted with all the international schools and could combine their ideas. However, economists from smaller countries often wrote in their own language, and consequently their work never became widely known. With so few professors of economics in small countries, it was furthermore necessary for them to be very versatile, and they therefore tended to move from one subject to another, and a more persistent approach is necessary to be established as a pioneer (one might recall Walras's battle over years to achieve recognition).

**Danish economists: generalists not specialists**

We can see from the above that the relationship between Danish economists and the various international schools has been like that between butterflies and flowers. They have generally fluttered from school to school, taking from each what they felt useable; very few Danish economists have been orthodox disciples of one of the recognized schools. A couple of examples can be mentioned. At the time of the great methodological battle in Germany between the neoclassical school and the Christian-Social-Historical School, Westergaard was in close contact with both schools. In the 1870s, he corresponded with Jevons concerning mathematical-economic problems, and at the same time he was the leading representative in Denmark of the Christian-Social-Historical school (Kærgård, 1995). During the debate among neoclassicists, monetarists and Keynesians in the 1960s and 1970s, Anders Ølgaard played a central role in economic debates in Denmark as Chairman of the Danish Board of Economic
Advisors, arguing from a typical Keynesian viewpoint, at the same time as he was writing a substantial treatise on neoclassical growth theory (Ølgaard, 1966).

Danish economists were almost always more than just theorists. Between 1870 and 1970 there were a total of 15 people who held chairs in political economy at the University of Copenhagen; of these, six were members of parliament, and of those six three held posts as members of the government. Another was member of the Copenhagen municipal government. Among the remaining eight were Bertil Ohlin, who was in Copenhagen only for a short time and later became politically active in Sweden; Erik Hoffmeyer, who was the first director of the Central Bank of Denmark for more than 30 years; Harald Westergaard, who was a leading church politician and social reformer; and Carl Iversen and Anders Ølgaard, two chairmen of the Board of Economic Advisors. All 15 were active in the public debate, writing numerous newspaper articles. Jointly, they held almost innumerable positions in commercial life, councils and commissions. Recent decades have revealed a completely different type of university economist, with purely academic and theoretical interests.

Norway after 1814

In 1814 Christen Smith (1785–1816) was appointed professor of botany and political economy at the first Norwegian university in Oslo. Botany and political economy would be considered a strange combination of subjects nowadays, but at that time the logic of such an arrangement was clear. The wealth of nature would create prosperity for the people. Unfortunately, before he could take up his position Smith died during a British-led botanic expedition to Congo.

Breakthrough of political economy

His successor, Gregers Fougner Lund (1786–1836), was not appointed until 1822. He wanted to move political economy away from mercantilism towards economic liberalism. His views were supported by Jacob Aall (1773–1844), ironmaster and member of parliament, who, with his essays on economic problems, became highly influential.

Anton Schweigaard (1808–70), who took over the chair in law, political economy and statistics in 1836, dominated economic thinking in Norway for almost half a century. He supported the liberal economic policy recommended by the classical economists. However, he did not follow them blindly, since in his opinion they sometimes carried their policies too far. In spite of being a spokesman for free trade he rejected the doctrine of laissez-faire. On many questions he was closer to the Continental economists, especially Say in France and Hermann and Rau in Germany. With Schweigaard political economy had gained a firm foothold as a science.

 Tradition and renewal

When Schweigaard died, his former student, Torkel H. Aschehoug (1822–1909), professor of law, took over his teaching responsibilities in economics and statistics. Until his death he dominated political economy within the academic world and beyond. He was behind, or strongly supported, several important events: the creation of the Statistical Bureau of Census in 1876 and the establishment in 1883
of Statsøkonomisk forening, an association for Norwegian economists, which he chaired for 20 years. The latter became a forum where the enlightened elite of bureaucrats, government ministers, parliamentarians and academics discussed economic issues. From 1887 it published an economic journal, Statsøkonomisk Tidsskrift (renamed Norsk Økonomisk Tidsskrift in 1997), in which economists discussed both theoretical and practical issues.

A second chair in ‘pure economics’ was created in 1877, and an independent study programme in ‘political economy’ was established in 1905. Aschehoug wanted to give an account of economic science in the Norwegian language. The first edition of his Socialøkonomik, completed in 1891, dealt with the theories of the classics, and the moderns Böhm-Bauwerk, Jevons, Menger, Schmoller and Walras. Later editions, however, were strongly influenced by Marshall's Principles of Economics and in particular his theory of value.

Professional build-up

Oskar Jæger (1863–1933), Peder Thorvald Aarum (1867–1926) and Ingvar Wedervang (1891–1961) were the central persons in the Norwegian economic profession between Aschehoug and Ragnar Frisch (1895–1973).

Jæger's contributions span from treatises on methodology to thoughts on public finance, including an active, although disputed, participation in economic politics. His historical lectures in political economy were concerned with the development of ‘modern’ analysis from an Austrian point of view. He mentions Marshall, of course, but his mainstay is Böhm-Bawerk.

Aarum's university career was relatively short, but his textbooks in theoretical and practical economics gave him considerable influence. He followed Marshall, and claimed that the interactions of demand and supply in the market simultaneously determined price and quantity. Market equilibrium became a key concept. He also introduced the extensive use of diagrammatic exposition in his lectures and books. Aarum was regarded as ‘the modern’ among Norwegian economists.

Wedervang is considered one of the great profession builders in Norwegian economics. He was behind the parliament's decision to create a new chair in economics at the university in 1931 for Ragnar Frisch. Together with Frisch, he was behind the establishment of the Rockefeller supported economic institute in 1932. He and Frisch were its first directors. Furthermore, he was in the forefront when a new five-year study programme in economics was adopted in 1934, and when the parliament decided to establish the Norwegian School of Economics and Business Administration in Bergen in 1936.

The Oslo School

In 1919 Ragnar Frisch graduated from the study programme in political economy. After studies in France, Germany, England, the USA and Italy he became Aarum's research assistant in 1925. After defending his doctoral dissertation ‘Sur un problème d'économie pure’ in 1926 he again went to the United States, but returned when the university made its offer in 1931. During the 1930s Frisch participated actively in international economic activities and conferences. He was among the small group of initiators who, in 1931, established the Econometric Society. In 1933 he became the first editor of Econometrica, a position he held for more than 20 years. When the Prize in Economic Sciences in Memory of Alfred Nobel was created in 1969, Frisch together with Jan Tinbergen received it for their
In the beginning of the 1930s not only Norway's economy was at a low ebb, so too was the status of economics as a science. Frisch started his grand project of bringing economics as a science out of ‘the fog’. He believed that economic theory should be based on mathematical models and quantitative analysis. The new economics should be shaped in a precise mathematical language. It was only with mathematical models that it would be possible to carry out complicated analysis and reasoning. He promoted this with enthusiasm, genius and force. All opposition was brushed aside. The study programme in economics was changed into a programme with a strong emphasis on mathematical analysis and economic research. His best students were attached to the institute as research assistants. Frisch created a revolution, but change did not come without conflict. He was applauded, but also met with opposition from his colleagues. There was, however, no organized opposition against him. When Wedervang left in 1937 to become the first rector of the new business school, his and other positions were filled with Frisch's students. On the strength of the new study programme and his new staff, Frisch succeeded, in a short time, in creating his own school within economic research. This Oslo School, which to this day influences Norwegian economics, particularly at the University of Oslo, broke with tradition by introducing quantitative methods into economic research and teaching. The development of national accounts, national budgets and economic planning were given top priority. This work was strengthened by Leif Johansen (1930–82), who became Frisch's assistant in 1952 and took over Frisch's chair when he retired in 1965. Among Johansen's most important contribution was his doctoral dissertation, ‘A Multi-Sectoral Study of Economic Growth’, which became the basis for the long-term economic planning by the Ministry of Finance. Macroeconomic planning, research and policy became the alfa and omega in the Norwegian post-war economy.

Trygve Haavelmo (1911–99) joined Frisch as a research assistant in 1933. In 1938 he was visiting professor at University of Aarhus and in 1939 a research fellow at Harvard University. Caught in the United States by the war, he worked for Nortraship, an organization set up by the Norwegian government in exile to administer the war effort of the Norwegian merchant marine. After the war he stayed a year with Cowles Commission in Chicago, where, according to Schumpeter (1954, p. 1163), he ‘exerted an influence that would credit to the lifetime work of a professor’. On returning to Norway he was appointed professor of economics in 1948, a position he held until his retirement in 1979. With his research contributions, teaching, generosity and gentle personality, he had a decisive influence on the development of economics. He won the Nobel Prize in 1989 for his fundamental contributions to econometrics.

During the economic depression of the inter-war period Frisch developed a deep mistrust of the market economy and the working of the price mechanism. National economic planning administered and managed by well-trained economists was, in his opinion, clearly superior to the shifting bustles of the market. As a consequence Frisch, as well as Johansen, who was a member of the Communist Party, were great admirers of the Soviet economic planning system, and claimed it was superior to the market economies of the Western world. They were therefore not easily attuned to other ideas.

**Challenges to the Oslo School**

Karl H. Borch (1919–86) was in 1959 recruited to the Norwegian School of Economics and Business Administration (NHH), first as a university fellow and from 1963 as a professor of insurance. This
Scandinavia, economics in: The New Palgrave Dictionary of Economics

Institution was at the time not so strongly focused on research. However, Borch stood out as an eminent researcher and a spiritual leader for the younger researchers. With his international network he strongly urged his students to pursue doctoral studies abroad and particularly in North America.

The new competence-building and international recognition achieved by Borch and his colleagues, together with the economic developments in the 1970s, slowly broke the monopoly and the influence of the Oslo School in Norwegian economics and politics. Economic planning in the Frisch–Johansen tradition was from the mid-1980s no longer central. More emphasis was placed on the functioning of competitive markets under uncertainty. Two of Borch's students should in particular be mentioned: Jan Mossin (1936–87) and Agnar Sandmo (b. 1938). Mossin was among a group of international researchers who independently contributed to the development of the modern theory for financial markets, the capital asset pricing model. Sandmo's research, to a large extent focused on the theory of taxation, is based on the assumption that we live in a world where we must deal with uncertainty and where there are limited opportunities for action. Markets and social institutions do not function in an ideal way. We must accept compromises and second-best solutions. Another prominent economist at NHH, Victor D. Norman (b. 1946), who earned his Ph.D. from MIT in 1972, has made significant contributions to international trade theory.

This work had a marked influence on Norwegian monetary and fiscal policies and also laid the basis for increased independence of the central bank. This line of research was also pursued by the Norwegian, Finn E. Kydland (b. 1943). from NHH, who, in 2004, together with Edward C. Prescott (b. 1940) was awarded the Nobel Prize for their contribution to dynamic macroeconomics, notably the time consistency of economic policy and the driving forces behind business cycles.

Sweden

Institutional evolution

As an academic discipline, political economy in Sweden can be dated back to 1741, when the first chair was created at Uppsala University. Official policy in the mid-1700s aimed at promoting economic growth, and economic debate was flourishing. The creation of three more chairs in political economy before 1760 was an element in this effort. However, because of changed priorities and loss of territories, a decline soon set in, and during most of the 19th century political economy at Swedish universities was quite weak.

At the end of the 19th century and beginning of the 20th century, culture and science in Sweden were especially influenced by the German-language area. Study tours were mainly directed to Germany. Doctoral theses in economics were written in either Swedish or German; the first in English was published in 1929, while virtually all have been in English in the 2000s. Half of the books on economics acquired by university libraries in 1903–7 were published in Germany or Austria, and only a fourth in the UK or the USA. Fifty years later the proportions were almost reversed. The two world wars and Nazi oppression help explain the transition from German to Anglo-Saxon influence, as do faster growth of American population and academic research, less importance of geographical proximity and possibly a lingering dominance of the Historical School in Germany (Sandelin, 2001).

In the absence of a better measure, the growth and specialization of academic economics may be described by the number and scope of chairs. At the beginning of the 20th century, there were only two
chairs of economics in Sweden, one in Uppsala (David Davidson) and one in Lund (occupied in 1901 by Knut Wicksell). Both were located in the faculty of law, and both also included fiscal law. In 1903 a chair in economics and sociology was created in Gothenburg (Gustaf Steffen), and in 1904 one in economics and public finance was created in Stockholm (Gustav Cassel). By comparison, in 1996, a few years before the principles for appointing professors were radically changed, there were 57 chairs in Sweden, of which 45 were directed towards a special field within economics, and only one formally included more than economics (Sandelin, 1998, p. 2; 2000; Sandelin, Sarafoglou and Veiderpass, 2000, p. 46).

Early Swedish economists such as Wicksell, Cassel, Heckscher, and the Stockholm School economists had a common forum in the journal *Ekonomisk Tidskrift*, founded by David Davidson in 1899. Its name was changed in 1965 to *The Swedish Journal of Economics* — then in 1976 to *The Scandinavian Journal of Economics*, when the circle of contributors and editors was widened. Those changes left room for a Swedish-language journal directed to a broader audience and dedicated to practical economic problems; so *Ekonomisk Debatt* was born in 1973, published by *Nationalekonomiska föreningen*, the economists’ association, founded in 1877.

**Before the neoclassical breakthrough**

International currents are visible in early Swedish thought. Some early authors have been labelled mercantilists, the most influential probably Anders Berch, who became the first professor of political economy appointed at a Swedish university (Uppsala, in 1741), and who published the first textbook, *Inledningen til almänna hushålningen* (1747), which then enjoyed a monopoly in academic teaching for more than 80 years. Opponents of mercantilist ideas arose, among them the clergyman Anders Chydenius, who published liberal booklets in the mid-1760s that have resulted in him being called a Swedish physiocrat.

Despite this beginning, political economy at Swedish universities was not strong at the beginning of the 19th century, though there were a few representatives of classical economic thought. Lars Rabenius – who appreciated Adam Smith’s ideas, though with reservations – published a textbook in 1829 which finally replaced Berch's old book. Carl Adolph Agardh, who had attended and been influenced by Say's lectures in Paris in the 1820s, thought that the classical economists gave the state too modest a role, so his ideas were more akin to the Historical School.

Gustaf Steffen, who was professor of economics and sociology in Gothenburg during 1903–29, was the last Swedish professor who can be classified with the Historical School. The majority of university economists during this period were turning towards neoclassical ideas (Lönnroth, 1991, 1998; Magnusson, 1987).

**The early modern generation**

David Davidson, Knut Wicksell and Gustav Cassel introduced modern economics into Sweden around 1900; Eli Heckscher may also be included in this group, although his main works were published later. David Davidson (1854–1942) was Wicksell's teacher and an important adviser on domestic monetary and fiscal policy, though he did not address an international audience. The editor of the *Ekonomisk*
Knut Wicksell (1851–1926), an ardent participant in public discussions on social matters of all kinds, was the most important introducer of neoclassical economic thought into Sweden. His book *Value, Capital and Rent* (1893) was permeated with derivatives and marginalist concepts. The original German edition has the subtitle nach den neueren nationalökonomischen Theorien (‘according to the new economic theories’) and it is the theories of Walras, Jevons, Menger, and — especially concerning capital — Böhm-Bawerk that he tries to bring together.

Wicksell’s analysis of just taxation from the perspective of the benefit principle in his next book, *Finanztheoretische Untersuchungen* (1896), has become an unavoidable point of reference. Likewise, his idea of a cumulative process of inflation, expounded in *Interest and Prices* (1898), is still referred to. Wicksell’s *Lectures on Political Economy* (vol. 1, 1901; vol. 2, 1906) is not simply a textbook version of the ideas developed in his earlier books, but contains refined and modified approaches to questions raised earlier.

Gustav Cassel (1866–1945) began as a mathematician but turned later to economics. He studied with Wagner and Schmoller in Berlin, and around 1900 evinced doubt about the benefit of unlimited competition; later he became more sceptical of government intervention. His basic economic thought, expounded in his *Theoretische Sozialökonomie* (1918), was evidently much influenced by Walras, although he did not give him proper credit in that book. During the 1920s Cassel worked in various positions with international monetary problems, and during many decades he was, like Wicksell, Heckscher, Ohlin, and others, a persistent participant in public discussions, publishing several hundred newspaper articles (Magnusson, 1991; Carlson, 1994).

Especially because of his book *Mercantilism* (1931), the youngest in the group, Eli F. Heckscher (1879–1952), is internationally known mainly as an economic historian. As such, he pleaded for the integration of historical and neoclassical analysis. His lasting contribution to economic theory is an article in the *Ekonomisk Tidskrift* in 1919, which provided the basis of the so-called Heckscher–Ohlin theory in international trade (Henriksson, 1991).

As noted, the early modern generation was extensively involved in public debate; Wicksell considered it his ‘foremost duty to educate the Swedish people’ (Jonung, Hedlund-Nyström and Jonung, 2001, p. 19). This attitude was taken over by several of the Stockholm School economists.

The Stockholm School

Both Cassel and Heckscher were advocates of traditional economic liberalism, and sceptical of major government intervention. Around 1930, when nobody could overlook the problem of unemployment, this scepticism was challenged by a group of young economists, some of whom were disciples of Cassel and Heckscher. Dag Hammarskjöld (1905–61), Alf Johansson (1901–81), Karin Kock (1891–1976), Erik Lindahl (1891–1960), Erik Lundberg (1907–87), Gunnar Myrdal (1898–1987), Bertil Ohlin (1899–1979), and Ingvar Svennilsson (1908–72) were members of this group, called ‘the Stockholm School’ by Ohlin in an article in the *Economic Journal* in 1937. Ohlin believed that the Stockholm School had developed a theory of employment and had demonstrated how employment can be stimulated by economic policy, before Keynes did so.
Although several individual members are well-known, sometimes for other contributions, such as Myrdal's institutional analyses and Ohlin's contributions to the theory of international trade, the Stockholm School did not live on in the way Keynes's thinking did; it was hardly more than a national phenomenon, for several reasons. The few university positions in Sweden could not absorb all of them. They wrote mainly in Swedish, often in the form of government reports. They emphasized the dynamics of economic problems, which were difficult to present pedagogically. They also tended to analyse special rather than general cases, in the belief that useful general conclusions were difficult to draw. And their approach in some ways conflicted with techniques coming into vogue after the Second World War (Siven, 1985; Jonung, 1987).

The first post-war decades

Although it can be considered as a national phenomenon in the sense that it had little influence outside Sweden, the Stockholm School itself was not devoid of influences from abroad. It was mainly a theoretical school, and theory is more international than empirical knowledge. Swedish economics was hardly more internationalized in the 1940s and 1950s than it was during the preceding decades. As before, most economic research was performed when students wrote their magnum opus, the doctoral dissertation. (A new system of graduate education, similar to the American, was introduced in 1969.) And most of the dissertations were more empirical than theoretical, focusing on the Swedish economy.

Outside the university world, the trade union economists Rudolf Meidner and Gösta Rehn developed ideas on the relationship between inflation and employment, and recommended a general deflationary policy, combined with selective measures directed towards those parts of the economy that would suffer from it. The latter part of the recommendation – selective means – was politically accepted and characterized the ‘Swedish model’ of actual economic policy for many years.

Disappearance of national traits

The closer we come to our own time, the less reason there is to classify economic thought geographically. National traits have become less evident as communications have improved. In an evaluation of Swedish economic research, Dixit, Honkapohja and Solow (1992, p. 129) concluded that over the past three or four decades the literature of analytical economics has become almost completely homogenous worldwide. Mainstream economists in all countries now contribute to a single international literature as part of a single intellectual community. … One can easily imagine a new idea or technique arising anywhere in the world of mainstream economics, and being pursued at first by its originator and his or her graduate students, but one cannot easily imagine a distinctively national school arising within the mainstream. Good ideas circulate much too rapidly.

Nevertheless, we may point to a couple of Swedish characteristics. Persson, Stern and Gunnarsson (1992, p. 118) found that non-mainstream economists like neo-Ricardians and Post Keynesians were
much less cited by Swedish economists than by the world's economists on average, and this probably remains true. Similarly, as found by Dixit, Honkapohja and Solow (1992, p. 139), the application of advanced econometric techniques seems still to prevail over the creation of new ones.

Stockholm University's Institute for International Economic Studies has remained the most successful research unit in Sweden for several decades. As in other small European countries, many Swedish university economists have traditionally been involved in government committees and commissions. A change may have occurred in recent years, however, partly as a consequence of faster growth in the supply of qualified economists than in the demand for people willing to accept such side-commissions, and partly because young economists may be giving pure research higher priority than before.

Schelling, Thomas C. (born 1921)

Timur Kuran
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Thomas Schelling has contributed path-breaking works to the study of coordination problems, group behaviour, and self-control. Early in his career, he framed the Cold War as a game in which parties have a mutual interest in coordinating their actions through a ‘focal point’. Later he explained how, in the absence of racism, racial segregation may be triggered by a ‘tipping’ process through which residential homogenization feeds on itself. His latest major insight has been that addictions stem from an inability to reconcile conflicting inner drives.

addiction; critical mass; focal point; game theory; multiple equilibria; network models; prisoner's dilemma; residential segregation; Schelling, T. C.; self-control; subgame perfection; tipping

Article

Thomas Schelling was born in 1921 in Oakland, California. He received a BA from the University of California at Berkeley in 1944 and a Ph.D. in economics from Harvard University in 1951. Between 1948 and 1953 he worked in the Paris Marshall Plan Headquarters, in the White House, and in the Executive Office of the president, on negotiations relating to foreign aid, the European Payments Union, and NATO. He taught at Yale University (1953–8), then at Harvard University (1958–90), and finally at the University of Maryland at College Park (1990–2003). He also had a long association with the RAND Corporation, with appointments as an adjunct fellow for most of his career (1956–2002) and as a full-time researcher in 1958. He was awarded the Nobel Prize in economics in 2005.

Schelling is known for works that use the tools of economics to illustrate major social phenomena while also making foundational theoretical advances. His publications illuminate patterns and paradoxes concerning military strategy and arms control, nuclear proliferation, conflict and bargaining, coordination and conventions, tipping points and critical mass, racial segregation and integration, addiction, health policy, and business ethics. In terms of style, he has avoided the formalization that now
characterizes most economic research. Using mathematics sparsely, he has managed to convey intricate theoretical arguments mainly through eloquent prose and penetrating examples.

In the 1950s, when Schelling's academic career took off, policymakers around the globe were consumed by the rivalry between the two nuclear-armed superpowers, the United States and the Soviet Union. His first classic book, *The Strategy of Conflict* (1960), framed the challenge facing the two sides as coordinating on a commonly expected and mutually acceptable outcome. Avoiding nuclear confrontation required the negotiators to focus on a particular set of concessions. The underlying logic, Schelling proceeded to show, applies to a very broad set of problems in which communication is incomplete, if not impossible. People who have a mutual interest in coordinating their behaviours will look for a ‘focal point’ capable of generating a common expectation as to what is feasible.

One of his famous examples involves two strangers who are instructed to meet each other on a particular day in New York City. Unable to communicate, they look for an obvious place to meet, so obvious that each will know that it is obvious to both of them. At the time that Schelling was writing, the information desk at Grand Central Station provided just such a focal point. In this case, people achieved coordination not by speculating on what the other would do but by identifying a common course of action with the understanding that the other party was trying to do the same. Typically, the solution entailed a set of actions that stood out among its numerous alternatives. Hence, there was no uniquely ‘correct’ answer. What made an alternative ‘correct’ was simply that enough people thought so.

In a class of contexts, the required focal point lies in the structure of the game being played. For instance, in certain games with multiple equilibria it consists of a Pareto-dominant equilibrium – an outcome that no one can improve upon without harming at least one other player. Schelling’s key insight, which the Grand Central Station experiment encapsulates, is that in a wide range of other contexts the focal point emerges from factors not captured by a formal representation of the game. It may depend on such factors as analogy, precedent, accidental arrangement, symmetry, aesthetic configuration, even on what the parties know about each other.

*The Strategy of Conflict* laid the foundations for a version of applied game theory that focuses not on zero-sum games in which players have diametrically opposed interests but on positive-sum games in which the players have both common and conflicting interests. The nuclear arms race offered the paradigmatic case: each superpower wanted to avoid touching off a mutually destructive nuclear showdown but also to dominate the other. In identifying lessons for policymakers, Schelling played a pioneering role in the development of various concepts included in the basic toolkit of modern game theory: commitment, credibility, threats, and brinkmanship. He also introduced, albeit informally, the concept now known as subgame perfection, which is a generalization of backward induction. His insight that mutual nuclear deterrence requires the threats of adversaries to be credible was an early illustration of an idea now central to thinking about strategic interactions in economics, political science, sociology, and beyond.

Another of Schelling’s classic books, *Micromotives and Macrobehavior* (1978), deals with settings in which a group’s aggregate behaviour is more than the sum of the behaviours of its members. What unites the members is that in acting and reacting to their environment they fail to perceive, and usually do not care, how their own choices combine with those of others to produce unintended and unanticipated consequences for the whole group. One of his influential applications of this insight concerns racial segregation. A popular explanation for racial segregation in American cities was deep-seated racism. Schelling showed that racial segregation could arise even in places where racism was not particularly
acute. It could emerge, in fact, even in a community whose members all wanted to live in a racially
mixed neighbourhood.
To see the underlying logic, consider a population whose members are either white or black. Regardless
of colour, everyone prefers to live in a racially diverse neighbourhood. By the same token, each member
of the population is also averse to being in the minority, though to varying degrees. Suppose now that a
certain neighbourhood is 52 per cent white and 48 per cent black. Because whites are in the majority, the
neighbourhood attracts disproportionately many whites. The accentuated imbalance is acceptable to the
white majority. Its members do not mind if their share rises, say, to 65 per cent. But black residents who
are most sensitive to being in the minority begin to move out, which reduces the proportion of blacks
even further. That reduction then triggers further exits. The upshot is that the neighbourhood becomes
fully white even though that was not the intention of anyone in either the majority or the minority.
In developing this analysis, Schelling familiarized the social sciences with concepts that have since
gained broad applications. One of these is ‘critical mass,’ a shorthand for the minimum level of activity,
often defined as a number or ratio, required to make that activity self-sustaining. If a neighbourhood will
experience black flight once the black proportion falls to 40 per cent, that percentage marks the critical
mass of blacks required to keep the neighbourhood integrated. A related Schelling concept is ‘tipping’,
which entails a cumulative process dependent on differences in critical mass across individuals. In the
presence of such differences, a behaviour can feed on itself. A few black departures can induce further
departures by making the share of blacks dip below more individual thresholds, and the process can
repeat itself until none remain.
Schelling's analysis points to the dangers of inferring individual characteristics from observations of
collective outcomes, and of jumping to conclusions about aggregate behaviour from what one knows
about individual preferences. That individually rational behaviours may generate persistent
inefficiencies was already understood. The ‘Prisoner’s Dilemma’ offers a case in point. Schelling’s work
on the tensions between ‘micromotives’ and ‘macrobehaviour’ helped to show that such tensions are
much more pervasive than had been appreciated. In the case of racial sorting, people who would rather
live in a more or less balanced neighbourhood than in a racially homogeneous one end up with the less
preferred outcome. Moreover, once racial segregation has run its course, it is difficult to reverse, because
few will voluntarily move into a neighbourhood in which they would form a tiny minority.
Identifying analogous tensions in a rich variety of other settings, Schelling demonstrated that market
activity can produce lasting inefficiencies when an expectation-driven interactive process shapes the
choices of participants. His examples included the custom of sending holiday cards. People feel obliged
to send cards, he observed, to people from whom they expect to receive them, even when they sense that
they will receive them only because the senders expect to receive cards themselves. Accordingly, two
acquaintances may send each other cards for years on end, even though both find the custom
burdensome and each is capable of ending the habit unilaterally. Individuals may keep sending cards to
people they have not seen for decades for no other reason than the suspicion that cessation could signal
something undesirable. Society as a whole would be better off, Schelling infers, with a ‘bankruptcy
proceeding’ through which all holiday-card lists are obliterated to allow people to start over, motivated
only by the holiday spirit, without accumulated obligations.
Schelling's insight into the possibilities of disharmony between ‘micromotives’ and ‘macrobehaviour’
has stimulated a wide range of other studies based on the observation that people fail to account for the
externalities of their decisions. Refined or extended versions of his framework have been used to
explain, among other phenomena, the emergence and disappearance of clothing fashions, the unpredictability of revolutions, the dynamics of jury decisions, the significance of momentum in political campaigns, the broadening of ethnic cleavages, norms against price competition, and economically dysfunctional behaviours inimical to development. The micro–macro interactions characteristic of Schelling's works appear also in various network models in which local interactions can trigger unintended and disproportionate global consequences.

Where *The Strategy of Conflict* and *Micromotives and Macrobehavior* address problems involving interactions among people, *Choice and Consequence* (1984), Schelling's third classic book, focuses on conflicts within individuals. Economics has traditionally treated the individual as a unified and internally consistent utility maximizer. Yet difficulties with reconciling conflicting impulses are central to the human experience. The problem of addiction, Schelling suggests, entails a failure to manage inner conflicts. It arises from inadequate self-control. The key insight of *Choice and Consequence* is that problems of self-control are commonly dampened, if not resolved fully, through tricks of the mind, social institutions, and public policies.

Many American taxpayers understate the number of their dependants to the Internal Revenue Service, the tax collection agency of the American government, to have an excessive portion of their income withheld, thus ensuring a hefty refund at the end of the year. Because excess withholdings yield no interest, this practice amounts to an expensive method of saving. If people find it convenient, the reason is that they see themselves as lacking the self-control to allow savings accumulate in a bank. By placing savings in the custody of the IRS, a person's responsible and forward-looking self gains control over the impulsive self that coexists with it.

Addictions stem from self-control difficulties, which anti-addiction treatments are designed to address. Obese people who cannot lose weight on their own check into ‘fat farms’ that regulate their diet. Likewise, alcoholics enrol in programmes that either directly limit their access to alcohol or boost their self-control through support networks. In either case, the addict effectively conspires with society to favour his responsible self over his impulsive self. In studying various self-control problems for which social remedies have been devised, Schelling finds that society does not always side with the responsible and forward-looking self. With regard to terminally ill people who are in so much pain that they want to die immediately, yet cannot bring themselves to take the final step, in most countries both the law and public morality side with the self that wants to keep living. Thus, people are prohibited from writing legally binding contracts to get assistance with dying.

The fundamental contribution of Schelling's writings on personal self-control has been in spreading awareness of a broad category of human problems that call for social intervention informed by a combination of economics and psychology. Education campaigns aimed at making people understand the consequences of their behaviours will not be effective, at least not by themselves. Most alcoholics know well that their addiction makes them unproductive, unhealthy and socially disconnected. Their troubles stem not from ignorance but from an inability to mediate conflicting demands within themselves. The period since Schelling published these insights has only raised their significance. With obesity now an acute social problem in developed and underdeveloped countries alike, and other addictions spreading as a result of rising prosperity, problems of self-control now lie at the centre of vast research programmes.

Over and beyond his penetrating and often pioneering insights into specific economic, social and political problems, Thomas Schelling has made an enduring contribution to economics and its sister
disciplines by showing that a deep understanding of social systems requires attention to cultural context, social dynamics, strategic interactions, and human complexities. To make sense of why a person would deliberately place an alarm clock far away from his bed, one must realize that he may be tormented by warring impulses. Although his problem can be modelled as one of utility maximization, only by taking account of the competition within him can one understand why one possible solution is likely to work better than another. Only by considering the cultural context can one understand why strangers asked to meet each other are more likely to succeed in certain cities and times than in others. No approach limited to the formal properties of payoff matrices, or the strangers’ formal decision problems, will suffice. And only by understanding the mechanics of strategic decision-making, and the factors that make threats credible, can one appreciate how the massive nuclear stockpiles of the United States and the Soviet Union allowed human civilization to survive the Cold War.

Karl Schlesinger was born in Budapest; in 1919, after Béla Kun's communist revolution in Hungary, he moved to Vienna, where he committed suicide when Hitler occupied Austria in March 1938. As early as 1914 he had published his important work on monetary theory, *Theorie der Geld- und Kreditwirtschaft*, which went, however, more or less unnoticed at that time because it used mathematical tools and was written in German – a forbidding combination at a time when the only German-speaking economists interested in theory, the Austrians, were rather averse to mathematical economics. Schlesinger was also an exceptional figure in so far as he was not a university teacher but a banker and influential member of the financial community. Nevertheless, he became a respected member of the Vienna Economic Society and, in the 1930s, one of the most active participants in Karl Menger's mathematical colloquium.

As an economic theorist, Schlesinger was a Walrasian, in fact the only Walrasian (with the exception, perhaps, of Wicksell) who significantly advanced Walras's theory of the demand for money balances and of equilibrium in the money market. In his 1914 book, Schlesinger clearly distinguished between payments the magnitudes and future dates of which are fixed, and those whose time profile is subject to uncertainty. While the first type of payment streams offers no choice but generates a money ‘demand’ equal to the maximum cumulative payments deficit for a given period (though Schlesinger correctly points to the possibility of modifying the payment stream by investing and disinvesting temporary cash surpluses), the second type, which lies at the centre of Schlesinger's analysis, gives rise to a choice between higher and lower cash reserves held as an insurance against illiquidity losses. Schlesinger determines the individual demand for these precautionary balances from the equality between the marginal utilities respectively of interest income lost due to holding a cash reserve and of the insurance service provided by this reserve. He also demonstrated the economies of scale from an increase in the
number (but not in the nominal magnitudes) of transactions. Finally, Schlesinger derives an aggregate money demand function, additively separable in transactions and precautionary demand, virtually identical to the one set up by Keynes much later, and determines the partial equilibrium money rate of interest as that which equalizes aggregate demand and stock supply of money. Schlesinger also addressed himself to problems of international monetary economics: in a publication of 1916 he advocated and gave a clear exposition of the purchasing power parity theory. In 1931, in the context of a book review, Schlesinger developed a rigorous and detailed mathematical analysis of money creation on the level of individual banks and for the financial system as a whole.

Apart from his writings on money, Schlesinger made another original and remarkable contribution to economic theory, viz. to the mathematical theory of Walrasian general economic equilibrium described by \( n \) zero-profit conditions (equating commodity prices which are given functions of quantities produced with the respective sums of products of factor input coefficients and factor prices) and \( m \) factor market equilibrium conditions (equating factor supplies with the respective sums of products of factor input coefficients and quantities of goods produced). At the beginning of the 1930s it came to be recognized that such a system of equations need not have a solution, at least not an economically meaningful solution (in non-negative output and factor prices). In 1934 Schlesinger suggested, in Menger's colloquium, to introduce non-negative slack variables on the demand side of the factor market equations and to enlarge the system of \( n+m \) equations by additional \( m \) equations setting the respective products of slack variables and factor prices equal to zero. Schlesinger had arrived at this ingenious idea independently of an identical proposal made by Zeuthen in 1932. Going definitely beyond Zeuthen, however, he also raised the conjecture that this procedure would solve the existence problem. Schlesinger's conjecture was proved to hold true by A. Wald, with whom Schlesinger had taken lessons in mathematics.

Schmoller, Gustav von (1838–1917)

B. Schefold

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

German Historical School; mercantilism; Methodenstreit; Schmoller, G. von

Article

Schmoller was born in Heilbronn, the son of a Württemberg civil servant. He studied Staatswissenschaften (a combination of economics, history and administrative science) in Tübingen. After a short period in the financial department of the Württemberg civil service, which he had to quit because of his pro-Prussian views, he became Professor in Halle (1864–72), Strassburg (1872–82), and Berlin (1882–1913).

Schmoller was the leading economist of Imperial Germany. He was the leader of the ‘Kathedersozialisten’ (socialists of the chair), and founder and long-time chairman of the Verein für Socialpolitik. He was editor or co-editor of several publications such as Staats- und sozialwissenschaftliche Forschung and Jahrbuch für Gesetzgebung, Verwaltung und Volkswirtschaft im Deutschen Reich – later known simply as Schmollers Jahrbuch; he was named official historian of Brandenburg and Prussia, and supervised the publication of the Acta Borussica and the Forschungen zur brandenburgischen und preussischen Geschichte. Thus Schmoller was one of the major organizers of research in the social sciences. He is said to have controlled almost every important academic appointment in economics in the German Reich.

As the outspoken leader of the ‘younger’ Historical School, Schmoller was against the abstract axiomatic–deductive approach of the classicals and neoclassicals (1893; 1900, pp. 1–124). When Menger, the Austrian marginal utility theorist, attacked Schmoller's point of view and asserted the necessity of applying the exact methods of natural sciences and abstract logical reasoning to political economy, the Methodenstreit (struggle over methods) began, which was by and large a dispute between the inductive and the deductive method. It occupied two generations of German-speaking economists, produced a vast literature and was perceived essentially as ‘a history of wasted energies’ (Schumpeter) by theoretical economists of the next generation. However, it may also be viewed as the expression of the endeavour to preserve seminal insights into the historical and changing nature of economic and
social phenomena against simplified and mechanistic views of the laws of 'rational' behaviour, and as such it had important consequences for the development of neighbouring disciplines, especially sociology.

Although Schmoller put the emphasis on the inductive method, he was not excluding deduction from economic reasoning. In his opinion, it was of the utmost importance for the application of deductive methods and for economic theory formation in general to be based on the knowledge of sufficient historical facts and material. He advocated a somewhat interdisciplinary approach that would also take into account the psychological, sociological and philosophical aspects of the problems. Through detailed and monographic historical research he intended to free political economy from ‘false abstractions’ (1904, p. vi), and to put it on a solid empirical foundation. His most important historical studies were his works on the history of the weavers guild of Strassburg (1879), on the guilds in 17th- and 18th-century Brandenburg and Prussia, on the Prussian silk industry in the 18th century, on the history of Prussian financial policy (1898a) and on the history of German towns in general and Strassburg in particular (1922). He was also interested in the history and formation of social classes and the historical development of class struggle (1900, Book II; 1904, pp. 496–577; 1918). He further made some important contributions to the study of mercantilism (1898a, ch. 1; 1904, pp. 580–605), which he regarded essentially as the process of the formation of the national state and the national economy. The adoption of mercantilist policies was of special significance for Germany, whose backwardness in the 17th and 18th century Schmoller ascribed to the absence of a centralized national state and the consequent domination of particularist regional and local interests. Schmoller perceived the enlightened and despotic sovereigns – especially the Prussian kings – as the only power that would implement a policy aimed at the breaking-up of these particularist tendencies and at the establishment of large and unified economic territories. An important step in that direction was the abolition of town autonomy after 1713 under Friedrich Wilhelm I (1922, pp. 231–428).

This glorification of the Prussian state and its rulers was probably the most characteristic feature of Schmoller's work. He regarded the Prussian monarchy with its corps of loyal civil servants, which he perceived as standing above the social classes and their egoistic interests, as the central achievement of German history. Only this type of government had been able to overcome the earlier feudal corporate state and the class rule of the Junker (1898a, p. 302), and was at present capable of implementing social reforms.

Social reform and social justice were central to Schmoller's thinking. We may regard him as a conservative in the specific German or, better, Prussian sense of the word. He rejected Marxism, Manchester Liberalism and also reactionary, anti-reformist views such as those of the historian Heinrich von Treitschke, with whom he had a famous polemic on the notion of social reform (1874–5; Small, 1924–5).

Schmoller advocated a paternalistic social policy to raise the material and cultural standard of the working classes as the only means to prevent revolution, integrate the workers into the monarchic state, and keep the traditions of Prussia alive. He even envisaged an alliance between the monarchy and the working classes (1918, p. 648).

It is nowadays generally agreed that Schmoller's influence on the development of the economic sciences in Germany was rather unfortunate: it contributed to the neglect of economic theory in Germany for a full half century. Neither Schmoller nor his pupils achieved their goal of building a new theory based on the historical material they collected, however valuable it was. Schmoller's main work, the Grundrisse
Schmoller, Gustav von (1838–1917) in The New Palgrave Dictionary of Economics (1900; 1904) remained rather traditional in its theoretical part – the treatment of value and prices was not too far away from mainstream neoclassical economics – and constituted all in all a rather incoherent analysis. Perhaps this was the main reason why Schmoller's work and with it the whole Historical School was to fall into oblivion in Germany soon after his death.

Schmookler, Jacob (1918–1967)

N. Rosenberg

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

economic growth; inventions; patents; Schmookler, J.; technical change

Article

Schmookler was born in Woodstown, New Jersey, in 1918 and died in Minneapolis, Minnesota, in 1967. In 1951 he received his Ph.D. in economics from the University of Pennsylvania, where he was a student of Simon Kuznets. He subsequently held teaching positions at Michigan State University and the University of Minnesota.

Schmookler's work helped to establish the importance of technological change as a contributor to economic growth. His article ‘The Changing Efficiency of the American Economy, 1869 to 1938’ appeared in 1952 (Schmookler, 1972, pp. 3–36), several years before the seminal papers of Abramovitz and Solow. However, in his later work he also analysed the specific economic mechanisms that determined the allocation of resources among different categories of invention. By an extremely careful and original use of patent data, Schmookler demonstrated the decisive role played by changes in demand in shaping the pattern of inventive activity. In his most important work, Invention and Economic Growth (1966), he showed how changes in demand have accounted for variations in inventive activity in a specific industry (such as railroad equipment, petroleum refining and building) over time, as well as different rates of inventive activity among different industries at a given moment of time.

Schmookler's writing showed that technological change need not be treated as an exogenous variable. On the contrary, he showed that the changing direction of inventive activity could be accounted for by readily identifiable economic variables, most especially changes in the pattern of demand that determine the size of the prospective market, and hence potential profitability, for particular classes of inventions. Thus, inventions are significant not only because they influence the growth rate of an economy but also because they constitute forms of economic activity in their own right.

Selected works

1972. *Patents, Invention and Economic Change*, ed. Z. Griliches and L. Hurwicz. Cambridge, MA: Harvard University Press. (This volume contains the patent data which formed the basis for Schmookler’s research. It also contains a complete bibliography of his writings.)

scholastic economics

Odd Langholm
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

For approximately four centuries prior to the Reformation and the break-up of Christianity, major advances in economic ethics and analysis were made by representatives of medieval scholasticism. Theologians and philosophers, aided by canonists and Romanists, the scholastics aimed at moral instruction based on an understanding of economic phenomena and relationships. Condemning avarice, fraud and economic coercion, they dealt with trade and price, money and usury, labour and wages. They thus forged a link between ancient and early modern economic thought.

Article

The tradition in economic thought known as scholastic economics was part of the system of scholastic moral theology and philosophy taught in the schools and universities of western Europe in the Middle Ages. Its purpose was the construction of viable norms of commercial behaviour in a Christian world. The literary authorities on which it was based include the Bible and the writings of the Church fathers, and papal and conciliar decrees from the time of the early Church to the Carolingian period. In the 12th century the theologian Peter Lombard in his Sentences and the canonist Gratian in his Decretum codified much of this material along with later decrees. In the 13th century Gratian's work was augmented with the Decretals of Pope Gregory IX to form the Corpus Juris Canonici. The major names in scholastic economics were theologians writing with a leaning towards canon law. A majority of them were mendicant friars. The canonists observed a distinction between the norms that apply in the internal forum of conscience and the more liberal ones that found expression in the external forum of the
ecclesiastical courts. The latter were partly adapted from Roman law expressed in the Code and Digest of the Corpus Juris Civilis. The translations of Aristotle's Ethics and Politics gave access to some other bits of ancient texts that invited economic reasoning. The literary vehicles of scholastic economics were commentaries on the Bible and the Sentences and on Aristotle's works, theological summae, records of academic disputations, sermons, handbooks for confessors, as well as a few treatises dealing specifically with some given economic subject.

The schoolmen were primarily concerned with external economics, that is, with buying and selling and other forms of exchange of goods and services. This is so because of the ethical problem encountered in the exchange situation. The key word is consent. Mutual consent is required for an economic contract to be valid, but traders may be tempted by avarice to obtain terms of exchange to which the other party does not truly consent. In the case of buying and selling, the schoolmen envisaged a positive and a negative approach to consent. Because no one suffers injustice voluntarily, the former approach consisted in estimating the just price. The latter consisted in identifying factors incompatible with consent. A just price could be estimated on the basis of cost or market factors, the main thesis being that a competitive market price is a just price and that cost must adapt to the market. According to Aristotle, justice requires equivalence between goods given and received in exchange or between goods and money. It used to be argued that this is meaningless because there would be no motivation for anyone to exchange if what he got was of equal value to what he gave. This objection rests on a confusion of exchange value with utility, a confusion of which the schoolmen were not guilty. In their discussions of justice, equality referred to value in exchange, though not to an exact point; in the words of Thomas Aquinas (d. 1274), the just price was rather an estimate that was not completely precise. According to John Duns Scotus (d. 1308) it permitted of a certain latitude. Scotus also noted that the parties to a sale would often disagree about the just price. Both might then yield a little in order to reach an agreement, and, if they were then satisfied, an element of gift was involved in the contract. Consent, and hence justice, was still preserved.

Consent and justice are precluded in cases of fraud and coercion. In reply to a Roman law maxim stating that a thing is simply worth the amount at which it can be sold, a number of schoolmen from William of Auxerre (d. 1231) and Roland of Cremona (d. 1259) protested that this is not true if the thing can be sold at that amount only by means of fraud. Fraud is wilful misrepresentation of the object or conditions of exchange. The buyer must know what he buys. But knowledge also presumes a mental capacity to receive and digest information. Peter Olivi (d. 1298) states that terms of exchange are invalid if their acceptance by the buyer is due to his mental backwardness, ignorance or inexperience. A confusion regarding fraud arose because Roman law permitted the parties to a sale to outwit and ‘deceive’ one another in the course of the haggling and bargaining about price. The law accepted agreements thus obtained unless the result of the bargaining involved a deviation of more than one half of the just price. The theologians were inclined to reject this one-half idea and insisted on a just price within rather narrower limits. In principle, ‘deception’ as an element of the bargaining process must be distinguished from deliberate and blatant fraud, such as telling lies about the nature and quality of merchandise, hiding defects, using false weights and measures, soaking wool or diluting wine, and the like, in order to obtain an unjust price. No law condones this. Thomas Aquinas's catalogue of fraudulent practices in the Summa Theologiae is representative of the schoolmen's position.

Besides fraud and deception, consent is incompatible with practices considered by the schoolmen to be coercive. Monopoly is mentioned in Aristotle's Politics but merely in a context that did not invite
disapproval. Monopoly and collusion among sellers to set minimum prices are prohibited in the Code of Justinian. The issue was brought into the commentary tradition on the Decretals by the canonist Hostiensis (d. 1271) and through him to a number of authors of works for the internal forum. Among the more important ones, mention may be made of John of Freiburg (d. 1314), Astesanus of Asti (d. 1330), Raniero of Pisa (d. c. 1348), Antonino of Florence (d. 1459), and Angelo Carletti (d. 1495). According to these thinkers, merchants agree among themselves that only one of them shall trade in a certain necessary commodity or that all shall sell at the same excessive price. A related tradition can be traced back to Alexander of Hales (d. 1240). Alexander, in his Summa Theologica (1951–7, III, 490, p. 724) berates those who ‘take over the whole marketplace of commodities’ in order to raise prices. Later authors, from Astesanus to Angelo Carletti, paraphrase Alexander and rebuke those who disturb the run of the market by such means. John Duns Scotus has a name for them: they are ‘regraters’. Angelo vividly describes the merchants standing at the city gates buying up all the new grain, preventing its reaching the marketplace to be sold there. Battista Trovamala (d. c. 1495) explains how the price of victuals can be raised by impeding or detaining ships bringing home such goods or by giving earnest money for the purchase of all the spice in the city in order to sell it later at a profit.

From Carolingian price regulation, transmitted via canon law, the schoolmen received two ordinances known by their incipits (opening words) as Placuit and Quicumque. Placuit forbids price discrimination against travellers in local markets. Such people should pay the market price or (in an alternative version, which comes to much the same thing) pay what the residents pay. This injunction was cited by John of Freiburg and Astesanus and numerous followers in the Dominican and Franciscan penitential traditions. The great preacher Bernardino of Siena (d. 1444) in his vernacular sermons in the cities of Tuscany repeatedly impressed on his crowds of listeners the simple message that all should pay the same price. It was argued that residents ganging up against foreigners is not morally very different from merchants conspiring against local customers.

Quicumque lacks this conspiracy element. Originally a capitulary of Charlemagne included in the Decretum, it censures the malpractice of buying up hoards of victuals or wine cheaply at the time of harvest or vintage in order later to sell them at a much higher price (practices known as ‘engrossing’ or ‘forestalling’). Large profits on such operations are possible because ‘scarcity is created’—literally: ‘dearth is induced’ (caristia inducatur). This phrase originated in canon law literature; its earliest known appearance is in a gloss by Laurence of Spain (d. 1248). It proved to possess a remarkable literary appeal. Besides later canonists, it was copied by Albert the Great (d. 1280), Ulrich of Strasbourg (d. 1277), Thomas Aquinas and Antonino of Florence in theological works, by John of Freiburg, Bartolomeo of San Concordio (d. 1347), Durand of Champagne (d. c. 1350), Angelo Carletti and Battista Trovamala in their penitential summas, and by Henry of Langenstein (d. 1397), Matthew of Cracow (d. 1410), and John Gerson (d. 1429) in their treatises on economic contracts, as well as by numerous other schoolmen. Many of these authors state that buyers faced with ‘created scarcity’ are forced to pay excessive prices. A person paying more than usual because of scarcity due to crop failure or other natural misadventures can of course also be said to be forced to do so. Unlike much of modern economics, however, scholastic economics maintained a distinction between personal and impersonal compelling agents, because the former could be held morally responsible for their acts.

The reason why the schoolmen came down so hard on creating scarcity is that scarcity is one of the basic phenomena of all economic life. Economic activity is, in a word, a common struggle against scarcity. Using a terminology adopted from Peter Olivi by Bernardino of Siena, value rests on raritas (scarcity),
Virtuositas (usefulness, in an objective sense), and complacibilitas (desirability, pleasingness). These factors vary from person to person, from time to time, and from place to place, and determine the outcome of all voluntary transactions. In a beautiful piece of analysis, Richard of Middleton (d. 1307) shows that, just as a profit can be made in long-distance trade because just prices differ with plenty and scarcity in different locations, thus, also, both parties can profit justly in local exchange because they value what they receive more highly than what they give – an argument that readily can be restated in Olivi’s terms. The idea that both parties to an exchange are better off because they would not otherwise have exchanged is not a major insight recently discovered. Moreover, it is a truism. The schoolmen’s point is that both parties profit by just exchange voluntarily agreed upon in the absence of fraud and duress.

The schoolmen held no comprehensive theory of wages. To some extent, arguments about the just price could be applied by analogy to the just wage. Possession of qualified labour skills and professional competence, when these are in demand, also represents economic power. The recognition of this fact by the Ethics commentator Gerald Odonis (d. 1349) and some of those who copied his cases should not be permitted to obscure the fact that power in medieval labour relations was heavily concentrated on the part of the employer rather than on the part of the employee. Thomas Aquinas emphasized that manual labourers should be paid a decent wage and that it should be paid promptly because they lived from hand to mouth. This admonition was repeated by numerous authors of penitential manuals, including some well-known names like Henry of Langenstein, John Gerson and Antonino of Florence. Because the wage was in large part fixed by custom or by institutions like the guilds, their emphasis was on paying promptly rather than on paying justly. Antonino’s main contribution in this area was his attack on abuse of the truck system, whereby workers were paid in goods rather than in money, goods that they had to sell at a loss. Battista Trovamala notes that a double fraud was sometimes involved in truck practices. Merchants who barter goods rather than buy and sell them may do so justly but ostensibly at more than the just price. If a merchant has workers in his employ, he might claim that the goods paid them in lieu of money were bought, rather than bartered, at these inflated prices.

Scholastic monetary theory was largely Aristotelian. Scholars do not agree on whether Aristotle held a metallist theory of money. The schoolmen were definitely metallists. Money is a medium of exchange, a measure of value, and a store of wealth. In order to serve well in these capacities, certain properties are required. A number of commentaries on the Ethics and the Politics contain lists of such properties. That by Henry of Friemar (d. 1340) has five items: small size, to prevent subtraction (clipping and so forth); a stamp of the sovereign to prevent falsification; a determined weight so that prices can be fixed exactly; durability to ensure uncorrupted future validity; a content of precious material, like gold and silver, for easy and prompt valuation. John Buridan (d. c. 1360) adds a sixth requirement: coins of small denomination for the petty purchases of the poor. In exchange between merchants of different regions, money-changing (campsoria) was necessary. Henry of Ghent (d. 1293) points out that the changer may grant himself a fee for his labour spent counting and guarding money. It is true that money is non-vendible, says Giles of Lessines (d. 1304), but money-changing is not properly a sale but a form of barter. Guido Terreni (d. 1342) makes a different distinction. Sometimes two kinds of money are exchanged in a place where both are current, one being domestic currency and the other foreign currency permitted at a certain rate of exchange. If this rate underestimates the foreign currency, it may be bought and sold by weight. If exchange is made in a place where neither or only one kind of money is current, non-current money becomes a commodity. It can be bought or sold by weight at a just price and taken to
Whereas tampering with coins for a quick profit might be tempting for the individual citizen, debasement of the currency in order to replenish the treasury proved irresistible to medieval monarchs. In early 14th-century France debasement had reached ruinous proportions. Some schoolmen spoke out against it. Drawing on Guido Terreni and others, John Buridan argues as follows. The primary measure of goods in exchange is human need. It is by that yardstick that money is a measure as well. Granted that we do not often need gold and silver, wealthy people desire them for display, and so we find that they are worth the same, or nearly the same, in specie as in bullion. Only if money is thus measured in proportion to need can goods be measured in proportion to money. For whatever proportion they have to need, the same proportion they will have to money proportioned to need. If a certain coin is in circulation and the king issues another coin, it is true that he can stipulate its value in relation to the former, for instance declaring that one new penny is to be given in exchange for three of the old. If it is not worth that much, however, or very near it, according to the relation of its material to human need, the king sins and profits unjustly at the cost of the common people. Much of the credit for the scholastic theory of money has been granted to Nicole Oresme (d. 1382), whose merit is a detailed and knowledgeable description of the various ways in which the currency can be debased and of the social consequences of debasement.

The gravest specific economic sin was usury, unjust profit on a loan, usually a loan of money. Usury could also occur in credit sales or other sales involving time. Such arrangements can be interpreted as combinations of a cash sale and a loan. The schoolmen considered usury to be condemned in Luke 6:35: ‘Lend, hoping for nothing again.’ In addition, several arguments from natural reason were put forward. According to Peter the Chanter (d. 1197), the usurer profits merely because time passes, but time belongs to God. Thomas Aquinas argued that money is consumed in use by being spent, just as natural fungibles like grain and wine are consumed when we eat and drink them; money, therefore, has no use separate from its substance, and to charge a profit for lending it is to make the borrower pay twice for the same thing or to pay for something that does not exist. Gerardo of Siena (d. 1336) tied in with Aquinas by declaring that money is sterile, not because it is ‘barren metal’ (an idea wrongly attributed to Aristotle) but because it is a fungible. Contrary to fruit-bearing things, all fungibles are barren because they are always of the same value in terms of themselves. This intriguing argument has proved difficult to refute. An argument from coercion was originally proposed by William of Auxerre. The borrower pays usury because he is forced by need to do so. Adopting a broad definition of need, Thomas accepted this argument and proceeded to demonstrate the analogy between exploiting a needy borrower and exploiting a needy buyer, thus combining the two main areas of scholastic economics by a common formula. Whereas usury was universally condemned, the schoolmen recognized the lender’s right to compensation for all damage incurred owing to default in repayment. Some extrinsic titles to interest within the period of the loan were also hesitantly recognized. After all, in the words of Gerald Odonis, two persons cannot use the same money at the same time. The full development of extrinsic titles was mainly the work of later canonists.

The decline of scholastic economics is a complex process impossible to date. In one sense part of it is still present in the European moral consciousness. In another sense, of a continuously developing system, it did not last much longer than to the latest authors cited in this article, that is, to the end of the 15th century. The so-called ‘second scholasticism’ associated with the Counter-Reformation School of Salamanca broke with medieval scholasticism to an extent that makes treatment under the same heading
unadvisable. The change is well illustrated by the shift of focus from the attack on usury to the defence of titles to interest. In a larger perspective this and other changes are expressions of the fading-out of the natural law philosophy of Aquinas in favour of the natural rights philosophy on which most of modern economic thought is based.

Scholes, Myron (born 1941)

Toni M. Whited

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Myron Scholes is best known for his contribution to the derivation of the widely used Black–Scholes option pricing formula. His contributions to financial economics are not, however, limited to his research on option pricing. His other notable work includes seminal empirical tests of the capital asset pricing model, both theoretical and empirical examinations of the effects of dividend taxation on stock returns, and studies of tax issues relating to the cost of capital, capital structure, real estate values, the optimal liquidation of assets, and employee compensation.

Article

Best known for his Nobel prize-winning work on derivatives pricing, Myron Scholes made significant contributions to a wide range of topics in financial economics, from asset pricing to dividend policy and tax incentives. Born 1 July 1941 in Timmins, Ontario, Canada, he earned a Bachelor's degree in Economics from McMaster University in Hamilton, Ontario in 1962. He then entered the MBA course at the University of Chicago, transferring to the Ph.D. course after his second year. He earned his MBA in 1964 and his Ph.D. in 1968, writing his dissertation on the effects of information and signalling on the shape of the demand curves for traded securities. Upon finishing graduate studies he took a position as Assistant Professor of Finance at the Sloan School of Management at the Massachusetts Institute of Technology. After five years he moved to the Graduate School of Business at the University of Chicago. He was first Visiting Professor, and then in 1974 he accepted a permanent position. He stayed there until 1981, when he became Visiting Professor at Stanford University for two years, becoming a permanent

faculty member of the university's Business School and Law Schools in 1983, remaining there until his retirement in 1996. He is currently the Frank E. Buck Emeritus Professor of Finance at Stanford, as well as a Managing Partner of Oak Hill Capital Management and the Chairman of Oak Hill Platinum Partners. He serves on the board of directors of several corporations.

It was during his time at MIT that Scholes worked with Fischer Black and Robert Merton to develop the Black–Scholes formula for option pricing. An option is the right but not the obligation to buy or sell a security on or before a certain date at a certain price. Options are members of a family of securities known as derivatives, because their value is derived from the value of another security. Scholes and Merton earned a Nobel Prize in economics in 1996 for ‘a new method to determine the value of derivatives’. Almost every MBA and many undergraduates across the world learn the famous Black–Scholes formula, which is widely used by derivatives traders; indeed, traders often quote option ‘prices’ not in dollars and cents but in terms of one of the inputs into the Black–Scholes formula – the volatility of the return on the stock on which the option is written, or ‘vol’. The formula has had ramifications far beyond the area of derivatives, offering new ways of thinking about related areas, such as corporate finance, capital budgeting, and financial markets and institutions.

Black (1989) and Bernstein (1992) provide detailed histories of the development of the formula, which can be summarized as follows. Between 1968 and 1969 Fischer Black derived a partial differential equation that described the value of an option as a function of the maturity of the option and the underlying stock price. He did so by applying the capital asset pricing model (CAPM) to options, rather than stocks, at each instant in time. Unable to solve the equation, Black teamed up with Scholes in 1969. Scholes's contribution to the formula was the logic used to solve the equation – logic that is still taught to students studying finance. Black and Scholes noted that the differential equation did not involve the expected return on the stock and that, therefore, any expected stock return is consistent with the option price, including the risk-free rate of interest. They then turned to a much earlier work, Sprengle (1961), which contains a formula for the expected future value of an option as a function of the stock return. Using the risk-free rate as the stock return in this formula gave them the expected future value of the option. Using the risk-free rate to discount this future value back to its present value, Black and Scholes came up with what is now known as the Black–Scholes formula, which did indeed solve Black's differential equation. The published version of this work appeared in the *Journal of Political Economy* in 1973. It did not, however, contain Black's derivation of the formula, but one suggested by Robert Merton, who pointed out that it is possible to replicate option payoffs with those from a portfolio of stocks and bonds. Hedging the option with this portfolio produces a risk-free position, and equating the return on this risk-free position with the risk-free rate of interest produces Black's differential equation. Scholes's contributions to financial economics are not limited to his research on option pricing. For example, Black, Jensen and Scholes (1972) performs one of the earliest and most prominent tests of the CAPM, finding that the systematic risk of a stock explains less of the stock's return than the amount predicted by the CAPM. In related work, Scholes and Williams (1977) devise a method for testing asset pricing models with high frequency data, even when stocks are traded asynchronously. This research was an outgrowth of Scholes's work to develop a database on daily stock prices for the Center for Research in Security Prices at the University of Chicago. Another notable paper is Bulow and Scholes (1983), which explores seeming anomalous features of pension plans such as early retirement benefits or ad hoc increases in benefits. These features allow employees to have claims, in excess of vested benefits,
on the assets of defined-benefit pension plans. They explain this anomaly as a product of employee human capital, which ends up being compensated via the pension plan in the optimal contract with stockholders.

Although important, these papers were diversions from Scholes's main line of research: the effects of taxation on financial decisions and financial markets. His most prominent work in this area examines the effects of dividend taxation on security prices. Black and Scholes (1974) was the lead article in the first issue of the *Journal of Financial Economics*. The paper tests the idea in Modigliani and Miller (1961) that changes in dividend policy can affect firm value if capital gains are taxed at a lower rate than dividends, because the firm can easily increase its value by cutting dividends and instead distribute cash to shareholders via stock repurchases. Black and Scholes found no evidence that dividend policy affects returns, despite the existence of differential taxation. Their explanation of the result appealed to the idea of tax clienteles. Firms adjust the supply of shares at any particular dividend yield to meet the demands of different groups of investors with different tax preferences. Market equilibrium then implies that no firm can increase its value by changing its dividend policy. Perhaps motivated by these results, Miller and Scholes (1978) present sufficient conditions for dividend policy to be irrelevant, even in the presence of taxes. Miller and Scholes (1982a) again test the relationship between returns and dividends, taking care to purge any reaction of returns to dividend of signalling or information effects. In contrast to Black and Scholes (1974), they find significant tax effects.

Scholes's interest in taxes extended beyond dividend policy. He also worked on tax issues relating to the cost of capital, capital structure, property values and the optimal liquidation of assets. His research with Mark Wolfson examined corporate tax planning under uncertainty and information asymmetry. Much of this work is summarized in their 1992 book, *Taxes and Business Strategy: A Planning Approach*. Scholes's interest in taxation also intersected with his interest in the use of stock to compensate employees. For example, Miller and Scholes (1982b) argue that deferred compensation programmes structured to optimize employee incentives are observationally equivalent to those structured to optimize taxes. In his 1990 presidential address to the American Finance Association (Scholes, 1991), he outlined the interplay between taxes and incentives in deferring employee compensation. When an employee accepts deferred compensation, he essentially agrees to allow the firm to invest in its own stock on his account. The tax advantage to deferred compensation therefore depends on the after-tax rates of return that can be earned by the corporation compared to the return an employee could earn investing on his own. The employee stock ownership implicit in deferred compensation, however, aligns incentives of employees with those of shareholders. Optimal compensation schemes trade off these benefits with any possible tax costs.

In the latter part of his career Scholes once again became interested in derivatives, this time from a more practical and institutional angle. He became the managing director and co-head of the fixed-income derivatives group at Salomon Brothers. In 1994 he and Robert Merton joined several colleagues from Salomon to start a firm called Long-Term Capital Management (LTCM). Their basic strategy was to take a long position in one instrument and to offset the long position by a short position in a similar instrument or its derivative. Most of LTCM's bets were variations on the same theme, convergence between short positions in liquid Treasuries and long positions in theoretically underpriced instruments that commanded a credit or liquidity premium. While profitable for several years, this strategy unravelled in 1998 when Russia defaulted on its rouble and domestic dollar debt. Money fled into high
quality instruments such as Treasuries, and LTCM's short positions in these instruments plummeted in value. Although LTCM failed, it presaged the enormous growth in hedge funds that we see today, in 2007.

school choice and competition

Caroline Hoxby
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The two insights behind school choice are that externalities motivate government financing, but not provision, of schools, and that government-run schools will probably, owing to lack of competition, be x-inefficient. Under school choice, students choose among schools that compete for them on a truly level playing field. Governments play a financing, auditing, refereeing, and market-design role. Modern research focuses on evaluating the effects of school choice on the x-efficiency of schools, analysing how programme design affects the supply of schools, and investigating how information and matching mechanisms affect demand.

Article

The economic idea of school choice and competition was introduced by Milton Friedman in two related essays, both entitled ‘The Role of Government in Education’ (1955; 1962). His proposals remain the core of the school choice idea, but myriad economists and non-economists have refined it since. The essence of the idea is that students should be free to choose among schools that compete for them on a level playing field. Students should carry the resources for their education with them in the form of a tax-financed fee. Schools that attract students should be able to expand, possibly by creating branded spin-offs. Schools that fail to attract students should close. Families should play the lynchpin role by making choices that govern students’ experiences and schools’ sustainability. The government, in contrast, should create structures that make schools compete on the basis of the value they add to students, where parents are the ultimate judges of value. For instance, the government should raise taxes that support
fees, ensure that schools provide accurate information to parents, prevent financial malfeasance, enforce contracts and health and safety standards, and provide mechanisms that clear students’ preference lists for schools and clear the market in school buildings and equipment.

The logic of school choice

Friedman's first insight was that externalities associated with primary and secondary education provide substantial motivation for the government to finance schools, but much less motivation for the government to run them. A more modern view would suggest that the government does not merely play a financing role but also plays the market referee role that it adopts in a variety of other industries with public goods dimensions. The government might also engage in limited regulation. For instance, if society decides that all students should learn civics in order to be responsible citizens, then a plausible regulation might impose a test of civics knowledge. So long as the government does not attempt to manage schools, but confines itself to setting parameters and auditing outcomes, the essence of the school choice idea is retained.

Friedman's second insight was that the typical state-run school has a virtual monopoly over certain students and is therefore likely to be x-inefficient, taking rents in forms such as overemployment and a quiet life for managers (for instance, overpaying for school supplies or failing to fire problem teachers). The effect of school choice on x-efficiency is paramount: most supporters envision it to be the main benefit of school choice. Some hypothesize that school choice might also deliver benefits by allowing students to match themselves to pedagogical methods or peers especially conducive to their learning. However, neither of these matching benefits is essential to the logic of school choice, and it is fairly easy to describe situations in which allowing students to choose their peers helps some to learn and hinders others (Epple and Romano, 1998).

School choice can be and has been implemented in numerous forms. The schools involved may be private (‘school vouchers’), state schools that are independently managed (‘charter schools’), or state schools run by fully autonomous local governments. In practice, it is the supply side that distinguishes true school choice. Beware of programmes that adopt the choice nomenclature but exhibit supply side inflexibility (schools do not readily open, expand, shrink or close) or that structure fees in such a way that schools do not compete on a level playing field. The essence of the school choice idea is that incentives flow from the consequences of competition among schools on the basis of their value-added (as judged by parents). If competition is inconsequential or biased in favour of certain schools, then the school choice idea is not being implemented. Most magnet school programmes, controlled choice programmes, and open enrolment programmes fail to be school choice – largely because competition is inconsequential. On the other hand, some phenomena not explicitly labelled as school choice fulfil the idea to some extent. Examples include tuition tax credits (see Lips and Feinberg, 2006) and competition among autonomous local school districts, a phenomenon called Tiebout choice (Tiebout, 1956).

Evaluations of school choice programmes

Modern work on school choice takes three main forms: empirical evaluations of school choice programmes, design work (theoretical analysis, simulation and experiments) on demand-side problems,
and design work on supply side problems.
The primary task for an evaluation is identifying the general equilibrium effects of school choice on schools’ x-efficiency and on students’ peer groups. (It is far more important to identify the effects on x-efficiency than the effects on sorting. This is because it appears – as explained below – that sorting is susceptible to management.) To identify the general equilibrium effects, a researcher needs to find fairly random circumstances that cause some geographic areas to have more pressure from school choice than other areas do. By comparing areas randomly subjected to more and less school choice, general equilibrium effects are revealed. So far, the most convincingly random circumstances have come from the prevalence of natural boundaries (more natural boundaries translate into more local jurisdictions and thus more Tiebout choice: see Hoxby, 2000) and laws that translate small differences in state schools’ performance into large differences in the school choice they face. For instance, Chakrabarti (2006c), using regression discontinuity combined with the implementation of a school choice policy, compares Florida schools ranked just above and below the state's threshold for failure. Those ranked just below were exposed to school choice pressure starting in a certain year; those just above were exposed to none. Chakrabarti finds statistically significant improvements in x-efficiency in the traditional state schools exposed to pressure. Unfortunately for the sake of research, the amount of pressure on these schools was small and discontinued after a short time because the programme in question ended.

Some researchers have attempted to rely solely on the implementation of school choice programmes to identify the general equilibrium effects of school choice. However, simple before–after comparisons rarely generate convincing estimates because societies do not implement school choice randomly. They usually do so when concerned about current conditions and after policy debates that often result in the simultaneous introduction of other educational policies. A counterfactual constructed from pre-school choice data is therefore rarely convincing. Even worse, because the policy they are studying is often uniform across the state or country in question, authors of before–after studies are often tempted to use endogenous geographic variation in the take-up of the choice programme. This is highly problematic because students who take up the programme are far less likely to be satisfied with their traditional state school than are students who have the same opportunity to take it up but refuse to do so. Hsieh and Urquiola (2006) is one example of such problematic studies. Of course, more credence can be given to studies that combine before–after variation with plausibly exogenous geographic variation in the availability (not take-up) of the choice programme (Akabayashi, 2006; Ahlin, 2003; Chakrabarti, 2006a; Hoxby, 2004).

If researchers are to have a serious chance of identifying the general equilibrium effects of school choice, they must study an instance in which the supply of choice schools is fairly ample and can expand with demand. After all, x-efficiency effects cannot be expected if students cannot leave traditional state schools because there are no places available at choice schools. Also, the student sorting consequences of a tiny programme (such as one that affects only a few per cent of students) are unlikely to be distinguishable. Ironically, the very conditions that impede general equilibrium analysis facilitate analysis of the partial effect of particular choice schools on the students who attend them. If choice schools are inadequately supplied so that they enrol only a tiny share of students and are routinely oversubscribed, then researchers are in a fairly good position to identify the change in achievement caused by attending a particular choice school – not including the effects that general equilibrium might have on the school.
Why is this? Because students select to participate in choice programmes, selection biases plague studies that attempt to estimate the partial effect of voucher-taking schools, charter schools, and other choice schools on the students who attend them. Researchers have attacked the selection problem with a variety of methods, but the only one that enjoys widespread approbation is randomizing applicants so that some are offered a place and others are not. Randomization often occurs naturally when a choice school is oversubscribed. It allows researchers to compare lotteried-in and lotteried-out students, all of whom have the motivation and other qualities that made them self-select into applying. Formally, one estimates a local average treatment-on-the-treated effect by instrumenting for attendance at a choice school with an indicator for being lotteried into a choice school (see Angrist, Imbens, and Rubin, 1996 for a description of the method). Most randomization-based studies have found positive and significant effects of attending a choice school on outcomes such as test scores, educational attainment, parental satisfaction, altruism, and some other social outcomes (Angrist et al., 2001; Angrist, Bettinger and Kremer, 2006; Bettinger and Slonim, 2006; Howell and Peterson, 2002; Howell et al., 2002; Hoxby and Rockoff, 2005; Hoxby and Murarka, 2007a; 2007b; Peterson and Howell, 2004; Peterson et al., 1999; Rouse, 1998; West, Peterson and Campbell, 2001; Wolf, Howell and Peterson, 2000; Wolf, Peterson and West, 2001; Wolf and Hoople, 2006). Randomization-based studies have non-trivial limitations, however. Most importantly, it is not obvious that the partial effect matters much. If a choice school created incentives or sorting such that students’ achievement rose equally in all schools (including the school itself), we would surely consider the school to be a success. Yet the school's partial effect would be nil. In addition, the results of randomized methods cannot be extrapolated to students who differ substantially from the applicants, and one cannot evaluate choice schools that are undersubscribed.

In addition to randomization, researchers have tried a variety of methods – instrumental variables, regression discontinuity, matching – to estimate an unbiased partial effect of choice schools. Although such methods could in theory be useful, they have in practice been substantially less convincing than randomization. Researchers have also often tried panel methods, but these are really never convincing owing to problems that are familiar to anyone who has studied the extensive programme evaluation literature on self-selection into training schemes. If a student attends a traditional state school for some years and then applies to, say, a charter school, his application is not a random event but deliberate selection into treatment. (Charter schools are state schools that families are fully free to choose and that have autonomous management and finances. The fee each child brings with him is tax-financed, applicants are admitted via a lottery, and schools can lose their charter if they do not produce positive results.) The student's pre-application achievement trajectory, no matter how well estimated, is an unreliable predictor of how he would perform post-application in the counterfactual world in which he was forced to stay in his traditional state school. His decision to apply to a choice school is an indication of concern about his current trajectory and of an intention to change it in some way. Therefore, in the counterfactual world, his trajectory might reasonably be expected to fall (if the choice school was the only treatment likely to help him) or rise (if he were to undertake other remedies in the absence of a choice school's being available): see Hoxby and Murarka (2007b) for further discussion of this point.

The final major problem that affects empirical evaluations is the substantial divergence between most actual school choice programmes and the school choice idea. For instance, many programmes have fees that are only a fraction of the per-pupil amounts enjoyed by traditional state schools, thereby creating a playing field that is obviously not level. Most school choice programmes have strict limits on the
Design work on demand-side problems in school choice

The second major form of modern work on school choice is design work (simulation, theoretical analysis and actual experiments) on demand-side problems. Prominent demand-side problems are how to ensure that families use accurate information about schools (especially schools’ value-added when making decisions; how to ensure that students get their most preferred school (given the competing demands of other students) in a world where students submit a preference ordering; and how to incorporate social priorities such as desires to have schools that are socio-economically integrated or neighbourhood-focused. Progress on demand-side problems is occurring in part because such problems are susceptible to remedy, though perhaps not solution, with established tools. Also, districts that run school choice programmes have demonstrated a willingness to provide data for simulations and even to run experiments. For instance, although no information on schools’ value-added is perfect or complete, econometrics and data systems have been focused on providing such information more often and more accurately. Districts like Charlotte-Mecklenberg, North Carolina, have engaged in experiments, giving more complete and digestible information to randomly selected families. Such experiments suggest that even modest improvements in the information received by families cause them to revise their choices (Hastings and Van Weelden, 2007).

Just as important, economists have proposed mechanisms for processing students’ preference lists in order to guarantee that students get their most preferred choice, given other students’ preferences. A good mechanism is one that is strategy-proof and that produces a stable match. A strategy-proof mechanism is one in which a student can do no better than submit his true preferences. A stable match is one in which there is no student and school pair where the student prefers the school over his assignment and the school gives the student a higher priority than a student who has been assigned to the school. For example, Random Serial Dictatorship is strategy-proof and stable. It takes the preference lists submitted by students, assigns each student a random number, assigns the first student his top choice, the second student his top choice among available schools, and so on. Not only theoretical proofs but also evidence based on actual experiments – that is, districts switching their mechanisms – have shown that such mechanisms successfully clear the market (Abdulkadiroğlu, Pathak and Roth, 2006; Abdulkadiroğlu et al., 2006; Pathak, 2006). For instance, after New York City switched to a stable, strategy-proof mechanism, families and schools engaged in substantially less strategic behaviour and families were more satisfied with the schools their children ended up attending.
Stable, strategy-proof mechanisms can incorporate some social priorities. In practice, priorities are most often given to siblings, economically disadvantaged children, children who attend schools classified as failing, disabled children, and children with limited English. (Race- and ethnicity-based priorities are being phased out by courts.) With social priorities, not only students but also schools submit ordered lists. Schools’ lists, however, are based on the priorities, not on the personal preferences of school staff. The deferred-acceptance mechanism deals with the lists as follows.

(Step 1) Each student ‘proposes’ to his first choice. Each school tentatively assigns its seats to its proposers one at a time following only their priority order. Any proposers who remain when all seats are assigned are rejected.

(Each subsequent step) Each student who was rejected in the previous step ‘proposes’ to his or her next choice. Each school considers the students it has been holding together with its new proposers and tentatively assigns its seats to these students one at a time following their priority order. Any proposers who remain when all seats are assigned are rejected.

(Termination) The mechanism stops when no student proposal is rejected. Each student is assigned to his or her final tentative assignment.

The above description is borrowed from Pathak (2006). Another mechanism that can be used in this situation is top trading cycles (Abdulkadiroğlu and Sönmez, 2003).

The availability of mechanisms that incorporate social priorities implies that the general equilibrium effects of school choice on student sorting can be managed. By managed, one means that unwelcome or extreme outcomes such as segregation can be avoided. One does not mean that a robust school choice programme would have no effects on student sorting: it is hard to imagine a programme in which students’ choices are meaningful and yet so micro-managed that sorting looked the same before and after programme implementation.

Design work on supply side problems in school choice

The third major form of modern work on school choice is design work on supply side problems. This work attempts to address the questions about which programme designs are most likely to ensure a level playing field for schools in competition with one another. Most importantly, what should the structure of fees be? What should vouchers or charter school fees be? How much should they be topped-up for students who are disabled, limited-English proficient, economically disadvantaged or otherwise expensive to educate? There is also a series of questions about growing and shrinking schools. For instance, should a school that is very oversubscribed be given funds to expand its school or move to a larger one? Should shrinking schools be given incentives to cede their space to growing schools? Unlike the demand-side work, supply side work is limited and may remain so for some time. This is partly because actual experiments are rare: governments choose the supply side policies of their school choice programme after considerable political wrangling and then stick with them. Moreover, supply side work that uses theory or simulation has so far not produced general truths. Instead, it generates results that are sensitive to assumptions about peer effects and the effects of school spending on achievement (see Epple...
School choice and competition: The New Palgrave Dictionary of Economics and Romano, 1998; Nechyba, 2003). Yet there is no way, at present, to ground such assumptions in agreed facts. Suppose one asks how much additional money is needed by a school if it is to achieve the same value-added with a child whose parents are poor secondary school drop-outs as it would with a child whose parents are affluent college graduates. Estimates vary enormously, are very imprecise, and are sometimes even ‘wrong-signed’ (Hanushek, 2002). Yet, an estimate is what one needs to model the effect of raising the amount by which the basic fee is topped up for disadvantaged students.

At present, as of 2007, evidence-based design work on the supply side is fairly indirect. Authors occasionally compare a programme before and after its design has been changed (Chakrabarti, 2006a; Hoxby, 2004). Comparing programmes across states has also been tried (Chakrabarti, 2006b; Hoxby, 2006), but this is inherently difficult because states differ along many lines, not just a single dimension of school choice design. Because, for a test of the school choice idea, it is crucial that schools compete on an even playing field, design work on supply side problems is important. It is most likely to be advanced by deliberate experimentation within school choice programmes – for instance, varying the fee structure in interesting ways across different metropolitan areas within a state.

Schultz, Henry (1893–1938)

Jacob L. Mosak

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
econometrics; exchange; mathematical economics; Moore, H. L.; Schultz, H.; statistics and economics

Article

Schultz was one of a small group of pioneering econometricians who, in the 1920s and 1930s, laid the groundwork for the phenomenal development of mathematical economics and econometrics that occurred after the Second World War. His graduate courses in mathematical economics and statistics inspired students to address themselves to economic problems in quantitative terms, to reformulate economic theory in empirically testable form, and to test theories by means of diligent search for relevant statistical information and careful application of appropriate statistical analysis. His own research, culminating in his magnum opus, *The Theory and Measurement of Demand* (1938), could well serve as a model for a proper approach to economic analysis today. Schultz devoted all his professional life to the integration of pure economic theory with empirical analysis. Unlike considerable econometric work today, which is often empirical without much grounding in economic theory, his statistical analysis is solidly based on mathematical economic theory, as well as on the statistical theory of correlation and curve-fitting. Elegant summaries of both fields, based in large part upon his lecture notes and his research work, appear in the book, along with the empirical studies of demand for a large number of agricultural commodities for which the theories served as the basic foundation. The student wishing to get a good introduction to mathematical economics as formulated by Cournot, Walras and Pareto, and to the fundamentals of Gaussian curve-fitting analysis, will find clear and lucid presentations of these subjects in Schultz's book. At the same time he will not fail to be impressed by the extraordinary concern for statistical accuracy and precision demonstrated in the empirical analysis throughout the book. Schultz, who was born in Russian Poland on 4 September 1893, was brought by his parents to the United States in 1907, as part of the large wave of migration of Russian Jews after the Russo–Japanese War of 1905. Despite the family's poverty, Schultz's drive and determination enabled him to enter college and even to pursue a graduate education — no small feat in those days for the oldest child of an immigrant family. After receiving his AB from City College in 1916, Schultz entered Columbia
University, where he came under the lasting influence of one of the world’s leading econometricians, Professor Henry L. Moore. Schultz felt so indebted to him that in 1938, when he was himself internationally recognized as an outstanding authority in econometrics, he dedicated his major work to ‘Professor Henry Ludwell Moore, trail blazer in the statistical study of demand’.

Schultz’s studies were interrupted by the First World War, during which he was wounded in the Meuse–Argonne offensive. In the spring and summer of 1919, an Army scholarship enabled him to study at the London School of Economics and at the Galton Laboratory of University College, London, under two leading statisticians, A.L. Bowley and Karl Pearson. After returning to the United States in 1920, he served with several agencies of the United States government and became Director of Statistical Research of the Children’s Bureau of the Department of Labor. At the same time he continued his academic work, receiving the Ph.D. degree from Columbia University in 1925. His dissertation on ‘The Statistical Law of Demand as Illustrated by the Demand for Sugar’ was published the same year in the *Journal of Political Economy*.

The following year Schultz received his appointment at the University of Chicago. His courses in mathematical economics and statistics were highly organized and presented his students with a clear and systematic exposition both of the classic texts and of the most important up-to-date journal articles from the English, French, Italian and Russian literature. He was a voracious reader of economic and statistical literature, and enriched his courses by examination of related material in the fields of biology, physics and psychology.

It was the research laboratory, however, that absorbed most of his energies. Almost from the time he came to the University of Chicago, he embarked on an ambitious research project intended to harness theory and empirical analysis for the purpose of filling some of the ‘empty boxes’ in the theory of exchange. At first his interest focused on determining the coefficients of elasticity of demand as well as the magnitudes of the average shifts in demand over time. At a later stage he became interested in testing the consistency of demand coefficients for a set of commodities whose demands were interrelated. The work was so thoroughly organized, documented and proof-checked, and the calculations were so systematically set out, with automatic sum-checks at every appropriate point, that research assistants picking up a worksheet prepared by others even a decade earlier had no difficulty tracing the sources and checking the accuracy of every figure on the sheet.

Shortly after his book was published, Schultz was killed, together with his wife and two daughters, on 26 November 1938, in a car accident in California, where he had gone to teach on sabbatical leave from the University of Chicago. Paul Douglas wrote of Schultz:

> All in all, he was about the finest man it has ever been my privilege to know in academic life. The world of scholarship and of science (for I may so use the term in connection with him) was the richer for his fruitful life. We are much the poorer for his death at the full height of his powers.

Abstract

Theodore W. Schultz transformed the study of agricultural economics and economic growth and development. He made seminal contributions advocating the importance of human capital and particularly education for understanding economic growth in developed and developing countries. In this brief sketch I review his intellectual contributions to economics.

Keywords

agricultural economics; economic demography; economic growth; education in developing countries; Green Revolution; human capital; Marshall, A.; measurement; poverty; Schultz, T. W.

Article

Theodore Schultz shared the Nobel Prize in 1979 with Sir Arthur Lewis ‘for pioneering research into economic development research with particular consideration of the problems of developing countries’. Early in his career, Schultz studied agricultural organization and production, which evolved into studies of economic growth and finally into studies of economic development. His training and early contributions were in agricultural economics, but it is too limiting to label him an agricultural economist (as did the press release announcing his Nobel Prize award). He made seminal contributions in agriculture but also was a 20th-century pioneer advocating the importance of human capital and particularly education for understanding economic growth in developed and developing countries. In this brief sketch I review his intellectual contributions to economics.

Biographical details

T.W. Schultz was born on 30 April 1902 in South Dakota and died on 26 February 1998. He received his undergraduate degree in 1927 from South Dakota State University. He was a student of John R.

Commons and received his Ph.D. in Agricultural Economics from the University Wisconsin in 1930. Besides the Nobel Prize he received the Francis A. Walker Medal from the American Economic Association (1972), and the Leonard Elmhurst Medal from the International Agricultural Economic Association (1976). He was President of the American Economic Association in 1960, a member of the National Academy of Science (1974), and a fellow of the American Farm Economic Association (1957), the American Academy of Arts and Sciences (1958), the American Philosophical Society (1962), a guest of the Soviet Academy of Science (1960) and a Founding member of the National Academy of Education (1965). Also, he received about half a dozen honorary degrees from universities in the United States and abroad. Nerlove (1999) offers a longer and more detailed appraisal of Schultz's contributions and provides a complete listing of Schultz's prolific writings; see Johnson (1998) and Nerlove (1999) for a commentary on Schultz's personality. They give strong testimony to Schultz's role as mentor and colleague.

Style

Three features of Schultz's style characterize his writings. First, his wit and humility are much on display. Schultz travelled the world and served as an advisor to many governments and international organizations but he retained his humble Midwestern perspective and values. His work is serious and deeply considered, but presented with an irreverence to self and others that makes for easy and enjoyable reading. (A hint of this irreverence is evident in his 1979 Nobel Banquet Speech; Schultz, 1980.) Second, his analysis is thoroughly modern; he thought in terms of supply and demand, and gained much analytical depth through careful assessment of opportunities, incentives and information. His analyses considered a broad sweep of potential factors such as political economy and institutional constraints, besides the more obvious economic factors all economists are trained to recognize. Indeed, one characterization of Schultz's approach is that he merged the analytical insight of Irving Fisher with the breadth and style of argumentation of (his mentor) John R. Commons. Schultz applied these tools with equal force to problems in agriculture, labour, public economics, macroeconomics and development. He was not bound by traditional field–subfield definitions, but, rather, his writing is problem-focused; for example, on understanding the economics of being poor. In his Presidential Address to the American Economics Association (AEA), for instance, Schultz (1961) applied ideas of human capital to age–earnings profiles, population flows from rural to urban areas and deciphering the mysteries of economic growth for developed and developing countries. And, as another example, in Transforming Traditional Agriculture (1964), analyses of the US agricultural market are seamlessly interwoven with analyses of agricultural markets in developing countries. This uniformity of approach is all the more astonishing when compared to his contemporaries who viewed farmers as ‘different’ from non-farmers and especially saw differences between farmers in the United States and those in developing countries. Schultz had enormous faith in people's common-sense response to incentives they face. He believed people were knowledgeable about economic opportunities and responded to those opportunities. He tacitly assumed preferences were constant and sought explanation and prediction in responses to differences in opportunities or abilities. This perspective also made him critical of many government-sponsored agricultural and anti-poverty programmes. Schultz recognized that programmes could distort individual incentives in unanticipated ways or would fail because they did not remove barriers permitting individuals to act on existing economic incentives.
Schultz wrote frequently about ‘disequilibrium’ and its importance. However, I think the appropriate modern term is ‘dynamics’, not disequilibrium. Academic economists perceive a clinical Walrasian auctioneer at work to obtain equilibrium. Schultz saw a myriad of ‘equilibrium distortions’ that create profit opportunities, which individuals perceive and arbitrage. Schultz was interested in how farmers, students and entrepreneurs reallocate resources in response to new information on economic costs and returns. In ‘The Value of the Ability to Deal with Disequilibrium’ (1975) Schultz argues that the more educated are more able and thus quicker to process information on the economic environment. Their early arbitrage activity provides, Schultz argued, another return to education.

Third, even more impressive than Schultz's broad conceptual approach to economics was his tireless work in linking economic theory with economic measurement. In his empirical studies, understanding the economic phenomenon takes centre stage, not statistical technique or theoretical elegance. Empirical measures are fully described. He considered possible biases and other deficiencies in each. Finally, Schultz assesses the likely quantitative magnitude of each bias and the consequences for empirical analysis. Every effort is made to get the closest connection between available (generally aggregate or tabular) measures and the theoretical concepts. The honesty and the fullness of the presentation makes the analysis compelling.

Agricultural economics

In his 1979 Nobel Prize lecture Schultz summarized the motivation for his research thus: ‘Most of the people in the world are poor, so if we knew the economics of being poor, we would know much of the economics that really matters. Most of the world's poor people earn their living from agriculture, so if we knew the economics of agriculture, we would know much of the economics of being poor’ (Schultz, 1992). His seminal works on agriculture include Agriculture in an Unstable Economy (1945) and Production and Welfare of Agriculture (1949) and Transforming Traditional Agriculture (1964).

According to Schultz (1993, p. 2) understanding the economics of being poor starts with the hypothesis that there are relatively few significant economic inefficiencies in established communities where most people are poor. In these traditional agricultural settings, farmers have used the same technology and the same factor inputs for generations. Consequently, they have acquired significant experience in their abilities and the means of production available to them. They live and operate within a stationary environment in which there has been no significant change in technology for generations. Thus, contrary to the claims of Schultz’s contemporaries, it is not that these households saved and invested too little and did not respond to normal economic incentives. Rather, it was that they did not have profitable opportunities. Schultz pushed the frontier on technological change in agriculture as the key factor for transforming traditional agriculture by creating profit opportunities for investment. Schultz recognized that the Green Revolution created new high-yielding varieties, which were more responsive to fertilizers and other modern inputs that helped offset the diminishing marginal utility of land and created profit opportunities that led to investment and economic growth. Indeed, it is the availability of new technology and high return investment opportunities that characterizes modern agriculture. Schultz encouraged his student Zvi Griliches to investigate the diffusion of the new hybrids (Griliches, 1957).

Transforming Traditional Agriculture (1964) is Schultz's forceful summary of the transition. Thomas Balogh's (1964) vitriolic review of Transforming Traditional Agriculture is the best evidence of its revolutionary nature.

Schultz's research in agricultural production evolved into a study of economic growth. In the 1930s, Schultz began to see that new fertilizers expanded the productivity capacity of land. Yet he quickly realized that technological advances could not explain all the gains in productivity; a search was on for a more complete explanation. In the 1940s he came to see ‘acquired ability of labour’ as a major source of the unexplained gains in productivity. Scarce resources produced these augmented abilities; the stage was set for a formal study of the investment in man.

To study the investment in man, a new concept of capital was needed. Schultz recognized that many eminent economists before him (notably Adam Smith, Irving Fisher and Frank Knight) considered human abilities as capital. In his writings in the 1950s and 1960s, Schultz was critical of Alfred Marshall’s perspective on capital that included only physical equipment. (Schultz, 1993, p. 4, presents a revised, more generous assessment of Marshall's perspective on human capital. From interactions with Marshall's defenders, Schultz accepted that analytically Marshall saw human investments as a form of capital but considered human capital as impractical because it was divorced from the marketplace.) Schultz argued that Marshall's narrow definition of capital, among other deficiencies, led to the popular perception that economics studied only material things. And more perniciously the restricted definition led to the notion that productivity of labour is homogenous and independent of capital, so only the number of hours of work matter. (Marshall's view remained popular among leading theorists outside Chicago and Columbia. The role of physical capital was emphasized by the World Bank, for example, throughout the 1960s and 1970s. Human capital made its way into aggregate growth models only in the 1980s. It is telling that the 1979 Nobel Committee press release considers ‘Schultz on the Human Factor’ and makes only one reference to human capital, and then only in quotes. Some 13 years later human capital was more accepted and used without quote marks in the press release announcing Gary Becker's Nobel Award.)

By the mid-1950s, while a Fellow at the Center for Advanced Study, Schultz's research in the economics of education took shape:

During the year at the Center, I began to see that the productive essences of what I was identifying as capital and labour were not constant but were being improved over time and that these improvements were being left out in what I was measuring as capital and labour. It became clear to me also that in the United States many people are investing in man are having a pervasive influence upon economic growth, and that the key investment in human capital is education. (Schultz, 1963, p. viii)

Schultz spent the last 40 years of his career understanding investments ‘in man’. Human capital to Schultz was the acquisition of all useful skills and knowledge that is part of deliberate investment (Schultz, 1961, p. 1). Rather than offer formal definitions, Schultz defined human capital by example:

Much of what we call consumption constitutes investment in human capital. Direct
expenditures on education, health, and internal migration to take advantage of better job opportunities are clear examples. Earnings foregone by mature students attending school and by workers acquiring on-the-job training are equally clear examples. Yet, nowhere do these enter our national accounts. The use of leisure time to improve skills and knowledge is widespread and it too is unrecorded. In these and similar ways the quality of human effort can be greatly improved and its productivity enhanced. I shall contend that such investments in human capital accounts for most of the impressive rise in real earnings per worker. (Schultz, 1961, p. 1)

Schultz's research on human capital sought to clarify the investment process and the incentives to invest in human capital. He studied mainly formal education and organized research. The application of the investment approach in the intervening 40 years expanded to consider an array of different forms in many vistas.

It was Schultz's overarching view of human capital that made him a 20th-century pioneer in human capital theory. Jacob Mincer and Gary Becker were pioneers as well, but they focused on the effect of human capital on the level and distribution of earnings: it was Schultz who pushed the profession to see human capital investments in their totality – education, training, work experience, migration and health. This totality of vision made Schultz a leader in the re-emergence of economic demography. He organized two conferences, in 1972 and 1973, whose proceedings were originally published in the March 1973 and March 1974 in issues of the Journal of Political Economy and subsequently published in book form as Economics of the Family: Marriage, Children and Human Capital (1974). The conferences generated several seminal papers, including Willis on fertility, Becker and Lewis on the quality–quantity dimensions of children, and Mincer and Polacheck on human capital and women's earnings. In 'Fertility and Economic Values' (1974) Schultz recognized the large advances published in these studies but pushed the field to extend the static models to consider richer models of life-cycle behaviour and to collect panel data necessary to support their estimation – this was a prophetic vision, as it neatly summarized work in the economics of fertility over the next 30 years.

Envoi

As I reread several of Schultz's papers, I lament the cost of the short half-life of ideas in economics; of what we miss by not reading some of the original formulations. Textbook treatments offer modern notation and language with a well-honed presentation of ideas that speeds initial learning. Yet the vibrancy and freshness (and, yes, sometimes confusion over issues that get sorted out later) of the original frequently is lost. We have lost sight of Schultz's original contributions and it is our loss. Researchers interested in migration, economic demography, development and economic growth would be well served to read some of T.W. Schultz classics. His broad view of economics continues to be fresh and makes for fruitful reading.

The National Science Foundation and the National Institute of Child Health and Human Development provided research support. I thank Glen Cain, T. Paul Schultz and Kenneth I. Wolpin for comments.

Schumpeter, Joseph Alois (1883–1950)

Arnold Heertje
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article on Joseph Alois Schumpeter depicts him as a visionary and as one of the greatest figures in the history of economics. Both his life and his work are described and discussed. His life has not been without disaster and turmoil, and his work on methodology, economic development, innovation, capitalism, socialism and democracy not without originality, antagonism and independence. Above all, his major work on the history of economics is a lasting monument for all students of the emergence and ups and downs of new ideas in a major field of social analysis.

Article

Economist and social scientist of Austrian origin, Schumpeter was born in Triesch, Moravia, on 8 February 1883, the son of the owner of a textile factory, and died in Taconic, Connecticut, on 8 January 1950. Schumpeter attended an academic high school in Vienna and studied law and economics at the University of Vienna. In 1908 he published an important book on the nature and content of economic theory, which established his fame as the ablest among the younger group of Austrian economists. Schumpeter had F. von Wieser and E. von Böhm-Bawerk as his teachers. After being nominated at the University of Czernowitz, he became professor of economics at the University of Graz in 1911. His famous book on The Theory of Economic Development was published in 1912. Much of his later work
on business cycles and the evolution of capitalism into socialism is to a certain extent an elaboration and improvement of the ideas and analysis presented in his book on economic development. From 1925 to 1932 Schumpeter was a professor at the University of Bonn and in 1932 he became a permanent professor of economics at the Harvard University, a post he held until 1950. His impressive work on *Business Cycles* appeared in 1939, and in 1942 he published *Capitalism, Socialism and Democracy*, in which he predicted the gradual decay of capitalism. On the basis of his numerous works, one would be inclined to think that Schumpeter devoted his whole life to teaching, writing and theorizing. In fact his life has been even more colourful. From spring 1919 up to October of the same year he held the position of Austrian Minister of Finance in Renner's cabinet. During his term he was in favour of sound finance and a capital levy; he even started as a strong defender of massive socialization. He changed his mind, however, partly because he acknowledged the necessity to import capital and gradually his attitude caused tensions with his socialist colleagues in the cabinet, which finally led to his downfall. Between his professorships in Graz and Bonn, Schumpeter accepted the presidency of a Viennese private bank, the Biedermann Bank. Around 1926 the bank went bankrupt and Schumpeter was left with huge debts, probably due to speculations with borrowed money. Schumpeter was married three times, for the first time in 1907 to an Englishwoman, a marriage that ended in divorce in 1920. In 1925 he married a Viennese, 21 years his junior, who died in 1926 in childbirth. In 1937 Schumpeter married Elizabeth Boody, who, after his death in 1950, edited his monumental work, the *History of Economic Analysis* (Stolper, 1994).

In Schumpeter's interpretation of capitalism, the entrepreneur, who applies new combinations of factors of production, plays a central role. He is the innovator, and the agent of economic change and development. Centred around the role of the Schumpeterian entrepreneur is the rise and decay of capitalism. The gifted few, pioneering in the field of new technologies, new products and new markets, carry out innovations and, joined some time later by many imitators, they are at the heart of the short and long cycles observed in economic life. The importance Schumpeter assigns to the creation of money and overexpansion of credit in his early work foreshadows his later work. He argues that since in static analysis there is no room for (a) new combinations of factors of production; (b) the entrepreneur (in the Schumpeterian sense); and (c) profit, there is no need for the further creation of money. He also questions whether in a static context one can speak of economic development at all. Here he is not questioning that economic phenomena and magnitudes change, but he is suggesting that the causes of change may not lie in economic factors. In modern economic theory, this would be expressed by asking whether economic development is due to endogenous or exogenous factors. In the case of exogenous factors, Schumpeter would not speak of economic development at all, for he regards factors such as population growth, consumer preferences, technical development and social organization as non-economic factors. On the other hand, he argues that changes in human nature and social organization can in fact be attributed to economic causes, which can then be regarded as endogenous factors. The somewhat ambiguous terminology Schumpeter uses in order to describe and explain the development of the economic process is repeated in his book on economic development. Saving is no longer regarded as a factor leading to economic development in the sense of entrepreneurial innovations. Capital formation and the increase of population determine the growth rate in the stationary economy. The terms ‘development’ and ‘economic development’ are not used to describe the actual course of economic events but to distinguish between changes caused in the economic process by endogenous factors and other changes.
Not all endogenous factors lead to economic development, and Schumpeter explicitly excludes continuous endogenous changes. His theory of economic development is reduced to the treatment of spontaneous and discontinuous changes in the economic cycle. The endogenous changes Schumpeter has in mind are not found on the demand side of the economic process, but on the supply side. Economic development consists of the discontinuous introduction of new combinations of products and means of production. The five examples mentioned by Schumpeter show that the term ‘new combination’ must be taken in a very broad sense; it comprises a new product, a new method of production, the opening-up of a new market, the utilization of new raw materials, and the reorganization of sectors of the economy. He restricts the meaning of the word ‘enterprise’ to the creation of new combinations, and the meaning of the word ‘entrepreneurs’ to those economic figures who introduce new combinations. Schumpeter's entrepreneur operates in an uncertain world, has the courage to start up new ventures, and must be strong enough to swim against the tide of society. In Schumpeter's view, new combinations can be financed only if a successful appeal can be made to the banking system to create money.

According to Schumpeter, ups and downs in economic development can be explained quite simply by the fact that new combinations or innovations appear, if at all, discontinuously in groups or swarms. The appearance of entrepreneurs in ‘bursts’ is due exclusively to the fact that the appearance of one or a few entrepreneurs facilitates the appearance of others. This is the only reason for an upswing in the business cycle. The downturn sets in as a result of smaller profit margins due to imitation and a new equilibrium will be reached after the diffusion process is completed.

In his book on business cycles, Schumpeter sharpened his analytical tools. He introduced the concept of the production function, which – in his words – tells us all we need to know about the technological aspects of production. Schumpeter regards the setting up of a new production function as the introduction of new combinations. The changes caused by innovations are no longer regarded as economic development but as economic evolution. He uses the term ‘technical development’ only for innovations that involve the introduction of new methods of production. Innovations must be distinguished from inventions. The application of new combinations by entrepreneurs is possible without inventions, while inventions as such need not necessarily lead to innovations and need not have any economic consequences. Innovation itself is the independent endogenous factor that causes economic life to go through a number of cycles.

Innovations lead to cyclical fluctuations whose length is determined by both the character and the period of implementation of the innovations. Schumpeter applies this general explanation to the 40-month Kitchin, the ten-year Juglar and the 60-year Kondratieff cycles. The combination of the use of the innovations, overinvestment and of credit expansion going too far, brings the upswing to an end. The recession, which in Schumpeter's view is a healthy phase of restructuring, sets in, paving the way for a new burst of future innovations. Schumpeter's prediction of the decay of capitalism is based on the vision that it is not economic failure but rather the economic success of capitalism that causes the march into socialism. Social rather than economic factors are according to Schumpeter responsible for the structural change in the organization of society (Schumpeter, 1939).

Typical of this economic scene is the process of creative destruction. In Schumpeter's view it is the essential fact about capitalism. The process of creative destruction concerns the implementation of new combinations that incessantly modifies the economic structure from within. The competitive character of capitalism is mainly determined by creative destruction and far less by the case of textbook competition, in which prices play such a dominant role. This process of creative destruction must be judged by its
long-term results. Schumpeter has the highest possible opinion of the dynamic character and productive capability of capitalism. In weighing up the static optimal allocation of resources in case of perfect competition, and dynamic efficiency of monopolistic structures, in particular with regard to innovative activities, he has an outspoken preference for monopoly and oligopoly and a disdain for free competition. Schumpeter did not adhere to the theory that vanishing investment opportunities and a slowdown of technical change would lead to stagnation and in the end to a breakdown of capitalism (Metcalfe, 1998).

The rate of growth of production is not reduced because the technical possibilities are exhausted, but because capitalism suffers from a change in the behaviour of entrepreneurs. On the one hand, it is now easier than before to do things that lie outside familiar routine – innovation itself is being reduced to routine. Technological progress is increasingly becoming the business of teams of trained specialists who make technical change a predictable process. On the other hand, characteristics such as personality, willpower and a dynamic attitude count less in environments which have become accustomed to economic and social change.

Economic development thus becomes more and more impersonal and mechanical. The success of the capitalist mode of production makes capitalism itself redundant: capitalism undermines the social institutions which protect it. These institutions are the remnants of the feudal system and the existence of many small businesses and farmers. The disappearance of these social forms weakens the political position of the bourgeoisie. The elimination of the socioeconomic function of the entrepreneur, especially in large corporations where technical change is a matter of routine and management is bureaucratized, reinforced by the growing influence of the public sector, further undermines the bourgeoisie. Above all, however, capitalism produces an army of critical and frustrated intellectuals who by their negative attitude contribute to the decline of capitalism and help to establish an atmosphere in which private property and bourgeois values are daily subjected to heavy criticism (for example, in newspapers). In short, capitalism's economic success leads to its political failure (Schumpeter, 1942).

Schumpeter's thoughts on the effects of monopolistic and oligopolistic markets on technical change and on the influence of technology on the emergence of big business have given a great impetus to the study of the relationship between technical change and market structure. His sharp distinction between innovations and inventions has triggered off several reactions, and both theoretical analysis and empirical research have been directed to the question whether innovations are really as independent of inventions as Schumpeter supposed. A critical evaluation of Schumpeter's theory has led to a discussion of the nature of technical change, the time-lag between invention and application, the significance of patents and the diffusion process of technical change. Schumpeter's predictions about the decay of capitalism have not come about (Heertje, 1981). He seems to have underestimated the dynamic character of capitalism, the importance of which he himself emphasized so eloquently. He did not realize that a new generation of entrepreneurs might come to the fore, prepared to apply new technology and start a new wave of innovations. There is much more room for Schumpeterian entrepreneurial activity, especially on a small-scale basis, than Schumpeter foresaw.

It can be admitted that in large firms in particular the emergence of new technical knowledge is to a certain extent mechanized and that the decision-making process about its application, in the sphere of both production and marketing, is often hampered by bureaucratic features, threatening the static and dynamic efficiency of the firm and therefore the level of output. But these decisions still take place in a world of uncertainty and financial risk. These latter aspects of the decision-making process come more
to the fore as the size of the firm becomes smaller. Within these firms, individuals who take final and major decisions and bear the responsibility of profits and losses do still exist. If, due to a lack of such individuals, Schumpeterian developments arise, the result will often be a new dynamic leadership. Many small firms still exist or come into being in order to gain a place in the market. Their managers take initiatives and often have to overcome resistance of consumers to achieve their market goals. It may be true that nowadays nearly everybody is confronted with change and new developments at a very high rate, but this does not imply that everybody accepts this state of affairs. So, on the whole, there are traces of a Schumpeterian development in Western economies, but mechanization and routinization of the entrepreneurial function are by no means the general picture. Economic life is still a melting pot of conflicting tendencies, ups and downs, major risks and minor certainties. In short, it is the dynamic, ever-changing scene for entrepreneurs who have to be innovative and sensitive to new opportunities. Those entrepreneurs who follow the Schumpeterian line will be punished by the market, that is, by competitors who are prepared to take risks and to bear losses.

On balance, it seems that innovation as a process of development, application and diffusion of new technical possibilities has not been reduced to routine. Nor have people become so reconciled to change that personal characteristics such as willpower and perseverance are no longer needed to break traditional patterns. However, even this kind of modification of Schumpeter's views does not mean that over some much longer run he may still not turn out to have been right. It therefore seems appropriate to look more carefully at the empirical evidence about the entrepreneurial function and about the acceptability of the level of output as the sole yardstick for economic performance. This may enable us to look into the future of capitalism, as well (Heertje, 2006).

Is the essence of the entrepreneurial function really the exploitation of new technical possibilities and of new opportunities in general? On the basis of Schumpeter's distinction between inventions and innovations, it is natural to identify entrepreneurial activity with innovative activity. But in the no man's land between invention and innovation there is a missing link; a link which according to Kirzner comprises three essential entrepreneurial components in human action: (a) the alertness to information; (b) the awareness of new existing opportunities, waiting to be noticed; and (c) the response to possibilities offered by the market system (Kirzner, 1986). Although in many cases those who are on the lookout for new opportunities are the same men and women who exploit them, Kirzner's refinement of Schumpeter's characterization of entrepreneurship is of the utmost importance – particularly if this view is combined with the idea of the market as an ongoing process of creative discovery. It may be argued that certain stages of the application and execution of new ideas can be routinized. However, the property of being alert to marketable applications of what already exists, but is currently overlooked by others, is still an individualistic characteristic, not one for being automatized. Even if we comprehend in the definition of the entrepreneurial function the application and implementation of new combinations, it is still true that first of all one has to be alert to what may be applied. In this sense entrepreneurship never was and never will be a matter of routine (Arena and Romani, 2002). With regard to the level of output as a yardstick for economic performance, it may be observed that other aspects of welfare are taken into account as well. The operational meaning of welfare, in the broad sense of the level of the satisfaction of wants in so far as this depends on the allocation of scarce resources, comes more and more to the fore. The level of output is no longer the only thing that matters; the quality of growth, job satisfaction and other immaterial aspects of welfare are becoming more and more important. They are often the source for new methods of production and products, which give new
impetus to capitalism. As an Austrian, Schumpeter would certainly welcome the broadening of the economic dimension to the formal and subjective concept of welfare (Hennipman, 1995). Furthermore, socialism as an alternative to capitalism is on a worldwide scale less and less attractive as a system able to take care of aspirations and heterogeneous preferences of individuals and of technical change. Since the beginning of the 1980s the economic recovery inspired the reinforcement of the market. Against this background a revival of Schumpeter's ideas in economic theory took place. While Keynes dominated economic thinking during a large part of the 20th century, Schumpeter is a major source of inspiration ever since. His concern with permanent and endogenous changes in economic life show up the limited significance of static equilibrium theory and paved the way for a neo-Austrian emphasis on the importance of the market mechanism as a vehicle for the discovery of new products and new methods of production, in short of the market as a dynamic institution. The dynamics of the market mechanism combined with the economics of research and development, new methods of production and products and of the diffusion of knowledge and of the application of new technology have led in modern economic theory to a Schumpeterian-inspired approach as part of endogenous growth theory (Aghion and Howitt, 1998). It comes as no surprise that in 1986 the International J.A. Schumpeter Society was founded in Augsburg, Germany. Since then every two years an international conference is organized. Within the realm of social theory, Schumpeter's distinction between political and methodological individualism should also be mentioned. In particular, the concept of methodological individualism has proved to be very important for the analysis of social phenomena, outside the sphere of the market mechanism. As a method of analysis, methodological individualism prescribes starting from the economic behaviour of the individual in order to build a theory about the structure and working of the political process and about the behaviour of groups. In this sense, Schumpeter's thinking is the opposite of Marx's analysis in terms of the class struggle. The modern theory of public choice, in which the maximization of individual welfare of politicians and bureaucrats plays an essential role, in order to describe their social behaviour as part of the government, is a direct application of methodological individualism. Related to this development is the economic theory of democracy, of which Schumpeter is a forerunner. In his view, the democratic method is that institutional arrangement for arriving at political decision in which individuals acquire the power to decide by means of a competitive struggle for the people's vote. In other words, Schumpeter introduces the idea that democracy is a type of horizontal coordination in the public sector that can be compared to the role of the market mechanism in the private sector of the economy. The political process is regarded as a market process in which the voters are the demanders and politicians and bureaucrats are the suppliers. This idea appears to be very fruitful in both theory and practice and contributes to Schumpeter's fame as a social and economic thinker of lasting significance.

Schumpeter's view of society is based on the integration of historical facts, philosophical considerations and sociological visions. While Marx predicted the breakdown of capitalism as an inevitable consequence of the objective inner structure of the system, determined in its development by technical change, Schumpeter, although also pointing out structural changes from within, leaves room for the role of individuals, who by their behaviour can turn the tide. His message on the march into socialism is not meant to be defeatist; it would only be so if all differences between individuals disappeared and, in particular, leadership vanished (Shionoya, 1995).

Schumpeter will always be referred to for his impressive contributions to the history of economic thought. His Economic Doctrine and Method, originally published in German in 1914, is an early
expression of his interest. His book *Ten Great Economists* provides further evidence, and his monumental work, the *History of Economic Analysis*, is a lasting culmination. It illustrates his detailed knowledge of the vast literature on economic theory since the days of the Greeks and Romans. On the whole his discussion of the theoretical contributions of numerous economists is fair, generous and well-balanced. There are, however, a few notable exceptions. He ranks Cournot higher than Ricardo, and although we find both economists in modern economic theory, it seems fair to conclude that Ricardo's contributions to economics leave a broader scope and impact. Furthermore, he considers Walras the greatest economist of all time, greater than, for example, Marshall. His great appreciation for two mathematical economists is in contrast with his own non-mathematical treatment of economics, although he even became a founder and first president of the Econometric Society.

Reading Schumpeter, one realizes that his lasting significance stems from historical description and non-mathematical theoretical analysis. His inability to put his ideas about the development of economic life into a mathematical form does change our assessment of him. But whatever the final evaluation of Schumpeter may be, it cannot be denied that he gave new direction to the development of economic science by posing some entirely new questions. Schumpeter's preoccupation with the dynamics of economic life broke the spell of the static approach to economic problems. Throughout his life Schumpeter was an *enfant terrible*, who was always ready to take extreme positions for the sake of argument, and often seized the chance to irritate people. But he was also a giant on whose shoulders many later scholars contributing to economic science stood. As a political economist he is no longer in the shadow of Keynes, but in the centre of the economic scene, both in the theoretical and empirical sense.

Schumpeterian growth and growth policy design

Philippe Aghion
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Schumpeterian growth theory features quality-improving innovations that displace previous technologies, and are motivated by prospective monopoly rents. It predicts, first, that a higher rate of growth should be associated with a higher rate of firm entry and exit, and that exit can enhance productivity growth; second, that some countries may converge to the technological frontier whereas others may diverge; third, that a given policy will have contrasting effects on sectors or countries at different distances from the frontier, and therefore growth policy must be adapted accordingly. In particular, entry and delicensing enhance growth more the closer sectors or countries are to the technological frontier.

Keywords

capital accumulation; Cobb–Douglas functions; competition policy; creative destruction; endogenous growth; entrepreneurs; entry and exit; growth policy design; horizontal innovation model; implementation innovations; industrial organization; information technology and economic growth; innovation; instrumental variables; monopoly rent; product variety; Ramsey model; research and development; Schumpeterian growth model; technology frontier; total factor productivity; Washington consensus

Article

Three main ideas underlie the Schumpeterian growth paradigm: (a) growth is primarily driven by technological innovations; (b) innovations are produced by entrepreneurs who seek monopoly rents from them; (c) new technologies drive out old technologies.

The Schumpeterian growth model (Aghion and Howitt, 1992; 1998) grew out of modern industrial organization theory (Tirole, 1988). It focuses on quality-improving innovations that render old products obsolete, and hence involves the force that Schumpeter called ‘creative destruction’. In this article we
argue that the Schumpeterian paradigm holds the best promise of delivering a systematic, integrated, and yet operational framework for analysing and developing context-dependent growth policies.

Schumpeterian theory begins with a production function specified at the industry level:

\[ Y_{it} = A_{it}^{1-\alpha} K_{it}^\alpha, \quad 0 < \alpha < 1 \]  

(1)

where \( A_{it} \) is a productivity parameter attached to the most recent technology used in industry \( i \) at time \( t \).

In this equation, \( K_{it} \) represents the flow of a unique intermediate product used in this sector, each unit of which is produced one-for-one by capital. Aggregate output is just the sum of the industry-specific outputs \( Y_{it} \). (Although the theory focuses on individual industries and explicitly analyses the microeconomics of industrial competition, the assumption that all industries are \textit{ex ante} identical gives it a simple aggregate structure. In particular, it is easily shown that aggregate output depends on the aggregate capital stock \( K_t \) according to the Cobb–Douglas aggregate per-worker production function:

\[ Y_t = A_t^{1-\alpha} K_t^\alpha \]

where the labour-augmenting productivity factor \( A_t \) is just the unweighted sum of the sector-specific \( A_{it} \)'s. As in neoclassical theory, the economy's long-run growth rate is given by the growth rate of \( A_t \), which here depends endogenously on the economy-wide rate of innovation.)

Each intermediate product is produced and sold exclusively by the most recent innovator. A successful innovator in sector \( i \) improves the technology parameter \( A_{it} \) and is thus able to displace the previous innovator as the incumbent intermediate monopolist in that sector, until displaced by the next innovator. 

First implication: faster growth generally implies a higher rate of firm turnover, because the process of creative destruction generates entry of new innovators and exit of former innovators.

There are two main inputs to innovation, namely, the private expenditures made by the prospective innovator, and the stock of innovations that have already been made by past innovators. The latter input constitutes the publicly available stock of knowledge to which current innovators are hoping to add. The theory is quite flexible in modelling the contribution of past innovations. It encompasses the case of an innovation that leapfrogs the best technology available before the innovation, resulting in a new technology parameter \( A_{it} \) in the innovating sector \( i \), which is some multiple \( \gamma \) of its pre-existing value.

And it also encompasses the case of an innovation that catches up to a global technology frontier \( \bar{A}_t \) which we typically take to represent the stock of global technological knowledge available to innovators in all sectors of all countries. In the former case the country is making a leading-edge innovation that builds on and improves the leading-edge technology in its industry. In the latter case the innovation is just implementing technologies that have been developed elsewhere.

For example, consider a country in which in any sector leading-edge innovations take place at the frequency \( \mu_n \) and implementation innovations take place at the frequency \( \mu_m \). Then the change in the economy's aggregate productivity parameter \( A_t \) will be:
Schumpeterian growth and growth policy design: The New Palgrave Dictionary of Economics

\[
A_{t+1} - A_t = \mu_m (Y - 1) A_t + \mu_m (A_t - A_t)
\]

(2)

and hence the growth rate will be:

\[
g_t = \frac{A_{t+1} - A_t}{A_t} = \mu_m (Y - 1) + \mu_m (a_t^{-1} - 1)
\]

(3)

where:

\[
a_t = \frac{A_t}{\bar{A}_t}
\]

is an inverse measure of ‘distance to the frontier’. We then obtain a second important implication of the paradigm.

Second implication: by taking into account the fact that innovations can interact with each other in different ways in countries or sectors at various distances from the frontier, Schumpeterian theory provides a framework in which to analyse how a country's growth performance will vary with its proximity to the technological frontier \(a_t\), to what extent the country will tend to converge to that frontier, and what kinds of policy changes are needed to sustain convergence as the country approaches the frontier.

We could take as given the critical innovation frequencies \(\mu_m\) and \(\mu_n\) that determine a country's growth path as given, just as neoclassical theory often takes the critical saving rate \(s\) as given. However, Schumpeterian theory goes deeper by deriving these innovation frequencies endogenously from the profit-maximization problem facing a prospective innovator, just as the Ramsey model endogenizes \(s\) by deriving it from household utility maximization. This maximization problem and its solution will typically depend upon institutional characteristics of the economy such as property rights protection and the financial system, and also upon government policy.

Equation (3) incorporates Gerschenkron's (1962) ‘advantage of backwardness’, in the sense that the further the country is behind the global technology frontier (that is, the smaller \(a_t\) is) the faster it will grow, given the frequency of implementation innovations. As in Gerschenkron's analysis, the advantage arises from the fact that implementation innovations allow the country to make larger quality improvements the further it has fallen behind the frontier. As we shall see below, this is just one of the ways in which distance to the frontier can affect a country's growth performance.
In addition, as stressed by Acemoglu, Aghion and Zilibotti (2006) (AAZ), growth equations like (3) make it quite natural to capture Gerschenkron's idea of ‘appropriate institutions’. Suppose indeed that the institutions that favour implementation innovations (that is, that lead to firms emphasizing $\mu_m$ at the expense of $\mu_n$) are not the same as those that favour leading-edge innovations (that is, that encourage firms to focus on $\mu_n$); we then obtain the following:

**Third implication:** far from the frontier a country or sector will maximize growth by favouring institutions that facilitate implementation; however, as it catches up with the technological frontier, to sustain a high growth rate the country will have to shift from implementation-enhancing institutions to innovation-enhancing institutions as the relative importance of leading-edge innovations for growth is also increasing.

As formally shown in AAZ, failure to operate such a shift can prevent a country from catching up with the frontier level of per capita GDP, and Sapir et al. (2003) argued that this failure largely explains why Europe stopped catching up with US per capita GDP from the mid-1970s. More specifically, suppose that the global frontier (the United States) grows at some rate $\bar{g}$. Then eq. (3) implies that in the long run a country that engages in implementation investments (with $\mu_m > 0$) will ultimately converge to the same growth rate as the world technology frontier. That is, the relative gap $a_t$ that separates this economy from the technology frontier will converge asymptotically to the steady-state value:

$$a_t \approx \frac{\mu_m}{\bar{g} + \mu_m - \mu_n(\gamma - 1)}$$ (4)

which is an increasing function of the domestic innovation rates and a decreasing function of the global productivity growth rate. An insufficient emphasis on innovation ($\mu_n$) in Europe will reduce $\hat{a}$, that is, the long-run level of European per capita GDP compared with that of the United States.

The model can also explain why, since the mid-1990s, the EU has been growing at a lower rate than the United States. A plausible story, which comes out naturally from the above discussion, is that the European economy caught up technologically to the United States following the Second World War, but then its growth began to slow down before the gap with the United States had been closed, because its policies and institutions were not designed to optimize growth when close to the frontier. That by itself would have resulted in a growth rate that fell to that of the United States but no further. But then what happened was that the information technology revolution resulted in a revival of $\bar{g}$ in the late 1980s and early 1990s. Since Europe was as not as well placed as the United States to benefit from this technological revolution, the result was a reversal of Europe's approach to the frontier, which accords with the Schumpeterian steady-state condition (4); and the fact that Europe is not adjusting its institutions and policies in order to produce the growth-maximizing innovation policy acts as a force delaying growth convergence with the United States. (Endogenizing $\mu_m$ can also generate divergence in growth rates. For example, human capital constraints as in Howitt and Mayer-Foulkes, 2005, or credit
Schumpeterian growth and growth policy design: The New Palgrave Dictionary of Economics

constraints as in Aghion, Howitt and Mayer-Foulkes, 2005, make the equilibrium value of $\mu_m$ increasing in $a$, which turns the growth equation (3) into a nonlinear equation. That $\mu_m$ be increasing in $a$ follows in turn from the assumption that the cost of innovating is proportional to the frontier technology level that is put in place by the innovation – Ha and Howitt, 2007, provide empirical support for this proportionality assumption – whereas the firm's investment is constrained to be proportional to current local productivity. Then, countries very far from the frontier and/or with very low degrees of financial development or of human capital will tend to grow in the long run at a rate which is strictly lower than the frontier growth rate $\bar{g}$. However, our empirical analysis in this paper shows that this source of divergence does not apply to EU countries.

In the next section we concentrate on a particular policy area, namely, entry and exit.

Entry and exit

Is it always growth-enhancing to liberalize entry and to facilitate exit? That exit could be growth-enhancing follows immediately from the fact that creative destruction is about better technologies or inputs replacing old and increasing obsolete technologies. Now, what about entry? Is it unambiguously good for innovation and growth by incumbent firms? As above, the answer may depend upon firms' distance from the technological frontier. In particular, suppose that firms can improve their technologies only in a gradual (or step-by-step) fashion, and that new potential entrants are endowed with the current frontier technology. Then, incumbent firms that are initially close to the frontier can match or even leapfrog a potential entrant's technology, and therefore can deter entry by innovating. In contrast, firms that are initially far below the frontier cannot prevent entry by innovating as they can never match an entrant's technology. What does this imply for how these firms will react to increased entry threat? The answer is simple: a greater entry threat will induce firms that are close to the frontier to invest more in innovation in order to protect their monopoly rents, whereas it will discourage firms far below the frontier from investing in innovation as such investment is less likely to be of any use the greater is the probability of entry.

In short, exit can be growth-enhancing and, regarding the effects of entry, the closer a firm or sector is to the frontier, the more positively (or the less negatively) it will react to increased entry threat. These predictions have been corroborated by a variety of empirical findings. First, Aghion et al. (2005a) investigate the effects of entry threat on total factor productivity (TFP) growth of UK manufacturing establishments, using panel data with more than 32,000 annual observations of firms in 166 different four-digit industries over the 1980–93 period. They estimate the equation:

$$Y_{ijt} = \alpha + \beta E_{jt} + \gamma E_{jit} \cdot D_{jt} + \eta_i + \tau_t + \epsilon_{ijt}$$

(5)

where $Y_{ijt}$ is TFP growth in firm $i$, industry $j$, year $t$, $\eta$ and $\tau$ are fixed establishment and year effects, and $E_{jt}$ is the industry entry rate, measured by the change in the share of UK industry employment in
foreign-owned plants. In order to verify that this effect of entry on incumbent productivity growth is a result of increased incumbent innovation rather than technology spillover from, or copying of, the superior technologies brought in by the entrants, Aghion et al. (2005a) also estimate eq. (5) using a patent count rather than productivity growth as the dependent variable. They provide direct evidence that the escape competition is stronger for industries that are closer to the frontier. Specifically, the interaction coefficient $\gamma$ is highly significantly negative in all estimations. A one-standard deviation increase in the entry variable above its sample mean would reduce the estimated number of patents by 10.8 per cent in an industry far from the frontier (at the 90th percentile of $D_{jt}$) and would increase the estimated number by 42.6 per cent in an industry near the frontier (at the tenth percentile). Thus it seems that the positive effect of entry threat on incumbent productivity growth in Europe is indeed much larger now than it was immediately after the Second World War, and that the relative neglect of entry implications of competition policy is having an increasingly detrimental effect on European productivity growth.

On exit and growth, in ongoing research Aghion, Antras and Prantl combine UK establishment-level panel data with the input–output table to estimate the effect on TFP growth arising from growth in high-quality input in upstream industries, and also from exit of obsolete input-producing firms in upstream industries. Specifically, we take a panel of 23,886 annual observations of more than 5,000 plants in 180 four-digit industries between 1987 and 1993, together with the 1984 UK input–output table, to estimate an equation of the form:

$$g_{ijt} = \alpha + \beta \cdot Q_{jt} - 1 + \gamma \cdot X_{jt} - 1 + \delta \cdot Z_{ijt} - 1 + \eta_i + \varphi_j + \tau_t + \epsilon_{ijt}$$

(6)

where $g_{ijt}$ is the TFP growth rate of firm $i$ in industry $j$, $Q_{jt} - 1$ is a measure of upstream quality improvement, and $X_{jt} - 1$ is a measure of exit of obsolete upstream input-producing firms.

Establishment, industry and year effects are included, along with the other controls in $Z_{ijt} - 1$, including a measure of the plant's market share.

The result of this estimation is a significant positive effect of both upstream quality improvement and upstream input-production exit. These results are robust to taking potential endogeneity into account by applying an instrumental variable approach, using instruments similar to those of Aghion et al. (2005a) described above. The effects are particularly strong for plants that use more intermediate inputs, that is, plants with a share of intermediate product use above the sample median. Altogether, the results we find are consistent with the view that quality-improving innovation is an important source of growth. The results are, however, not consistent with the horizontal innovation model, in which there should be nothing special about the entry of foreign firms, and according to which the exit of upstream firms should if anything reduce growth by reducing the variety of inputs being used in the industry.

Conclusion and comparison with alternative endogenous growth models
What have we learned from our discussion so far? First, that Schumpeterian growth theory features quality-improving innovations that displace previous technologies, and that such innovations are motivated by the prospect of monopoly rents. Second, that, due to the natural conflict between new and old technologies, a higher rate of growth is likely to be associated with a higher rate of firm turnover (entry and exit).

In particular, exit can have a positive effect on productivity growth in downstream industries because it replaces less efficient input producers by more efficient ones. Third, that quality improvements can be generated, either by imitating current frontier technologies or by innovating upon previous local technologies, and that the relative importance of either type of innovation depends upon a sector's or a country's initial distance from the corresponding technological frontier. Fourth, that the same policy will tend to have contrasting effects on sectors or countries at different distances from the frontier, and that therefore growth policy must be adapted to the particular context of a sector or country. Fifth, that entry and delicensing have a more positive effect on growth in sectors or countries that are closer to the technological frontier, but have a less positive effect on sectors or countries that lie far below the frontier. This suggests that, although disregarding entry was of no great concern during the 30 years immediately after the Second World War, when Europe was still far behind the United States and catching up with it, nevertheless, now that Europe has come close to the world technology frontier this relative neglect of entry considerations is having an increasingly depressing effect on European growth. It also suggests a role for complementary policies aimed at reallocating resources and workers from laggard to more frontier sectors and activities in order to maximize the positive effects of competition and entry on productivity growth.

Finally, one may want to contrast the Schumpeterian growth paradigm with the two alternative models of endogeneous growth. The first version of endogenous growth theory was the so-called AK theory (see Frankel, 1962; Romer, 1986; Lucas, 1988), whereby knowledge accumulation is a serendipitous by-product of capital accumulation by the various firms in the economy. Here thrift and the resulting capital accumulation are the keys to growth, not novelty and innovation. The second model of endogenous growth theory is by Romer (1990), according to which aggregate productivity is a function of the degree of product variety. Innovation causes productivity growth in the product-variety paradigm by creating new, but not necessarily improved, varieties of products. The driving force of long-run growth in the product-variety paradigm is innovation, as in the Schumpeterian paradigm. In this case, however, innovations do not generate better intermediate products, just more of them. Also as in the Schumpeterian model, the equilibrium R&D investment and innovation rate results from a research arbitrage equation that equates the expected marginal payoff from engaging in R&D with the marginal opportunity cost of R&D. But the fact that there is just one kind of innovation, which always results in the same kind of new product, means that the product-variety model is limited in its ability to generate context-dependent growth, and is therefore of limited use for policymakers.

In particular, the theory makes it very difficult to talk about the notion of technology frontier and of a country's distance from the frontier. Consequently, it has little to say about how the kinds of policy appropriate for promoting growth in countries near the world's technology frontier may differ from those appropriate for technological laggards, and thus little to say by way of explaining why Asia is growing fast with policies that depart from the Washington consensus, or why Europe grew faster than the United States during the first three decades after the Second World War but not thereafter. In addition, nothing in this model implies an important role for exit and turnover of firms and workers; indeed increased exit
Schumpeterian growth and growth policy design: The New Palgrave Dictionary of Economics

in this model can do nothing but reduce the economy's GDP, by reducing the variety variable that uniquely determines aggregate productivity. As we just argued above, these latter implications of the product-variety model are inconsistent with an increasing number of recent studies demonstrating that labour and product market mobility are key elements of a growth-enhancing policy near the technological frontier.

Schumpeterian growth and growth policy design: The New Palgrave Dictionary of Economics

How to cite this article

The importance of the economics of science is substantially due to the importance of science as a driver of technology, and technology as a driver of productivity and growth. Believing that science matters, economists have attempted to understand the behaviour of scientists and the operation of scientific institutions. One goal is to see how far science can be understood as a market, and how far the market for science and scientists can be understood as efficient. When inefficiency is found, a related goal is to propose changes in resource levels or incentives, to increase the speed of scientific advance.

Article

The economics of science aims to understand the impact of science on the advance of technology, to explain the behaviour of scientists, and to understand the efficiency or inefficiency of scientific institutions.

The first economics of science may have been Adam Smith's idealistic, but sadly untrue, discussion in the Theory of Moral Sentiments (1759, p. 124) of Newton having been motivated purely by curiosity rather than a desire to achieve fame and fortune. If Smith's account was the beginning of a positive economics of science, then Charles Babbage's argument (1830) for the reform of British scientific institutions may count as one of the earliest instances of a mainly normative economics of science. Also
usually mentioned as an early founder of the normative economics of science is the American philosopher C.S. Peirce (1839–1914), who advocated the application of economic tools of analysis to decide which scientific projects to adopt (see Wible, 1998).

The ‘modern’ economics of science grew out of three main topics. The first topic addressed how the advance of science contributed to the advance of technology, and hence productivity and growth. The second topic, which overlaps with concerns in the history and philosophy of science, addressed how science advances. A third topic is the empirical data collection and econometric analysis of the supply, demand, compensation and productivity of scientists. Diamond (1996) and Stephan (1996) both provide broad surveys of the economics of science, with Diamond perhaps devoting more space to interdisciplinary and policy issues. Special attention has been paid to the contributions to the economics of science of three of the field's founders: Mansfield, Griliches and Stigler (Diamond, 2003; 2004; 2005). Several of the more important papers in the economics of science through 1998 are included in the two-volume collection edited by Stephan and Audretsch (2000).

In what follows, we first consider the literature that most makes the case for why the economics of science should be a priority for our attention: the literature on science as a contributor to economic productivity and growth. We proceed to briefly summarize some economic discussion of some of the ‘deep’ issues in the economics of science, which sometimes overlap with issues in philosophy of science, such as the objectives of scientists (truth, fame, fortune?), and the constraints that are most relevant to their choices about which projects to pursue and which theories to adopt. Next we look at some of the studies that have attempted to model and measure a variety of aspects of the market for science and scientists. Finally, we give examples of some of the studies in normative economics of science that argue for changes in funding or for institutional reform.

**Impact of science on technology, productivity, and growth**

The importance of technology as a driver of economic growth and well-being has been appreciated since Adam Smith's *Wealth of Nations* (1776), and emphasized most notably by Schumpeter (1942). If technology is the main driver of economic growth, the next question is: what is the main driver of technology?

Rosenberg (1982) made the credible point that most economists, for most of the history of the profession, had viewed the process by which new technologies are developed and adopted as a ‘black box’. In the years since, partly led by Rosenberg himself, economists have increasingly attempted to say more about what goes on inside the box, especially concerning the role of science in advancing technology.

Several economic historians have examined the role of science in the advance of technology and economic growth over the broad sweep of history. Mokyr (1990; 2002), Rosenberg (Mowery and Rosenberg, 1989; Rosenberg and Birdzell, 1986), and Landes (1998), broadly agree that the advance of science is a necessary but not sufficient condition for substantial and rapid advance in technology and economic growth.

Nelson (1959) catalogued many examples of how science had contributed to the advance of technology. More recently, Rosenberg (Mowery and Rosenberg, 1989, pp. 11–14) has claimed that the distinction
between science and technology is often hard to make, providing several examples of how scientific advances have resulted from the pursuit of ‘practical’ results. Although most economists adopt Nelson's view that mainly new science enables the advance of new technology, it is not hard to find examples where the advance of science was enabled by new instruments provided by advanced technology (Ackermann, 1985).

Mokyr (1990), in his broad economic history of the advance of technology over the ages, generally finds the advance to be slow and fitful until the industrial revolution. Until the mid-1800s, the relationship between science and technology was loose (Mansfield, 1968; Mokyr, 1990, pp. 167–70). Those who advanced science and technology shared an attitude of optimism about the prospects of understanding and controlling nature (Landes, 1969). But, beginning in the mid-19th century, and especially with the development of commercial laboratories toward the end of the 19th century, the relationship between science and technology became closer, with advances in science more often and more clearly being a necessary condition for technological advances.

Beginning with Nelson's taxonomic paper (1959), evidence for this latter claim has been provided by economists in a variety of forms. Griliches's main contribution, in a pair of papers (1957; 1958), was to measure the return to scientific research on hybrid corn and to measure and explain varying rates of adoption (see Diamond, 2004). Surveys of research managers by Nelson (1986) and by Mansfield (1991; 1992) provided evidence that science is sometimes important for technical change, although the importance varies considerably with the industry and with the sub-field of science.

The development by Romer (1986; 1990) and others of the ‘new growth theory’ attracted further attention to science as a driver of technology, because such models include a more prominent role for knowledge (‘recipes’) than earlier models. Such models implied the possibility of increasing returns to investments in knowledge if various spillover effects were large enough. Stimulated partly by such models and partly by independent research by economists such as Griliches (see Diamond, 2004), considerable empirical work has been undertaken measuring the spillover effects of scientific knowledge; for example, Jaffe (1989), Adams (1990) and Jaffe, Trajtenberg and Henderson (1993).

Deep understanding of science

Stigler and Becker (1977) have argued that everyone has the same utility function. This contrasts with Adam Smith's suggestion in his Theory of Moral Sentiments (1759, p. 124) that scientists, or at least the best scientists, were more purely motivated by curiosity. Gordon Tullock (1966, pp. 34–6), and Kenneth Arrow (2004) suggest that scientists have a range of motives, from those who fit the Smith ideal to those motivated by fame and fortune (Levy, 1988). However, in their research on the behaviour of scientists, economists usually follow Stigler and Becker in assuming that scientists mainly value income and prestige. Scientists valuing both income and prestige might explain Stern's finding (2004) that industrial scientists are willing to give up some income in exchange for greater ability to publish their results.

The process of theory choice among scientists has been explained using economic tools (Diamond, 1988b; Hull, 1988; Goldman and Shaked, 1991). The explanations have been criticized by Hands (1997). Brock and Durlauf (1999) build on the work of Kitcher (1993) in their construction of a dynamic model of scientists’ adoption of new theories. A key assumption of their set-up is that one source of a
scientist's utility is the ‘conformity’ of a scientist's views with those of other scientists. The model allows the possibility that science is progressive, even if social considerations have some weight in scientists’ utility functions, partially answering many of those in the social studies of science field who believe that the admission of social considerations undermines the special cognitive status of science. Stigler authored several papers that presented evidence on hypotheses about the determinants of successful science. He provided evidence and arguments on questions such as: does a scientist's biography help us understand the scientist's contributions (1976), and how efficiently is error weeded out in science (1978)? Stigler generally framed his studies as seeking just to understand, not to reform, although the results sometimes stimulated thoughts of reform in others. A fuller account of Stigler's contributions to the economics of science appears in Diamond (2005).

The market for science and scientists

Michael Polanyi (1962) optimistically portrayed science as an efficient marketplace of ideas. Much research in the economics of science in the last few decades shares Polanyi's research programme of explaining the behaviour of scientists and scientific institutions on the basis of rational optimization within an efficient marketplace. Many studies in the economics of science fall within the domain of labour economics, and assume that scientists are rational maximizers of income, and sometimes of prestige. Within labour economics, a significant theoretical and empirical literature has developed that examines the economics of higher education. Since many scientists, and especially most scientists who are credited with major scientific discoveries, have been associated with universities, this literature is relevant to the economics of science, even when the examples or data are not drawn explicitly from science.

Some of the earliest economics of science studies collected data to analyse the supply of and demand for scientists. Early examples of this genre were Blank and Stigler (1957) and Arrow and Capron (1959). Richard Freeman's ‘cobweb’ model (1975) of the labour market for physicists had an unstable equilibrium because students’ occupational choices in the model are based on systematically biased forecasts of the future demand for physicists. Siow later (1984) showed that professional labour markets are better characterized by assuming the students’ forecasts are based on rational expectations. Human capital theory and measurement have been used to estimate earnings functions for scientists, including as independent variables measures of productivity, such as articles produced, citations received, and teaching evaluations. Many of the studies also include one or more variables intended to measure hypotheses of discrimination, such as gender and race variables (for example, McDowell, 1982). Yet other studies include variables intended to measure what has recently been called ‘social capital’ and has previously been identified with Robert K. Merton's (1968) ‘Matthew effect’ (the rich get richer) or with ‘old-boy’ networks.

One goal of many of the earnings regression studies has been to learn how much of the variation in academic salaries can be explained on the basis of variation in measures of academic productivity. Lovell's (1973) paper was one of the first to include measures of research productivity in an academic earnings regression. Early studies tended to focus on number of articles published as the measure of research productivity. A pair of papers by Stigler and Friedland (1975; 1979) helped establish the
credibility of citations as a measure of academic productivity. One of the first to include citations in an earnings function as a measure of productivity may have been Laband (1986). Subsequent studies using the citation measure include Hamermesh, Johnson and Weisbrod (1982), Diamond (1986b), Sauer (1988), and Kenny and Studley (1995). A review of the literature on bibliometric measures of productivity can be found in Diamond (2000).

The simplest models of compensation assume that workers are paid the value of their current productive output (their ‘marginal revenue product’). To account for observed anomalies with this hypothesis, especially in professional labour markets, a literature has developed supposing that there are long-term implicit labour contracts. For example, universities may provide scientists with insurance for variability of research output by paying the scientist more than the value of their output in low-output years and less than the value of output in high-output years. If scientists are uncertain at the beginning of their careers whether they will become high- or low-productivity scientists, they may also demand insurance against the possibility of their being low-productivity scientists (S. Freeman, 1977). This might explain the observed greater variability in measures of scientists’ productivity than in measures of their salaries.

An alternative explanation is to make use of a compensating differentials argument (Frank, 1984). The assumption is that scientists receive utility from being paid more than other scientists. So the top scientist would be paid less than the value of her productivity, because she is receiving a compensating differential in the form of being at the top of the pecking order.

Implicit contract models have also been developed to try to explain important scientific labour market practices, such as academic tenure. For example, Carmichael (1988) argues that tenure is an institutional device to reduce the costs to incumbent faculty of correctly identifying promising new faculty, while Waldman (1990) claims that faculty value tenure because it serves as a signal to outside institutions of the faculty members’ quality, and hence increases outside higher salary offers. Siow (1998) claims that specializing is risky, since sub-fields of specialization may suddenly become obsolete; so without tenure as a form of insurance, faculty would under-specialize.

Implicit contract models are often clever and sometimes plausible. But as clever, plausible models multiply that explain the same stylized facts (for example, the existence of academic tenure), the credibility of the exercise may suffer. It may also be worth mentioning that, ceteris paribus, economists will be more popular with their peers if they create models justifying tenure, and other academic institutions, than if they create models showing tenure is inefficient.

Other mainly empirical studies have examined the mobility of academic scientists between university positions (Rees, 1993), and the mobility of industrial scientists between technical and managerial jobs (Biddle and Roberts, 1994). Another extensive, mainly empirical, literature makes use of standard theory on the optimal allocation of time over the life cycle to motivate analysis of scientific productivity over the life cycle. Life-cycle investment models (for example, Diamond, 1984) often suggest that it makes sense to invest in human capital early in the life cycle. These models often imply concave age–productivity profiles. Empirical evidence confirms this generalization (Diamond, 1986a; Stephan and Levin, 1992), but with very different peak productivity ages for different fields of science. Age-related differences in the rate of acceptance of new theories have also been examined (Hull, Tessner and Diamond, 1978; Diamond, 1980; 1988a; 1988b; Levin, Stephan and Walker, 1995).
In the previous section we discussed research that for the most part argues that the institutions for rewarding and allocating resources to scientists can be explained as efficient aspects of a well-functioning market of ideas. Bartley (1990) has argued that while a ‘marketplace of ideas’ is an appropriate goal and standard, it is an inaccurate description of the current institutions of science. In one of his headings (1990, p. ix), he claims that our current institutions for academic science are ‘where consumers do not buy, producers do not sell, and owners do not control’.

In an early study, Stigler (1965) provided evidence that, when economics underwent a transition from a science done by amateurs to one done by professionals, the discipline became much more theoretical and mathematical, and much less applied and policy-oriented. Stigler's friend and colleague, Milton Friedman, argued (1981) that the funding of the National Science Foundation (NSF) had had a similar effect, and argued further that this effect had slowed the advance of knowledge. The debate was renewed 13 years later (Friedman, 1994; Griliches, 1994). Edward Lazear (1997) has developed a model implying more modest advice for the NSF: the foundation should give fewer but larger awards.

Other economists have studied the funding of science. Arrow (1962), Johnson (1972) and others have argued that science is a public good that will be under-provided by the private sector. Dasgupta and David (1994) accept the public goods argument of the ‘old’ economics of science of Arrow (1962), but want to add to it findings of some sociologists on the secrecy that sometimes results from the competition for priority, in order to develop a ‘new’ economics of science. Their ‘new’ economics of science argues for greater government funding of science, accompanied by increased incentives for scientists to share their findings sooner with other scientists and with those seeking to apply the findings to new technologies.

Romer (2001) argues that, if roughly half a million more scientists and engineers were supplied and appropriately deployed, the US economy could sustain a half a per cent greater rate of growth in GDP. He suggests that major changes would be required in academic institutions and government policies to achieve this goal, but he believes the resulting implications for the economy of success would be ‘staggering’ (2001, p. 227).

Kealey (1996) and Martino (1992) explicitly dispute the traditional public goods argument for government support of science on the grounds that private industry often has both the incentives and the ability to do substantial high-quality scientific research. Hanson (1995) supports an alternative private form of science funding when he argues that greater scientific innovation would occur if more of the funding for science came from a betting market, where those who predict accurately the ultimate outcome of currently debated scientific questions receive more resources.

Although not opposing the science-as-public-good theory as strongly as Kealey and Martino, Rosenberg (1990) has emphasized the incentives that private firms have to invest in science. He examined firms that hired Ph.D. scientists and that allowed the scientists considerable leeway in the allocation of their time and in the publication of their results. He argues that this was in the firm's interest because of the value of such scientists as a resource in keeping up with and explaining scientific advances relevant to the firm's product development efforts. Besides Rosenberg's paper, there is a considerable literature measuring returns to firm investment in R&D. Some of these studies might be considered part of the economics of science to the extent that they study ‘basic research’, a label that is sometimes used...
interchangeably with ‘science’. Examples of this literature are surveyed in Audretsch et al. (2002).

Several scholars have attempted to measure the extent to which public expenditures on science add to the total funding of science, or the extent to which they simply crowd out private funding on science. Diamond (1999), for example, using highly aggregated time-series measures of government and industry investment in science, found no evidence of crowding out. An evaluative survey of this literature has been published by David, Hall and Toole (2000).

Some economists have explained the behaviour of some scientists and the structure of some scientific institutions in terms of rent-seeking behaviour. Rent seeking is a zero-sum process in which an agent invests resources to obtain an uncompensated transfer from another agent (Tullock, 1967). In one example, McKenzie (1979) suggested that there is a fixed fund for department salaries, and that department members can increase their share of the fund either by being more productive themselves or by sabotaging the productivity of others, perhaps, for example, by the calling of unnecessary meetings. Other rent-seeking accounts of academic institutions have been provided by Brennan and Tollison (1980) and Grubel and Boland (1986).

We mentioned in the previous section economic models of academic tenure that attempt to explain the institution as an efficient response to features of the academic labour market. Others (for example, Rogge and Goodrich, 1973) have followed Alchian (1959) in presenting a basically rent-seeking account of tenure as an inefficient institution that exists because it is in the interests of a sufficiently powerful special interest group.

In an account highly complementary to the rent-seeking hypothesis, Goolsbee (1998) has studied data on federal funding of science and found that it largely results in windfalls for scientists. Goolsbee's results call into question the extent to which federal funding actually increases the amount of science produced.

scientific realism and ontology

Uskali Mäki
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article defines the concept of realism and explores its implications for ontology, defending the idea of ontological realism and its relevance to economics, while rejecting the idea of some special ‘realist ontology’ that informs us about the ways of the real world. The main focus is on what it is for the world (its constituents, structure, and ways of functioning) to exist. Economics-relevant scientific realism suggests that much of the social world is characterized by non-causal science-independence. Implications of this are outlined for causation, social construction, economics-dependence of the economy, modelling, and truth in economics.

Keywords

causal realism; causality in economics; Granger-causality; Hume, D.; methodological individualism; microfoundations; mind-independence; models; neuroeconomics; normal science; ontological realism; ontology; rhetoric of economics; science-independence; scientific realism; social constructivism

Article

Economists customarily talk about the ‘realism’ of economic models and of their assumptions and make descriptive and prescriptive judgements about them: this model has more realism in it than that model, the realism of assumptions does not matter, and so on. This is not the way philosophers mostly use the term ‘realism’; thus there is a major terminological discontinuity between the two disciplines. The following remarks organize and critically elaborate some of the philosophical usages of the term and show some of the ways in which they relate to economists' concerns. In the philosophy of science, scientific realism is the mainstream position – or rather a heterogeneous collection of positions – that includes ideas about the nature of scientific theories and how they are related to the real world and about the goals and achievements of scientific inquiry. However, most of what philosophers have contributed around these ideas is not designed to deal with the peculiarities of economics, so some important
adjustments are needed to make scientific realism an interesting position for economists. Economists and their critics, as well as the consumers of economic research, are often intrigued by two kinds of issue that connect with realism: Is this model about something real, something that really exists (or instead about some imaginary fiction or social construct perhaps)? Is this model true (partly true, approximately true) about something real (instead of just being useful or convenient or persuasive)? These are the general questions discussed here – not by answering them, but by way of clarifying the conceptual prerequisites of trying to answer them, and in particular by way of examining what it is to be a realist about them. Misuses of ‘realism’ are abundant enough to warrant this exercise. The focus will be on ontology, and on how realism relates to it, so we will be mainly talking about ontological realism.

What exists?

Ontological realism is a philosophical thesis that deals with two questions: What exists? What is existence? Consider the first question. Slightly different ways of putting it include:

- What is there in the world?
- What is the furniture of the world?
- What is the world made of?
- What is its structure?
- What is the case?
- What is the way the world is?
- What is the way the world works?

To such questions one expects answers of the form, ‘X exists’ or ‘Z is the case’ or ‘WWW is the way the world works’. But isn’t it the task of science to provide answers of this form to such questions? What is the role of distinct ontological reflection? The quick response is in two parts: the answers provided by ordinary scientific practice (‘normal science’) are often implicit and only presupposed, while ontological reflection seeks to make them explicit; and the explicit answers that daily scientific practice supplies are mostly more specific and concrete than those offered by focused ontological scrutiny. There is an overlap and continuity between ‘normal’ science and ontological reflection regarding the kinds of answers they seek to offer to those questions. Consistency between the two is desirable, even though occasional (and often fruitful) conflicts arise.

Scientists may claim that there are neural brain states and processes that cause human behaviour, or that there are beliefs and wants that causally produce such behaviour. Scientists may make claims about there being causal connections between certain aggregate variables, such as the money stock and inflation, or between inflation and unemployment. Such claims have ontological presuppositions, but practising scientists seldom engage themselves in explicating and elucidating them. Are there mental states such as beliefs and wants in addition to brain states? In referring to preferences and expectations in their explanations, are economists presupposing that they exist? Are there macroeconomic aggregates in addition to individuals and their attributes? Do economists commit themselves to their existence when invoking them in explaining economic phenomena? And what is causation all about? Is there just one kind of causation out there, or are there perhaps different kinds of causal connections and other causal facts, depending, among other things, on whether we talk about connections between brains, minds,
individual actions, institutions, or economic aggregates?
Explicitly or implicitly, economists hold presuppositional beliefs about such ontological matters. They
give, or imply, answers to the sorts of questions above, provoked by developments and debates in
economics, such as those around neuroeconomics and microfoundations. What does this have to do with
realism? Not much, as such. Various alternative answers to those questions are compatible
ontological realism. One can be a realist about brains or minds, or both, and one can be a realist about
human individuals or social institutions, or both. There is no single privileged ‘realism’ that would
determine the contents of our ontology – there is no such thing as ‘the realist ontology’. It indicates a
misunderstanding of ‘realism’ to suggest that there is one general ‘realist ontology’ that has specific
contents concerning issues such as law and causation, or the relations between human individuals and
social structures. Realism as such does not imply specific answers to questions ‘What exists?’ or ‘What
is the case?’ and the like.

Ontological realism is always Realism-about-X, so we get a variety of realisms depending on the value
of X. So one can choose to be, or not to be, a realist about electrons, molecules, cells, minds, human
individuals, and social organizations, as well as more generally about relations and causal processes,
natures and necessities, numbers and sets, parts and wholes, material states and moral values. One can
coherently be a realist about some such things while being an anti-realist about others; one can be a
realist about molecules without being a realist about morality, or vice versa. And, again, choosing to be a
realist does not as such determine what you are a realist about. You choose Realism-about-X as a
package, so it is not your choice of realism that implies your choice of some specific X.

What is existence?
It also works the other way around. Your choice of X as the kind of thing that you think exists does not
yet make you a realist. In order to qualify as a realist it is not enough to hold that the hardware of the
brain exists or that social structures are causally powerful, or what have you. The general form of the
thesis of ontological realism is ‘X exists’ or ‘Z is the case’ or some such. It is not enough to be specific
about the X and the Z; one also needs to say more about the meanings of ‘exists’ and ‘is the case’. No
answer to ‘what exists’ – no list of things that are claimed to exist or to be the case – is alone sufficient
for ontological realism. We also need to carefully answer the question, ‘What is existence?’

Irreducible existence
Two requirements are needed in order to come up with an appropriate idea of existence. First, realism
requires that existence claims be understood literally. Thus, one is a realist about X if one takes X to
exist, and by this one means, literally, that X exists rather than ultimately meaning that something else
exists. One is a realist about ions and institutions just in case one takes ions and institutions to exist,
period. On the other hand, one is not a realist about X if one holds that X exists in the sense that Y exists
by virtue of the fact that X is ultimately Y. In such an anti-realist manoeuvre one substitutes a
reductionist reading for a literal reading of existence claims. This table at which I write exists in the
sense that a certain bundle of atoms exists – tables are ultimately nothing but bundles of atoms. Or to say
that the table exists is another way of saying that a certain collection of sense data exists – middle-sized
material objects are collections of sense data, literally speaking. Minds and mental states such as
expectations exist, but their existence is a matter of human brains and neurons existing. A business corporation exists, but to say so is just a convenient way of speaking: it exists more precisely in the sense that an organized collective of human individuals exists – social collectives are sets of individual people after all. This way of using existence claims amounts to an ontologically reductionist strategy that allows for existence claims that are not supposed to be taken literally: an appropriately literal reading is a post-reduction reading. In contrast, an ontological realist about X reads ‘X exists’ literally and insists on its irreducibility to ‘Y exists’.

Consider causation. In order to qualify as a realist about causation it is not sufficient to hold the view that there are causal facts in the world. It is also required that causation be viewed as an irreducible notion, one that cannot be analysed fully in terms of other, non-causal notions. For example, an ontological empiricist about causation might say that causation exists, and then add that it exists in the sense that empirical regularities or constant conjunctions of observable events exist – simply because this is what causation is, in the end. Here causation will be reduced to, or analysed into, non-causal facts. In philosophers’ jargon, ‘causal realism’ is a name for a position that denies such a reduction and instead requires claims about causation to be taken at face value. For a realist, causation is, literally, a matter of causing, producing, bringing about, propagating, enabling, inhibiting and so on. A causal realist analyses causation in causal terms, whereas a causal anti-realist analyses causation in non-causal terms and thereby analyses causation away.

So conceived, causal realism is an ontological position. This is compatible with epistemologies of causation that employ non-causal terms. David Hume seems to have been a causal realist – causation in the world is a matter of causes producing their effects – while at the same time his epistemological scepticism suggested that we only have epistemic access to constant conjunctions (see, for example, Strawson, 1989). Or consider Granger-causality, defined partly in terms of predictability of effects. Predictability is an epistemic notion, so a causal realist should not include it in his concept of causation in the world. But Granger-causality does not require such inclusion, so as such it does not rule out the possibility of causal realism. The general idea behind it, that of providing an ‘operational definition’ of causation, does not require Humean scepticism either: Granger-causality can be thought of as a (fallible) element in the economists' imperfect epistemic endeavours to discover irreducibly causal relations in the world.

Independent existence

The second requirement for a position to qualify as realist is that it must hold that whatever exists has to exist in some suitable independent way. On this issue the peculiar features of society and the social sciences impose special requirements on the appropriate conception of realism. Ontological realism about some X – in its answer to the question, ‘what is existence?’ – claims that X exists independently of some Z. Further versions of this idea depend on how ‘independent’ and ‘Z’ are specified. The usual manner of defining ontological realism is in terms of mind-independence: some X exists independently of the human mind. But even though this idea would seem to apply to many sorts of things, it is problematic in the social sciences. While it may be plausible to claim that galaxies and quarks exist mind-independently, this does not seem a good idea in the case of, say, people's preferences and expectations or a society's institutions and organizations. The conventional existence test that tends to appeal to most people's intuitions is to imagine a situation without minds: take away human minds,
will galaxies survive? Yes, they will. Take away human minds, will social institutions survive? No way. Social objects are mind-dependent. This does not require, of course, that whatever there is in society is intentionally created by people, as intended results of their purposeful action. Much of what there is in society is being produced as unintended consequences of the actions of people with minds. Not only are social objects mind-dependent in general, they are also representation-dependent. They are dependent on representations in general for the trivial reason that people are animals active in producing and using representations as an integral feature of human action. Moreover, and more strongly, many – but surely not all – social things are dependent on representations about them: the existence of X is dependent on representations of X – on being represented as X. Many contracts between economic actors only exist when linguistically represented. Take away the representation, and the contract ceases to exist. Likewise, the euro, the currency in use in most members of the European Union, is partly constituted by representations, among them certain treaties of the European Council. In contrast, the existence of DNA molecules is not dependent on any particular representations of them: supposing they exist at all, they existed both before and after Watson and Crick's double helix representation, and independently of it.

Social reality is variously shaped by, and dependent on, people's beliefs and expectations, goals and wants, plans and impulses, emotions and reasonings, speech acts such as promises and persuasions, agreements and disagreements, collaborations and rivalries, meanings and their interpretations, customs and conventions, and so on. None of this is mind-independent in certain obvious senses.

**Science-independence**

Thus ontological realism about society and social sciences requires some other idea of independent existence. Here it is advisable to start being more precise about the issue: we are concerned with the ontology of *scientific* realism. This suggests that we need some notion of science-independence (an idea that has been largely ignored by philosophers debating scientific realism). A scientific realist takes galaxies and quarks to be independent of astronomy and physics, of the theories and explanations and procedures in these sciences. But consider social facts. Much of what there is in society is increasingly dependent on science, natural science included. This dependence works through various powerful influences of science on the world views and technologies prevalent in society. It is through these channels that people's beliefs and aspirations, and society's norms and institutions, are shaped by science. These constitute the stuff of which societies are made, so social matters are not science-independent in an obvious sense.

What about the economy and the science of economics, how do they relate to one another? We can repeat some of the things we said above, and we can add an idea of a stronger dependence. The Lucas critique provides one expression to the old and obvious idea that the economy is not fully economics-independent. Many economic facts seem to be dependent on theories and procedures in the science of economics. Among the more striking cases, just think of the dependence of certain practices of finance in the real world on certain theories of finance – such as the Black–Scholes–Merton formula for option pricing (see MacKenzie, 2006). Economic theories and research results shape people's beliefs and worldviews, and policy advice based on economic theories and research results shapes economic policies, and these in turn shape the economy. Economic theories, people's beliefs and economic facts are furthermore often connected through mechanisms of self-fulfilment and self-defeat. The economy is thus variously
dependent on economics. One might suspect that the notion of science-independence does not serve scientific realism well in the case of economics.

In order to see why all this does not undermine scientific realism about economics and the economy, we need to pay attention to the notion of independence itself in ‘exists independently of’. Of the many kinds of independence, it will be sufficient to distinguish two general categories (Mäki, 2002).

Consider again the idea above about society being science-dependent just because science shapes the world views and technologies in society, and these in turn shape people's behaviour and social institutions. What kind of claim is this? I take shaping (or whatever similar terms one may want to use) to be a matter of causal influence. Thus, a causal claim is being made: social matters are causally dependent on science. This is a relief to a realist about society and social sciences since such causal dependence can easily be accommodated by scientific realism.

Scientific realism does not need to deny or despair over the causal dependence of the economy on economics either. The causal influences of economics on the economy travel through obvious channels. Policymakers and others (such as students, investors, entrepreneurs, workers, consumers) learn, directly or indirectly, about economic theories, explanations and predictions, and are inspired by them enough to modify their beliefs. These modified beliefs make a difference for the behaviour of these actors, and this has consequences for the economy. The connections, and hence the dependencies, are causal.

The same holds for cases in which the connections from theory to the world change the latter so as to make the theory more closely correspond to the world – often characterized as the ‘performativity’ of theory. If it is the case that students of economics act more than other students in accordance with the conventional behavioural assumptions of economic theory, this might be because their image of appropriate human behaviour and thereby their actual behaviour is influenced by what they are taught in class. If certain practices in real world finance are in line with the Black–Scholes–Merton formula for option pricing, this may be because the theoretical formula has managed to travel from academic research to economic practice so as to shape the latter. In such cases, the connections are causal.

Rather than constituting a threat to realism, such causal connections between economic theory and the economy pose a constructive challenge to realism. The economy is organized into causal structures and processes, and investigated by economists. Adding economic theory to the picture in some cases means adding another causal set of connections to our image of social reality – science is not done outside of society, it is very much part of social reality, after all. This invites further scientific inquiry into the detailed features of these causal connections. Good social science illuminates the roles that ideas play in the social world. Good social science should also illuminate the roles that scientific ideas play in the social world.

A realist is comfortable with causal connections in general, and so is not disturbed by causal connections from theories to the world either. To see why, it is important to be precise about the nature of this dependence. Indeed, literally speaking, there is no causation flowing from theories to the world here. Economic theories do not shape the economy. People do. People, in various roles as economic actors, are inspired, directly or indirectly, by the contents of economic theories, this shapes their beliefs, their beliefs shape their motives, and those motives drive them in action that shapes the economy. Phrases such as ‘self-fulfilling’ and ‘self-defeating’ theories and predictions are therefore not to be taken literally: theories do not fulfil or defeat themselves (Mäki, 2002; 2005a). If they had the capacity to do so, scientific realism would be defeated. Likewise, the idea of ‘performativity’ of economic theories is not to be understood literally: theories or their utterances alone do not serve performative functions in
the sense of themselves giving rise to what those theories are about.

Social construction

So scientific realism is comfortable with a lot of science-dependence of society. What sort of science-dependence does scientific realism rule out? As an analogy, consider any of the numerous economist jokes (such as ‘No reality, please. We're economists.’ Blaug, 2002, p. 36). There is no way the joke could be funny without being perceived as such. The joke's being funny is constituted by some people – not necessarily economists – finding it funny. Being funny and being perceived as funny are inseparable, not because the funniness of the joke (causally) makes people laugh, but because their laughter (conceptually) makes it funny. The connection is not causal – as in funny jokes causing people to find them funny – but rather conceptual or constitutive – being perceived as funny is part of the definition of ‘funny,’ or partly constitutes what it is to be funny.

Economic facts in social reality would have the same status as funny jokes if they were facts only if perceived to be so by economists. The economy being in state S and some of its developments being governed by mechanism M are so just because economists hold theories and other beliefs that say so. This is what the realist will deny. A realist will grant there is a formal contract between two economic actors only provided these actors believe it is there, and they – perhaps together with third parties – have agreed to represent the contract. But a scientific realist about the economics of contracts takes those contracts to be science-independent in the sense of not being created by acts of economic theorizing. The contracts exist and have the properties they have independently of being believed or claimed to be so by economists. While facts about contracts are constituted by the beliefs and representations by contracting parties, they are not constituted by acts of scientific theorizing about them. Creating a theory of X is not a matter of creating X. Creating a theory of (the causation of) business cycles does not, just by that token, create (that very causation of) business cycles. Saying so does not make it so.

This idea of non-causal science-independence suggests how to identify some of the opponents of scientific realism. They are those who do not subscribe to the non-causal science-independence of matters of fact in the world, including social and economic facts. Of contemporary (both academic and broader cultural) relevance are forms of social constructivism (see Hacking, 1999). This is a doctrine that comes in an obscure variety of forms that are characteristically not distinguished from one another. Modest versions claim that beliefs about the world are outcomes of social construction (including education, negotiation, persuasion, testimony, imitation, indoctrination, herd behaviour, group pressure, cognitive path dependency, and other social processes). More radical versions claim that the world itself is socially constructed. More weakly, one may argue that beliefs and myths about gender, race and schizophrenia are socially constructed – or that scientific theories about atomic structure and evolution are so constructed. More strongly, one may argue that gender and race, as well as quarks and evolution, are products of social processes of cognitive construction.

Realism is comfortable with weaker forms of social constructivism. Generally held beliefs about the world are socially constructed – simply because cognition is essentially social activity, with numerous cognitive agents interacting with one another under changing institutional constraints. Moreover, parts of the world itself are socially constructed in obvious ways. Indeed, society itself is socially constructed: social objects, properties, states, and processes are outcomes of social processes. Since this is a general fact about social reality, ontological realism about society grants it.
So what does realism rule out when it comes to society and social sciences? It is incompatible with positions that deny the non-causal science-independence of social matters. Claiming that social facts are socially constructed by social scientists just by way of constructing concepts and theories about society is beyond the scientific realist. A special version of this is the idea that social facts—certain ordinary kinds of facts about society outside of academia—emerge as an outcome of rhetorical persuation by economists of their audiences: certain facts about, say, the causation of inflation emerge as soon as masses of economists and others are persuaded by monetarist economists about the causal link between money and inflation. What precisely is the problem with this thought that bothers a realist? First consider what realism accepts. What the realist will accept is that the beliefs held by economists about the causation of inflation are socially constructed by ordinary social processes of academic (and possibly non-academic) persuasion. The realist also accepts that the beliefs held by people other than academic economists—such as politicians, journalists, union leaders and consumers—are outcomes of persuasion. Finally, realism accepts that such beliefs may motivate behaviour that has consequences for the causal connection between money and inflation. Such a connection between beliefs and behaviour is part of the causal structure giving rise to actual inflation rates. So what does realism deny? It denies the radical social constructivist idea that, when an economist puts forth a theory about the causation of inflation and manages to get it generally accepted, this alone will give rise to the causal facts described by the theory. This is to deny that agreement without action is sufficient for making or changing the world. For a realist, theory construction does not amount to world construction. Even theory dissemination alone is not sufficient for world construction (where ‘world’ refers to what the theory is about). Of course, it is a social fact that masses of people are persuaded about whatever, and this indeed is an outcome of rhetorical practices. What a realist should deny is that what those people are persuaded about is itself constructed just by those rhetorical practices. Again, it is a different idea that people so persuaded may take action and this action may make a difference for some social facts. This requires that the beliefs adopted in consequence of persuasion become causally efficacious in relation to actual behaviour. But this gives us what I called causal construction, and it is compatible with scientific realism.

Model worlds

Much of social constructivism may be inspired by the observation that scientists do not have direct access to the details and complexities of the real world. Scientists do not directly investigate the messy concreteness and complexity of the world, but rather engage in various manoeuvres that seek to ‘prepare’ that world for closer inspection. Economists will easily recognize this as part of their model building practices. Faced with the immense complexity of the world, economists are forced to simplify their images of it by way of using various procedures of omission, idealization and abstraction. The models they build and employ isolate small slices of the world for detailed scrutiny while leaving most details out of the picture. Such procedures of isolation are among those manoeuvres of preparation, and they result in models that appear to describe simple imaginary model worlds rather than the real world. One may then say that models and model worlds are constructed rather than, say, discovered, and that they are socially constructed just because scientific work is intrinsically a social activity. The realist grants this much, but then goes on to insist that, even if economic models of the social world are socially constructed by economists, the social world itself is not socially constructed by the modelling practices of economists.
At this point it will be helpful to have an account of models that is able to deal with this set of issues (Mäki, 2005b). I take models to be what can be called substitute systems or surrogate systems that serve as direct subjects of inquiry. They are substitute systems in that they are examined instead of the real systems that they replace and stand for. The real systems ‘out there’ may be too complex (such as social systems), too far away in time or space (such as the origin of the species) to be capable of being directly investigated, or it might be unethical to examine the real system directly (such as using human subjects for medical experimentation). Much of scientists’ activity is a matter of building and manipulating such substitute systems in order to learn about their properties and behaviour. A realist about models and the real world would add that the properties of models are directly examined by scientists in order to indirectly learn about the properties of the real world.

A radical social constructivist will not buy this image. In a radical constructivist framework, there is no distinction between model systems and real systems, nor is there room for an idea of indirect acquisition of information about the latter by way of examining the former. There are only socially constructed model systems, and it is a matter of power and persuasion which models will be taken to provide the facts. This is one way of illuminating the strong social constructivist ontology in a nutshell.

Truth

This takes us to the issue of truth. Economists appear to have great difficulties with applying the concept of truth. They characteristically believe that, since models do not reproduce the whole complexity of their subject matter, they are necessarily false, or that, because models involve false assumptions, models themselves are false. In order to see why these beliefs about the falsehood of models are false, we should take a realist perspective to the ontology of truth. This will help further clarify the very concept of realism. Here the focus is on what truth is (rather than what is true) (see Mäki, 2004).

Truth is a property of truth bearers. A truth bearer is true just in case there is a truth maker that makes the truth bearer true. The sentence, or statement, ‘The cat is on a mat’ is a truth bearer that is made true by its truth maker in the world, namely, the cat being on a mat. ‘Education is a major cause of economic growth’ is a truth bearer that is made true by its truth maker, namely, education being causally responsible for at least 15 per cent of the growth in the output of an economy (supposing this is how we have defined ‘major’). Now all models of the connection between education and growth omit lots of things in the world and make false idealizing assumptions about others. But whether one takes a model to convey true information about the world depends on what one takes the relevant truth bearers to be. In the case that the intended truth bearer is, say, ‘Education is responsible for about one quarter of economic growth (in some spatio-temporally specified location)’, then its truth makers include those situations in the real world in which education is causally responsible for 23–27 per cent of growth (supposing this interval is what we meant by ‘about one quarter’). In the case that the intended truth bearer is something different, namely, a description of the causal mechanism by way of which education contributes to growth, then its truth maker would be that mechanism in the real world (such as some skill mechanism or a signalling mechanism, depending on what we seek to describe with the model).

No model offers the whole truth of its domain, and no model, if spelled out in full, is devoid of false elements (false if considered as potential truth bearers). Understanding that models can be true, or can be used for making true claims, requires understanding the intended relevant truth bearers. These intuitions provide the basis for resisting the popular idea that models cannot possibly be true.
The realist ontology of truth so conceived is rather straightforward. Realism requires that the relevant truth makers be real, that they exist in a suitably independent manner. Truth makers are, after all, just those things the existence of which ontological realism deals with. Truth makers must exist without being non-causally science-dependent. Creating a model of a signalling mechanism does not create that signalling mechanism: the mechanism exists (if it does) independently of any economic models about it – it exists even though there were no models about it.

What does realism say about truth making, the way in which truth makers make truth bearers true? Again, a suitable independence requirement is imposed. The way in which truth makers make true statements or models true must be independent of our ways of coming to hold beliefs about their truth. In particular, epistemic matters do not enter truth by way of, say, making truth making dependent on evidential considerations or our capacity to recognize truth. So we do not make true models true by coming to recognize them as true in virtue of having collected lots of supportive evidence, or having become persuaded by the most prestigious economists, or the like. While we make truth bearers, we do not make them true. Facts do.

Possible existence and possible truth

Here is an important further qualification of what it takes to be a realist about the world and models about it. Above, I have said that it is not sufficient to hold that some entity X exists and that theory T is true about X in order to count as a realist about X and T (it is not enough because one has to add further restrictions in terms of irreducibility, non-causal science-independence, and independence of epistemic attitudes, for example). It is now time to weaken this by saying that holding those ideas is not necessary either. It is enough for a realist to hold the view that X might exist and T might be true about X, that it is possible for X to be the case and T to be true. Such a view will reveal a realist attitude: there is a fact of the matter concerning whether or not X exists and whether or not T is true. It is an attitude that will give real existence and objective truth a chance, but one that at the same time is prepared for concluding that X does not exist or T is not true, after all. This is an advisable attitude for epistemically insecure and self-critical scientific practice based on consistent fallibilism.

Ontological realism about X is primarily an account of what it is for X to exist (if it does). To this, one may add the weaker claim that X might exist, or the stronger claim that X does exist. Likewise with truth. Realism about truth is primarily an account of what it is for a truth bearer T to be true. One may then add the weaker claim that T might be true, or the stronger claim that T indeed is true. Naturally each such claim requires different sorts of supportive argument.

The bite of ontology

Does ontology make a difference for scientific practice and its evaluation? That ontology may have some bite is evident even in the case of the weak version of realism put in terms of possible existence. Some economists criticize the model of perfect competition on the grounds that perfect competition is not even conceivable: its perfection has been taken so far that such a competitive market has become an impossibility (Richardson, 1960). If this is correct, then ontological realism would be an inappropriate attitude regarding perfect competition as depicted by the model.
In general, economists hold, or entertain, ontological convictions, explicitly or implicitly, and these may have consequences regarding the preferred ways of theorizing and explaining. Whatever mismatch there may be between ontology and economic theory, sometimes it plays an important role in driving intellectual progress, sometimes not. When there is a clash between the ontological convictions of an economist and the apparent ontological implications of a theory held by this economist, there may be a healthy pressure to revise the theory so as to realign ontology and theory. Such a clash may, in suitable circumstances, serve as a driving tension that creates pressure to modify theories or invent new theories such that the economist will be able to take the theory with an ontologically realist attitude. An economist may, deep down in his convictions, view certain facts – such as increasing returns, bounded rationality, and institutional structure – as causally powerful features of the economy. At the same time, the modelling conventions and techniques of the discipline may be such that the economist will be unable to incorporate such things in his models. There is a tension that needs to be resolved, and the resolution will be sought in the spirit of ontological realism.

Yet, in general, one's favourite ontology does not determine the contents of theory or model used, nor is it determined by these. The impact of ontology is rather a matter of constraint. In many cases even this much impact is too much. An economist may correctly say things that are quite appropriate in their respective contexts even though those things may clash with deeper ontological convictions. An economist may appropriately say ‘this country is applying monetarist tenets in its economic policies’ even though the deeper conviction may be in line with ontological individualism claiming that no such collective entities as countries exist – only individuals do. Or an economist may say that ‘individuals have preferences’ while a philosopher of mind or a neuroeconomist may endorse the ontological claim to the effect that ‘preferences do not exist’ simply because she believes nothing mental does: preferences really are just configurations of neural states. To claim that individuals have preferences as part of economic discourse does not contradict the eliminativist materialism endorsed by the philosopher – just as the claim ‘there are 15 chairs in the seminar room’ may be correct even though one's philosophical ontology may imply that chairs do not exist, while bundles of atoms do. In such cases, there is no conflict between the two claims in each pair due to the idea that one of the claims, and only one of the claims, informs us, after all, how things are ‘at bottom’ or ‘ultimately’.

A parallel idea is that ontology does not determine methodology, but rather serves as a constraint on it. Thus ontological individualism (the belief that only individuals exist) does not imply a commitment to methodological individualism – the obligation to spell out the microfoundations of economic theories and explanations. The economist may legitimately decide that the things he or she wishes to know can be established using aggregative models not grounded in individual behaviour. For example, it may be that certain facts depend on distributions across individuals and not on individuals themselves. Similarly, the conventional procedure of theoretical isolation (isolating certain phenomena that are to be analysed) by building models of small and simple hypothetical worlds does not imply the ontological conviction that the actual systems in the real world are equally simple and isolated from other aspects of reality. What economists do believe is that, in order to study complex systems, simple models are needed, because the real world is too complicated and because the limited questions asked about it require focusing attention on a limited set of mechanisms (while ontological realism may be used to require that these mechanisms exist also in the complex real world).

Methodology is under-determined by ontology. It depends on ontology but it also depends on other things such as the cognitive interests of the inquirers and their limited cognitive capacities. But even this
much is enough for concluding that ontology matters.

Scitovsky, Tibor (1910–2002)

Irma Adelman

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

external economies; final distribution of income; free trade; initial and final distributions of income; pecuniary external economies; Scitovsky, T.; tariffs; technological external economies; value judgements

Article

Tibor Scitovsky was born in Budapest. He received a degree in law from the University of Budapest and a degree in economics from the London School of Economics. He migrated to the United States in 1939 and served in the US Army during the Second World War. He taught at Stanford, the University of California at Berkeley, Yale, Harvard, and the London School of Economics. He also worked at the OECD from 1966 to 1968.

His writings are brilliant, original, succinct, lucid and full of subtlety. They always enlighten and move the debate forward. He made fundamental and lasting contributions to a large number of subjects: welfare economics, international trade, economic development and microeconomics. One can discern a unifying theme to these varied contributions; it is to indicate ways in which neoclassical equilibrium analysis fails to capture important aspects of economic reality and, therefore, leads to misleading policy implications from efficiency, stability or welfare points of view. He stresses dynamics, and interdependence among the utilities of consumers and decision-outcomes of producers, as the major sources of divergence of social optima from market equilibria of perfectly competitive economies. His work in welfare economics points to the impossibility of purging policy analysis from value judgements concerning the optimality of the initial and final distributions of income. This is true whether the initial and final situations are efficient or inefficient, in static terms, or whether or not the possibility for compensation of losers by winners exists. (Compensation restores the original distribution and therefore implies the judgement that the original distribution was optimal.) Rather than abandon the possibilities for policy recommendations entirely, economists should make explicit the value judgements that underlie their policy advice.

His contributions to economic development make the capturing of external economies the cornerstone of development strategy. His classic paper ‘Two Concepts of External Economies’ (1954) distinguishes
between technological and pecuniary external economies. In developing countries, the existence of pecuniary externalities argues for the planning of coordinated investment decisions since market prices provide imperfect signals when those decisions are interdependent. He also argues for economic integration and export-led growth in economies too small to secure the advantages of both economies of large-scale production and pecuniary economies of balanced growth.

In trade theory, his ‘Reconsideration of the Theory of Tariffs’ (1942) points to the parallelism between tariffs and the monopolist's markup (or monopsonist's markdown) for exploiting his trading partners and argues that market forces could never approximate free trade, which would have to be imposed and enforced by international agreement or by a dominant large power against each nation's selfish preferences.

His most controversial but most original book, *The Joyless Economy* (1976), tries to introduce into consumption theory the psychologist's classification of satisfactions into comfort, stimulation and pleasure, with emphasis on the psychological trade-off between them. The second part of the book explores the implications of the consumer's ignorance of that psychological trade-off on the rationality of his choice behavior, using American lifestyles as an illustration.

Reading Scitovsky's writings, one is made painfully aware of how much has been lost by the modern trend to mathematize and computerize. By comparison, modern economics appears mechanical and myopic, lacking in subtlety and sweep. Many of the themes raised in his writings appear as fresh today as they were when they were first written. And there are many points still worth following up decades after they were first made. His later work on the integration of microeconomics with macroeconomics, contained in his analysis of the real side of inflation, which builds on the price-maker price-taker distinction first introduced by him in his book on *Welfare and Competition* (1952), is a case in point.

**Selected works**

W.R. Scott (‘the chief’ as A.L. Macfie used to describe him) was born in Armagh on 31 August 1868, the eldest son of Charles and Margaret Scott. He was educated at Canon Stewart's Preparatory School and then St Columba’s College, Rathfarnham. Scott went to Trinity College Dublin in 1885, graduating BA in 1889 and MA two years later. 1891 saw his first major publication, *An Introduction to Cudworth's Treatise Concerning Eternal and Immutable Morality*. Scott's philosophical interests were also marked by his *Simple History of Ancient Philosophy* (1894).

In 1896 Scott took up the post of assistant to the professor of moral philosophy in the University of St. Andrews, and three years later became the University's first lecturer in political economy. Scott was responsible for planning the teaching of economics until 1915 when he was translated to the Adam Smith Chair of Political Economy in Glasgow, in succession to William Smart. Scott died in Glasgow on 3 April 1940, after a brief illness. Scott was extremely active as examiner, teacher, researcher, and adviser to government with a marked interest in contemporary, as well as historical, issues. There are three identifiable strands to his work. The first was through his interest in contemporary economic and social problems, encouraged by his chairmanship for many years of his family's firm of millers in Tyrone. It led to an active involvement in public affairs, in days when economists were less consulted than subsequently. Apart from his membership and chairmanship of committees, national and regional, especially in the 1920s, Scott's name became attached to several departmental and other reports, even when he was not the sole or main author.

He was appointed by the Secretary for Scotland to examine home industries in the North. The ensuing report was published in 1914. He subsequently addressed the *Economic Problems of Peace after War* (1917; 1918), and later worked (with James Cunnison) on *Industries of the Clyde Valley during the War* (1924a) as part of a Carnegie Series.
A second stream is represented by his pioneering work in economic history. Scott published an edition of *The Records of a Scottish Cloth Manufactory at New Mills, Haddingtonshire 1681–1703* (1905). This was followed by one of his best known studies, the definitive, three volume, *Constitution and Finance of English, Scottish and Irish Joint Stock Companies to 1720* (1910–12). He was president of the Economic History Society from 1928 until his death.

A third contribution is represented by Scott's work as an historian of ideas. His book on *Francis Hutcheson* (1900) is the work of a philosopher well versed in economics and is still a classic. Scott also dramatically advanced contemporary knowledge of Hutcheson's most famous pupil with the publication of *Adam Smith as Student and Professor* (1937) which featured his discovery of important Smith papers in the Buccleuch MSS. Scott's ability to find records was impressive. Some criticism of his handling of them is possible but many of the difficulties which impeded his work have been reduced for later scholars by the discovery and cataloguing of many relevant records of economic and intellectual history which he helped to bring about.

At the time of his death Scott was working on a bibliography, which was published under the auspices of the British Academy, and edited by his successor in Glasgow, Alec Lawrence Macfie. As his obituarist noted in the *Glasgow Herald* (4 April 1940),

> If one today were to seek the model of his famous and beloved predecessor (Adam Smith) it would be impossible to find a closer re-incarnation than William Robert Scott. He had the same temper, controlled, wide-eyed impartiality of mind allied with an absorbing fire of enthusiasm for reasoned practice and disinterested policy. This is the tribute he would most have appreciated, and it is one which all his friends and students would endorse as the most appropriate.

Scrope, George Poulett (1797–1876)

Barry Gordon
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
abstinence theory of interest; cost of production; gluts; Malthus's theory of population; quasi-rent; Ricardo, D.; risk–effort theory of profit; Scrope, G. P.

Article

George Poulett Scrope was one of the most prolific contributors to the literature of political economy in the mid-19th century. He was also one of the more able critics of features of the Ricardian economic orthodoxy which came to dominate that literature. Scrope is at his best as an economist in the series of articles he contributed when chief economics reviewer for the Quarterly Review (1831–3). His Principles of Political Economy (1833c) is disappointing by comparison.

After education at Harrow, Scrope entered Pembroke College, Oxford in 1815. During the following year he moved to St John's College, Cambridge where he graduated in 1821. He married the heiress Emma Phipps Scrope, altering his surname (which had been ‘Thomson’) to that of his wife, and establishing himself as one of the leading gentlemen of the county of Wiltshire. Scrope was appointed a magistrate of the county in 1823.

Research in geology was an early and enduring involvement. Scrope's distinguished work in this field led to his election to the Geological Society (1824). Two years later, he became a Fellow of the Royal Society, and he continued to publish papers on geological subjects until shortly before his death.

Scrope entered Parliament, and he remained Member for Stroud from 1833 to 1867. During his first 20 years in the Commons he spoke frequently and was a member of numerous parliamentary committees. His contributions in the legislature distinguish him as a ‘man with a philosophic and inquiring mind, trying to explain the upheavals in economic relations, and also to guide policy on behalf of interests that went beyond his own personal gain’ (Fetter, 1980). In debate, Scrope found himself in alliance at times with doctrinaire Ricardians such as Joseph Hume. Scrope supported repeal of the Corn Laws and the Navigation Acts. He was also in favour of parliamentary reform. On a variety of issues, however, he was decidedly ‘unorthodox’. Those issues included: the nature of the currency and the structure of the banking system; the public funding of education; the maintenance of outdoor relief for the unemployed;
and closer government regulation of working conditions in factories. The problems of Ireland were among his special concerns, and he was a leading advocate of the extension of poor law provisions to that country.

The interventions of Scrope within Parliament were supplemented by his publication of numerous pamphlets on current policy issues. In addition, he contributed periodical articles in which he assailed the economic theories of the followers of David Ricardo, and the population doctrine of Thomas Robert Malthus. Scrope rejects a theory of value based on cost of production and he argues for recognition of a relationship between value-in-use and value-in-exchange. He finds the reasoning of Richard Jones on rent much superior to that of Ricardo. Noting the absence of any account of a basis for profit in Ricardian theory, he constructs an abstinence theory of interest and allies this to a risk–effort theory of profit which incorporates the concept of quasi-rent. Scrope is also concerned with the possibilities of over-saving and of a general glut of markets. In this latter respect, his ideas are akin to those of Malthus. However, Scrope is a persistent and incisive critic of Malthusian population theory and the policy implications which his contemporaries drew from it.

Selected works

Scrope's bibliography (Sturges, 1984) contains 175 items on economic, geological, and local history topics. The following is a list of some of the more notable publications dealing with economic issues.

search models of unemployment

David Andolfatto
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Unemployment, as it is conventionally defined, is a measure of full-time job search. Individuals generally have the option of allocating their time across many competing uses. It follows that an economic interpretation of unemployment data requires a theory that explains the circumstances in which people may prefer to engage in job search at the expense of other activities. Search models of unemployment are designed to do just this.

Keywords

Beveridge curve; business cycles; efficient allocation; involuntary unemployment; leisure; matching; matching markets; natural rate of unemployment; reservation wage; search models of unemployment; search theory; unemployment; unemployment insurance; wage determination

Article

To the average person (perhaps even the average economist), unemployment is often equated with a state of involuntary idleness. This commonly held view, however, is inconsistent with the way in which unemployment is in fact defined and measured. According to International Labor Organization (ILO) conventions, which are followed by most national labour force surveys, unemployment relates to those individuals who are not employed but who are actively searching for work (over the reference period of the survey – for example, the previous four weeks). Non-employed (jobless) individuals who have not engaged in active job search are classified as non-participants. This latter category includes the set of so-called ‘discouraged workers’.

Since active job search consumes time and other resources, relating unemployment to a state of idleness seems wrong. Furthermore, since individuals are free to allocate their time across many competing activities, with time devoted to search yielding at least the prospect of a future payoff, the notion of unemployment as an involuntary state is potentially misleading. To understand unemployment – or, at
least, unemployment data (as opposed to some other pet notion of unemployment) – one must therefore entertain a theory that explains the circumstances under which individuals find it in their interest to remain non-employed while searching for work. Search models of unemployment are designed to do just this.

**Search theory**

A hallmark of conventional labour market theory (the neoclassical model and its sticky-wage variants) is the assumption that labour is exchanged in a centralized marketplace. Among other things, a centralized market embodies the idea that there is perfect information concerning the location of all jobs and workers. In any such environment, devoting precious time to an activity like search literally makes no sense (whether or not the wage is market-clearing); that is, individuals either have a worthwhile job opportunity to exploit or they do not. In the former case, they become employed; in the latter, they become non-employed (and would be labelled as non-participants by standard labour force surveys). The starting point for any search model of unemployment then is to dispense with the notion of a centralized marketplace for labour. Instead, the labour market is viewed as a set of decentralized locations, where firms and workers can potentially meet to form mutually beneficial relationships. In a decentralized market, meetings are to some extent determined by search effort and to some extent by chance. In many ways, the labour market resembles a matching market for couples; that is, one is generally aware that the opposite side of the market consists of better and worse matches (we seldom take the view that there are no potential matches). The exact location of the better matches is unknown, but may be discovered with some effort. In the meantime, it may make sense to refrain from matching with ‘substandard’ opportunities that are currently available. But since search is costly, it will generally not be optimal to wait for one's ‘soulmate’ to come along. Furthermore, since relationships are not perfectly durable, there is no reason to expect the stock of singles to converge to zero over time. Nor is it clear, given the technology of match-formation, that having everyone matched at all times (irrespective of match quality) is in any way desirable – even if it is feasible; and even if people generally desire to be matched.

In the context of the labour market then, the key friction that potentially rationalizes job search (and, hence, unemployment) is imperfect information over the location of one's best job opportunity. In such an environment, job search constitutes a form of investment in the acquisition of information. The idea of job search as an information-gathering activity has been in place for some time; see, for example, Stigler (1962) as well as the several papers and references contained in Phelps (1970). Perhaps the most influential early formalization of the theory of job search is provided by McCall (1970); see also Sargent (1987, ch. 2). In the next section, I present the basic idea of this classic literature by way of a simple model.

**A simple model**

I begin by describing a simple ‘one-sided’ search model; for example, the case in which an individual searches for a job opportunity that pays a given wage depending on match quality. Each time period $t = 1, 2, \ldots, \infty$ is divided into two subperiods that I call stage 1 and stage 2. There will be no
search models of unemployment: The New Palgrave Dictionary of Economics

intertemporal aspect to individual decision-making, so the model's dynamic equilibrium can be thought of as a sequence of static equilibria.

Each person enters stage 1 endowed with one unit of (indivisible) time, a job opportunity that pays a real wage $w \in [0, \bar{w}]$, and a leisure opportunity that generates a return $0 < b < \bar{w}$. One can interpret $b$ as either an unemployment insurance benefit or, more generally, as the consumption available when non-employed (for example, home production). The real wage $w$ can be interpreted as the quality of the job–worker match associated with any given job opportunity. Let us assume that individuals do not know the precise location of their best job match (that is, the match that would yield them $\bar{w}$). However, it is assumed that individuals know the distribution of match qualities associated with the given set of available jobs; let $F(w)$ denote the fraction of job matches that yield a wage no greater than $w$. The act of job search is modelled as a random draw from $F(w)$.

At the beginning of stage 1, a choice has to be made: should I search or not? The act of not searching means that time must be allocated during stage 1 across one of two activities: work or leisure. The utility payoff to work is $u(w)$, while the utility payoff to leisure is $u(b)$, where $u'' < 0 < u'$. On the assumption that I choose not to search, optimal behaviour entails choosing to work if $w \geq b$. Alternatively, I could choose to search instead. In this case, my time endowment is ‘transported’ to stage 2. Here, the cost of job search is given by the assumption of no recall; that is, I must abandon my current opportunity $w$ to exercise my search option. Let $w' \sim F(w')$ denote the wage associated with a new job opportunity I find as a result of my search. At this stage, I now have the opportunity to either work or enjoy leisure; that is, I will only choose to work at this new job if $w' \geq b$. Hence, the expected utility payoff from search is given by:

$$S(b) = F(b)u(b) + \int_{b}^{w} u(w')dF(w').$$

Implicit in this discussion is the assumption that consumption levels during stage 1 and 2 are viewed as perfect substitutes. I am also assuming that consumption is non-storable and the absence of insurance/loan markets.

The problem has been set up here in such a way that it will never be optimal for a person to choose leisure during stage 1. This is because there is always a zero-cost option to consume leisure during stage 2. Hence, the relevant choice during stage 1 is whether to work or search. The optimal strategy is to set a reservation wage $w_R(b)$, such that one should choose work if $w \geq w_R(b)$ and choose search if $w < w_R(b)$. This reservation wage must satisfy:

$$u(w_R) = S(b).$$

(1)
search models of unemployment: The New Palgrave Dictionary of Economics

That is, a person's reservation wage is defined to be the wage that would make a person just indifferent between working at that wage and abandoning it in favour of another activity (in this case, job search). In other words, the reservation wage is a measure of an individual's 'choosiness' over job opportunities.

Note that as \( S'(b) = F(b) \beta'(b) > 0 \), the reservation wage is an increasing function of the option value associated with leisure. Intuitively, a person with a good outside option \((b)\) can afford to be more discriminating with respect to the quality of any given job opportunity \(w\).

Thus far I have described the choice problem of an individual beginning with an endowed wage/leisure opportunity \((w, b)\). I would like to now describe how this behaviour translates into the evolution of aggregates over time. To render static decision-making optimal in this environment, assume that all individuals begin each period with a match quality \(w\) drawn from the distribution \(G(w)\). The interpretation here is that economy experiences a 'structural' shock every period that 'shuffles' individual match qualities, but otherwise leaves aggregate production possibilities unchanged. Following this structural shock, individuals behave in the manner described above. For the sake of simplicity, assume that all individuals share a common value for \(b\) that remains constant over time.

It is an easy matter now to characterize the equilibrium unemployment rate. At the beginning of each period, individuals are randomly assigned a match quality \(w\), whose distribution is \(G(w)\). The fraction \([1-G(w_R)]\) will choose to exploit their employment opportunity and the fraction \(G(w_R)\) will find it optimal to abandon their opportunity in favour of search. Job searchers find new job opportunities with associated match qualities \(w'\) drawn from the distribution \(F(w')\). Those who find a job that pays \(w' \geq b\) choose to work; those that find a job that pays \(w' < b\) choose leisure instead. Thus, \(F(b)\) denotes the fraction of job-searchers who are 'unsuccessful' in their search. On the assumption that the reference period for a labour force survey is the length of a period (and that the survey is performed at the end of the period), the equilibrium unemployment rate is given by:

\[
U = G(w_R)F(b).
\]

In other words, the unemployed are those who: (a) performed no work during the reference period; and (b) were actively searching for work during the reference period.

Associated with the 'steady-state' unemployment rate \(U\) are steady-state flows of workers making transitions from employment to unemployment (job destruction) and transitions from unemployment to employment (job creation); these flows are given by:

\[
JC = [1 - G(w_R)F(b)]U; JD = G(w_R)F(b)(1-U).
\]

Any given individual may, of course, experience a variety of employment/unemployment histories. The model developed above constitutes an example of the modern approach to the theory of unemployment. Note that unemployment here is interpreted as an equilibrium phenomenon; in
particular, it is not the product of irrational behaviour or markets that fail to clear. Instead, unemployment is the natural by-product of an economy subject to ongoing structural disturbances that depreciate the value of existing employer–employee matches, and where match formation takes time owing to the imperfect information pertaining to the location of new job opportunities.

One by-product of the modern theory of unemployment is that renders obsolete much of the traditional language that was used to describe the phenomenon (see Rogerson, 1997). Consider, for example, the traditional classification of unemployment into its ‘voluntary’ and ‘involuntary’ components. In the model developed above, there is a sense in which unemployment is both voluntary and involuntary. It is voluntary in the sense that the model people (as with real people) can choose not to search, and instead allocate time to inferior job opportunities or home production activities. On the other hand, it is also involuntary in the sense that the economic circumstances that compel individuals to become unemployed are often beyond their immediate control. By the same token, however, the same classification might be made for employed workers (for example, the existence of those who cannot afford not to work, or the so-called working poor). Whether these traditional labels have any substantive meaning, however, is questionable. In particular, note that the well-being of these model people (and presumably, people in reality) does not depend of how we (as theorists) choose to label them.

**Welfare**

A classic question in the theory of the labour market is whether an equilibrium level of unemployment corresponds in any way to an efficient allocation. Not surprisingly, the answer to this question depends critically on the nature of the economic environment; see Diamond (1982), Mortensen (1982), Hosios (1990) and Moen (1997). In the present context, the optimal level of unemployment can be characterized as the solution to the following planning problem:

$$\max_{c, w_R} \left\{ u(c) : c \leq \int_{w_R}^w wdF(w) + F(w_R) \left[ F(b) b + \int_b^{w'} w' dF(w') \right] \right\}. $$

The socially optimal reservation wage is given by:

$$w_R^* = F(b) b + \int_b^{w'} w' dF(w').$$

The optimal unemployment rate corresponds to the equilibrium unemployment rate if $w_R^* = w_R$, where $w_R$ is the solution to (1). As it turns out, this will be the case if $u'' = 0$ (risk-neutral individuals).
However, with risk-averse individuals, one can easily establish that $w^*_R < w_R$, which implies here that the equilibrium unemployment rate is too low. The suboptimality of equilibrium in this particular model has nothing to do with search per se; rather, it is due to the assumed lack of insurance. The intuition is straightforward: in the absence of a well-functioning insurance market, individuals are too willing to hold on to marginal jobs rather than risk an even worse outcome in the event of an unsuccessful job search.

One striking implication of the modern theory of unemployment is that the unemployment rate bears no obvious relation to any sensible measure of social welfare. Consider, for example, two economies $A$ and $B$, identical in every respect except that $b_A > b_B$ (so that the residents of economy $A$ are in some sense ‘wealthier’ than those of economy $B$). In this case, the unemployment rate in economy $A$ will be higher than in economy $B$. Nevertheless, given the choice, individuals would rather live in the high-unemployment economy. On the other hand, suppose that the two economies differ only in terms of $F$, with $F_A$ stochastically dominating $F_B$. In this case, economy $A$ will have lower unemployment and higher welfare. The basic lesson here is that ‘economic performance’ should not be measured in terms of how individuals choose to allocate their time across competing activities, but rather should be measured in terms of the level and distribution (or stochastic properties) of broadly defined consumption.

Unemployment insurance

Governments in many countries operate a fiscal policy known as unemployment insurance (UI). UI systems are characterized by transfers of income to those who are unemployed (or otherwise meet certain eligibility requirements) that are typically financed via a payroll tax (or out of general tax revenue). Presumably, the motivation for such transfers rests on the belief that: (1) private insurance markets are unavailable (or work poorly) and (2) self-insurance (via precautionary saving) is either grossly inefficient, or perhaps beyond the means of many workers (a more cynical view interprets UI as one of many government transfer schemes designed to benefit various special interests at the expense of the general taxpayer).

Search models of unemployment have been applied in both positive and normative investigations concerning the effects of UI programmes. For example, in the context of the model developed above, let $b$ denote a UI benefit that is financed via a payroll tax $\tau$. For given programme parameters $(b, \tau)$, the reservation wage now satisfies:

$$u((1 - \tau)w_R) = F(b)u(b) + \int_b^{w^*} u((1 - \tau)w^{'}) dF(w^{'})$$

which implicitly characterizes $w_R(b, \tau)$. In equilibrium, the tax and benefit level is related by the government budget constraint:
For a given UI policy parameter (say, an exogenous level of $b$), eqs (2) and (3) characterize an equilibrium $(\hat{w}_R, \hat{T})$. The positive and normative implications of the theory can then be deduced by varying the policy parameter $b$. Andolfatto and Gomme (1996) consider a similar such experiment, albeit in a considerably richer environment that (among other things) models the UI system in greater detail (in particular, UI programmes are typically characterized by several programme parameters, including eligibility requirements, replacement rates and benefit duration parameters).

Several papers have recently examined the issue of how an optimal UI system should be designed. This question becomes particularly interesting when one reasonably assumes that workers have private information concerning the nature of their job opportunities and/or the intensity with which they search. In a classic paper, Shavell and Weiss (1979) demonstrate that an optimal UI programme should ‘front load’ UI payments, with benefit levels declining monotonically over the unemployment spell. The high initial benefit level provides the desired insurance, while the declining benefit profile mitigates adverse incentive effects by stimulating (unobserved) search intensity. Wang and Williamson (1996) and Hopenhayn and Nicolini (1997) flesh out other properties of optimal UI systems in the context of dynamic moral hazard environments. Among other things, these authors report that optimally designed programmes can deliver potentially large welfare benefits relative to existing systems.

### Business cycles

Search models of unemployment have also been used to interpret various aspects of the business cycle. Naturally, a key set of questions deal with the cyclical properties of unemployment itself. However, researchers have also investigated the extent to which ‘search frictions’ in the labour market shape the pattern of the business cycle more generally (see Mortensen and Pissarides, 1994; Merz, 1995; Andolfatto, 1996).

An empirical relationship that has drawn considerable attention in the literature is the so-called Beveridge curve; that is, the tendency for unemployment and vacancies to move in opposite directions over the business cycle (for example, see Blanchard and Diamond, 1989). The level of job vacancies, as measured by the help-wanted index, is highly volatile and tends to lead unemployment over the cycle. A natural interpretation of these facts is that as job opportunities become more plentiful, unemployed workers are able to find jobs more easily, with search frictions preventing instantaneous adjustment. Vacancies themselves can be interpreted as the business sector equivalent of unemployed workers. Since finding suitable workers is costly and time-consuming, and since employment relationships once formed are durable, recruiting intensity constitutes a form of capital spending that presumably reacts to actual and expected shocks in much the same way as other forms of capital spending (for example, see Howitt, 1988).
A seminal paper in this area is Pissarides (1985), who appeals to the concept of an aggregate matching technology to model (in a reduced-form manner) the outcome of uncoordinated search in the labour market (see also Pissarides, 2000; Petrongolo and Pissarides, 2001). According to this approach, match formation (job creation) is the product of the aggregate search intensity of workers (unemployment) and firms (vacancies), both of which serve as complementary inputs into an aggregate matching function, that is, \( m_t = M(v_t, u_t) \). Ignoring individual differences, \( m/v \) and \( m/u \) can be interpreted as the probabilities that vacant jobs and unemployed workers contact each other. If \( M \) displays constant returns to scale, then these probabilities depend only on the labour-market tightness variable \( \theta \equiv v/u \). In particular, \( m/v = q(\theta) \) and \( m/u = p(\theta) \), where \( q(\theta) \equiv M(\theta, 1) \) and \( p(\theta) \equiv M(1, \theta^{-1}) \). Note that \( q'(\theta) < 1 \) and \( p'(\theta) > 1 \). In other words, firms find it more difficult to find workers in a tighter labour market; while the converse is true for workers.

With a fixed labour force \( L \), the stock of employed workers at date \( t \) is given by \( L - u_t \). Again note that the stock of employment constitutes a form of capital. Employment capital depreciates over time as matches dissolve owing to idiosyncratic shocks that affect the viability of individual relationships. Let \( 0 < \sigma < 1 \) denote the fraction of employment relationships that are terminated at the end of each period. In this case, the job destruction flow is given by \( \sigma(L - u_t) \). For simplicity, assume that \( \sigma \) is exogenous. At the same time, the stock of employment is replenished by the flow of job creation, \( p(\theta_t)u_t \), so that the stock of unemployment evolves over time according to:

\[
\frac{u_{t+1}}{u_t} = u_t - \sigma(L - u_t) + p(\theta_t)u_t.
\]

In a steady state, the flow of job creation just offsets the flow of job destruction, so that the ‘natural’ rate of unemployment satisfies (normalizing \( L = 1 \)):

\[
\sigma = \left( \frac{\sigma}{\sigma + p(\theta)} \right).
\]

Equations (4) and (5) relate the dynamics of the unemployment rate to the labour-market tightness variable \( \theta \), as well as to parameters describing the structure of the matching market. In the simple version considered here, the unemployed search passively (workers have one unit of time that they allocate either to work or search at zero utility cost). Consequently, the equilibrium \( \theta_t = v_t / u_t \) is determined entirely by vacancy creation, which is endogenized as follows. Assume that each firm has a single job that, together with a worker, produces \( y_t > 0 \) units of output.
Assume that $y_t$ follows a first-order Markov process with $G(y', y) = \Pr[y_{t+1} \leq y' | y_t = y]$. For simplicity, assume that match quality is identical across all firm–worker pairs and that wages are determined by an exogenous bargaining process that divides output in some manner between firm and worker; that is, let $0 < \xi < 1$ denote the fraction of output that accrues to the firm (alternatively, one could model wage determination by imposing a Nash bargaining solution). Let $J$ denote the capital value of a firm currently matched with a worker; this value must satisfy the following Bellman equation:

$$J(y) = \xi y + \beta (1 - \sigma) \int J(y') G(dy', y),$$

(6)

where $0 < \beta < 1$ denotes a discount parameter. Implicit in this formulation is that the value of the firm falls to zero in the event that the match is dissolved. Note that if match productivity exhibits positive persistence, then $J(y) G(dy', y)$ is increasing in $y$. In other words, a positive productivity shock (increase in $y$) is associated with information that leads firms to revise upward their estimate of the returns to match formation.

Finally, consider the cost–benefit analysis associated with vacancy creation. Assume that creating (and maintaining) a vacancy entails the flow cost $\kappa > 0$, measured in units of output. A vacant job potentially meets an unemployed worker with probability $q(\theta)$, with the match producing a flow of output beginning in the subsequent period. Let $Q$ denote the capital value of a vacant job; this value must satisfy the following Bellman equation:

$$Q = -\kappa + \beta \left[ q(\theta) \int J(y') G(dy', y) + (1 - q(\theta)) Q' \right].$$

(7)

Assuming free entry into vacancy creation, the level of $v$ will expand as long as $Q > 0$. But note that for a fixed level of unemployment $u$, any expansion in the number of vacancies increases labour-market tightness $\theta$ and therefore reduces the success probability $q(\theta)$. In equilibrium, $\theta$ adjusts to a point that renders further vacancy creation unprofitable; that is, $Q = Q' = 0$. Consequently, the equilibrium labour-market tightness variable $\theta(y)$ is determined by:

$$q(\theta) \beta \int J(y') G(dy', y) = \kappa.$$  

(8)
The economic mechanism at work here can be described as follows. Consider a positive productivity shock. Since the shock is persistent, the return to job creation (contemporaneous recruiting activities that augment the future stock of employment) increases (see (6)). Naturally, in response to these bright prospects, firms increase their recruiting activities and create new vacancies. However, as the competition for new workers intensifies, the probability of success falls to the point where further expansion becomes uneconomical (see (8)). On impact then, the effect of the shock leaves current unemployment unchanged, but increases the demand for labour (supply of vacancies). The dynamic effects of the shock can then be traced out by appealing to eq. (4). In particular, note that since the job-finding probability for workers \( p(\theta) \) is increasing in \( \theta \), the effect of the shock is to lower the future rate of unemployment. These effects continue to be propagated forwards in time through the search mechanism.

**Current issues**

Several authors have observed that the unemployment rate appears to exhibit a type of cyclical asymmetry, rising sharply at the onset of a recession, but declining only slowly over the course of a subsequent recovery (for example, see Neftçi, 1984; Hussey, 1992). In an influential study, Davis and Haltiwanger (1992) investigate US manufacturing data and report that job destruction appears to be significantly more volatile than job creation over the cycle. The natural conclusion that follows from this body of work is that recessions are attributable to shocks that lead to brief, but sharp, increases in job losses followed by relatively dampened, but prolonged, periods of job creation as the business sector slowly rebuilds its employment capital (see, for example, Hall, 1995).

Shimer (2005a) has recently cast doubt on this ‘conventional’ view of the cycle. In his detailed examination of Current Population Survey data, Shimer concludes that almost all the cyclical variability in the unemployment rate is attributable to fluctuations in the job-finding probability (and in particular, the job-finding rate associated with transitions from unemployment to employment, rather than from non-employment to employment). Surprisingly (relative to received wisdom), the separation rate appears to be very nearly acyclical and relatively stable. In addition to these patterns, Shimer reports a very high degree of correlation between the job-finding probability and the vacancy–unemployment ratio. Taken together, this new body of evidence suggests that, at least for the purpose of understanding cyclical behaviour, one may reasonably begin by organizing ideas around a simple Pissarides-style search model along the lines described above; that is, with a constant labour force \( L \), an exogenous separation probability \( \sigma \), and a job-finding probability \( p(\theta) \) that varies with labour-market tightness.

Whether a suitably calibrated version of this model can account for observation, however, remains a topic of current debate (for example, see Shimer, 2005b; Hagedorn and Manovskii, 2005; Hall, 2005; Mortensen, 2005; as well as Hornstein, Krusell and Violante, 2005 for a nice summary).

Apart from cyclical phenomena, several outstanding issues remain unresolved in terms of understanding secular and cross-country measures of labour-market activity. At the forefront of these phenomena is the dramatic rise in European unemployment rates relative to the United States since the early 1970s (for example, Ljungqvist and Sargent, 1998; Blanchard and Wolfers, 2000). But unemployment is just one of
the three major classifications of time allocation, along with employment and non-participation (the latter two of which contain many more people than the former). Rogerson (2001) documents several interesting facts concerning the cross-country differences and low-frequency movements in employment-to-population ratios. Among other things, cross-country differences are large and persistent over time, with considerable movement within the distribution of employment-to-population ratios across countries. Furthermore, while employment and unemployment closely mirror each other at business cycle frequencies, the same is not true at lower frequencies. This latter observation suggests that the commonly invoked short-cut of abstracting from participation decisions for business cycle analysis may be inappropriate when investigating the causes of secular movements and cross-country differences in time allocation.

On the theoretical front, several issues remain the subject of ongoing research. Paramount among these are investigating the microeconomic foundations of the matching technology and the process of wage determination in decentralized markets. On these and related matters, the interested reader may refer to Rogerson, Shimer and Wright (2005) – a recent survey that contains 167 references while claiming to only ‘scratch the surface’ of this interesting and rapidly expanding body of research.

search theory (new perspectives)

Shouyong Shi
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article reviews the recent development of search theory. We begin with a standard model of undirected (or random) search and illustrate that the equilibrium is generically inefficient. Then, we show that the market can restore efficiency by allowing individuals on one side of the market to use prices to direct other individuals’ searches. Two mechanisms of directed search – price posting and auction – are analysed and a number of applications of the framework are discussed. In addition, we briefly describe search theory as a microfoundation for monetary economics. Finally, we conclude by speculating a few directions of future research.

Article

Search theory is an analysis of resource allocation in economic environments with trading frictions. These frictions include the difficulty of bringing potential traders together, coordinating agents’ decisions, informing agents of trading opportunities and keeping records of agents’ trading histories. In the market, trading frictions appear in various forms of transactions cost and they generate important regularities in quantities and prices. For example, there are unemployed workers, underutilized capital, and unsold goods in inventory, which indicate that markets are unable to exhaust all potentially desirable trades. Also, the law of one price predicted for a frictionless economy is at odds with the dispersion of prices often observed for similar goods.
In his classic article on search theory in the 1987 edition of *The New Palgrave* (reproduced in this edition), Diamond surveyed the early development of the theory. He formulated two types of search models. One is sequential search models, in which agents on one side of the market post prices. Agents on the other side receive price quotes at an exogenous rate and decide sequentially whether to accept the quotes. The other type is random-matching models, in which agents determine prices through bargaining after they are matched. Diamond explained how these models can generate price dispersion in the equilibrium. He also showed that the market fails to allocate resources efficiently in these models. Since 1987, the literature has extensively applied the two models to analyse economic issues such as price (wage) inequality, unemployment, business cycles, marriages, and investments in physical and human capital.

Search theory has also experienced developments on the theoretical side. One development is the exploration of the mechanisms which can improve efficiency of the market. A particular mechanism is directed search or competitive search, as pioneered by Peters (1991). This exploration has led to the formulations of search as a strategic game. Another development uses search to construct a microfoundation for monetary theory. This article will focus on directed search, with only a brief description of the search theory of money. For reference, we call the models in Diamond's search theory random (or undirected) search models.

The main difference between directed and undirected search lies in whether individual agents are able to use pricing mechanisms to change their matching frequency. Random search models specify pricing and matching as two independent processes. In particular, the matching frequency is either a parameter or a function of aggregate variables only. Because prices play a limited role, the market cannot internalize the externalities in the search process. By contrast, directed search models allow individual agents to use pricing mechanisms to directly affect the matching frequency. The explicit trade-off between the matching frequency and price improves efficiency.

Because efficiency is a fundamental issue in economics, it is the primary motivation for studying directed search. Another motivation is simply the fact that directed search is a realistic description of many markets. Sellers often advertise prices and buyers know many price offers before they visit stores (firms). Incorporating directed search may lead to a robust explanation for phenomena such as persistent unemployment – however, we will not pursue this empirical agenda here.

Instead, we will start with random search models and illustrate the inefficiency of the equilibria. Then, we will describe three models of directed search and related issues. Our conclusion will follow the brief description of monetary search theory. To simplify the language, we will treat the market as a labour market and let the time horizon be one period. The models are applicable to the goods market with straightforward modifications and they can be extended to infinite horizon (see Cao and Shi, 2000).

**Random search and inefficiency**

Consider a labour market that contains a large number of workers and firms. The number of workers searching for jobs is a fixed number \( u \). All workers are the same and they are risk neutral. When employed, a worker produces goods whose value is \( y > 0 \). When unemployed, a worker enjoys leisure, the utility of which is normalized to 0. The number of vacancies is \( v \), which is determined by competitive entry of firms. A potential firm can incur a cost \( c \) to create a vacancy, where \( 0 < c < y \). The technology of
production has constant returns to scale so that a firm treats each vacancy separately. Normalize the production cost to 0.

Let us use a matching function, \( M(u, v) \), to describe the total number of matches in the period. Let \( \theta = u / v \) denote the ‘tightness’ of the market. The matching probability for a worker is \( p(\theta) = M(u, v) / u \) and the matching probability for a vacancy is \( q(\theta) = M(u, v) / v \). Assume that \( M \) is increasing, concave and differentiable in each argument for all \( \theta \) such that \( \theta, p, q \in (0,1) \). Moreover, the function has constant returns to scale. Thus, \( p(\theta) \) is decreasing in \( \theta \), \( q(\theta) \) is increasing in \( \theta \), and \( q(\theta) = \theta p(\theta) \). Moreover, assume that \( q(\theta) \) is concave, \( q(0) = 0 \), and \( q(\infty) = 1 \). The matching share of workers is defined as

\[
 s(\theta) = \frac{u}{M} \frac{\partial M(u, v)}{\partial u} .
\]

Then, \( s(\theta) = 1 + \theta p'(\theta) / p \). The matching share of firms is \((1-s)\).

Once a worker and a firm are matched, the two choose the wage for the worker, \( w \). Assume that this is done with Nash bargaining, which maximizes the geometrically weighted surplus of the two sides of the match: \( w^\sigma (y-w)^{1-\sigma} \). Here, the worker's bargaining weight is \( \sigma \in [0,1] \). The solution for the wage share is \( w/y = \sigma \).

The value of a vacancy is \( J = q(\theta) (y-w) \) and the value of a worker's search is \( V = p(\theta) w \). With competitive entry of firms, a firm's net profit is zero; that is, \( J = c \). This equilibrium condition can be rewritten as \( (1-\sigma)q(\theta) = c / v \). A unique solution for \( \theta \) exists if \( 0 < c < (1-\sigma) v \).

In the equilibrium, some workers are unemployed and some jobs are vacant. However, the existence of unemployment alone is not a sufficient indication of inefficiency. With the matching technology, not all resources can be fully utilized. The appropriate notion of efficiency must respect the constraint of this technology.

Let us measure efficiency with a social welfare function. Define social welfare as the weighted sum of expected values of agents in the economy, where all agents are given the same weight. This measure is also equal to the expected utility of an agent who is ignorant of whether he or she is a worker or a firm. Because firms earn zero net profit, the welfare level is equal to the sum of workers' values, \( uV \). Using the condition of competitive entry to substitute \( w \), we can express the welfare level as aggregate output minus the vacancy cost, that is, \( u[ p(\theta) y - c / v ] \). Because \( u \) is exogenous, the level of \( \theta \) that maximizes welfare satisfies \( \theta^2 p'(\theta) = c / v \). If we compare this efficient outcome with the equilibrium outcome, we can see that the equilibrium is efficient if and only if:

\[
 \sigma = s(\theta) .
\]
This condition is the Hosios condition (see Hosios, 1990). It is required for efficiency for the following reason. The social value created by a marginal firm is \( \nabla [\partial M(u,v) / \partial v] = \gamma (1 - s) q \). In contrast, the firm's value in the equilibrium is \( q(y-w) \). For the equilibrium to be efficient, the firm's value in the equilibrium must be equal to its social value. This requirement is met if and only if the wage share is equal to the matching share of workers, as the Hosios condition requires.

More specifically, a firm's entry into the market creates two externalities. One is positive – the presence of an additional firm increases the matching frequency of workers. The other externality is negative – an additional firm reduces the matching frequency of other firms. The Hosios condition ensures that the two externalities cancel out with each other. If \( \sigma > s(\theta) \), a firm is under-compensated for its entry cost and the amount of entry is deficient; if \( \sigma < s(\theta) \), a firm is over-compensated and the amount of entry is excessive.

With random matching, the equilibrium cannot satisfy the Hosios condition generically, because both sides of the condition involve exogenous elements of the model. In particular, when the matching function is Cobb–Douglas, the matching share \( s \) is a constant which is unrelated to the workers’ wage share.

The inefficiency is not specific to the random-matching model. Instead, it is common to all undirected search models. For example, if a sequential search model is used instead of a random-matching model, then firms post wages rather than bargain over wages. There can be a non-degenerate distribution of wage shares in the equilibrium (see Burdett and Mortensen, 1998). However, the matching share will still be independent of the wage share and the independence leads to the violation of the Hosios condition.

**Directed search and efficiency**

Directed search links the wage share to the matching share by explicitly modelling an agent's trade-off between the wage and the matching frequency. To capture this trade-off, suppose that all agents expect each wage level to be associated with a market tightness by a function \( \theta (w) \). Search is ‘directed’ in the sense that, by posting a particular wage, a firm expects to change the matching probability by affecting workers’ applications. For a firm posting wage \( w \), the matching probability is \( q(\theta (w)) \); for a worker who applies for wage \( w \), the matching probability is \( p(\theta (w)) \). The functions \( p(\theta) \) and \( q(\theta) \) have the properties assumed above. Given the tightness function, each firm chooses a wage to post to maximize the expected value \( J = q(\theta (w)) (y-w) \), and each worker chooses to apply for a wage that maximizes the expected value \( V = p(\theta (w)) w \). The equilibrium tightness must be consistent with competitive entry and workers’ application decisions.

Without restricting the function \( \theta (\cdot) \), there can be many equilibria. For example, take an arbitrary wage \( w_0 \in (0,y) \), and let \( \theta_0 \) satisfy: \( q(\theta_0) (y - w_0) = \xi \). Suppose that workers believe that all firms will post only wage \( w_0 \). With this belief, workers will apply only for wage \( w_0 \). But if no worker applies to other wages, then all firms will indeed post only wage \( w_0 \). That is, the pair \((w_0, \theta_0)\), together with the particular belief, is an equilibrium. In this equilibrium, \( \theta (w) \) is not well-defined for \( w \neq w_0 \), because there is no firm or worker at such wages.

One way to avoid this problem is to introduce a small measure of non-optimizing firms that post every feasible wage and to analyse the limit of the equilibrium when this measure approaches zero. Another
way is to impose restrictions on the beliefs out of the equilibrium, as we do here. Let $E$ be the set of equilibrium wages. For $w^* \in E$, denote the expected value of applying to $w^*$ as $V^* = p(\theta(w^*))w^*$. We require that, for every $w^* \in E$, the function $\theta(\cdot)$ must satisfy $p(\theta(w))w = V^*$ for $w$ in a neighbourhood of $w^*$. That is, a firm believes that workers will apply for a deviating wage to such an extent that they will be indifferent between the deviating wage and the equilibrium wage.

The restriction implies the following features of the trade-off between the wage level and the matching probability. First, because $p(\theta)$ is a decreasing function, a worker who applies for a wage higher than an equilibrium wage expects to face a tighter market and, hence, a lower matching probability. Similarly, a firm that posts a wage higher than an equilibrium wage expects to increase its matching probability. Second, because $p(\theta)$ is differentiable, the restriction implies that the function $\theta(\cdot)$ is differentiable. Thus, the trade-off between the wage level and the matching probability is smooth.

To characterize the equilibrium, suppose $w^* \in E$, with $V^* = p(\theta(w^*))w^*$. Each firm takes $V^*$ as given and chooses $w$ to solve the following problem:

$$
\max q(\theta(w))(y - w) \text{ s.t. } p(\theta(w))w = V^*.
$$

Under the earlier assumptions on the function $q(\theta)$, the problem above is a concave problem and the solution is interior for all $V^* \in (0, \infty)$. Using the relationship $q(\theta) = \theta p(\theta)$, we can derive the first-order condition of the problem as $w^* / y = s(\theta)$. The equilibrium satisfies the Hosios condition!

As before, we can determine the tightness in the equilibrium by the entry condition, $J = c$. Then, the worker's indifference condition recovers $V^*$. It is easy to see that the market tightness is identical to the efficient one. Thus, the equilibrium is efficient.

The reason why the equilibrium is efficient can be related to hedonic pricing. With directed search, the market functions as if there is a price (in terms of wage) for every level of tightness. The inverse of the function $\theta(\cdot)$ serves as such a pricing function. Given this function, each worker chooses to apply for a wage level that maximizes his or her expected utility and each firm posts a wage to maximize expected profit. In the equilibrium, the market prices the tightness efficiently. That is, the increase in wage that a firm is willing to give for a marginal increase in the tightness is equal to the increase in wage that a worker asks for to compensate for a tighter market. As a result, the equilibrium internalizes search externalities. Because of this link to hedonic pricing, directed search is also called competitive search (see Moen, 1997).

Directed search can also induce the efficient amount of investment. Suppose that each firm chooses the level of capital before entering the labour market. Anticipating that the equilibrium wage will divide the match surplus efficiently, firms will choose the efficient level of capital.

**Strategic formulation of directed search**

In the above analysis, the matching function is a black box – it is specified exogenously as in models of
undirected search. Because the matching function is important for the analysis of efficiency, it is important to derive a matching function from agents' strategic behaviour. Peters (1991) and Burdett, Shi and Wright (2001) formulate such a strategic game of directed search. The formulation also justifies the restriction above on the beliefs out of equilibrium. Let us describe the game where both \( u \) and \( v \) are fixed numbers greater than or equal to two. Competitive entry can be introduced in the same way as above. The one-period game is as follows. First, all firms post wages simultaneously. Each worker observes all firms’ posted wages. (The essence of the model is the same if each worker can observe only two wages that are randomly drawn from posted wages.) Then, all workers choose the firms to which they apply. Assume that a worker can apply for only one job in the period, but the worker can use mixed strategy in the application. After receiving applicants, a firm randomly chooses one to be employed. Production takes place immediately and an employed worker is paid the posted wage. Then, the game ends.

There are many equilibria of this game that are asymmetric in the sense that identical agents do not use the same strategy. When \( u=v=2 \), for example, one asymmetric equilibrium is that one worker applies only to one firm and the other worker applies only to the other firm, while the two firms post zero wage. In this equilibrium, there is no unemployment – unemployment is eliminated by implicit coordination between the two workers. That is, a worker believes that the other worker will not apply for the same job as he or she does. Other asymmetric equilibria involve trigger strategies that also feature implicit coordination. Such coordination is unlikely to be attainable when there are many agents in the market. To emphasize the lack of coordination, we focus on the symmetric equilibrium, where all (identical) workers use the same mixed strategy to apply for the jobs. In this equilibrium, it is probable that two or more workers will apply for the same job, in which case some workers will be unemployed.

To characterize the equilibrium, consider a particular firm, called firm A. Suppose that other firms post wage \( w \), but firm A posts wage \( x \). If \( x \) is close to \( w \), some workers will apply to firm A: if no other worker applied to firm A, a lone applicant to firm A would be employed with certainty, which would generate higher expected utility than applying to \( w \). In fact, workers will increase the probability of applying to firm A until the expected utility from this application is the same as that from applying to other firms. Let \( a \) be the probability with which a worker applies to firm A. Then, firm A will receive one or more workers with probability \( [1-(1-a)^u] \), and the expected number of applicants received by the firm will be \( ua \). A worker who applies to firm A will be employed with probability \( [1-(1-a)^u]/(ua) \). Because a worker's application probabilities across the firms must add up to one, a worker applies to each firm other than firm A with probability \( \pi(a) = (1-a)/(v-1) \). The probability of employment in such a firm is \( [1-(1-\pi(a))^u]/(u\pi(a)) \). For a worker to be indifferent between firm A and other firms, the expected payoff must be the same from these firms. That is,

\[
\frac{1 - (1 - a)^u}{ua} x = \frac{1 - [1 - \pi(a)]^u}{u\pi(a)} w.
\]

This equation defines a smooth function \( a = f(x, w) \). This function serves the same role as the tightness function did in the above formulation of directed search – it describes how a firm's wage offer will affect
workers’ application, given other firms’ wage offers. Note that \( f \) is an increasing function of \( x \). Taking other firms’ wage offers as given, firm \( A \) chooses \( x \) to solve:

\[
\max (y - x)[1 - (1 - a)^u] \quad \text{s.t.} \quad a = f(x, w).
\]

Denote the solution to this problem as \( x = g(w) \).

A symmetric equilibrium is a wage level \( w \) such that \( w = g(w) \). In this equilibrium, \( a = \pi(a) = 1/v \). The first-order condition of the above maximization problem, evaluated in the equilibrium, yields:

\[
w = y \left[ \frac{(1 - 1/v)^{-u} - 1}{u/v - 1} \right]^{-1}.
\]

The formulation above reveals two features of a market with a finite number of agents. First, the number of matches generated in the equilibrium is \( v[1 - (1 - 1/v)^u] \). This matching technology exhibits decreasing returns to scale. The reason is that when the number of agents increases, the coordination failure becomes more severe, and so the number of matches per agent falls. Second, when a firm chooses its wage offer, it cannot take as given the payoff which a potential applicant can get by applying elsewhere. We have made this interdependence explicit with the notation \( \pi(a) \). That is, when firm \( A \) raises the offer, it will attract all workers to apply for it with a higher probability, which will increase the probability of employment at other firms. For any given offer by other firms, a worker’s payoff of applying to those firms will increase as a result of the wage increase by firm \( A \). These two features complicate the analysis.

Fortunately, the complexity disappears in the limit when the market becomes infinitely large. Suppose that \( u \) and \( v \) approach infinity, with a fixed ratio \( \theta = u/v \). Then, the matching probability is \( (1 - e^{-\theta}) \) for a firm and \( (1 - e^{-\theta})/\theta \) for a worker. These matching probabilities have all the properties assumed above and, in particular, they are independent of the scale. Moreover, \( u\pi(a) \rightarrow \theta \), which is independent of an individual firm’s offer, \( x \). The payoff to a worker who applies to a firm other than firm \( A \) is \( w(1 - e^{-\theta})/\theta \), which is also independent of \( x \). In the limit economy, the equilibrium satisfies the Hosios condition and it is efficient.

Other pricing mechanisms and price dispersion

Price-posting is not the only mechanism to direct search. There are other mechanisms of directed search that can generate efficiency, such as auction (for example, Julien, Kennes and King, 2000). In contrast to price-posting, auction induces price dispersion. Thus, efficiency does not necessarily require identical
workers to be paid the same wage in an economy with risk-neutral agents.

Consider the following game with first-price auctions. Each firm announces a reserve wage and the following scheme. If two or more workers participate in the firm's auction, the participants bid on the wage and the lowest bidder is employed at the bid wage; if two or more workers have the lowest bid, one of them is chosen randomly by the firm; if only one worker participates, the worker is paid the reserve wage. After observing all firms’ announcements, workers choose the auction in which they will participate. A worker can participate in only one firm’s auction, although the choice can be a mixed strategy.

Choose an arbitrary firm and call it firm $A$. Let $x$ be the reserve wage announced by firm $A$ and $a$ the probability with which a worker participates in this firm's auction. For a worker who participates in firm $A$'s auction, there are two possible outcomes. The first is that the worker is the only participating worker, in which case the worker gets wage $x$. This outcome occurs with probability $(1-a)^u-1$. The other possibility is that the firm receives one or more other participants. In this case, the participants bid the wage down to 0. Thus, by participating in firm $A$'s auction, a worker expects to obtain a value $(1-a)^u-1x$.

For firm $A$, there are also two cases. If only one worker participates in the firm's auction, profit is $(y-x)$. This case occurs with probability $ua(1-a)^u-1$. If two or more workers participate, profit is $y$. The probability for this case is $[1-(1-a)^u-ua(1-a)^u-1]$. Thus, the expected value (profit) of firm $A$ is:

$$ua(1-a)^u-1(y-x) + [1 - (1-a)^u - ua(1-a)^u-1]y.$$

For a firm other than firm $A$, let $r$ be the reserve wage announced by the firm, $\pi(a)$ the probability of a worker's participation in the firm's auction, and $V(r, a)$ the expected value for a worker from such participation.

In order for a worker to be indifferent between firm $A$'s auction and other firms’ auctions, the expected value must be the same; that is, $(1-a)^u-1x=V(r,a)$. Taking this condition as a constraint and taking other firms’ auctions as given, firm $A$ chooses $x$ to maximize the expected profit above. Let $x=g(r)$ be the optimal choice. Then, a symmetric equilibrium is a reserve wage $r$ such that $r=g(r)$.

As in the case of wage-posting, the characterization of the equilibrium is simplified in the limit economy where $u\to \infty$ and $\theta = u/v \notin (0, \infty)$. In such a limit, we have $\pi(a)v\to 1$. Hence, $\pi(a)$ and $V(r,a)$ are independent of $a$. Solving the above maximization yields $r=y$. Thus, in contrast to directed search with wage posting, auction generates a wage differential. Some employed workers are paid their productivity but others are paid their reservation wage, 0.

Despite the dispersion of wages, the equilibrium is efficient. With risk-neutral agents, it is expected wage, rather than the actual wage, that is important for efficiency. With auction, the expected payoff is $ye^{-\theta}$ to a worker and $y[1-(1+\theta)e^{-\theta}]$ to a firm. These expected payoffs are the same as those in directed search with wage posting.

Related issues
**Risk aversion and asymmetric information:** when workers are risk averse, different mechanisms of directed search can differ in efficiency. For example, price-posting generates lower risks in workers’ income than auction. If the insurance market is imperfect, then wage-posting may give higher expected utility to workers than auction. Moreover, unemployment insurance, financed by lump-sum taxes, can improve welfare in this case (see Acemoglu and Shimer, 1999). On the other hand, price-posting is unlikely to be efficient when there is asymmetric information about the quality of goods or workers’ productivity. Auction can allocate resources more efficiently in the presence of private information.

**Heterogeneity and assortative matching:** directed search models can be extended to allow workers to be heterogeneous. To achieve efficiency in such an extension, firms must rank different types of workers in addition to announcing wages. Heterogeneity can also appear on both sides of the market. In this case, an interesting question is whether the matching pattern is assortative, that is, whether similar attributes are matched with each other. In a frictionless economy, the efficient matching pattern is positively assortative, provided that the attributes on the two sides of the market are complementary. Moreover, the competitive equilibrium can implement the efficient matching outcome. When search frictions are introduced through undirected search, the equilibrium pattern of matches is neither assortative nor efficient (for example, Sattinger, 1995; Shimer and Smith, 2000). Introducing directed search can restore efficiency. However, the efficient matching pattern may be non-assortative when utility is transferable. There is a trade-off between the matching quality and the matching rate (for example, Shi, 2001; 2002).

**Multiple applications:** most search models assume that an agent on one side of the market can visit only one agent on the other side of the market in a given period; for example, a worker can apply only for one job at a time. This assumption may not be realistic in some markets. When workers can apply for multiple jobs simultaneously, there is a new source of the failure of coordination among firms: two firms may select the same worker and one of them will fail to obtain the worker. If the left-out firm has no recourse to other applicants it received, then the equilibrium is inefficient even with directed search. However, there are rules of selection, such as the one described by Gale and Shapley (1962), that can eliminate this difficulty of coordination and restore efficiency.

**On-the-job search:** search on the job is rarely examined in directed search models; sequential (undirected) search models have dominated the analysis on this topic (see Mortensen, 2003; 2007; labour market search). These models are constructed typically in continuous time. They assume that each worker, whether employed or not, receives a wage offer according to a Poisson process. While an unemployed worker receives one offer at a time, an employed worker effectively receives two offers – his current wage and the new offer from another firm. In this environment, the equilibrium must have a continuous distribution of wages with no mass point in the interior of the support; otherwise, a firm’s payoff function would be discontinuous on the right side of the mass point. These models yield strong predictions on the shape of the wage distribution, some of which are counter-factual. Allowing on-the-job search to be directed can make the predictions more realistic and generate limited wage mobility endogenously, as shown by Delacroix and Shi (2006).

**Search as a microfoundation for monetary theory**

A surprising development of search theory is its use in monetary theory. For monetary economics, a fundamental question is why intrinsically useless objects, such as fiat money, can have a positive value.
in the equilibrium (see Wallace, 2007: fiat money). A familiar but informal answer is that such objects relieve the difficulty of exchange by acting as media of exchange. To capture this role of money, traditional monetary theory has used shortcuts while keeping the assumption of frictionless (Walrasian) markets. Examples include the requirement that agents must hold cash in advance of purchases and the assumption that money yields direct utility which cannot be generated by other assets. These short cuts seem incompatible with the Walrasian markets in the model and they are unable to explain why different media of exchange can have different values. To formalize the difficulty of exchange, Kiyotaki and Wright (1993) abandoned the short cuts and replaced the Walrasian exchange with random bilateral matches. The resulting model is a value theory of money, which gives money a role in improving efficiency of the market. Shi (1995) and Trejos and Wright (1995) integrate sequential bargaining into monetary search models to determine prices: see Shi (2006), Wright (2007) and matching for a survey. Monetary theory has gone one step further to analyse optimal trading mechanisms. Using the method of mechanism design, the theory characterizes the set of allocations that are compatible with agents’ incentives in the presence of search frictions. Next, the theory examines the efficient allocations and asks whether the implementation of these allocations entails particular types of trade, such as the use of money, banking, or a payments system – for example, Green and Zhou (2005). This analysis has clarified the relationship between optimal trading mechanisms and different components of search frictions, such as the difficulty for agents to meet, the difficulty for the society to keep record of agents’ transactions, and the difficulty of enforcing trades.

**Conclusions**

Search theory was initially formulated to understand price dispersion and unemployment. Recent research has shifted the focus to the pricing mechanism and efficiency in frictional economies. Directed search is formulated to allow agents to explicitly make a trade-off between prices and matching frequency. The main finding is that directed search can restore efficiency that failed in earlier search models. However, even the efficient allocation cannot fully utilize all resources, because of the constraint of the matching technology. Moreover, the efficient allocation may not have the assortative pattern that emerges in a frictionless economy. The literature has explored different pricing mechanisms of directed search and used search to develop a microfoundation for monetary theory. By focusing on pricing mechanisms and efficiency, the research has brought search theory close to the task of analysing the interactions between trades inside economic organizations and outside in the market. These interactions are important for explaining the observed forms of contracts and trading institutions. Monetary search theory has already taken up this task by using the approach of mechanism design. Other fields can also benefit from incorporating search frictions. An example is the literature on optimal dynamic contracts. By introducing search, one can endogenize the duration in which an agent stays with a particular contract. In general, the integration of search theory and contract theory awaits future research.

Another direction of future research is to explore the empirical implications of directed search. Most empirical work on wage distribution and business cycles has employed random search models (see Mortensen, 2003; Andolfatto, 2007; search models of unemployment). It is known that wage dispersion in these models is sensitive to the assumption of undirected search. Moreover, these models need a large
search theory (new perspectives): The New Palgrave Dictionary of Economics

amount of heterogeneity among workers and firms to explain the observed distribution of wages, which seems to diminish the spirit of search. Directed search may offer a useful alternative approach in the empirical investigation.

search theory

P. Diamond
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Search theory analyses resource allocation with imperfect technologies for informing agents of trading opportunities and for bringing together potential traders. This article examines some search theory analyses using a variety of special allocation mechanisms together with very simple preferences and production technologies. It explores models where information is gathered from visiting stores, and then looks at the changes that come from additional devices for information spread. It examines price setting both on a take-it-or-leave-it basis and resulting from idealized negotiations. While the presentation is in terms of a retail market, a similar approach has been useful in labour economics.

Article

Walrasian analysis presumes that resource allocation can be adequately modelled using the assumption of instantaneous and costless coordination of trade. In contrast, Search Theory is the analysis of resource allocation with specified, imperfect technologies for informing agents of their trading opportunities and for bringing together potential traders. The modelling advantages of assuming a frictionless coordination mechanism, plus years of hard work, permit Walrasian analysis to work with very general specifications of individual preferences and production technologies. In contrast, search theorists have explored a variety of special allocation mechanisms together with very simple preferences and production technologies. Lacking more general theories, we examine the catalogue of analyses that have been completed. Paralleling the Walrasian framework, we first examine individual choice and then equilibrium. There are a large number of variations on the basic search-theoretic choice problem. We explore one set-up in detail, while mentioning some of the variations that have been developed. Coordination of trade involves two separate steps: information gathering about opportunities, and arrangement of individual trades. One simple case is where information gathering is limited to visiting stores sequentially, combining the costs of
collecting goods and of gathering information. Alternatively, there can be an information gathering mechanism which is independent of the process of ordering and receiving the good. We begin with models where the only information gathering is associated with visiting stores, and then look at the changes that come from additional devices for information spread.

Once two potential traders have met there are several ways of determining whether they trade and the terms of trade if they do. Among these are price setting on a take-it-or-leave-it basis, idealized negotiations where any mutually advantageous trade occurs at a price satisfying some bargaining solution, and more realistic negotiation processes that recognize the time and cost of negotiation, the possibility of a negotiating impasse, and the possible arrival of alternatives for one or the other of the trading partners. We explore the first two mechanisms.

One final distinction in the literature is between one-time purchases of commodities and ongoing trade relations. Infrequently purchased consumer goods are the classic example of the former, while the employment relationship is the classic example of the latter. Introducing on-going relationships permits the exploration of delayed learning of the quality of a match and associated rearrangements through quits and firings. Intermediate between these two cases is a situation such as that of frequently purchased consumer goods, where past trades facilitate future trades but do not bring about the closeness of an employment relationship. We discuss mainly the one-shot purchase. The discussion of individual choice and partial equilibrium will be given in terms of a consumer purchase. The parallel discussion of labour markets is only briefly mentioned.

I Individual choice

Consider a consumer in a store who is deciding whether to make a purchase or to visit another store with an unknown price. Denote by $U(p, 1)$ the utility that the consumer receives (net of purchase costs) if the purchase is made in the first store at a price equal to $p$. This assumes an ability to purchase the optimal number of units at a constant per unit price of $p$. If the purchase is made at the second store at price $p$, utility is $U(p, 2)$. This utility is less than $U(p, 1)$ because of the cost and the time delay from visiting a second store. We assume that the entire purchase is made at a single store, that it is impossible to return to the first store, and that there are no other stores that can be visited. Ignoring the possibility of making no purchase and no further searches, the alternative to purchasing in store 1 at price $p$, is a single visit to store 2 where the price will be drawn from a (known) distribution which we denote $F(p)$. The purchase should be made in store 1 if the utility of purchase there is at least as large as the expected utility of purchase in store 2:

$$U(p, 1) \geq \int U(p, 2) dF(p).$$

(I–1)

As long as the consumer views the distribution of prices in store 2 as independent of the price in the first store, the rule in (I–1) yields a cut-off price, $p^*$, given by (I–2):

$$U(p, 1) = \int U(p, 2) dF(p).$$

(I–2)
For prices above \( p^* \), optimal behaviour calls for visiting the second store, while for prices below \( p^* \), optimal behaviour calls for making a purchase in the first store. Thus \( p^* \) is the cut-off price. Implicit in this formulation is the assumption that it is not desirable to make some purchase in store 1 and the remaining purchase in store 2. While this assumption is true for many consumer goods it is certainly not true for all of them. Without this assumption the decision resembles portfolio choice and has not been explored in the literature. A similar analysis applies to the search for high quality.

If the consumer does not know with certainty the distribution of prices in the second store, the consumer's beliefs about those prices may depend upon the price observed in the first store. We write the subjective distribution of prices in the second store, conditional on an observed price of \( p_1 \) in the first store as \( F(p; p_1) \).

The purchase should be made in the first store if \( p_1 \) satisfies the inequality:

\[
U(p_1, 1) \geq \int U(p, 2) dF(p; p_1).
\] (I-3)

With no restriction on the beliefs of the consumer as to the structure of prices found in both stores, the set of prices resulting in a purchase in store 1 does not necessarily satisfy a cut-off price rule. For example, if either a high or a low observed price implies the same price in both stores, while an intermediate price in store 1 implies a low price in store 2, then the consumer should purchase in store 1 at the high and low prices but not at an intermediate price. Thus, the intermediate price might signal a price war. If the information content of the price found in store 1 is a greater likelihood of similar prices in store 2, the optimality of a cut-off price rule is restored (Rothschild, 1974). For the remainder of this entry we restrict analysis to the case of known distributions. The caveats implicit in this counter example should be kept in mind.

Returning to the set-up with a known distribution, we can increase the options of the shopper by adding the possibility of returning to the first store after observing the price in the second store. Denote by \( U(p, 3) \) the utility that is realized if this option is followed. The utility function \( U(p, 3) \) is less than \( U(p, 2) \), which, in turn, is less than \( U(p, 1) \). Once in the second store, the choice is between buying there and returning to the first store with both prices known. Therefore it pays to purchase in the first store in the first period if the price there, \( p_1 \), satisfies the inequality:

\[
U(p_1, 1) \geq \int \max [U(p, 2), U(p_1, 3)] dF(p).
\] (I-4)
That is, the purchase should be made in store 1 if utility there is higher than expected utility with optimal behaviour in choosing between the second store and returning to the first store. This is a particularly simple example of the backwards induction that can be used to solve the finite horizon sequential shopping problem. Behaviour in the first store, (I–4), again satisfies a cut-off price rule if the utility function has constant search costs and discount rate.

We now specialize the example by assuming additive, constant search costs $c$ and utility discounting with a discount factor $R$. That is, $U(p, 2) = R U(p, 1) - c$, with $R \leq 1$. Returning to the choice problem without a return to store 1, we denote by $V(p_1)$ expected utility on observing the price $p_1$ in store 1, given optimal behaviour:

$$V(p_1) = \max \left[ U(p_1), -c + R \int U(p) dF(p) \right].$$

(I–5)

The value of being in a store that has price $p_1$ is the larger of (i) the utility from making the optimal purchase at that price, and (ii) the expected utility if the search cost $c$ is paid and the purchase is made in the second store. Using this function $V$, we can describe choice in the first period of a new three-period search problem with no return to previous stores. The optimal rule is to purchase if

$$U(p_1) \geq -c + R \int V(p) dF(p).$$

(I–6)

That is, purchase is made in the first period if the achievable utility there is at least as large as that achievable with optimal behaviour, beginning with a visit to a randomly selected second store. The latter utility is the discounted expected optimized utility minus the search costs of the visit, recognizing that the second period choice is again a choice between a purchase and a search in the following period. By having $F(p)$ independent of $p_1$, we are sampling with replacement rather than sampling without replacement from the known distribution of prices. The choice rule given in (I–6) again shows cut-off price behaviour for period one choice. However, the cut-off price is higher in the second period than in the first because of the reduction in options as the end of the search process comes closer. Denoting the cut-off prices in the two periods by $p_1^*$ and $p_2^*$, they satisfy the two equations:

$$U(p_1^*) = -c + R \int V(p) dF(p).$$

http://www.dictionaryofeconomics.com.proxy.library.csi.c...edu/article?id=pde2008_50000566&goto=B&result_number=1527 2009-1-3 0:39:51
V(p) is at least as large as U(p) since it represents the choice between purchase and searching again. Thus \( p_1^* \leq p_2^* \), with a strict inequality in problems where the search cost and discount rate are not so large as to always imply a purchase in the current store.

There are additional reasons for cut-off prices to rise over time or equivalently, in a job search setting, for reservation wages to fall over time. In many settings, search costs rise over time. The utility of a purchase or of finding a job can fall over time. In the job setting, these can arise from declining wealth being used to finance consumption while searching for a job and from the shortening period over which any job might be held.

A known finite horizon for the end of search is incorrect in many settings. In addition, with many periods, the backwards induction optimization process is a cumbersome description of individual choice. Fortunately, the infinite horizon stationary case is easy to analyse. In this setting, a parallel analysis to that in (I-7) is a straightforward application of dynamic programming principles. With the assumption of a stationary environment the cut-off price is the same period after period. Denote by \( p^* \) the cut-off price and by \( V \) the optimized expected value of utility after paying the search cost to enter a store but before observing its price. Then \( V \) equals the utility of purchase if a purchase is made plus the probability of not making a purchase times the discounted optimized utility from facing the same problem one period later after paying search cost \( c \):

\[
V = \int_{0}^{p^*} U(p) dF(p) + [1 - F(p^*)] \left[ -c + RV \right].
\]

(Solving (I-8) for \( V \) we have:

\[
V = \frac{\int_{0}^{p^*} U(p) dF(p) - c[1 - F(p^*)]}{1 - R[1 - F(p^*)]}.
\]
The optimal $p^*$ maximizes $V$ and can be calculated by differentiation. More intuitively, we note that a purchase just worth making will give the same utility as will waiting to search again:

$$U(p^*) = -c + RV.$$  
(I–10)

Rearranging terms, we can write the implicit equation for $p^*$:

$$(1 - R)U(p^*) = -c + R\int_{0}^{p^*} [U(p) - U(p^*)]dF(p).$$  
(I–11)

Using this first order condition we can analyse the comparative statics of optimal search behaviour. Naturally, the cut-off price increases if the search cost increases or if the discount factor becomes smaller. Interestingly, an increase in the riskiness of the distribution of prices (holding constant mean utility from a randomly selected price, $\int U(p)dF$) makes search more valuable and so lowers the cut-off price. This result follows from the structure of optimal choice – decreases in low prices make search more attractive while increases in high prices are irrelevant since no purchase is made at high prices. Analysis of the relationship between the expected number of searches and the distribution of prices is complicated since it depends on the shape of that distribution.

Thus far we have assumed that all stores are **ex ante** identical; that is, that a choice to search is a choice to draw from the distribution $F(p)$. In many problems one can choose where to search. In that case, one is choosing which distribution $F(p)$ to sample from or, if there are limited draws allowed from a particular distribution, the sequence of distributions from which prices should be sampled. Interestingly, the reservation prices which tell whether to purchase or to sample again from a given distribution also serve to rank distributions.

In the choice problem analysed so far we have used discrete time, with the arrival of one offer in each time period. There are two straightforward generalizations. First, one might have the opportunity to receive more than one offer in any period, with the number of offers received being a function of the chosen level of search costs. In this way one can model the choice of search intensity. Second, the process of attempting to locate stores might have a stochastic rather than a determinate time structure. The simplest such model has the arrival of purchase opportunities satisfying the Poisson distribution law. That is, at any moment of time there is a constant flow probability of an offer arriving, any such offer being an independent draw from the distribution of available prices. Let us denote by $a$, the arrival rate of these offers; and by $c$, the constant
search cost from being available to receive these offers. Utility is discounted at the constant (exponential)
rate \( r \). One can derive the optimal cut-off price and the optimized level of expected utility by analysing the
discrete time process as above and passing to the limit. As a more intuitive alternative, let us think of the
opportunity to purchase as an asset, where \( V \) now represents the value of that asset. The utility discount rate
plays the role of an interest rate in asset theory. The asset is priced properly when the rate of discount times
the value of the asset equals the expected flow of benefits from holding that asset. The expected flow of
benefits is the gain that will come from making a purchase at a price below the cut-off price rather than
continuing to search, adjusted for the probability of such an event, less search costs. Thus asset value
satisfies

\[
rv = a \int_0^{p^*} [U(p) - V] dF(p) - c.
\]

(I–12)

It is worthwhile to make any purchase with a higher utility than that from continued search. Thus the cut-off
price satisfies

\[
ru(p^*) = a \int_0^{p^*} [U(p) - U(p^*)] dF(p) - c.
\]

(I–13)

Again, one can introduce search intensity by having the Poisson arrival rate be a function of the search cost.
In the equilibrium discussions below we will use the choice problem in the form (I–13).
So far we have ignored events after a purchase. In the labour setting this is equivalent to the assumption that
taking a job is the end of search. In practice individuals frequently shift from job to job with no intervening
period of unemployment. One can model job choice recognizing the possibility of continued search while
working. Such an analysis must consider the rules that cover compensation between the parties in the event
of a quit or firing, with no compensation and compensatory and liquidated damages being the situations
analysed in the literature. The search for a better job is only one aspect of turnover. Also, one can model
learning about the quality of match in a particular job as a function of the time on the job and the stochastic
realization of experience. With a shadow value for quitting to search for a new job, one then has a second
aspect of the theory of turnover.
The formulation of job taking given above has been combined with data on individual experience to
examine empirically the determinants of the distribution of spells of unemployment. Since this essay
focuses on equilibrium and the empirical literature has not examined the determinants of the distribution of
opportunities, we do not explore this sizeable and interesting literature, nor the estimates of the effect of
unemployment compensation on the distribution of unemployment spells. For an example, see Kiefer and
Neumann (1979).
In the model above we have assumed that no additional information is received during the search process. In practice, individuals are simultaneously searching for many different consumer goods and often for jobs and investment opportunities as well. The relations among search processes coming from the arrival of information and the random positions with simultaneous search for many different goods have not been explored in the literature. Focusing on search for a single good, we have added several new factors to the theory of demand, particularly the cost of attempting to purchase elsewhere and the knowledge and beliefs of shoppers about opportunities elsewhere. In practice, these are important determinants of demand.

II Equilibrium with bargaining

The theory of choice above is a simple version of the complex problem people face when making decisions about information gathering and purchases over time. That simplicity yields a choice theory that can be embedded in an equilibrium model. To complete an equilibrium model, we need to model the determination of two endogenous variables: the arrival rate of purchase opportunities and the distribution of their prices. In this section, we consider prices that satisfy the bargaining condition of equal division of the gains from trade. In the next section, we consider take-it-or-leave-it prices set by suppliers. In both cases we assume that there are no reputations either of soft bargaining or low price setting that affect the arrival rate of potential customers. We begin by assuming that all buyers are identical and all sellers are identical. This case brings out the role of search in determining the level of prices. Below we consider determinants of the distribution of prices.

Axiomatic bargaining theory relates the terms of trade to the threat points of the two bargainers and the shapes of their utility functions. To avoid complications from the latter, we assume that a single unit is purchased and utility from purchase equals a constant, \( u_d \), minus the price paid. We also assume that each seller has a single unit to sell. The utility from a sale is the price received less the cost of the good, \( u_s \). One might think of this as a homogeneous used car market. To divide equally the gains from trade, the differences between the utility position with the trade and the utility position without it are equalized for the two parties. The value of purchasing at price \( p \) is \( u_d - p \); expected utility without a trade is \( V_d \), the optimized expected utility from continued search. We restrict ourselves to an economic environment where all trades take place at the same price. With a degenerate distribution of prices, we can rewrite the value equation (I–12) as

\[
rV_d = a_d(u_d - p - V_d) - c_d. \tag{II–1}\]

For suppliers, the utility from a sale is \( p - u_s \). The gain from selling now rather than later is \( p - u_s \), less the value of having a car for sale, \( V_s \). The carrying cost of having a car available for sale can be incorporated in the search cost. The value equation for suppliers is

\[
rV_s = a_s(p - u_s - V_s) - c_s. \tag{II–2}\]
We ignore the sufficient conditions for search to be worthwhile \((V_d, V_s \geq 0)\).

Equal division of the gains from trade implies

\[
\begin{align*}
    u_d - p - V_d &= \frac{r(u_d - p) + \zeta_d}{r + a_d} = \frac{r(p - u_s) + \zeta_s}{r + a_s} = p - u_s - V_s.
\end{align*}
\]  

(II–3)

We have assumed the same utility discount rate for both parties. Thus we have a relationship between the equilibrium price, the arrival rates of trading opportunities, the search costs, and the utility from ownership. Solving (II–3) for the equilibrium price, we have:

\[
    p = \frac{(r + a_s)(ru_d + \zeta_d) + (r + a_d)(ru_s - \zeta_s)}{r(2r + a_s + a_d)}.
\]  

(II–4)

Without direct search costs \((\zeta_d = \zeta_s = 0)\), the position of the price between the seller's reservation price of \(u_s\) and the demander's reservation price \(u_d\) depends on the relative ease of finding alternative trading partners. As it becomes very easy to find buyers \((a_s\) becomes infinite), the price goes to \(u_d\). Alternatively, as it becomes very easy to find suppliers \((a_d\) becomes infinite), the price goes to \(u_s\). Furthermore, an increase in one's search cost pushes the price in an unfavourable direction. In this extremely simplified setting, (II–4) brings out the new element that search theory brings to equilibrium analysis, namely, the dependence of equilibrium prices on the abilities of traders to find alternatives. Implicit in Walrasian theory is the idea that a perfectly substitutable trade can be found costlessly and instantaneously. In this restricted sense, there is no consumer surplus in a Walrasian equilibrium.

To complete the theory we need to determine the two endogenous arrival rates of trading partners. Assuming a search process without history, these depend on the underlying technology for bringing together buyers and sellers and the stocks of buyers \((N_d)\) and sellers \((N_s)\). We write the arrival rates as \(a_d \cdot (N_d, N_s)\) and \(a_s \cdot (N_d, N_s)\). The two arrival rate functions satisfy the accounting identity between the numbers of purchases and of sales:

\[
a_d(N_d, N_s)N_d = a_s(N_d, N_s)N_s.
\]  

(II–5)
Next, we must examine the determinants of the stocks of buyers and sellers. This theory can be based on the stocks of traders or the flows of new traders. One extreme example is that the steady state stocks of buyers and sellers are exogenous. One then inserts the functions $a_d$ and $a_s$ in the price equation (II–4).

An alternative extreme to perfect inelasticity is the assumption of perfectly elastic supplies of buyers and sellers at given reservation values for search, $\bar{V}_s$ and $\bar{V}_d$. Assuming reservation values that are consistent with the existence of equilibrium with positive trade, the equality of gains from trade (II–3) implies

$$p = \frac{u_d + u_s + \bar{V}_s - \bar{V}_d}{2}.$$  

(II–6)

The numbers of traders actively searching adapts to give this simple formula. Substituting from (II–6) in (II–1) and (II–2) we have the necessary values of $a_d$ and $a_s$ and so two equations for $N_s$ and $N_d$.

For a market with professional suppliers one can consider the case of inelastic demand ($\bar{N}_d$) and a perfectly elastic supply ($\bar{V}_s$). If we assume further that demanders visit suppliers at a rate and cost independent of the number of suppliers, then $a_d$ and $c_d$ are parameters. Solving (II–3) for $p$ in terms of the exogenous variables we now have

$$p = \frac{(r + a_d)(u_s + \bar{V}_s) + ru_d + c_d}{2r + a_d}.$$  

(II–7)

In this case the response of price to an increase in the cost of the good or the reservation utility of suppliers is $(r + a_d) / (2r + a_d)$, which is less than one. The speed of the search process relative to the interest rate determines the extent to which search equilibrium is different from Walrasian equilibrium. In a labour setting, an analogue to (II–7) shows how unemployment compensation affects wages by changing search costs.

**Efficiency**

There are two decisions implicit in the model above – whether to enter the search market and whether to accept a particular trade opportunity. The decision to enter a search market, like the choice of search intensity, affects the ease of trade of others. There is nothing in the process that determines prices which reflects the externalities arising from the impact of changed numbers on the opportunities to trade. Thus, in general, equilibrium will not be efficient and one has the possibility of both too much entry and too little entry.
In order to explore the efficiency of the choice of acceptable trades, we need a reason for waiting for a better deal in the future. This can be done by introducing differences in traders or differences in matches between preferences of demanders and goods on sale. However formulated, we have the proposition that the marginally acceptable trade generates no surplus to the two agents making that trade, yet the marginal trade changes the search environment of others. This involves externalities of the same kind as the entry decision already discussed. Again, in general, equilibrium is not efficient.

**Individual differences**

There are many patterns of differences among demanders in their evaluations of different goods. We explore two simple cases which have been dubbed quality differences and variety differences. With quality differences, all demanders have the same utility evaluation of goods. One asks how the price of a good varies with the quality of the good. With variety differences, all demanders have the same distribution of utility evaluations of the set of goods in the market, but demanders disagree as to which is better. There is then an issue of ‘matching’ preferences with goods. One asks how the price in a transaction varies with the quality of the match.

We use $q$ as the index of universally agreed on quality, and denote by $p(q)$ the price paid in a transaction for a good of quality $q$. By suppressing all other differences, we have the same price in all the purchases of a good of any quality. We denote by $V_s(q)$ the optimized net value to a supplier of having a unit of quality $q$ for sale. Paralleling (II–2), we can calculate the net gain to a supplier of selling his unit. This gain, $p(q) - u_s(q) - V_s(q)$, satisfies

$$p(q) - u_s(q) - V_s(q) = \frac{r[p(q) - u_s(q)] + \zeta_s}{r + \alpha_s}.$$

(II–8)

For the demander, we denote by $V_d$ the value of entering the search market to make a purchase, and by $u_d(q)$ the utility, gross of purchase price, of purchasing a unit of quality $q$. Paralleling (I–12), the utility discount rate times the value of being a demander is equal to the net flow of gains from search. The gross flow of gains equals the arrival rate of purchase opportunities times the expected gain from a purchase. The expected gain is the utility of buying the good less the price that has to be paid for the good less the shadow value of being a searcher. Denoting the distribution of qualities in a randomly selected trade encounter by $F(q)$, the value of being a demander satisfies

$$rV_d = \alpha_d \int [u_d(q) - p(q) - V_d] dF(q) - \zeta_d.$$

(II–9)
A full equilibrium analysis of this model would require determination of the distribution $F(q)$ as well as the arrival rates $a_d$ and $a_s$. $V_s(q)$ would play an important role in determining $F(q)$. Such a model could consider investment in human capital with a search labour market. We will not carry out such an analysis, but focus merely on the relative prices $p(q)$, given a non-degenerate distribution $F(q)$. This problem is kept simple by the uniformity of product evaluations, which results in consumers’ purchasing the first unit encountered, just as in the homogeneous case above. In any trade, the gains are shared equally between buyer and seller. Using (II–8) and (II–9) to eliminate $V_d$ and $V_s(q)$ in the equal gain condition (II–3), we have the equilibrium price function

$$(2r + a_s) p(q) = (r + a_s) u_d(q) + ru_s(q) - c_s + (r + a_s) \left\{ c_d - a_d \int [u_d(z) - p(z)] dF(z) \right\} / (r + a_d).$$

(II–10)

This generalization of the homogeneous case, (II–4), shows a price that rises with quality assuming that cost does.

$$p'(q) = \frac{(r + a_s) u'_d(q) + ru'_s(q)}{2r + a_s}.$$  

(II–11)

The speed of search relative to the interest rate determines the magnitude of deviation from the Walrasian result that with identical demanders all transactions give the same utility level $[ p'(q) = u'_d(q) ]$. With pure quality differences, all consumers have the same expected utility from search, while suppliers have expected utilities which vary with the quality of goods for sale. In a symmetric variety model, both demanders and suppliers have the same expected utility from search. The variable $q$ now represents the quality determined by the particular match of demander and good. We view the distribution of these qualities, $F(q)$, as given and the same for all demanders and all goods. Implicitly we are assuming random matching between demanders and different goods. It is now the case that a sufficiently poor match will not result in a trade. We denote by $u_d(q)$ the utility evaluation, gross of purchase price, of buying a good, by $u_s(q)$ the cost of supplying a good, and by $p(q)$ the price when the quality of a match is $q$. The value of search for a supplier satisfies

$$rV_s = a_s \int_{q_1}^{q_2} [ p(q) - u_s(q) - V_s ] dF(q) - c_s$$

(II–12)
where $q_1$ is the lower bound of match qualities at which it is mutually advantageous to carry out a trade. At the lowest acceptable quality, $q_1$, $p(q_1)$ is equal to $u_s(q_1) + V_s$. The value of search for a demander continues to satisfy (II–9). The assumption that all mutually advantageous trades are taken implies that $q_1$ also equates the gain from a purchase $u_d(q_1) - p(q_1)$ with the utility from search $V_d$. Equating the gains from trade for buyer and seller and solving for the price we have

$$2p(q) = u_d(q) + u_s(q) - V_d + V_s.$$  

(II–13)

Price increases with match quality to reflect the changed cost of supply, $u'_d(q)$, plus half the change in surplus, $[u'_d(q) - u'_s(q)]/2$.

Recapitulating our analysis of search equilibrium with bargaining, we have seen two themes. The first is how the search for trading partners introduces an additional element in the determination of trading prices: namely, the relative ease of the two potential trading partners in finding alternative trades. Secondly, the presence of a costly trade coordination mechanism is naturally replete with externalities as the availability of traders affects the trading opportunities of others.

In the model used in this section negotiation is instantaneous while search is slow. A fascinating literature explores equilibrium in models where the negotiation process is an explicit game of exchanging bids that can be interrupted by the arrival of an alternative trading partner (cf. Rubinstein and Wolinsky, 1985).

III Equilibrium with price setting

In contrast to the bargaining theory used above, we now assume that prices are set on a take-it-or-leave-it basis by suppliers. This rule of (not) bargaining over prices gives the supplier a potential for monopoly power. The search for alternatives limits this monopoly power. The fundamental question is how much. We begin with the assumption that the only source of price information is visiting randomly chosen suppliers sequentially one at a time. We assume many identical suppliers, implying equal profitability of different pricing strategies used in equilibrium. If all buyers have identical positive search costs and identical demand curves that yield a unique profit maximizing price, then the unique equilibrium is the price that would be set by a monopolist. This result assumes a sufficient number of suppliers that buyers will not search for a single low price. This extreme result comes from the uniformity of trading opportunities. The best a buyer can do is wait to make exactly the same deal in the future. Therefore a buyer is always willing to pay a little bit more today than he has to pay in the future. Thus the demand curve for an individual seller coincides with the underlying demand curve in the neighbourhood of the equilibrium price. Even though this result is limited to unrealistic cases, it is interesting that the price is independent of the cost and speed of search, as long as search is not costless and instantaneous.

Given the pervasive reality of price distributions in retail markets, it has been natural for the literature to concentrate on generating equilibria without uniform prices. With differences in demanders, either from differences in underlying characteristics or from differences in their history of past purchases, the
equilibrium can involve a distribution of prices and the structure of that distribution will depend upon search costs. In this case, consumers care about the characteristics of other consumers since these characteristics affect price setting behaviour. Similarly, with differences among suppliers the equilibrium price distribution varies with search costs.

Information gathering

When visiting a store is the only way to learn its price, price quotations are gathered one at a time. Separating the gathering of price information from going to stores does not necessarily change the model. If price quotations are still gathered one at a time, the cost of going to purchase the good can be deducted from the utility of acquiring it, leaving the model unchanged. However, the separation of the gathering of information from the collection of goods opens up the possibility of sometimes receiving price quotations one at a time and sometimes two or more at a time. This possibility destroys the single price equilibrium in the model of identical buyers and sellers. To see this result, note that profit per sale is continuous in price but, with uniform prices, the number of sales is discontinuous in price since a slight decrease in price wins all sales when a firm's price is one of two that are learned simultaneously. With positive profit made on each sale it would always pay to decrease price slightly below the uniform price of all other suppliers. With constant costs the competitive price is not a possible equilibrium either since a price increase gains profits when one is the only price quote while losing zero profit sales when one is not the only price quote. Thus there is necessarily a distribution of prices in equilibrium. Without price reputations, a store can choose any price it wants without affecting the flow of information about that store. Therefore, with identical firms the equilibrium will satisfy an equal profit condition. There will be low-price high-volume stores and high-price low-volume stores. One way to complete this model is to allow purchasers a choice of intensity of search which stochastically generates varying numbers of price quotations per period. We examine three additional models – price guides, advertising, and word of mouth.

Price guide

In this extension of the model we continue to have consumers seek price information one price at a time. In addition, consumers can purchase a guide to lowest cost shopping, with the purchase cost varying across consumers. A consumer who purchases such a guide is directed to one of the lowest price stores; a consumer who does not follows the search procedure described above. Assuming free entry of identical firms with U-shaped costs and an equilibrium where some consumers purchase the price guide and some do not but otherwise consumers are identical, we have a two-price equilibrium. Some of the stores set the price at the competitive equilibrium level. These stores sell to all consumers who purchase price information and those sequential shoppers who are lucky enough to find one of these stores on their first shopping visit. The remaining stores have higher prices, equal to the cut-off price for searching consumers or the profit maximizing price for selling to such a consumer, whichever is lower. The fraction of stores of the two kinds and the aggregate quantity of stores per consumer are determined by the zero profit condition for the two pricing strategies. When more consumers purchase the price guide, there will be more stores setting the competitive price and a drop in the cut-off price of searching consumers. This external benefit to searching consumers implies the inefficiency of the original equilibrium. A very slight subsidization of the cost of the price guide involves a second-order efficiency cost to the purchase of guides, no effect on firms (which have zero profits), and a first-order gain to searching consumers.
Advertising

It is obviously counterfactual to have all the information flows resulting from actions by shoppers. Advertising is a pervasive modern phenomenon. We continue to assume that stores have no price reputations. If the form of advertising is direct communication of prices to individual consumers, we can construct a model that again results in a distribution of prices. Stochastic communication from stores to consumers naturally generates a distribution of the number of price quotes that consumers receive. Any specific model of the stochastic structure of attempted communication will generate a distribution of numbers of price quotes learned by consumers. Free entry then implies a particular equilibrium distribution of prices provided some consumers receive a single price quotation and others receive more than one.

Word of mouth

It is natural to model both the seeking of price information and the spreading of price information as costly activities. However, some price information passes between consumers as a costless activity, part of the pleasure of discussing life. The presence of word-of-mouth communication in addition to sequential shopping alters equilibrium. The natural way to model word-of-mouth price communication brings price reputations into the model, since the prices set in one period affect communications about stores in future periods when their prices might be different. In order to isolate the effect of word of mouth we consider a very artificial model. Stores set prices which must hold for two periods. Consumers shop in the first or second period but are otherwise identical. In the first period, there is only sequential search, visiting stores one at a time as modelled above. Between the first and second periods there are random contacts between first-period shoppers and second-period shoppers. In this way, each second-period shopper receives information about the price in some positive number of stores. We assume that some people hear of only one store, while others hear of at least two. Then there will be a distribution of prices, with the structure of the distribution depending on the details of the word-of-mouth process. This analysis can be extended by having shoppers tell not only of the prices they paid, but also of prices they have heard from others. Both types of communication require a model of memory. The density of stores has different effects on equilibrium prices for different models of memory. This approach has been used in a setting of search for quality rather than low price to argue that doctors’ fees can be higher where there are more doctors per capita (Satterthwaite, 1979).

Recapitulating the analysis of search equilibrium with price setting but not price reputation, we have seen two themes. One is the tendency for even low-cost search to generate sizeable amounts of monopoly power because of similar incentives for all suppliers. The second is a tendency for equilibrium to have a distribution of prices. Since price distributions are a widespread phenomenon in decentralized economies, it is reassuring that the theory produces such distributions.

IV Additional issues

We have considered the search analogue to competitive equilibrium. It was assumed that there were many small firms, whose behaviour was adequately approximated while ignoring their impacts on certain aspects of equilibrium. Search theory has also examined equilibria with small numbers of firms. It may pay a monopolist to have a distribution of prices across his outlets rather than a single price as a method of
discriminating among consumers with different search costs, even though the need to search for a low price adds to the cost of purchase of the good (Salop, 1977). In a duopoly or oligopoly setting, it is natural to consider randomized pricing strategies which again give rise to a distribution of prices (Shilony, 1977). This may be one of the many factors that go into the empirical fact of sales by retail outlets.

The technology of shopping in the models above is extremely simple. Little has been done to marry the underlying search issues with some of the realities of the geographic distributions of consumers and firms and the normal travels of shoppers. Similarly, little has been done to model the search basis for the role of intermediaries.

Price reputations

All the models mentioned above omit or severely limit the inter-temporal links in profitability that arise from price reputations. This is a major hole in the existing literature. Probably significant progress in this area will have to await the discrimination of cases in which optimal strategies (whether determinate or stochastic) are stationary, from those in which optimal strategies involve building up a reputation which is then run down. In such a setting analysis will be very sensitive to the assumptions made about consumer knowledge both of existing prices and of price strategies followed by firms. It would be nice to have both an empirical evaluation of the level of consumer ignorance about opportunities, and a theoretical structure capable of examining the relationship between equilibrium and the extent to which consumers are accurately informed.

Conclusion

Walrasian theory assumes that consumers are perfectly informed about the prices of all commodities in the economy. This assumption is central for the law of one price, that a homogeneous commodity sells at the same price in all transactions in a given market. This assumption is also central for a variety of inequalities on prices, limiting price differences to be less than transportation costs. These inequalities are consequences of the absence of opportunities for arbitrage profits. In order to make a rigorous arbitrage argument, there must be simultaneous purchase and sale of the same commodity at different prices net of transportation costs. If the purchase and sale are at different times, there is likely to be risk for the would-be arbitrageur. Similarly, a proper arbitrage argument requires homogeneous commodities. It is improper to apply arbitrage arguments to labour markets for example, although migration arguments may lead to similar conclusions. In search theory with a known distribution of prices, there is a cost to finding any trading partner and possibly a large cost to finding one willing to trade at some particular price. This idea captures one aspect of the limitations on the extent of arbitrage arguments.

Realistically, one must recognize that infrequent traders are often ill-informed about the distribution of prices in the market. This introduces two important changes in the basic theory. One is that gathering information changes beliefs about the distribution of prices, as well as revealing the location of possible transactions. The second is the incentive created for sellers to find consumers whose beliefs make them willing to transact at high prices. The differences between the search for suckers and the hunt for the highest value use of resources has not been clearly drawn in the literature, yet this distinction is valid and important for evaluating the functioning of some markets. Search-based theory and empirical work have a long way to go until we have satisfactory answers to a number of allocation questions that are totally ignored in a Walrasian setting. Nevertheless, the theory has already shown how informational realities can
search theory: The New Palgrave Dictionary of Economics

seriously alter the conclusions of Walrasian theory. It would have been highly duplicative to have reviewed search theory of the labour market as well as that of the retail market. For a survey of labour search theory and a partial guide to the literature, see Mortensen (1984). Individual patterns of unemployment spells are the key empirical fact requiring revision of the Walrasian paradigm.

The failure of the profession, thus far, to produce a satisfactory integration of micro and macroeconomics based on the Walrasian paradigm (with or without price stickiness) raises the thought that such an integration might come out of search theory. For a presentation of this view and discussion of some applications of search ideas to macro unemployment issues, see Diamond (1984).

search-and-matching models of monetary exchange

Randall Wright
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

We review a class of equilibrium search (matching) models that can be used to study the trading process and develop a theory of money as a medium of exchange. Developing such a theory is one of the longest-standing issues in economics, and search-based models provide a natural framework in which to formalize venerable stories about money facilitating trade by avoiding the double coincidence of wants problem in pure barter. The approach provides a compelling microfoundation for monetary theory: it is based on sound economic thinking going back to the classical economists, brought up to date with modern and rigorous methods.

Keywords

bargaining; barter; Bellman equation; commodity money; fiat money; matching; microfoundations; money; multiple equilibria; overlapping generations models; search-and-matching models of monetary exchange; trigger strategies

Article

In this article we review a class of equilibrium search (matching) models that can be used to study the trading process, and in particular to develop a formal theory of money as a medium of exchange. Developing such a theory is one of the longest-standing issues in economics, but it met with at best limited success prior to the development of search-based models, which provide a natural framework in which to formalize venerable stories about money helping to facilitate exchange. These stories, going back to Smith, Jevons, Menger, Wicksell, and others – many of which are reprinted in Starr (1990) – concern a double coincidence of wants problem in bilateral exchange, as discussed below. Overlapping generations models (for example, Wallace, 1980) provide an alternative approach. Ostroy and Starr (1990) survey earlier attempts to develop microfoundations for monetary theory, including Jones (1976), which is similar in spirit if not detail to modern search models. There is not the
search-and-matching models of monetary exchange: The New Palgrave Dictionary of Economics

space here to discuss the pros and cons of the various approaches, but it seems fair to say search and matching models now dominate the area.

Background

Diamond (1982) introduced a framework that, although it cannot be used directly, can be extended naturally to build microfoundations for monetary economics. In his model, a [0,1] continuum of infinitely lived agents interact in an economy where activity takes place in two distinct sectors: one for production and one for exchange. In the first sector, agents encounter potential production opportunities randomly over time according to a Poisson process with arrival rate $\alpha$. Each opportunity yields a unit of output at cost $c$, where $c$ is random with CDF $F(c)$. Since $c$ is observed before a production decision is made, given an opportunity, there is a reservation cost $k$ such that agents produce if $c \leq k$. For now, these goods are indivisible, and agents can store at most one at a time.

All goods yield utility of consumption $u > 0$, except by assumption agents cannot consume their own output; hence they must trade. Traders with goods meet bilaterally in the exchange sector according to a Poisson process with arrival rate $\gamma$. Upon meeting they trade, consume, and return to production. Since all goods are the same, and indivisible, every meeting yields trade, and every trade is a one-for-one swap. Generally, $\gamma = \gamma(N)$ depends on the measure of agents in the exchange sector $N$. This is based on a matching technology that gives the number of agents who meet a partner per unit time as $m(N)$, with $m'(N) > 0$, implying $\gamma(N) = m(N) / N$ for all $N > 0$.

Let $V_0$ and $V_1$ be the value functions for producers and traders. The flow Bellman equation for a producer is

$$rV_0 = \alpha \text{E} \max \{V_1 - V_0 - c, 0\} = \alpha \int_0^k (k - c) dF(c),$$

where $k = V_1 - V_0$. Similarly, for a trader

$$rV_1 = \gamma(N) (u + V_0 - V_1) = \gamma(N) (u - k).$$

(We focus on steady states; for dynamics, see for example Diamond and Fudenberg, 1989.)

In words, the flow value $rV_0$ equals the arrival rate of opportunities times the expected option value of switching from production to exchange, while $rV_1$ equals the arrival rate of meetings times the gain from trading and switching back. Combining these equations,
Given $N$ this has a unique solution for $k$. Given $k$, in steady state, the flow of agents from production to exchange must equal the flow back,

$$(1 - N)\alpha F(k) = m(N).$$

An equilibrium is a pair $(N, k)$ satisfying these last two equations. It is simple to derive results concerning existence, comparative statics, and so on. As Diamond emphasizes, under increasing returns in $m(N)$, if any non-degenerate equilibrium (one with production) exists then multiple such equilibria exist. Under constant returns, a unique non-degenerate equilibrium exists if parameters fall in a certain range – for example, $u$ is not too low, $r$ not too high, and so on. To complete our review of this basic model, notice that exchange is trivial, even though it is restricted to bilateral trade, because there is only one good (or, all goods are the same). To make money interesting we need to generalize this. (Diamond, 1984, took a short cut to getting money into the model with a cash-in-advance constraint. By changing the environment as we do below, we see this is not only uninteresting, it is unnecessary.)

To ease the presentation we first simplify the production process. Assume everyone is always in the exchange sector, and, instead of carrying goods around, they can produce whenever they meet someone, at deterministic cost $\zeta \geq 0$. Now, following Kiyotaki and Wright (1991; 1993), assume goods come in varieties, say colours. Each agent produces a particular colour, but different agents like to consume different colours. The simplest specification assumes agents get $u = U > C$ from any good in some set, and $u = 0$ from other goods, and $x$ is the probability output in the relevant set (that is, an agent wants what the other agent can produce) in any random meeting. Also, since agents can produce whenever they want, to simplify things we assume goods are non-storable.

When goods are storable, Kiyotaki and Wright (1989) determine endogenously which objects serve as media of exchange, potentially including commodity plus fiat money. That model illustrates the trade-off between fundamental properties like storability and equilibrium properties like acceptability. It has many implications – for example, there can be multiple equilibria with different monies, objects with bad fundamental properties may end up as money, and so on. Generalizations and applications of the model include Marimon, McGrattan and Sargent (1990); Aiyagari and Wallace (1991; 1992); Kehoe, Kiyotaki and Wright (1993); Wright (1995); and Duffy and Ochs (1999). Here, by making goods non-storable, we focus on determining how an economy operates when there is a single candidate medium of exchange, namely, fiat money.

On the assumption that exchange requires mutual agreement, which occurs when I want to consume your good and you want to consume mine, trade now occurs only in a meeting with probability $x^2$, at least if the event that I want your good is independent of the event that you want mine (see below). This captures nicely the famous double coincidence problem with direct barter: trade requires meeting
someone who produces something you like – which would be a coincidence – and also likes what you produce – a double coincidence. Payoffs are given by $r V_B = \gamma x^2 (U - C)$, where the subscript on $V_B$ stands for ‘barter’. If $x$ is small, which is the case if there is a lot of specialization, double coincidence meetings are rare and $V_B$ is very low.

But is it really necessarily the case that trade occurs iff both parties want to consume what the other produces? Following ideas in Kocherlakota (1998), suppose agents get together at the start of time and discuss when to trade. Clearly, they agree that whenever either agent wants what the other produces he should get it, since this maximizes ex ante welfare

$$r V_C = \gamma \left[ x^2 (U - C) + x(1 - x)U - (1 - x)xC \right] = \gamma x(U - C),$$

where the subscript on $V_C$ stands for ‘cooperation’ (or perhaps ‘commitment’ or ‘credit’). As long as $x<1$, $V_C > V_B$. However, suppose agents cannot commit now to do things when they meet later that are not in their interest at that time. Then trades must satisfy incentive compatibility (IC), the binding condition being that you should be willing to produce in meetings where you do not consume.

If we can keep a public record of all agents’ behaviour, we can try to use trigger strategies to support cooperative trade as follows: instruct agents to cooperate as long as everyone else does; but if anyone deviates, trigger to … ‘something bad’. One can argue the worst trigger is ‘autarky’ which yields $V_A=0$; or it may be ‘barter’ which yields $V_B$. In the former case the relevant IC condition is $-C + V_C \geq V_A$, which simplifies to $r C \leq \gamma x(U - C)$; in the latter case it is $-C + V_C \geq V_B$, which simplifies to $r C \leq \gamma x(1 - x)(U - C)$. In either case, if $r$ is small we can sustain cooperative trade. Moreover, one can prove formally that money has no role here (Kocherlakota, 1998; Wallace, 2001); instead of proving this here we move to models where money does have a role.

**First-generation search models of money**

Suppose it is difficult to use triggers because, say, there is incomplete monitoring or record keeping, or, to take the simplest situation, suppose agents have no memory – they just cannot recall what happened in previous meetings! Kocherlakota (1998), Kocherlakota and Wallace (1998), Wallace (2001), Corbae, Temzilides and Wright (2003), Araujo (2004), and Aliprantis, Camera and Puzzello (2007) explore less extreme variations, but our assumption allows us to make the point more easily. In our ‘memoryless’ world, your continuation payoff $V_M$ cannot depend on what you do in a given meeting. Hence, the relevant constraint to get you to produce without consuming is $-C + V_M \geq V_M$, which is violated for any $C>0$. There is no scope for using threats to sustain cooperation without memory (generally, there is limited scope when memory is imperfect, which is what we need; we use the starkest case merely for tractability).

Suppose we introduce into this world a new object called fiat money. By definition, a medium of
search-and-matching models of monetary exchange: The New Palgrave Dictionary of Economics

Exchange is an object that is accepted in trade not to be used for consumption – or production – but to be traded again later for something else. When an object serving as a medium of exchange is for some people at some times a consumption good, it is called commodity money. When an object with no consumption value serves as a medium of exchange it is fiat money. At the start of time, we endow a fraction \( M \) of the population each with \( m=1 \) unit of money and the rest with \( m=0 \). Initially, those with \( m=0 \) can produce; after this, agents can produce after they consume but not before. This implies agents with money cannot produce, and at any point in time everyone either has \( m=1 \) or \( m=0 \). Now, even without memory, agents have an option other than pure barter: offer money for goods. Let \( \Pi \) be the probability a random producer accepts such an offer, and let \( \pi \) be your best response.

If \( V_m \) and \( V_p \) are the value functions of agents with and without money,

\[
rV_p = \gamma(1 - M)x^2(U - C) + \gamma Mx\pi(V_m - V_p - C)rV_m = \gamma(1 - M)x\Pi (U + V_p - V_m).
\]

For example, \( rV_p \) equals the arrival rate of agents with goods \( \gamma(1 - M) \), times the double coincidence probability \( x^2 \), times the gain from barter \( U - C \); plus the arrival rate of agents with money \( \gamma M \), times the probability of trade \( x\pi \), times the gain \( V_m - V_p - C \). We restrict attention to pure strategies (mixed strategy equilibria are not robust here; see Shevchenko and Wright, 2004). Then the best response condition is \( \pi = 0 \) if \( V_m - V_p < C \) and \( \pi = 1 \) if \( V_m - V_p > C \). It is easy to see \( \pi = 0 \) is always an equilibrium, and \( \pi = 1 \) is an equilibrium iff

\[
rC \leq \gamma(1 - M)x(1 - x)(U - C).
\]

Naturally, \( \pi = 0 \) is an equilibrium – if no one else accepts money, why would you? It is more interesting that \( \pi = 1 \) can be an equilibrium, since then intrinsically worthless money is valued, as a medium of exchange. Given \( M \), one can check \( \pi = 1 \) yields higher payoffs than \( \pi = 0 \). Alternatively, if we choose \( M \) to maximize welfare, one can check \( M > 0 \) iff \( x \) is not too big. Hence, introducing money can improve welfare, even given the assumption that money holders cannot produce. The convention of money as a medium of exchange is good because it eases trade. Now, \( \pi = 1 \) is only an equilibrium when \( r \) is not too high, and one can check the cutoff for \( r \) here is more stringent (and payoffs lower) than when we had memory and triggers – that is, money is not a perfect mechanism. One reason money is not as good as memory is the random nature of matching. The problem is that you might, for example, have two meetings in a row where you want a good from someone who does not want your good, and in the second one you will have run out of money (this can also happens with positive probability when we relax the upper bound of unity on money holdings). However, in an endogenous (rather than random) matching model this never happens – when you have no money you do not go to someone whose good you like, but to someone who likes your good; see Corbae, Temzilides and Wright (2003). Still, money
can do pretty well here, and if we cannot use triggers it is the only way to improve on pure barter. The model is obviously crude, yet it gets at the essence of money. To recap, the results assume the following explicit frictions: (a) a double coincidence problem (generated here by random bilateral matching, although there are other devices in the related literature); (b) imperfect commitment; and (c) imperfect memory (or anything else that makes it difficult to use triggers). These frictions are severe—but no one said it was going to be easy to get money into economic theory in an interesting way. There are many extensions and applications of this model (some of which are surveyed in Rupert et al., 2000), but in the interest of space, we now move on to models where prices are endogenous. We mention one extension to endogenous specialization in Kiyotaki and Wright, 1993, based on ideas in Adam Smith. Consider the case where the probability that someone accepts your good \( x \) is a choice variable: if you want a large fraction of the population to like your output, you cannot specialize too much, which reduces productivity. Thus, the arrival rate in the production sector—return to Diamond’s two sector set-up—is \( \alpha(x) \), with \( \alpha’ < 0 \). When choosing \( x \), you take the average \( \bar{X} \) as given, and in equilibrium \( x=\bar{X} \). Two results follow. First, monetary equilibria have lower \( x \) than non-monetary equilibria, so the use of money enhances specialization and productivity. Second, \( x \to 0 \) as \( \gamma \to \infty \), so when frictions vanish, agents specialize completely, and since the double coincidence probability is \( x^2 \), barter completely disappears.

Second-generation models

Suppose that goods are no longer indivisible, but can be consumed and produced in any amount \( q \geq 0 \), which yields utility \( U(q) \) and disutility \( -C(q) \), respectively. These functions have all the usual properties, plus \( C(0)=U(0)=0 \). We maintain for now the assumptions that money is indivisible, money holders cannot produce, and everyone holds \( m \in \{0,1\} \). But we relax the assumption of independence in generating the double coincidence problem: the probability that I like your good is \( x \), but now the probability that I like your good and you like mine is \( y \), and not necessarily \( x^2 \), in general. (Consider \( N \) goods and \( N \) types, where type \( n \) produces good \( n \), but likes good \( n+1 \) modulo \( N \). If \( N=2 \) then \( x=y=1/2 \) (if I like your good you must like mine), while if \( N \geq 3 \) then \( x=1/N \) and \( y=0 \) (if I like your good you cannot like mine). It is only under independence, which does not hold in these examples, that we necessarily have \( y=x^2 \).) Conditional on money being accepted \((\pi=1)\), we have

\[
rv_p = \gamma(1-M)\gamma[U(\bar{q}) - C(\bar{q})] + \gamma M x[RV_m - V_p - C(\bar{q})]rv_m = \gamma(1-M)x[U(\bar{q}) + V_p - V_m],
\]

where \( \bar{q} \) is the amount traded in barter and \( \bar{q} \) the amount traded for money. It facilitates the presentation to start with the case \( y=0 \) and then give general results. Now, to determine the equilibrium value of money, as in Shi (1995) or Trejos and Wright (1995), we say the following: when I meet you and want your good, if I have \( m=1 \) while you have \( m=0 \), we bargain over the \( q \) you produce for my money, taking as given \( \bar{q} \) in all other meetings. Equilibrium is a fixed point, \( \bar{q} = \bar{q} \), and the price level is \( p=1/q \).
One can use any bargaining solution, including generalized Nash

\[
\max \left[ U(q) + V_p - V_m \right]^\theta \left[ V_m - V_p - C(q) \right]^{1-\theta},
\]

for any \( \theta \in (0,1) \); we use \( \theta = 1 \) because it is so easy. (See Rupert et al., 2001, for \( \theta \in (0,1) \) and other generalizations. Alternatives to bargaining studied in versions of this model include posting – for example, Curtis and Wright, 2004 – and auctions – Julien, Kennes and King, 2007. Or, instead of imposing a particular pricing mechanism, one can study the entire set of incentive-feasible trades – Wallace, 2001.) When \( \theta = 1 \), agents with \( m=0 \) get no gains from trade since they have no bargaining power (and \( y=0 \)). Hence \( V_p=0, V_m=C(q) \), and the Bellman equation for \( V_m \) reduces to

\[
rC(q) = \gamma(1 - M) x [U(q) - C(q)].
\]

This is 1 equation in \( q \), with two solutions: 0 and a unique \( q > 0 \). Again, we get equilibrium where an intrinsically worthless object is valued as a medium of exchange. It is easy to do comparative statics, welfare analysis, and so on in this model (for example, it is immediate that \( q \) falls and \( p \) rises when \( M \) or \( r \) increase).

Once we reintroduce some barter – that is, once we allow \( y > 0 \) – one can show that, in addition to \( q=0 \), generically there either exist two equilibria with \( q > 0 \) or no equilibrium with \( q > 0 \). If \( y \) is small then equilibrium with \( q>0 \) always exists. It is not much harder to analyse the general case \( \theta \in (0,1) \). This model has a large number of variations, extensions and applications – too many to review here (again see Rupert et al., 2000). Suffice it to say that the basic results of first-generation models more or less go through, with additional insights concerning prices.

**Third-generation models**

The approach sketched above provides a compelling microfoundation for monetary theory: it is based on sound economic thinking going back to some very famous economists, brought up to date with modern and rigorous methods and ideas. Still, obviously those first- and second-generation models are quite abstract and quite special. In particular, the assumption that agents hold \( m \in \{0,1\} \) is severe, and precludes using the models for much quantitative and policy analysis. The difficult part of relaxing this and allowing any \( m \geq 0 \) is that we need to keep track of the distribution of \( m \) across agents, which is complicated by the random nature of matching and the endogenous amount of money spent in each match. There are several ways to deal with this problem. Some analytic results are available in Green and Zhou (1998) and Camera and Corbae (1999) for example, while computation methods are used by Molico (2006).
Another approach is to amend the environment to get around this problem while hopefully maintaining the spirit and essence of the matching models outlined above. There are two main ways to do this, following either Shi (1997) or Lagos and Wright (2005). The Shi model assumes the fundamental decision makers are not individuals, but families, each with a large number of members. If the individual members experience independent random meetings, when they return to the household at the end of each period the total amount of money in the family is pinned down by the law of large numbers. Hence, each household starts the next period with the same (deterministic) amount of money. There are many extensions and applications of this framework (see Shi, 2006, for some references).

The Lagos–Wright model alternatively assumes that at the end of each round of decentralized trade agents go to a centralized market where they can (among other things) rebalance their money holdings. On the assumption of quasi-linear utility, all agents choose the same \( m \) for next period, independent of the amount with which they start. Again, agents enter each round of decentralized trade with the same \( m \) here, just as in the family model (although there are several interesting differences between the approaches). Versions of either model are easily used for quantitative and policy analysis. These models are perhaps still special, since they use ‘tricks’ to harness the distribution of \( m \), but this is merely for technical convenience in deriving analytic results. If one is willing to use a computer, most of the special assumptions can be avoided (see, for example, Chiu and Molico, 2006).

Conclusion

We have reviewed several generations of search-and-matching models of the exchange process that can be used to provide microfoundations for monetary economics. While the literature is big, and growing fast, it is to be hoped that this article conveys some of the main ideas and models in an accessible fashion.

seasonal adjustment

Svend Hylleberg
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The main objective of seasonally adjusted time series is to provide easy access to a common time series data-set purged of what is considered seasonal noise. Although the application of officially seasonally adjusted data may save costs, it may also imply less efficient use of the information available, and data may be distorted. Hence, in many cases, seasonality may need to be treated as an integrated part of an econometric analysis. In this article we present several ways to integrate seasonal adjustment into econometric analysis in addition to applying data adjusted by the two most popular adjustment methods.

Article

Seasonal adjustment of economic time series dates back to the 19th century and it is based on an attitude properly expressed by Jevons, who wrote:

"Every kind of periodic fluctuation, whether daily, weekly, monthly, quarterly, or yearly, must be detected and exhibited not only as a subject of a study in itself, but because we must ascertain and eliminate such periodic variations before we can correctly exhibit those which are irregular or non-periodic, and probably of more interest and importance. (1884, p. 4)"

The most popular model behind seasonal adjustment in the beginning of the 20th century was either the so-called additive unobserved components (UC) model

\[ X_t = T_t + C_t + S_t + I_t, t = 1, 2, \ldots, n \]  

(1)

where the observed series \( X_t \) is divided into a trend component, \( T_t \), a business cycle component, \( C_t \), a seasonal component, \( S_t \), and an irregular component, \( I_t \), or the multiplicative UC model

\[ X_t = T_t \cdot C_t \cdot S_t \cdot I_t, t = 1, 2, \ldots, n \]  

(2)

http://www.dictionaryofeconomics.com.proxy.library.csi.cuny.edu/article?id=pde2008_S000496&goto=B&result_number=1529(第1/14页)2009-1-3 0:41:30
which is applied if the series is positive and the oscillations increase with the level of the series.
The definitions of the individual components could vary, but Mills (1924, p. 357) defined the trend component, \( T_t \), as the smoothed, regular, long-term movement of the series \( X_t \), while the seasonal component, \( S_t \), contains fluctuations that are definitely periodic in character with a period of one year, that is, 12 months or 4 quarters. The business cycle component, \( C_t \), is less markedly periodic, but characterized by a considerable degree of regularity with a period of more than one year, while the irregular component, \( I_t \), has no periodicity. A detailed description of the historical development is given in Hylleberg (1986).
The rationale behind seasonal adjustments is that the unobserved components model is useful, that the components are independent, and that the components of interest are the trend and cycle components.
The assumption of independence is highly questionable, as the actual economic time series is a result of economic agents’ reaction to some exogenous seasonally varying explanatory factors such as the climate, the timing of religious festivals and business practices. For typical economic agents, decisions designed to smooth seasonal fluctuations will naturally interact with non-seasonal fluctuations, since the costs of such smoothing will necessarily be interrelated through budget constraints and so forth. Therefore, not only is the independence assumption economically unreasonable, but seasonal patterns may be expected to change if economic agents change their behavioural rules.
Hylleberg (1992, p. 4) defines seasonality as

A systematic, although not necessarily regular, intra-year movement caused by the changes of the weather, the calendar, and timing of decisions, directly or indirectly through the production and consumption decisions made by agents of the economy. These decisions are influenced by endowments, the expectations and preferences of the agents, and the production techniques available in the economy.

Such a view of seasonality is somewhat different from the views expressed by most statistical data-producing agencies. The views of the statistical offices are well represented by the arguments put forward by OECD (1999, p. vii), where the implied definition of seasonality stresses the fixed timing of certain events during the year. Likewise, they indicate that the reason for changes in the seasonal pattern is ‘the trading day effect’, that is, the changing number of working days in a month, the changing number of Saturdays, and movable feasts such as Easter, Pentecost, Chinese New Year and Korean Full Moon Day. Obviously, such factors do influence the seasonal pattern in economic time series, but in the longer run technical progress and economic considerations based on these will imply changes in the seasonal pattern as well. In addition, the seasonal economic time series may constitute an invaluable and plentiful source of data for testing theories about economic behaviour, as the seasonal pattern is a recurrent though changing event where the pattern, despite the changes, is somewhat easier to forecast than many other economic phenomena. (For a general discussion of seasonality and the literature, see Hylleberg, 1986. For a presentation and discussion of the results since then, see Hylleberg, 1992; Franses, 1996; Ghysels and Osborn, 2001; Brendstrup et al., 2004.)
Seasonal adjustment and treatment of the seasonal components may in practice be undertaken in two ways: simply applying the seasonally adjusted data produced by the statistical agencies, or integrating the modelling and adjustment into the econometric analysis undertaken.

Officially applied seasonal adjustment programmes

Several different methods for seasonal adjustment are in actual use, but the most popular programme is the X-12-ARIMA seasonal adjustment programme (see Findley et al., 1998) which is a further development of the popular X-11 seasonal adjustment programme (see Shiskin, Young and Musgrave, 1967; Hylleberg, 1986). Another popular seasonal adjustment programme is the TRAMO/SEATS programme developed in Gomez and Maravall (1996).

X-12-ARIMA seasonal adjustment programme

The main characteristics of the X-11 seasonal adjustment method for the monthly multiplicative model (see (2)),

\[
X_t = TC_t \ast S_t \ast TD_t \ast H_t \ast I_t, \tag{3}
\]

where \( TC_t \) is the combined trend-cycle component, while \( TD_t \) is the trading day component, and \( H_t \) the holiday component, is the repeated application of selected moving averages such as a 12-month centred moving average to estimate \( TC_t \), followed by an actual extraction of the estimated trend-cycle component. The extraction by the moving average filters takes place after a prior
adjustment for trading days and certain holidays, and a varying seasonal pattern is taken care of by applying so-called Henderson moving averages with a 9, 13 or 23 number of terms. The Henderson trend filters are used in preference to simpler moving averages because they can reproduce polynomials of up to degree 3, thereby capturing trend-turning points. In addition, treatment for so-called extreme observations was possible, and a refined asymmetric moving averages filter is used at the ends of the series. In order to robustify the initial seasonally adjusted series against data revisions, the X-11 seasonal adjustment method was improved by extending the series by forecasts and backcasts from an ARIMA model before seasonally adjusting the series (see Dagum, 1980).

The X-12-ARIMA seasonal adjustment programme described in Findley et al. (1998) extends the facilities of X-11-ARIMA by adding a modelling module denoted RegARIMA, which not only facilitates modelling the processes in order to forecast and backcast the time series, but also facilitates modelling of trading day and holiday effects, detection of outlier effects, dealing with missing data, detection of sudden level changes, and detection of changes in the seasonal pattern, trading day effects and so forth. The second major improvement on the earlier programmes is the inclusion of a module for diagnostics which contains many helpful ‘tests’. The third improvement is a user-friendly interface. Although X-12 is a major improvement to X-11, it has its critics. For example, Wallis (1998) doubts that the trend estimation procedure taken over from X-11 is still the best available despite the results obtained since the mid-1970s, and he stresses the need to give the user of the adjusted numbers an indication of their susceptibility to revision.

TRAMO/SEATS seasonal adjustment programme

The main difference between the X-12 programme and the TRAMO/SEATS programme is that the former uses signal-to-noise ratios to choose between the different moving average filters available while SEATS uses signal extraction with filters derived from a time series (ARIMA) model. The programme also contains a preadjustment programme, TRAMO, which basically performs tasks similar to RegARIMA in X-12. The signal extraction is based on an additive model such as (1) or

\[ Y_t = \mu_t + \gamma_t + \epsilon_t, \]  

(4)

where \( \mu_t \) is the trend-cycle component, \( \gamma_t \) the seasonal component, and \( \epsilon_t \) is the irregular component. It is then assumed that the \( \mu_t \) and \( \gamma_t \) can be modelled as two distinct ARIMA processes

\[ A_C(L) (1 - L)^d \mu_t = B_C(L) \nu_t \quad \text{and} \quad A_S(L) (1 - L)^D \gamma_t = B_S(L) w_t, \]  

(5)

where the processes \( \nu_t, w_t \) and \( \epsilon_t \) are independent, serially uncorrelated processes with zero means and variances \( \sigma^2_{\nu}, \sigma^2_{\omega} \) and \( \sigma^2_{\epsilon} \), and \( d \) and \( D \) are integers, while \( L \) is the lag operator. This class of model is also called the unobserved components autoregressive integrated moving-average model (UCARIMA) by Engle (1978).

Hence, the TRAMO/SEATS programme requires the estimation of the UCARIMA parameters for each specific series, which in principle should allow computation of the correct number of degrees of freedom. This is not possible in X-12 due to the adjustments undertaken within the programme based on the characteristics of the individual series. A discussion of the merits and drawbacks of X-12 and TRAMO/SEATS may be found in Ghysels and Osborn (2001), Hood, Ashley and Findley (2004), and several working papers from EUROSTAT (see Mazzi and Savio, 2005), which find that X-12 is slightly preferable to TRAMO/SEATS when applied to short time series – a result to be expected as the model-based approach requires more data. In fact, the main differences between the two leading competitors reflect the difference between the model-based approach of TRAMO/SEATS, which tailors a seasonal filter to each series, and the uniform filter applied by X-12 (see below). However, the model-based approach relies on a very restrictive set of models, and the uniform filter approach is not really applying the same filter, as individual characteristics like outliers, smoothness, and so on, have an influence on the filter.

Seasonal adjustment as an integrated part of the analysis

The main objective of the production of seasonally adjusted time series is to give the policy analyst or adviser easy access to a common time series data-set that has been purged of what is considered noise contaminating the series. Obviously, the application of the seasonally adjusted data may be more or less formal and meticulous, ranging from eyeball analysis to thorough econometric analysis. However, although the application of officially seasonally adjusted data may have the advantage of saving costs, it also implies that the user runs a severe risk of not making the most effective use
of the information available and – perhaps more serious – of applying a dataset distorted by the applied seasonal filter. The possible reasons for these shortcomings are:

- the seasonal component is a noise component but
  - the wrong seasonal adjustment filter has been applied, or
  - the data have been seasonally adjusted individually without consideration being given to the fact that they are often used as input to a multivariate analysis;
- the seasonal components of different time series may be closely connected and contain valuable information across series.

Filtering the data before they are applied may of course distort the outcome of the analysis if the wrong filter is used, but even if the filter is ‘correct’ as seen from the individual series, the filtering may produce biased estimates of the parameters in certain cases where, for instance, a regression model is applied (see Hylleberg, 1986, p. 3). However, this result is complicated by the application of other transformations to the original series. Which filter to apply may in fact depend on the order of the applied transformations, as shown by Ghysels (1997).

Hence, in order to optimally model many economic phenomena, seasonality may need to be treated as an integrated part of an econometric analysis based on unadjusted quarterly, monthly, weekly and daily time series or panel data observations. This may be done in many different ways depending on the specific context and the set of reasonable assumptions one can make within that context. As both X-12 and TRAMO/SEATS seasonal adjustment programmes are available to the individual researcher, they may both be applied as part of an integrated approach and their use somewhat adapted to the specific analysis. In what follows we discuss some alternative methods, of three kinds: pure noise models, time series models and economic models.

Pure noise models

The first group comprises seasonal adjustment methods which are based on the assumption that the seasonal component is noise. Thus, the group also contains the officially applied seasonal adjustment programmes presented earlier. The seasonal adjustment methods in this group are distinguished by their ability to take care of a changing seasonal component.

Seasonal dummies

The use of seasonal dummy variables to filter quarterly and monthly times series data is a very simple, straightforward and therefore popular method in econometric applications. The dummy variable method is designed to take care of a constant, stable seasonal component. The popularity of the seasonal dummy variable method is partly due to its simplicity and the flexible way it can be used either as a pre-filtering device whereby the series are regressed on a set of seasonal dummy variables and the residuals used in the final regression, or within the regression as an extension of the set of regressors with seasonal dummy variables (see Frisch and Waugh, 1933; Lovell, 1963).

Band spectrum regression and band pass filters

A natural and quite flexible way to analyse time series with a strong and somewhat varying periodic component is to perform the analysis in the frequency domain, where the time series is represented as a weighted sum of cosine and sine waves. Hence, the time series are Fourier-transformed and the seasonal filtering of the time series may take place by removing specific frequency components from the Fourier-transformed data series.

Application of such filters dates back a long time (see Hannan, 1960). Band spectrum regression is further developed and analysed by Engle (1974; 1980) and Hylleberg (1977; 1986). The so-called real business cycle literature has since named it ‘band pass filtering’ (see Baxter and King, 1999).

Let us assume that we have data series with \( T \) observations in a vector \( y \) and a matrix \( X \) related by \( y = \beta'X + \varepsilon \), where \( \varepsilon \) is the disturbance term and \( \beta \) a coefficient vector. Band spectrum regression is then performed as a regression in the transformed model \( \mathcal{A}y = \mathcal{A}X\beta + \mathcal{A}\varepsilon \), where the transformation by the matrix \( \mathcal{A} \) is a finite Fourier transformation of the data. The transformation by the diagonal matrix \( \mathcal{A} \) with zeros and ones on the diagonal, symmetric around the south-west north-east diagonal, is a filtering which removes the frequency components corresponding to the elements with the zeros. Hence, by an appropriate choice of zeros in the main diagonal of \( \mathcal{A} \) the exact seasonal frequencies and possibly a band around them may be filtered from the series.

An obvious advantage of the band spectrum regression representation is that the model \( \mathcal{A}y = \mathcal{A}X\beta + \mathcal{A}\varepsilon \) tends itself directly to a test for the appropriate filtering, as argued in Engle (1974). In fact the test is just the well-known so-called Chow test applied to a stacked model with the null hypothesis that the parameters are the same over the different frequencies. A drawback of band spectrum regression is that the temporal relations between series may be affected in a complicated way by the two-sided filter (see Engle, 1980; Bunzel and Hylleberg, 1982).

Seasonal integration and seasonal fractional integration

A simple filter often applied in empirical econometric work is the seasonal difference filter \( (1 - L^s)^d \), where \( s \) is the number of observations per year and \( d \) the number of times the filter should be applied to render the series stationary at the long run and seasonal frequencies (see Box and Jenkins, 1970).
In the unit root literature a time series is said to be integrated of order \( d \) if its \( d \)th difference has a stationary and invertible ARMA representation. Hylleberg et al. (1990) generalize this to seasonal integration and denote, for instance, a quarterly series \( y_t \), \( t = 1, \ldots, T \) represented by the model \((1 - L^4)y_t = \varepsilon_t, \varepsilon_t \sim i.i.d. \) \((0, \sigma^2)\) as integrated of order \( 1 \) at frequency \( \theta \) since \((1 - L^4) = (1 - L)(1 + L)(1 + L^2)\) has real roots at the unit circle at the frequencies \( \theta - \left\{ \frac{1}{2}, \frac{1}{4}, \frac{3}{4} \right\} \), where \( \theta \) is given as the share of a total circle of \( 2\pi \).

Many empirical studies have applied the so-called Hylleberg, Engle, Granger, and Yoo (HEGY) test for seasonal unit roots developed by Hylleberg et al. (1990) and Engle et al. (1993) for quarterly data, extended to monthly data by Beaulieu and Miron (1993), and to daily data integrated at a period of one week by Kunst (1997). These tests are extensions of the well-known Dickey–Fuller test for a unit root at the long-run zero frequency (Dickey and Fuller, 1979) and at the seasonal frequencies (Dickey, Hasza and Fuller, 1984).

The HEGY test is the simplest and most easily applied test for seasonal unit roots. In the quarterly case the test is based on an autoregressive model \( \varphi(L)y_t = \varepsilon_t, \varepsilon_t \sim i.i.d. \) \((0, \sigma^2)\) where \( \varphi(L) \) is a lag polynomial with possible unit roots at frequencies \( \theta = \left\{ \frac{1}{2}, \frac{1}{4}, \frac{3}{4} \right\} \). A rewritten linear regression model where the possible unit roots are isolated in specific terms is

\[
\varphi(L)y_{1t} = \pi_1 y_{1t-1} + \pi_2 y_{2t-1} + \pi_3 y_{3t-1} + \pi_4 y_{4t-1} + \varepsilon_t, \varepsilon_t \sim i.i.d. \) \((0, \sigma^2)\)
\]

The lag polynomial \( \varphi(L) \) is a stationary and finite polynomial by assumption. Denoting integration of order \( d \) at frequency \( \theta \) by \( I_0 \ast(d) \) we thus have \( \varphi_1 = I_{\theta} \ast(0), \varphi_2 = I_{\theta} \ast(1), \) and \( \varphi_3 = I_{\theta} \ast(2) \) where \( I_0 \ast(0) \) is a stationary finite polynomial by assumption.

The HEGY tests of the null hypothesis of a unit root are conducted by ‘\( t \)-value’ tests on \( \varphi(L) = 1 \) and \( \varphi_2 = 1 \) for the long-run unit root, \( \varphi_2 = 1 \) for the semi-annual unit root, and ‘\( F \)-value’ tests on \( \varphi_3 = 1 \) for the annual unit root. In fact, the ‘\( t \)-value’ tests on \( \varphi_1 = 1 \) is just the unit root test of Dickey and Fuller with a special augmentation applied. As in the Dickey–Fuller cases the statistics are not \( t \) or \( F \) distributed but have non-standard distributions, which for the ‘\( t \)’ are tabulated in Fuller (1976) while critical values for the ‘\( F \)’ test are tabulated in Hylleberg et al. (1990).

As in the Dickey–Fuller case the correct lag-augmentation in the auxiliary regression (6) is crucial. The errors need to be rendered white noise in order for the size to be close to the stipulated significance level, but the use of too many lag coefficients reduces the power of the tests.

Obviously, if the data-generating process (DGP) contains a moving average component, the augmentation of the autoregressive part may require long lags (see Hylleberg, 1995) and the HEGY test may be seriously affected by autocorrelation in the errors, moving average terms with roots close to the unit circle, and noisy data with outliers.

The existence of seasonal unit roots in the DGP implies a varying seasonal pattern where ‘summer may become winter’. In most cases such an extreme situation is not logically possible, and the findings of seasonal unit roots should be taken as an indication of a varying seasonal pattern and the unit root model as a parsimonious approximation to the DGP.

Another test where the null is no unit root at the zero frequency is suggested by Kwiatkowski et al. (1992) and extended to the seasonal frequencies by Canova and Hansen (1995), and further developed by Busetti and Harvey (2003). See Hylleberg (1995) for a comparison of the Canova–Hansen test and the HEGY test. See also Taylor (2005) for a variance ratio test.

Arteche (2000) and Arteche and Robinson (2000) have extended the analysis to include non-integer values of \( d \) in the definition of a seasonally integrated process. In case \( d \) is a number between 0 and 1 the process is called fractionally seasonally integrated. The fractionally integrated seasonal process is said to have strong dependence or long memory at a frequency \( \omega \) since the autocorrelations at that frequency die out at a hyperbolic rate, in contrast to the much faster exponential rate in the weak dependence case where \( \omega = 0 \). In the integrated case where \( \omega = 1 \) the autocorrelations never die out.

The difficulty with the fractional model is estimation of the parameter \( d \). Even in the quarterly case there are three possible \( d \) parameters, and the testing procedure may become very elaborate, requiring, for instance, a sequence of clustered tests as in Gil-Alana and Robinson (1997).

**Time series models**

The time series models may be univariate models such as the Box–Jenkins model, unobserved components models, time varying parameter models or evolving seasonal models, or multivariate models with seasonal cointegration or periodic cointegration, or models with seasonal common features.

**Univariate seasonal models**

*The Box–Jenkins model*. In the traditional analysis of Box and Jenkins (see Box and Jenkins, 1970), the time series where \( s \) is the number of quarters, months, and so on, in the year were made stationary by application of the filters \((1 - L)\) and/or \((1 - L^s) = (1 - L)S(L)\), where \( S(L) = (1 + L + L^2 + L^3 + \ldots + L^{s-1})\), as many times as was deemed necessary from the form of the resulting
autocorrelation function. After stationarity had been obtained, the filtered series were modelled as an autoregressive moving average model (ARMA) model. Both the AR and the MA part could be modelled as consisting of a non-seasonal and seasonal lag polynomial. Hence, the so-called seasonal ARIMA model has the form

\[ \varphi(L) \psi(L^s) (1 - L)^D (1 - L)^d \gamma_t = \theta(L) \theta_s(L^s) \varepsilon_t \]  

(7)

where \( \varphi(L) \) and \( \theta(L) \) are invertible lag polynomials in \( L \), while \( \varphi_s(L^s) \) and \( \theta_s(L^s) \) are invertible lag polynomials in \( L^s \), and \( D \) and \( d \) integers.

In light of the results mentioned in the section on seasonal unit roots, the modelling strategy of Box and Jenkins may easily be refined to allow for situations where the non-stationarity exists only at some of the seasonal frequencies.

The 'structural' or unobserved components model. When modelling processes with seasonal characteristics, one must apply complicated and high-ordered polynomials in the ARMA representation. As an alternative to this, the unobserved components model (UC) discussed earlier was proposed. It is easily seen that the UCARIMA model is a general ARIMA model with restrictions on the parameters. Alternatively, the UC model may be specified as a so-called structural model following Harvey (1993).

The structural model is based on a very simple and quite restrictive modelling of the components of interest such as trends, seasonals and cycles. The model is often specified as (4). The trend \( \mu_t \) is normally assumed to be stationary only in first or second differences, whereas the seasonal component \( \gamma_t \) is stationary when multiplied by the seasonal summation operator \( S(L) \). In the basic structural model (BSM) the trend is specified as

\[ \mu_t = \mu_{t-1} + \beta_{t-1} + \eta_t \beta_t = \beta_{t-1} + \zeta_t \]  

(8)

where each of the error terms is independently distributed. (If \( \sigma^2 = 0 \) this collapses to a random walk plus drift. If \( \sigma^2 = 0 \) as well it corresponds to a model with a linear trend.) The seasonal component is specified as

\[ S(L) \gamma_t = \sum_{j=0}^{n-1} \gamma_{t-j} = \omega_t \]  

(9)

where \( s \) is the number of periods per year and where \( \omega_t \sim N(0, \sigma^2) \). (This specification is known as the dummy variable form, since it reduces to a standard deterministic seasonal component if \( \sigma^2 = 0 \). Specifying the seasonal component this way makes it slowly changing by a mechanism that ensures that the sum of the seasonal components over any \( s \) consecutive time periods has an expected value of zero and a variance that remains constant over time.) The BSM model can also be written as

\[ \gamma_t = \frac{\eta_t}{S(L)} + \frac{\sigma_0}{S(L)} + \varepsilon_t \]  

(10)

where \( \xi_t = \eta_t - \eta_{t-1} + \xi_{t-1} \) is equivalent to an MA(1) process. Expressing the model in the form (10) makes the connection to the UCARIMA model in (4) clear.

Estimation of the general UC model is treated in Hylleberg (1986) and estimation of the structural model is treated in Harvey, Koopman and Shephard (2004).
In the structural approach the problems of specifying the ARMA models for the components is thus avoided by a priori restrictions. Harvey and Scott (1994) argue that the type of model above, which has a seasonal component evolving relatively slowly over time, can fit most economic time series, irrespective of the apparently strong assumptions of a trend component with a unit root and a seasonal component with all possible seasonal unit roots present.

**Periodic models and other time varying parameter models.** The periodic model extends the non-periodic time series models by allowing the parameters to vary with the seasons. The so-called periodic autoregressive model of order h (PAR(h)) assumes that the observations in each of the seasons can be described using different autoregressive models (see Franses, 1996).

Consider a quarterly times series $y_t$ which is observed for $N$ years. The stationary PAR(h) quarterly model can be written as

$$
\phi_L y_t = \sum_{l=1}^{h} \phi_l D_{l,t} y_{t-l} + \varepsilon_t
$$

with $s = 1, 2, 3, 4, t = 1, 2, \ldots, T = 4N$, and where $D_{s,t}$ are seasonal dummies, or as $\phi_L y_t = \phi_{1,t} y_{t-1} + \ldots + \phi_{h,t} y_{t-h} + \varepsilon_t$.

It has been shown that any PAR model can be described by a non-periodic ARMA model (Osborn, 1991). In general, however, the orders will be higher than in the PAR model. For example, a PAR (1) corresponds to a non-periodic ARMA(4,3) model. Furthermore, it has been shown that estimating a non-periodic model when the true DGP is a PAR can result in a lack of ability to reject the false non-periodic model (Franses, 1996). Fitting a PAR model does not prevent the finding of a non-periodic AR process, if the latter is in fact the DGP. In practice it is thus recommended that one starts by selecting a PAR(h) model and then tests whether the autoregressive parameters are periodically varying using the method described above.

A major weakness of the periodic model is that the available sample for estimation $N = n / s$ is often too small. Furthermore, the identification of a periodic time series model is not as easy as it is for non-periodic models.

Now, let us rewrite the series $y_{st}, t = 1, 2, 3, \ldots, T$, as $y_{s,t},$ where $s = 1, 2, 3, 4$ indicating the quarter, and $t = 1, 2, \ldots, n$ indicating the year. The PAR(1) process can then be written as

$$
\phi_L y_{s,t} = \psi_1 y_{s,t-1} + \varepsilon_{s,t}, s = 1, 2, 3, 4; t = 1, 2, \ldots, n
$$

where $y_{0,t} = y_{4,t-1}$, or in vector notation

$$
\Phi(L) y_{s,t} = \varepsilon_{s,t}
$$

where

$$
\Phi(L) = \begin{bmatrix}
1 & 0 & 0 & 0 \\
-\psi_2 & 1 & 0 & 0 \\
0 & -\psi_3 & 1 & 0 \\
0 & 0 & -\psi_4 & 1 \\
\end{bmatrix}
\begin{bmatrix}
0 & 0 & 0 & -\psi_1 \\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
\end{bmatrix}
$$
Seasonal adjustment: The New Palgrave Dictionary of Economics

with \( L \) operating on the seasons, that is, \( Y_{S,T} = Y_{S-1,T} \) and especially \( Y_{1,T} = Y_{0,T} = Y_{4,T-1} \). The PAR(1) process in (13) is stationary provided \( |\Phi(z)| = 0 \) has all its roots outside the unit circle, which is the case if and only if \( |\Phi(z)| < 1 \).

The model may be estimated by maximum likelihood or OLS. Testing for periodicity in (11) amounts to testing the hypothesis \( H_0: \phi_{1s} = \phi_i \) for \( s = 1, 2, 3, 4 \) and \( i = 1, 2, \ldots, p \), and this can be done with a likelihood ratio test, which is asymptotically \( \chi^2_p \) under the null, irrespective of any unit roots in \( Y_t \). (see Boswijk and Franses, 1995).

The vector representation of the PAR model forms an effective vehicle for generating estimation and testing procedures directly from the general result for stationary vector autoregression (VAR) models, but it also creates an effective way to handle the non-stationary case and compare the periodic models with the models with seasonal integration.

In the non-stationary case, a periodically integrated process of order 1(PI(1)) is defined as a process, where there exists a quasi-difference

\[
D_\delta Y_{S,T} = 1 - \alpha_1 Y_{S-1,T} \alpha_2 \alpha_3 \alpha_4 \neq 1 \text{ not all } \alpha_j = 1, s = 1, 2, 3, 4.
\]

such that \( D_\delta Y_{S,T} \) has a stationary and invertible representation. Notice that the PI(1) process is neither an integrated I(1) process nor a seasonally integrated process as shown in Ghysels and Osborn (2001).

The periodic models can be considered special cases of what are referred to as the time-varying parameter models (see Hylleberg, 1986). These are regression models of the form

\[
\gamma_t = \chi_t' \beta_t + u_t \Theta(\lambda) (\beta_t - \bar{\beta}) = \Lambda Y_t + \xi_t
\]

which can be written in state-space form and estimated using the Kalman filter. However, the number of parameters is often greater than the number of observations, and in practice one may be forced to restrict the parameter space. Gersovitz and MacKinnon (1978), applying Bayesian techniques, adopt the sensible assumption that the parameters vary smoothly over the seasons.

The evolving seasonals model. The evolving seasonals model was promulgated by Hannan, Terrell and Tuckwell (1970). The model has been revitalized by Hylleberg and Pagan (1997), who show that the evolving seasonals model produces an excellent vehicle for analysing different commonly applied seasonal models as it nests many of them. The model has been used by Koop and Dijk (2000) to analyse seasonal models from a Bayesian perspective.

The evolving seasonals model for a quarterly time series is based on a representation like

\[
\gamma_t = \alpha_1 \cos(\lambda_1 t) + \alpha_2 \cos(\lambda_2 t) + 2 \alpha_3 \cos(\lambda_3 t) + 2 \alpha_4 \sin(\lambda_4 t) = \alpha_1 t^0 + \alpha_2 t^0 (-1)^t + \alpha_3 t^0 + \alpha_4 t^1 + (-1)^t \bar{t}^1 + (-1)^{t-1},
\]

where \( \lambda_1 = 0, \lambda_2 = \pi, \lambda_3 = \pi / 2, \cos(\pi t) = (-1)^t, \cos(\pi / 2) = [1 + (-1)^t], \sin(\pi / 2) = [(-1)^t - (-1)^{t-1}], \bar{t}^2 = 1 \), while \( \alpha, \beta = 1, 2, 3, 4 \), is a linear function of its own past and a stochastic term \( e_{jT}, j = 1, 2, 3, 4 \). For instance,
In such a model, \( x_{1t} \) represents the trend component with the unit root at the zero frequency, \( x_{2t} \) represents the semi-annual component with the root \(-1\), while \( x_{3t} \) represents the annual component with the complex conjugate roots \( \pm i \). In Hylleberg and Pagan (1997) it is shown that the HEGY auxiliary regression in (6) has an evolving seasonals model representation, and also that the Canova–Hansen test and the PAR(h) model may be presented in the framework of the evolving seasonals model.

### Multivariate seasonal time series models

The idea that the seasonal components of a set of economic time series are driven by a smaller set of common seasonal features seems a natural extension of the idea that the trend components of a set of economic time series are driven by common trends. If the seasonal components are seasonally integrated, the idea immediately leads to the concept of seasonal cointegration, introduced in Engle, Granger and Hallman (1989), Hylleberg et al. (1990), and Engle et al. (1993). In case the seasonal components are stationary, the idea leads to the concept of seasonal common features (see Engle and Hylleberg, 1996), while so-called periodic cointegration considers cointegration season by season (see Birchenhal et al., 1989; Ghysels and Osborn, 2001).

**Seasonal cointegration.** Seasonal cointegration exists at a particular seasonal frequency if at least one linear combination of series which are seasonally integrated at the particular frequency is integrated of a lower order. Consider the quarterly case where \( y_t \) and \( x_t \) are both integrated of order 1 at the zero and at the seasonal frequencies, that is, the transformations corresponding to 6 are \( \{ y_{1t}, x_{1t}\} \sim l_0(1) \), \( \{ y_{2t}, x_{2t}\} \sim l_1/4,3/4(1) \), and \( \{ y_{3t}, x_{3t}\} \sim l_1/4,3/4(1) \). Cointegration at the frequency \( \theta = 0 \) then exists if \( y_{1t} - k_1 x_{1t} \sim l_0(0) \) for some non-zero \( k_1 \), cointegration at the frequency \( \theta = 1/2 \) exists if \( y_{2t} - k_2 x_{2t} \sim l_1(0) \) for some non-zero \( k_2 \), while cointegration at the frequency \( \theta = [1/4,3/4] \) exists if \( y_{3t} - k x_{3t} - k_4 x_{2t} \sim l_1/4,3/4(0) \) for some non-zero pair \( \{ k_3, k_4 \} \). The complex unit roots at the annual frequency \([1/4,3/4]\) lead to the concept of polynomial cointegration, where cointegration exists if one can find at least one linear combination including a lag of the seasonally integrated series which is stationary.

In Hylleberg et al. (1990) and Engle et al. (1993), seasonal cointegration is analysed along the path set up in Engle and Granger (1987). The well-known drawbacks of this method, especially when the number of variables included exceeds two, is partly overcome by Lee (1992), who extends the maximum likelihood (ML)-based methods of Johansen (1995) for cointegration at the long-run frequency, to cointegration at the semi-annual frequency \( \theta = 1/2 \).

To adopt the ML-based cointegration analysis at the annual frequency \( \theta = [1/4,3/4] \) with the complex pair of unit roots \( \pm i \) is somewhat more complicated, however. The general results may be found in Johansen and Schaumburg (1999), and Cubadda (2001) applies the results of Brillinger (1981) on the canonical correlation analysis of complex variables to obtain tests for cointegration at all the frequencies of interest, that is, at the frequencies 0 and \( \pi \) with the real unit roots \( \pm 1 \) and at the frequency \( \theta = [1/4,3/4] \) with the complex roots \( \pm i \).

**Periodic cointegration.** Periodic cointegration extends the notion of seasonal cointegration by allowing the coefficients in the cointegration relations to be periodic (see Ghysels and Osborn, 2001). Consider the example given above with two quarterly time series \( y_t \) and \( x_t \), which are integrated of order 1 at the zero and seasonal frequencies implying that a transformation by the fourth difference \( 1 - L^4 \) will make the two series stationary. Such series are called seasonally integrated series. Let us rewrite the series as \( y_{st}, x_{st} \) with \( s = 1, 2, 3, 4 \) indicating the quarter, and \( t = 1, 2, \ldots, n \) indicating the year. Hence, the eight yearly series \( y_{st}, x_{st} \) for \( s = 1, 2, 3, 4 \) are all integrated of order 1 at the zero frequency.

Hence, full periodic cointegration exists (see Boswijk and Franses, 1995) if \( y_{1t} - k x_{1t} - l_{0}(0) \) for some non-zero \( k \), \( s = 1, 2, 3, 4 \). In case stationarity is only obtained for some \( s = 1, 2, 3, 4 \), partially periodic cointegration exists.

Several interesting and useful results reviewed in Ghysels and Osborn (2001) follow:

1. Two seasonally integrated series may fully or partially periodically cointegrate.
2. Two \( I(1) \) processes cannot be periodically cointegrated. They are either non-periodically cointegrated or not cointegrated at all.
3. If two \( PI(1) \) processes cointegrate in one quarter, they cointegrate in all four quarters.

Periodic cointegration is a promising but currently not fully exploited area of research, which has the inherent problem that it requires a large sample. It is therefore not surprising that the recent advances in this area happen when data are plentiful (daily) and it is possible to restrict the model appropriately (Haldrup et al., 2007).
Common seasonal features. Although economic time series often exhibit non-stationary behaviour, stationary economic variables exist as well, especially when conditioned on some deterministic pattern such as linear trends, seasonal dummies, breaks and so on. However, a set of stationary economic times series may also exhibit common behaviour and, for instance, share a common seasonal pattern. The technique for finding such patterns, known as common seasonal features (see Engle and Hylleberg, 1996; Cubadda, 1999) is based on earlier contributions defining common features by Engle and Kozicki (1993) and Vahid and Engle (1993).

Consider a multivariate autoregression written in error correction form as

$$\Delta Y_t = \sum_{j=1}^{p} \beta_j \Delta Y_{t-j} + \Pi v_{t-1} + \Gamma z_t + \epsilon_t, \quad t = 1, 2, \ldots, T,$$

(18)

where $Y_t$ is $k \times 1$ vector of observations on the series of interest in period $t$ and the error correction term is $\Pi v_{t-1}$. The vector $v_t$ contains the cointegrating relations at the zero frequency, and the number of cointegrating relations is equal to the rank of $\Pi$. If $\Pi$ has full rank equal to $k$ the series are stationary. In the quarterly case the vector $z_t$ is a vector of trigonometric seasonal dummies, such as $\{\cos(2\pi n/4 + 2\pi j/4), \sin(2\pi n/4 + 2\pi j/4), h = 1, 2, j \in (-5T \leq j \leq 5T), \sin(2\pi n4 + 2\pi j/4), h = 1, 2, j \in (-5T \leq j \leq 5T), j \neq 0\}$, when $n = 2$. The use of trigonometric dummy variables facilitates the ‘modelling’ of a varying seasonal pattern, since a proper choice of $\delta$ takes care of the neighboring frequencies to the exact seasonal frequencies. If $\delta = 0$, the filter is equivalent to the usual seasonal dummy filter. The implication of a full rank of the $k \times m$ matrix $\Gamma$, equal to $\min[k, m]$, is that different linear combinations of the seasonal dummies in $z_t$ are needed in order to explain the seasonal behaviour of the variables in $Y_t$. However, if there are common seasonal features in these variables we do not need all the different linear combinations, and the rank of $\Pi$ is not full. Thus, a test of the number of common seasonal features can be based on the rank of $\Pi$ (see Engle and Kozicki, 1993).

The test is based on a reduced rank regression similar to the test for cointegration by Johansen (1995). Hence, the hypotheses are tested using a canonical correlation analysis between of $z_t$ and $\Delta Y_t$, where both sets of variables are purged of the effect from the other variables in (18).

This kind of analysis has proved useful in some situations, but it is difficult to apply in cases where the number of variables is large, and the results are sensitive to the lag-augmentation as in the case of cointegration. In addition, the somewhat arbitrary nature of the choice of $z_t$ poses difficulties.

Economic models of seasonality

Many economic time series have a strong seasonal component, and obviously economic agents must react to that. Hence, the seasonal variation in economic time series must be an integrated part of the optimizing behaviour of economic agents, and the seasonal variation in economic time series must be a result of the optimizing behaviour of economic agents, reacting to exogenous factors such as the weather, the timing of holidays, and so on.

The fact that economic agents react and adjust to seasonal movements on one hand and influence them on the other, implies that the application of seasonal data in economic analysis may widen the possibilities for testing theories about economic behaviour. The relative ease with which the agents may forecast at least some of the causes of the seasonality may be quite helpful in setting up testable models for production smoothing, for instance.

Apart from what is caused by the easiness of forecasting exogenous factors, the type of optimizing behaviour and the agents’ reactions to a seasonal phenomenon may be expected not to differ fundamentally from what is happening in a non-seasonal context. However, the recurrent characteristic of seasonality may be exploited.

The economic treatment of seasonal fluctuation has been discussed in the real business cycle (RBC) literature (for example, Chatterjee and Ravikumar, 1992; Braun and Evans, 1995), working with a utility optimizing consumer faced with some feasibility constraint. However, in most of this RBC branch seasonality arises from deterministic shifts in tastes and technology. A few other papers incorporate seasonality through stochastic productivity shocks (see for example Wells, 1997; Cubadda, Savio and Zelli, 2002).

Another area is the production smoothing literature (for instance, Ghysels, 1988; Miron and Zeldes, 1988; Miron, 1996) and habit persistence (for example, Osborn, 1988), where a model for seasonality and habit persistence is presented in a life-cycle consumption model.

The general theorem for the second best optimum states that if there is introduced into a general equilibrium system a constraint which prevents the attainment of one of the Paretian conditions, the other Paretian conditions, although still attainable, are, in general, no longer desirable.

The implication of this theorem was that most of the simple and general guidelines for policy provided by welfare economics – for example, the ‘Paretian conditions’ stating that price should equal marginal cost – would not be relevant for real-world economies which are likely to be subject to constraints on policy. The Lipsey–Lancaster article seems to have come as a shock to economists in general and has since had a significant impact on the theory, and practice, of economic policy. Apparently, until the publication of this article, the conventional wisdom was that it was desirable to pursue a ‘piecemeal policy’, here and there fulfilling the ‘Paretian conditions’ – which, if applied everywhere, would lead to a Pareto optimum – regardless of whether these conditions actually were attained elsewhere.

This state of affairs in 1956 was somewhat puzzling considering that the Lipsey–Lancaster conclusion was not entirely novel. As early as 1909, V. Pareto himself had argued that free trade (which in modern terminology may be interpreted as fulfillment, as far as possible, of the ‘Paretian conditions’) may not be preferable to protection and that individuals may not end up in a better position if one of several distortions to resource allocation were eliminated. Both of these arguments are in line with the general theory of second best. Even closer to the Lipsey–Lancaster result was the statement by Paul Samuelson...
in his *Foundations* (1947, p. 252) that a ‘given divergence in a subset of the optimum conditions necessitates alterations in the remaining ones’.

Second best reasoning had also been prevalent in various areas of applied welfare economics. (For reviews using different perspectives, see Lipsey and Lancaster, 1956; Negishi, 1972; and McKee and West, 1981.) Thus, concerning *optimal pricing* in the presence of monopolies and other forms of imperfect competition, Hicks (1940) had argued that price equal to marginal cost in an industry A is not compatible with efficiency if other industries B are not competitive. As marginal inputs in A at the expense of B are then worth more than is reflected by input prices, the marginal cost confronting A is less than the true social marginal cost and therefore unsuitable as a benchmark for the price in this industry.

Early ‘second best results’ had also been obtained in *public finance*. For example, given that leisure is untaxable, ordinary income taxation cannot be considered more efficient than indirect taxation of one commodity, as in both cases at least one ‘Paretian condition’ (that between commodities and leisure vs. that between the commodity subject to an indirect tax and the other commodities, respectively) is violated. Hence, it is an open question which tax system is the better of these two imperfect alternatives (Little, 1951). Somewhat later, it was shown that a ‘second best optimal’ way of raising a given amount of government revenue, barring the use of lump-sum taxes, was a set of unequal indirect taxes with low tax rates on commodities which are substitutes for leisure and high tax rates on commodities complementary to leisure (Corlett and Hague, 1953). In fact, a similar result had already been obtained by Ramsey in 1927. These cases clearly illustrate that when all ‘Paretian conditions’ cannot be met, it may not be efficient to fulfill some of them.

The field of *trade policy* had been especially rich in providing examples of second best reasoning. Viner (1950) showed that in a world of trade protection, a reduction of some trade barriers or introduction of a customs union for some of the trading countries – both of which constitute steps towards free trade and the fulfillment of some of the ‘Paretian conditions’ – will not necessarily increase efficiency in world production. In the customs union case, the explanation is that the positive welfare effect of trade creation within the union may be outweighed by the negative welfare effect of trade diversion between member countries and the rest of the world.

Meade (1955a; 1955b) dealt with a number of trade policy problems as well as some domestic policy problems where it would not be possible to reach a Pareto optimum – or Utopian optimum, as he tellingly called it. Assuming the existence of several market imperfections and efficiency-distorting policy interventions, he analysed the effect of reducing or eliminating one of them and tried to determine what policy rule would perform better. Meade coined the term ‘theory of second best’ for this type of policy analyses whose real-world relevance and basic similarities were elucidated especially in his *Trade and Welfare* (1955a).

In retrospect, it may be argued that the catalogue of separate but similar policy issues in distorted economies provided by Meade goes as far as the theory of second best has reached. But Lipsey and Lancaster were the ones who put second best problems on the map of the average economist. This was accomplished by their attempt to present a general theory of second best, covering the main characteristics of the particular cases dealt with by Meade and others up to that point. Although their 1956 article contained a number of comments on these particular cases as well as reservations on their general theory, it was their concise version of this theory that gained most of the attention.
The Lipsey–Lancaster general theorem of the second best departs from ‘the typical choice situation in economic analysis’ where an objective function $F(x_1, \ldots, x_n)$ is to be maximized or minimized subject to a constraint $\Phi(x_1, \ldots, x_n) = 0$. Lipsey and Lancaster called the solution to this problem the Paretian optimum. To make the problem explicitly harmonize with what is generally meant by a Paretian optimum, we may interpret $x_1, \ldots, x_n$ as the elements of the consumption vectors of all individuals in the economy in some given order ($x_1$ being Alpha’s consumption of commodity I, $x_2$ Alpha’s consumption of commodity II, and so on, up to $x_n$, the last individual’s consumption of the last commodity). As in most of the literature on the subject, we assume for simplicity that the objective function reveals an interest in efficiency alone (that is, attaining any Pareto optimum) and not in distribution (that is, one particular Pareto optimum).

Optimizing $F(\cdot)$ subject to $\Phi(\cdot)=0$, where $\Phi$ can be seen as the transformation function specifying the constraint given by available technology and initial resources, we get the following necessary optimum conditions (assuming that all functions are well behaved):

\[
\frac{F_i}{F_n} = \frac{\Phi_i}{\Phi_n} = 1, \ldots, n-1.
\]  

(1)

These ‘Paretian conditions’ – or first best Pareto optimum conditions as they are now commonly called – may be interpreted as requiring equality between the marginal rates of substitution and the marginal rates of transformation. The purpose of deriving these conditions in the present context, it should be stated explicitly, is (a) to check whether they are fulfilled in a particular situation and, if they are not, (b) to provide guidelines for policy.

Lipsey and Lancaster then tried to formulate an additional constraint which would cover most of what the literature had observed as obstacles to achieving a first best Pareto optimum. They attempted to accomplish this about as generally as when the function $\Phi$ is taken to represent the production constraint of the economy. They argued that, if for some reason monopoly elements, externalities or other so-called imperfections were ‘out of bounds’ for policy intervention, one of the conditions (1) could not be fulfilled due to a constraint

\[
\frac{F_1}{F_n} = k\Phi_1 / \Phi_n
\]

(2)

with $k \neq 1$ and $k$ – ‘for simplicity’ – assumed to be constant. The resulting problem amounts to the optimization of the Lagrangean function

\[
F - \lambda \Phi - \mu(F_1 / F_n - k\Phi_1 / \Phi_n)
\]
where \( \lambda \) and \( \mu \) are Lagrangean multipliers. A solution to this problem, it should be noted, is also a Pareto optimum as it does not allow anyone to become better off without making someone else worse off, given the two constraints now in force. The necessary optimum conditions can be written

\[
\frac{F_i}{F_n} = \frac{\Phi_i + (\mu / \lambda) (Q_i - kR_i)}{\Phi_n + (\mu / \lambda) (Q_n - kR_n)}, \quad i = 2, \ldots, n - 1
\]

where

\[
Q_i = \langle F_n F_1_i - F_1 F_n_i \rangle / F_n^2 \quad \text{and} \quad R_i = \langle \Phi_n \Phi_1_i - \Phi_1 \Phi_n_i \rangle / \Phi_n^2.
\]

Aside from some special cases (see below), this means that, in second best optimum, \( F_i / F_n \neq \Phi_i / \Phi_n \), from which follows the theorem quoted in the introduction.

These second best optimum conditions are obviously quite complicated – in fact, so complicated that in many cases a great deal of detailed information would be required even to determine the signs of the second derivatives \( F_{ni}, \Phi_{ni} \), etc. Hence, it would often be impossible to know whether in second best optimum \( F_i / F_n > \Phi_i / \Phi_n \) or the opposite. Moreover, it is no longer possible to translate the second best optimum conditions into intuitively simple relationships between price and marginal cost, which was true for (some of) the first best optimum conditions (eq. 1).

The great impact of this result on economists in general must be attributed to the simplicity of the theorem itself, given that, in essence, the same thing had been said on earlier occasions. A large part of the ensuing debate concerned whether this simplicity was warranted by real-world conditions. In particular, \( a \) the origin and form of the additional constraint were questioned. A second dominating issue in the debate concerned \( b \) the complexity of the rules for second best policy and attempts at identifying important cases where simple first best optimum conditions are still valid in second best situations. We deal with these two issues in turn.

**The nature of the additional constraint**

In regard to the alleged generality of the formulation of the Lipsey–Lancaster theory, the question was asked: What exactly does this constraint (2) stand for? Clearly, the optimization problem in the ‘second best literature’ refers to a national government or an independent unit of government (such as a public
second best: The New Palgrave Dictionary of Economics

monopoly) which operates as if it tried to optimize function F. Obviously, the government-unit perspective (represented for example, by, the work of Davis and Whinston, 1965; 1967, and developed by McFadden, 1969) could allow a number of constraints like (2) concerning variables that are out of reach for this unit. But what about additional constraints imposed on the overall allocation problem confronting the national government? Here, two interpretations have been considered in the literature. First, for an initial state of the economy in which one of the conditions (1) is violated, it may be technically impossible for the government to have this condition fulfilled along with all the others. For example, markets for certain commodities such as specific kinds of insurance may not be possible to introduce or may be too costly to administer. Or it may be impossible or prohibitively expensive to correct for certain externalities or instances of imperfect competition. Likewise, when the government, in an attempt to attain a feasible Pareto optimum, needs to raise money for subsidies or for the production of public goods, there may not be any non-distortive taxation scheme available (note, for example, the ‘impossibility’ of taxing leisure assumed above).

It should be noted that constraints of this technical type are irremovable, in the same way that the constraint imposed by the transformation function is irremovable. Thus, if a market economy does not by itself reach a first best Pareto optimum, the government could not reach one either when policy constraints of this type are strictly binding. Then, a Lipsey–Lancaster Paretian optimum does not exist and the only optimum conceivable is in fact what has here been called a second best optimum (see, for example, McKee and West, 1981).

Second, the constraint (2) can be interpreted as a behavioural constraint on policy, reflecting the fact that certain measures, although technically speaking feasible and in principle capable of removing the restraint, are not at the government’s disposal or just not believed to be so. For example, the law may prohibit or delimit the use of a specific policy instrument. Or the government may have other and hierarchically higher goals than Pareto optimality: it may for example, simply dislike nationalization of certain industries. Or the government may want to avoid the use of a policy for ‘political reasons’, believing, for example, that it would lose the next election if this policy was used. Traditions, idiosyncrasies, and so on could play a similar role. Economists who have paid attention to the origin of constraints like (2) seem to have adhered primarily to this ‘behavioural’ interpretation.

Obviously, the ‘behavioural’ type of constraint need not be such that all policies with the same effects on the objective function are restrained to the same extent. (For a different perspective which holds that constraints are or should be, in some narrow sense, ‘rational’, see Faith and Thompson, 1981.) For example, assume that there are two policy instruments, say, a tax and a regulation, each of which, if unconstrained, would have attained the first best, as $k$ could then be made equal to 1, but that policy now is constrained so that just one of them is ruled out. If so, a constraint of type (2) would not exist. This means that, in general, it is not possible to presume what constraints on policy instruments imply in terms of the relations between endogenous variables such as the marginal rates of transformation and substitution in (2). (Actually, the literature has not been able to present any great number of cases where policy constraints yield an expression like (2) with $k$ constant and not equal to one.) Instead, to obtain a solution to the allocation problem, it must be specified exactly what the actual constraints on policy instruments are, that is, to what domain or what combinations with other instruments or variables each policy instrument is restricted.

Specifying the policy constraints in this way has some important implications for a general theory of
second best (McManus, 1959; 1967; Bohm, 1967).
First, it cannot be known beforehand whether policy constraints prevent the attainment of a first best optimum or not.
Second, the actual impact of policy constraints, including now also the technical ones mentioned earlier, will depend on the actual behavioural properties of the agents operating in the market economy. Thus, actual rules of market behaviour would, at least in principle, have to be added as constraints on the objective function along with the constraints on policy.
Third, the many possible forms of the policy constraints imply that there cannot be any general second best optimum conditions in the sense that there exist general first best optimum conditions (when no policy constraints exist) in terms of a specific relationship between marginal rates of substitution and marginal rates of transformation. In fact, constraints on policy instruments will require that the optimum-feasible solution be derived directly in terms of optimum-feasible values for the policy instruments.
Thus, there would not even be any role for policy guidelines in the form of second best conditions such as (4). This, of course, does not preclude the existence of special cases, which ex post turn out to coincide with the Lipsy–Lancaster formulation. These are the cases where the constraint on policy happened to affect only the relationship between one marginal rate of substitution and one marginal rate of transformation exactly in the way specified by (2), with no impact whatsoever on the use of policy instruments that could influence other such rates in the economy.
Given that additional constraints on the allocation problem can have any shape – with (2) being a possible ex post formulation of one of many special cases – the use of the term ‘second best’ becomes somewhat unclear. Should a second best problem be defined as an allocation problem with constraints on policy regardless of whether a first best optimum will turn out to be impossible? Or should it be reserved for such problems where analysis will eventually show that a first best optimum cannot be reached? Although the second alternative is in line with the intended problem formulation in Lipsey–Lancaster, it is obviously inconvenient as it cannot be used until after the problem has been solved. The term second best optimum, on the other hand, is predominantly used for a constrained optimum not equal to a first best optimum and is not likely to cause much of a problem. Hence, a practical, and nowadays probably the dominant, terminology is to distinguish between first best and second best problems according to the first-mentioned definition, where a second best problem may have a first best or a second best optimum solution.

First best rules for second best problems

To deal with the second issue prominent in the literature on second best, we return to the problem as it was formulated by Lipsey and Lancaster. They had argued that second best conditions, in contrast to first best ones, were so complicated and required so much information that, on this account, the conditions could not be used for practical policy. This spurred a number of economists to undertake a rescue operation, in which they tried to show that in many instances the simple first best conditions would still be relevant for the controllable part of the economy. To the extent this was true, it would restore at least part of the relevance of piecemeal policy, that is, policy guided by principles which are unaffected by the exact nature of the circumstances in the uncontrollable part of the economy.
First, it has been pointed out that first best rules may be optimal even with the particular Lipsey–
Lancaster formulation of the second best problem, for example when $Q_i - kR_i = Q_j - kR_j = 0$; $i, j = 2, \ldots, n$; $i \neq j$ (see Santoni and Church, 1972; Dusansky and Walsh, 1976; Rapanos, 1980). Similar special cases may be found for other forms of additional constraints on the objective function (Mishan, 1962).

Second, and of more general interest for practical policy, it was pointed out that if the additional constraints affect only a limited set of markets in the economy, the relation between this sector and the remaining ‘perfectly controllable’ sector may be such that first best conditions are optimal in the latter sector even when they turn out to be unattainable in the former sector. This must be true, of course, if the two sectors are completely independent of each other with different primary inputs, no input deliveries between the sectors and different final consumers. Approximately the same results hold if interdependence between sectors is negligible, for example due to one of the sectors being relatively small (Mishan, 1962).

Other attempts at identifying similar cases of separability have been made without much success in terms of general and easily applicable principles for ascertaining when the first best optimum conditions that are still attainable should in fact be attained. Moreover, the very idea of identifying two sectors, one of which is imperfectly controllable, has appeared to be less and less attractive as a description of the real world. Instead, in most countries, income taxes, distorting institutional rules and regulations, and so on emerge as irremovable constraints affecting the economy as a whole. Moreover, as the typical allocation problems confronting real-world governments are beset with a multitude of policy constraints – technical as well as behavioural – it is only by pure chance that optimum conditions for the irrelevant first best problem can be found to be a priori relevant. This does not mean, of course, that first best optimum conditions never will turn out to be valid in second best optimum or that information may not be so inadequate that these conditions appear to be acceptable as a rule of thumb (see Ng, 1977).

Thus, the outcome of the literature on general second best theory up to this point is disillusioning in several respects. There do not seem to be any general second best problems of the type formalized by Lipsey and Lancaster, much less any general second best optimum conditions. Granted that there remains some disagreement on the purpose of second best theory, what has emerged from the literature by way of a general description of second best problems can be summarized as follows:

All economies – even real-world centrally planned economies – have at least some (most often, a very large number of) given behaviour functions which contribute to determining the outcome of any policy ‘intervention’. Hence, these functions must be observed in the formulation of the allocation problem; or, which is the same thing, they must be included as constraints on the optimization of the objective function. ‘At the same time, the authorities have at their command a set of policy instruments which enter these functions as arguments. The optimum is then found by [optimizing the objective function] subject to all the constraints over the domain of these instruments. Indeed the whole problem has little practical interest without some such explicit policy formulation’ (McManus, 1967, p. 321). The fact that this is a highly demanding analytical task in actual practice requires simplifications and approximations of the models to be used, but it cannot justify an oversimplification of the actual problem to be tackled. This in effect may seem to take us back to the case-by-case approach of applied welfare economics that was used by Meade and others in the beginning of the 1950s (represented in later and technically more elaborate studies by, for example, Boiteux, 1956; Rees, 1968; and Guesnerie, 1975). However, matters have changed in one important respect since then. Much more empirical knowledge is now available concerning behaviour of individual markets which in itself improves the outlook for practical second
This is not to say that attempts to construct a general theory of second best have not made a significant contribution to economic theory and policy. Should one result be highlighted, it may quite likely be the general theorem of second best as quoted in the introduction. If nothing else, this theorem has probably made economists more careful when providing governments with policy prescriptions.

second economy (unofficial economy)

Michael Alexeev
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The second (shadow, unofficial) economy played a major role in Soviet-type economies (STEs) and served as a precursor of unofficial sectors in the transition economies. This article lists the main causes of the second economy, outlines approaches to its measurement, and examines its effect on the economic performance of the STEs. The main focus is on the unofficial economy during transition to markets. The article presents estimates of the unofficial economy, describes negative externalities that it generates, discusses reasons for its different size and dynamics in different countries, and outlines approaches to reducing it. Positive aspects of the unofficial economy are also noted.

Keywords

bribery; command economy; corruption; developing economies; entrepreneurship; informal economy; liberalization; path dependency; price control; public goods; rationing; repressed inflation; rule of law; second economy; shadow economy; Soviet economic reform; speculation; state-owned enterprises; tax evasion; transfer pricing; transition and institutions; trust; unofficial economy; wealth effects

Article

The second economy in the Soviet-type command economies (STEs) was defined by Grossman (1977) as all economic activities that are either undertaken directly for private gain or are knowingly illegal in some substantial way. Both legal and illegal economic activities fall within this definition. The second economy served as a precursor of the unofficial sector in the economies in transition. Accordingly, the institution of unofficial economy in transition is properly understood as an heir to the second economy in the STEs.

The official primary coordination mechanism in the STEs was central planning. The well-known difficulties with implementing this mechanism created both the incentives and the opportunity for the existence of a large second economy. The scope of the legal part of the second economy depended on
the laws of a given STE, but it usually included private agriculture, small-scale construction, certain professional services (for example, lawyers working privately), and so on. While the legal second economy was important, it was usually smaller than the illegal sector, also referred to as unofficial, underground, shadow economy, or black or parallel markets. Moreover, the concept of legal second economy is not applicable to market economies. Accordingly, this article focuses on the unofficial economic activities both in the STEs and during transition to markets, with less attention devoted to the legal second economy in the STEs. For the economies in transition, the unofficial economy is defined here as all value-added market-based economic activities that either evade taxation or are not registered, or both.

The most common illegal economic activities performed by individuals in the former USSR and other STEs were the theft of state property, corruption, and ‘speculation’ defined as resale of goods by individuals for profit (Grossman, 1979). While the first two types of activities are present in all modern economies, the dominant role of the state and state-owned enterprises made these activities particularly widespread in the command economies. The general illegality of speculation was unique to the STEs. Other significant illegal economic activities included unofficial production by individuals and small teams, much of it taking place at state-owned enterprises on company time and using state-owned equipment.

The unofficial economic activities among individuals in the STEs were mainly caused by pervasive price controls, prohibition of many private economic activities that are common in market economies, high taxes on the permitted activities, ubiquitous and poorly protected public property, enormous discretionary power of the bureaucracy, and social attitudes that accommodated economic crimes that did not directly harm specific individuals. None of these causes was unique to the STEs, but their rarely found confluence provided a hospitable environment for the unofficial economy, so that the entire system could be called a quasi-market economy (Leitzel, 1995). In many STEs the second economy was a normal part of everyday life for a typical consumer (see Grossman, 1977; 1979; 1989, for fascinating descriptions related to the former USSR).

A large ‘shadow economy’ existed also among socialist enterprises. Much of it had to do with the informal or semi-formal exchanges of goods between state-owned enterprises performed without the prior direction by the planners. Such exchanges, even when legal by themselves, were often accompanied by illegal side payments and other informal inducements. In addition, enterprises sometimes hired labour or acquired other inputs from individuals in the unofficial economy.

Measuring the unofficial economy

The more or less precise dimensions of the illegal economy are all but impossible to ascertain. The approaches to measuring it in various countries are reviewed by Schneider and Enste (2000). With respect to STEs and the economies in transition, the two most commonly used methods have been the surveys of either consumers or firms, and the electricity consumption method. Both approaches have certain advantages and disadvantages. Unless a survey is conducted among emigrants, as was usually the case prior to the collapse of the Communist regimes, the survey questions about unofficial economy are often indirect. For example, the consumers may be asked about their expenditures and official incomes and savings. If reported expenditures exceed legitimate incomes, the difference can serve as a basis for
estimating unofficial income. In surveys of firms, the managers may be asked about hidden sales in their industry rather than in their specific firm. The reliability of the survey method depends crucially on the sample selection and on the veracity of the respondents’ answers.

The electricity consumption approach assumes a close connection between electricity consumption and the true size of economic activity in a country. In the simplest case, the elasticity of electricity consumption with respect to the combined official and unofficial GDP is taken to be one, implying that the dynamics of electricity output coincides with the dynamics of total GDP. Assuming some initial size of the unofficial economy and knowing the change of the official GDP would then permit calculating the change in the size of the unofficial sector. The two main disadvantages of this method are the need to know the initial size of the unofficial economy and the elasticity of electricity consumption by GDP. The latter information is particularly difficult to infer for the economies in transition that are undergoing structural reforms and experiencing large changes of relative prices. However, an important advantage of this approach is its ease of implementation in a uniform fashion across time and countries. Moreover, it can be used to extrapolate a point estimate of the unofficial economy both into the future and into the past.

Among the major STEs, survey-based estimates of the second economy have been published only for the former USSR. The estimates based on the surveys of Soviet emigrants relate to the second half of 1970s and range approximately between ten per cent and 30 per cent of incomes of urban households. (The lower estimate is due to Ofer and Vinokur, 1992. The higher estimate is from Grossman, 1991.) An alternative set of estimates based on the Soviet-era official family budget survey data puts the second economy at around 23 per cent of household income (Kim, 2003). Using these estimates to obtain the shares of second economy in GDP is difficult, however, particularly because no estimates of the shadow economy among the socialist enterprises have been published. The size of the second economy also varied greatly across the former Soviet republics. In the Caucasus and in central Asian republics both legal and illegal private economic activities were widespread, while in the Baltic republics the second economy was relatively insignificant (Grossman, 1991; Kim, 2003; Alexeev and Pyle, 2003).

Kaufman and Kaliberda (1996) cite a number of micro studies of the unofficial economy in east European countries in the early 1990s and extrapolate these estimates backwards to 1989 using the electricity consumption method. The results range from six per cent of GDP in Czechoslovakia to over 20 per cent of GDP in Bulgaria, Romania and Hungary.

The unofficial sectors in the economies in transition have been measured by the above methods as well as by currency demand method and the latent variable estimation. The former approach estimates a currency demand function for a country and assumes that all ‘excess’ demand for cash relative to this demand function is due to the growth of the unofficial economy. The latter approach uses latent variable estimation techniques to infer the size of the unofficial economy as an unobserved variable influenced by a number of different factors and affecting several observed economic indicators. Each of these methods has its strengths and weaknesses that are discussed in Schneider and Enste (2000) and Schneider (2005). The latter work combines the two approaches to estimate the unofficial economy as a share of GDP in 110 countries in year 2000 and some earlier years. The 2000 estimates for the economies in transition range from 13.1 per cent in China to over 60 per cent in Georgia and Azerbaijan.

The quantitative importance of the second economy raises the issue of the nature of its impact on welfare, on the ‘first’ economies, and on the attempts at partial reform. More important for the
The second economy (unofficial economy): The New Palgrave Dictionary of Economics

Economics of transition is the transformation of the relationship between the official and unofficial economies and the dynamics of the latter as a result of radical market-oriented reforms.

The second economy's impact on the STEs

The second economy appears to be necessary for the survival of an STE. The marginal effect of the second economy's expansion is less clear. A growing second economy increases the influence of market forces on a STE, obviating various types of non-price rationing and correcting some resource misallocations. For instance, rationing was undermined even for such a seemingly easy-to-control good as residential housing (Alexeev, 1988). Also, certain theoretical concepts applied to a STE such as ‘forced savings’ or ‘monetary overhang’ become questionable in the presence of a developed second economy (Alexeev, Gaddy and Leitzel, 1991). On the other hand, second economy growth may have significant negative effects, as is discussed later.

Ericson (1983) provides the first formal analysis of the second economy's impact on the official sector. In his model, enterprise manager \( i, i = 1, \ldots, n \), receives a planned output target, \( \bar{y}^i \in R^+ \), and the input allocations given by \( \omega^i \in R^{m+1} \), where the first component, \( \omega_0 \), represents the amount of official funds and the last \( m \) components denote the amounts of material inputs. The production function is described by \( f^i: x^i \rightarrow R^+ \), where \( x^i \in R^m_+ \) is the set of all feasible combinations of material inputs. Given \( f^i \), the plan is not necessarily feasible. The manager's preferences are represented by a utility function monotonic in \( x^i_0 \in R^+ \), and \( \bar{y}^i = f^i(x^i) \). If the initial inputs are misallocated, the managers have incentives to trade legally at the official prices \( p = (1, p_1, \ldots, p_m) \). However, these fixed prices are not likely to equilibrate the secondary market. The disequilibrium generates incentives for the managers to induce other managers to trade by offering informal side-payments from the manager's hidden slush fund of loose cash, the initial amount of which is \( c^i \). The flexible prices in this informal market are denoted by \( a = (0, a_1, \ldots, a_m) \in R^{m+1} \). It is also assumed that a fixed proportion, \( \alpha \), of this cash ‘sticks’ to the palms of individuals who handle the transactions. Given this leakage, the manager faces the following problem (index \( i \) is suppressed):

\[
\text{Max}_{z} \{u(x_0, f(x))\} \quad \text{s.t.} \quad pxz \leq 0 \quad \text{and} \quad az \leq \epsilon - \alpha(a_+z_+ + a_-z_-),
\]

where \( z_j = x_j - \omega_j, \quad j = 0, 1, \ldots, m \), represent trades of inputs among managers and cash prices of material inputs may be either positive or negative, depending on whether payment is necessary to induce a purchase or sale. In addition, \( z_+ \equiv \max(0, z) \) and \( z_- \equiv \max(0, -z) \), with \( a_+ \) and \( a_- \) defined similarly. Note that \( a_0 = 0 \), reflecting the assumption that the official funds cannot buy cash and there is no need for financial inducements to transfer official funds. (As is discussed below, the wall between the official funds and loose cash had seriously eroded by the late 1980s as a result of partial reforms in the
second economy (unofficial economy): The New Palgrave Dictionary of Economics

USSR and other STEs. This erosion was in part responsible for the eventual collapse of the command economic system.

Under certain technical conditions, this exchange economy has a suitably defined equilibrium, and any trades that occur with the inducement of loose cash represent a Pareto improvement. Given the managers’ preferences, the second economy in this model always enhances plan fulfillment. (This equilibrium, however, is not in general constrained Pareto-optimal – where the ‘constraint’ is given by $\rho_2 \leq 0$ – because the leakage might stop trading before Pareto optimal allocation is reached.)

Of course, the first economy and the overall economic welfare may suffer if the official plans are inefficient. Also, the second economy always enhances plan fulfilment in Ericson's framework only because enterprise managers’ preferences do not exhibit a trade-off between plan fulfillment and personal gain from unofficial dealings. Ericson's model takes no account of the potential negative externalities that the second economy transactions can create in an otherwise distorted economy. Some of these externalities are examined by Stahl and Alexeev (1985) in a model of a queue-rationed exchange economy. Here, N consumers face inelastic supply of goods $x \in R^n_+$ with a fixed official price $p_1 \in R^n_+$. If a shortage arises, the demand is rationed by queues with a deterministic waiting time $\tau \in R^n_+$. Consumers are endowed with money, $M_i$, and leisure, $L_i$. Consumer $i$ has well-behaved preferences $u_i(x, l)$ with respect to consumption of goods, $x_i \in R^n_+$, and leisure, $l_i \in R_+$. In the absence of black markets, each consumer solves (superscript $i$ is suppressed):

$$\text{Max}_{x, l} u(x, l) \text{ s.t. } p_1 x \leq M \text{ and } \tau x + 1 \leq L$$

An appropriately defined equilibrium that requires no excess demand always exists. Black markets are introduced by allowing consumers to resell goods they have purchased in the official markets. Denote the black market trades by $y^i \in R^n$, with $y^i_j > 0$ if the consumer buys the corresponding good and $y^i_j < 0$ if he sells. Black market prices, $\rho_2 \in R^n_+$, are flexible. The new budget constraints become (superscript $i$ is suppressed):

$$p_1(x - y) + p_2 y \leq M$$

$$\tau(x - y) + 1 \leq L$$

A necessary condition for no excess demand is $p_2 = p_1 + w\tau$, where $w$ is interpreted as an implicit wage for standing in line. Accordingly, the additional requirements for an equilibrium include $p_2 = p_1 + w^*\tau^*$ and $\Sigma \lambda = 0$. Equilibrium exists if $\Sigma M \leq p_1\lambda$. Given the aggregate queuing time and $p_1$, the equilibrium with black markets is efficient while this is not usually true in the absence of black markets.

The main insight, however, is that the introduction of black markets does not always result in a Pareto improvement over pure queue rationing. This happens because black markets create wealth effects that may result in longer queues. Nonetheless, in this framework the poor typically prefer queuing with black markets to pure queue rationing (Polterovich, 1993). The comparisons for the rich are ambiguous.

In addition to the above effects, the unofficial economic activities both in the consumption sector and among socialist enterprises reduce the feedback to the policymakers from their actions by covering up policy consequences and resource misallocations, and rendering the official statistics, including those on consumer incomes, savings, consumption and employment, less relevant. Also, the efficiency of unofficial transactions is reduced by the need for secrecy, which impedes information flows within black markets and limits the range of available contract enforcement mechanisms, resulting in greater uncertainty and a suboptimally small scale of operations, among other things. Moreover, the potential profitability of illegal transactions breeds corruption and weakens the official institutions.

On balance, the effect of the second economy on the official economy and on overall welfare is theoretically ambiguous on the margin.

**The second economy's impact on pre-reform crises and on reforms within an STE**

As a command economy matures and becomes increasingly complex, the functioning of the traditional administrative coordination mechanism deteriorates. Many STEs responded to their worsening economic situation by introducing reforms aimed at liberalizing parts of the economy, particularly labour markets and consumer-oriented sectors. Such partial reforms had generally failed to improve overall economic performance, largely because of the second-best considerations. Black markets, however, may alleviate some of the adverse consequences of partial reforms. For example, Boycko (1992) and Osband (1992) demonstrate that wage increases caused by partial liberalization of labour markets in an STE lead to a cycle of greater shortages, longer queues, and, therefore, lower output if prices of consumer goods remain fixed. This ‘pre-reform crisis’ is moderated when black markets are brought into the picture, because the additional queuing is done mainly by lower-productivity agents who can then resell the goods in black markets while without the unofficial economy everybody has to queue up more (Alexeev and Sabyr, 2004). In another example, Leitzel (1998) shows beneficial effects of black markets by introducing them into a simple model of repressed inflation developed by Lipton and Sachs (1990). In Leitzel's model, retail trade employees divert goods in short supply to black markets, thereby reducing welfare losses due to rising repressed inflation and pre-empting the adverse distributional consequences of full price liberalization.

The presence of black markets may also worsen the effects of partial reforms. Consider, for example, the so-called ‘dual track’ partial reform mechanism (Lau, Qian and Roland, 2000). It attempts to conduct
reforms in a Pareto-improving fashion by preserving the output and supply quotas that exist in an STE while liberalizing the markets for the above quota output. If the government can enforce the pre-reform quotas, this mechanism avoids the potential severe misallocation of resources due to partial liberalization emphasized by Murphy, Shleifer and Vishny (1992) and, at the same time, prevents excessive redistribution that may result from full liberalization. However, the violation of pre-reform quotas via the unofficial trades can generate large rents. If such violations are allowed to take place, resource misallocation may easily occur.

The growth of the second economy by itself represents an implicit market reform of an STE, so that partial reforms simply provide an official permission for certain unofficial activities that have been already widespread (Leitzel, 1995). In part, the second economy growth pre-empts the potential negative effects of full liberalization, making radical market reforms politically more acceptable. In addition, the second economy familiarizes the general population with the workings of the market, develops trust and entrepreneurship, thereby facilitating popular acceptance of the market mechanism (Grossman, 1989). However, to the extent the second economy improves the functioning of the overall economy, it also reduces the potential benefits of full liberalization relative to the unreformed or partially reformed economy and, therefore, may postpone radical reforms.

Whatever the impact of the second economy on the performance of partial reforms, it is clear that historically such reforms spurred an explosive growth of the unofficial sector in the STEs. Leitzel (2003) argues that this growth was unavoidable given partial relaxation of state controls that made evasion harder to detect while leaving most of the formal distortions in place. In the USSR, for example, the permission of crypto-private firms and transactions between them and state-owned enterprises greatly reduced the ability of central planners to monitor state-owned enterprises. Enterprise managers then employed transfer pricing schemes and self-dealing to channel state-provided resources to private firms related to the managers. Tax collections plummeted while subsidies increased, undermining the state budget and the entire state sector.

The unofficial economy during transition to markets

Radical market reforms of the STEs seek to turn these economies, including most of their unofficial sectors, into well-functioning legal markets. Due to general economic liberalization, particularly the removal of such a major cause of black markets as price controls, the unofficial economies can be expected to diminish. This indeed seems to have occurred in some countries, but not in others. Using the electricity consumption approach, Johnson, Kaufmann and Shleifer (1997) estimate that between 1989 and 1995 the unofficial economy grew significantly in Russia, Ukraine and some other former Soviet republics while it remained approximately the same in Hungary, Slovakia and Estonia, and declined noticeably in Poland. (Note that the electricity consumption approach attributes the entire change – decline – in measured output relative to electricity consumption to the unofficial economy. Alternatively, the dynamics of GDP-to-electricity consumption ratios in these economies could have been influenced by relative prices and availability of electricity, government policies with respect to energy conservation, and the changing structure of the economy.)

Also, according to Johnson, McMillan and Woodruff (2000), private manufacturing firms in Russia and Ukraine tend to hide their activities from tax authorities on a dramatically greater scale than do their
second economy (unofficial economy): The New Palgrave Dictionary of Economics

counterparts in eastern Europe. The firms in Russia and Ukraine under-reported around 30–40 per cent of their sales and 25–40 per cent of their employee salaries, as compared with five to ten per cent in Poland, Slovakia and Romania.

On the assumption that the measurements are approximately correct, what may explain such different dynamics? One answer relies on path dependency that arises from the possibility of multiple equilibria in the relationship between the official and unofficial economies. Consider, for example, a labour allocation model by Johnson, Kaufmann and Shleifer (1997). The aggregate amount of labour normalized to one is allocated between the official economy (subscript $F$) and the unofficial sector (subscripted by $I$), $L_F + L_I = 1$. The agents in each sector $J=F, I$ maximize their utilities, $U_J = (1-t_J)Q_J$, where $t_J$ is the tax rate and $Q_J$ denotes the quantity of the output-enhancing public good in each sector by, respectively, the government and the mafia. ($Q_J$ can be used only by sector $J$ agents.) Let $Q_J = (T_J)^\beta$, where $T_J = t_J Q_J L_J$ is aggregate tax revenue collected in sector $J$. This model has an unstable interior equilibrium and two stable corner equilibria: in one $L_F=L, L_I=0$, and in the other $L_F=0, L_I=L$. Therefore, depending on the initial conditions, the economy may end up either entirely above or below ground. If parameter $\beta$ is greater in the official economy than in the unofficial sector, the latter equilibrium is inefficient.

An important assumption in this model is that, while the government is hurt by labour escaping underground, it does not attempt to either stop the escape or fight the mafia that facilitates underground activities. Roland and Verdier (2003) show that one reason for government passivity may be the lack of resources for law-enforcement activities. Suppose economic agents choose between becoming producers and predators. Producers pay taxes to fund law enforcement to fight off predators. The more agents become producers, the greater are the resources for law enforcement. That is, similarly to Johnson, Kaufmann and Shleifer (1997), a fiscal externality is present. Assume also that law enforcement has fixed costs in order to become effective and that a ‘compliance externality’ exists, so that the probability of a predator being punished is inversely related to the number of predators. Under certain assumptions on the utilities of producers and predators, this model again has multiple equilibria, in some of which the government lacks the resources to fight the predators. (The government may also refrain from fighting the mafia that provides public goods underground because the presence of predatory mafia actually benefits predatory government. Alexeev, Janeba and Osborne (2004) demonstrate that, when public goods are expensive to provide, the state has higher revenues in the economy with the mafia than without it. This is because, when public goods provision is difficult and few of them are provided, the main effect of the mafia is to increases the costs of underground economic activities. This makes it possible for the state to increase its tax rate without having too many entrepreneurs escape underground.)

On the assumption that the above models reflect some essential features of the transition processes, an important policy issue is how a country can avoid a ‘bad’ equilibrium or escape one if it finds itself in it. Roland and Verdier suggest that the promise of EU accession can be one mechanism that solves coordination problems in their model described above. Obviously, this solution is not available to all economies in transition. Some argue that the collapse of government institutions and the ensuing flight of taxpayers underground can be avoided by conducting reforms gradually. China is often cited as a successful example of a gradual approach. However, such strategy is risky both because it may not avoid the deterioration of government institutions (for example, despite Ukraine's gradual reforms, the data
second economy (unofficial economy) - The New Palgrave Dictionary of Economics

mentioned in the beginning of this section testify to the similarities between Ukraine's and Russia's unofficial economies) and because it may postpone genuine reforms indefinitely, as appears to have happened in Belarus and Uzbekistan. Friedman et al.'s (2000) findings based on a cross-section of countries suggest a rather pessimistic conclusion that the size of the unofficial economy depends largely on the quality of institutions, which in turn is determined by exogenous factors such as geography, religion, linguistic fractionalization, and the origin of the legal system, while the policy parameters that are more easily controlled by governments such as tax rates do not matter very much. These empirical results imply that over-regulation, corruption and a weak rule of law are associated with larger unofficial economy. (The positive relationship between corruption and unofficial economy is less intuitive than the other correlations. This is because the economic agents may either use the unofficial economy to escape bribe requests or bribe officials to evade taxation and regulations.)

The high tax burden can, of course, also serve as a reason for shifting resources into the unofficial economy. However, high tax rates can also generate revenues necessary to increase the output of productivity-enhancing public goods, making the official economy more attractive. The net effect of tax rates on the unofficial economy is ambiguous. We note also that the impact of taxation presumably depends on the effective tax rates that are often determined by how the tax system is administered rather than on the statutory tax rates as long as the latter are within a reasonable range.

Despite the above considerations, if the government of an economy in transition is truly intent on legalization a significant part of the unofficial economy, the rationalization of the tax system can serve as a reasonable first step, as Alexeev, Conrad and Hay (2004) argue and as Russia's tax reforms of 2001–3 demonstrate. Ivanova, Keen and Klemm (2005) and Sinelnikov-Mourylev et al. (2003) show that a dramatic reduction of the highest marginal tax rates on personal income in Russia induced many taxpayers to legalize their incomes, leading to an increase in government revenues. Of course, tax reform alone is not sufficient. At the very least, it needs to be accompanied by reform of government regulations, administration and the courts. Unfortunately, these administrative reforms may be difficult to implement in those economies in transition that need them most.

While many economies in transition may find it difficult to reduce the unofficial sector, its size appears to be smaller than in a number of developing countries at a comparable level of development such as Mexico, South Korea and Chile. (See Schneider and Enste, 2000. Campos, 2000, argues, however, that the nature of the unofficial sectors in the economies in transition and the developing economies may be different. In the latter, the unofficial economy appears to consist mostly of small labour-intensive businesses trying to escape excessive government regulation and taxation. In the former, large firms hiding their activities account for a larger part of the unofficial economy. If true, these differences would testify to a greater degree of government capture by large firms in the economies in transition, implying that reforms aimed at reducing unofficial economies there may be more difficult to implement. This argument may be plausible, but it is hard to test given the available data and the structural differences between major economies in transition and developing economies. For example, greater capital intensity of the unofficial sector in the economies in transition can be simply a consequence of greater capital intensity of the overall economy.)

More important, the impact of the unofficial economy on welfare in any real-world institutional environment, and particularly in the rather distorted economies in transition, is ambiguous, even on the margin. Among other things, this is because the possibility of going underground often provides an effective check on the power of governments to over-regulate and overtax.

seemingly unrelated regressions

Hyungsik Roger Moon and Benoit Perron
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article considers the seemingly unrelated regression (SUR) model first analysed by Zellner (1962). It describes estimators used in the basic model as well as recent extensions.

Keywords

bootstrap; feasible generalized least squares estimator; quasi-maximum likelihood estimator; generalized least squares estimator; heteroskedasticity; heteroskedasticity and autocorrelation; minimum distance estimator; ordinary least squares estimator; seemingly unrelated regressions; vector autoregressions; Zellner, A.

Article

A seemingly unrelated regression (SUR) system comprises several individual relationships that are linked by the fact that their disturbances are correlated. Such models have found many applications. For example, demand functions can be estimated for different households (or household types) for a given commodity. The correlation among the equation disturbances could come from several sources such as correlated shocks to household income. Alternatively, one could model the demand of a household for different commodities, but adding up constraints leads to restrictions on the parameters of different equations in this case. On the other hand, equations explaining some phenomenon in different cities, states, countries, firms or industries provide a natural application as these various entities are likely to be subject to spillovers from economy-wide or worldwide shocks.

There are two main motivations for use of SUR. The first one is to gain efficiency in estimation by combining information on different equations. The second motivation is to impose and/or test restrictions that involve parameters in different equations. Zellner (1962) provided the seminal work in this area, and a thorough treatment is available in the book by Srivastava and Giles (1987). A recent survey can be found in Fiebig (2001). This article selectively overviews the SUR model, some of the estimators used in such systems and their properties, and several extensions of the basic SUR model. We adopt a classical perspective, although much Bayesian analysis has been done with this model (including Zellner's contributions).

Basic linear SUR model

Suppose that $y_{it}$ is a dependent variable, $x_{it} = (1, x_{it,1}, x_{it,2}, ..., x_{it,K_i-1})'$ is a $K_i$-vector of explanatory variables for observational unit $i$, and $u_{it}$ is an unobservable error term, where the double index $it$ denotes the $t$th observation of the $i$th equation in the system. Often $t$ denotes time and we will refer to this as the time dimension, but in some applications $t$ could have other interpretations, for example as a location in space. A classical linear SUR model is a system of linear regression equations,
where \( i = 1, \ldots, N \), and \( t = 1, \ldots, T \). Denote \( K = K_1 + \cdots + K_N \). Further simplification in notation can be accomplished by stacking the observations either in the \( t \) dimension or for each \( i \). For example, if we stack for each observation \( t \), let \( Y_t = [Y_{1t}, \ldots, Y_{Nt}]' \), \( X_t = \text{diag}(x_{1t}, x_{2t}, \ldots, x_{Nt}) \), a block-diagonal matrix with \( x_{1t}, \ldots, x_{Nt} \) on its diagonal, \( U_t = [u_{1t}, \ldots, u_{Nt}]' \), and \( \beta = [\beta_1', \ldots, \beta_N']' \). Then,

\[
Y_t = \tilde{X}_t \beta + U_t.
\]

Another way to present the SUR model is to write it in a form of a multivariate regression with parameter restrictions. For this, define \( X_t = [x_{1t}', x_{2t}', \ldots, x_{Nt}']' \) and \( \mathcal{A}(\beta) = \text{diag}(\beta_1, \ldots, \beta_N) \) to be a \((L \times N)\) block diagonal coefficient matrix. Then, the SUR model in (1) can be rewritten as

\[
Y_t = \mathcal{A}(\beta)' X_t + U_t
\]

and the coefficient \( A(\beta) \) satisfies

\[
\text{vec}(A(\beta)) = G \beta,
\]

for some \((NL \times L)\) full rank matrix \( G \). In the special case where \( K_1 = \cdots = K_N = K \), we have \( G = \text{diag}(i_1, \ldots, i_N) \otimes \mathcal{I}_K \), where \( i_j \) denotes the \( j \)th column of the \( N \times N \) identity matrix \( \mathcal{I}_N \).

**Assumption**

In the classical linear SUR model, we assume that for each \( i = 1, \ldots, N \), \( X_i = [x_{i1}, \ldots, x_{iT}]' \) is of full rank \( K_i \), and that conditional on all the regressors \( X' = [X_1, \ldots, X_T] \), the errors \( U_t \) are i.i.d. over time with mean zero and homoskedastic variance \( \Sigma = E(U_t U_t'|X) \). Furthermore, we assume that \( \Sigma \) is positive definite and denote by \( \sigma_{ij} \) the \((i,j)\)th element of \( \Sigma \); that is,

\[
\sigma_{ij} = E(u_{it} u_{jt}'|X).
\]

Under this assumption, the covariance matrix of the entire vector of disturbances \( U' = [U_1, \ldots, U_T] \) is given by

\[
E(\text{vec}(U) (\text{vec}(U))') = \Sigma \otimes \mathcal{I}_T.
\]
Estimation of $\beta$

In this section we summarize four estimators of $\beta$ that have been widely used in applications of the classical linear SUR. Other estimators (such as Bayes, empirical Bayes or shrinkage estimators) have also been proposed. Interested readers should refer to Srivastava and Giles (1987) and Fiebig (2001).

1. *Ordinary least squares (OLS) estimator.* The first estimator of $\beta$ is the ordinary least squares (OLS) estimator of $Y_t$ on regressor $X_t$,

$$\hat{\beta}_{OLS} = \left( \sum_{t=1}^{T} \hat{X}_t \hat{X}_t' \right)^{-1} \sum_{t=1}^{T} \hat{X}_t' Y_t.$$

This is just the vector that stacks the equation-by-equation OLS estimators, $\hat{\beta}_{OLS} = (\hat{\beta}_1,_{OLS}, ..., \hat{\beta}_N,_{OLS})'$, where $\hat{\beta}_i,_{OLS} = \left( \Sigma_{t=1}^{T} \hat{X}_{it} \hat{X}_{it}' \right)^{-1} \Sigma_{t=1}^{T} \hat{X}_{it} V_{it}$.

2. *Generalized least squares (GLS) and feasible GLS (FGLS) estimator.* When the system covariance matrix $\Sigma$ is known, the GLS estimator of $\beta$ is

$$\hat{\beta}_{GLS} = \left( \sum_{t=1}^{T} \hat{X}_t \Sigma^{-1} \hat{X}_t' \right)^{-1} \sum_{t=1}^{T} \hat{X}_t \Sigma^{-1} Y_t.$$

When the covariance matrix $\Sigma$ is unknown, a feasible GLS (FGLS) estimator is defined by replacing the unknown $\Sigma$ with a consistent estimate. A widely used estimator of $\Sigma$ is

$$\hat{\Sigma} = \left( \hat{\sigma}_{ij} \right),$$

where $\hat{\sigma}_{ij} = \frac{1}{T} \Sigma_{t=1}^{T} \hat{e}_{it} \hat{e}_{jt}$ and $\hat{e}_{kt}$ is the OLS residuals of the $k$th equation: that is, $\hat{e}_{kt} = Y_{kt} - \hat{\beta}_{OLS} X_{kt}$, $k = i, j$. Then

$$\hat{\beta}_{FGLS} = \left( \sum_{t=1}^{T} \hat{X}_t \hat{\Sigma}^{-1} \hat{X}_t' \right)^{-1} \sum_{t=1}^{T} \hat{X}_t \hat{\Sigma}^{-1} Y_t.$$

The FGLS estimator is a two-step estimator where OLS is used in the first step to obtain residuals $\hat{e}_{kt}$ and an estimator of $\Sigma$. The second step computes $\hat{\beta}_{FGLS}$ based on the estimated $\Sigma$ in the first step. This estimator is sometimes referred to as the restricted estimator as opposed to the unrestricted estimator proposed by Zellner that uses the residuals from an OLS regression of (2) without imposing the coefficient restrictions (3), that is, from regressing each regressand on all distinct regressors in the system.

3. *Gaussian quasi-maximum likelihood estimator (QMLE).* The Gaussian log-likelihood function is
\[ L(\beta, \Sigma) = \text{const} + \frac{T}{2} \det \Sigma - \frac{1}{2} \sum_{t=1}^{T} \left( y_t - \hat{x}_t' \beta \right)' \Sigma^{-1} \left( y_t - \hat{x}_t' \beta \right), \]

or equivalently,

\[ L(\beta, \Sigma) = \text{const} + \frac{T}{2} \det \Sigma - \frac{1}{2} \sum_{t=1}^{T} \left( y_t - A(\beta)' x_t \right)' \Sigma^{-1} \left( y_t - A(\beta)' x_t \right), \]

where \( A(\beta) \) denotes the coefficient \( A \) in (2) with the linear restriction of (3), and the QMLE \( \hat{\beta}_{QMLE} = \hat{\Sigma}_{QMLE} \) maximizes \( L(\beta, \Sigma) \). When the vector \( U_t \) has a normal distribution, this estimator is the maximum likelihood estimator.

4. Minimum distance (MD) estimator. The idea of the MD estimator is to obtain an estimator of the unrestricted coefficient \( A \) in (2), \( \hat{A} \), and then, obtain an estimator of \( \beta \) by minimizing the distance between \( \hat{A} \) and \( \beta \) in (3). For this, assume that \( T > L \) and that the whole regressor matrix \( X \) has full rank \( L \). When \( \hat{A} \) is the OLS estimator of \( A(\beta) \), that is \( \hat{A} = (X'X)^{-1}X'Y \), the optimal MD estimator \( \hat{\beta}_{MD} \) minimizes the optimal MD objective function

\[ Q_{MD}(\beta) = (\text{vec}(\hat{A}) - C\beta)' \left( \hat{\Sigma}^{-1} \otimes \sum_{t=1}^{T} x_t x_t' \right)^{-1} \left( \hat{\Sigma}^{-1} \otimes \sum_{t=1}^{T} x_t x_t' \right) (\text{vec}(\hat{A}) - C\beta). \]

In this case, we have

\[ \hat{\beta}_{MD} = \left( C' \left( \hat{\Sigma}^{-1} \otimes \sum_{t=1}^{T} x_t x_t' \right) C \right)^{-1} C' \left( \hat{\Sigma}^{-1} \otimes \sum_{t=1}^{T} x_t x_t' \right) \text{vec}(\hat{A}). \]

Relationship between the estimators

Some of the above estimators are tightly linked. For example, if we use the same consistent estimator \( \hat{\Sigma} \), the FGLS and the MD estimators above are identical: that is, \( \hat{\beta}_{FGLS} = \hat{\beta}_{MD} \). Also, if we use the QMLE estimator of \( \Sigma \), \( \hat{\beta}_{QMLE} \) in place of \( \hat{\Sigma} \), \( \hat{\beta}_{QMLE} \) is identical to \( \hat{\beta}_{FGLS} \) (and to \( \hat{\beta}_{MD} \)). By the Gauss–Markov theorem, the GLS estimator \( \hat{\beta}_{GLS} \) is more efficient than the OLS estimator \( \hat{\beta}_{OLS} \) when the system errors are correlated across equations. However, this efficiency gain disappears in some special cases described in Kruskal's theorem (Kruskal, 1968). A well-known special case of this theorem is when the regressors in each equation are the same. For other cases, readers can refer to Greene (2003, ch. 14) and Davidson and MacKinnon (1993, pp. 294–5). The efficiency gain relative to OLS tends to be larger when the correlation across equations is larger and when the correlation among regressors in different equations is smaller.

Note also that efficient estimators propagate misspecification and inconsistencies across equations. For example, if any equation is misspecified (for example some relevant variable has been omitted), then the entire vector \( \hat{\beta} \) will be inconsistently
seemingly unrelated regressions: The New Palgrave Dictionary of Economics

estimated by the efficient methods. In this sense, equation-by-equation OLS provides some degree of robustness since it is not
affected by misspecification in other equations in the system.

Distribution of the estimators

In the literature on the classical linear SUR, the FGLS estimator $\hat{\beta}_{FGLS}$ is often called the SUR estimator (SURE). The usual
asymptotic analysis of the SURE is carried out when the dimension of index $t, T$, increases to infinity with the dimension of
index $i, N$, kept fixed. For asymptotic theories for large $N, T$, one can refer to Phillips and Moon (1999). Under regularity
conditions, the asymptotic distributions as $T \to \infty$ of the aforementioned estimators are

$$\sqrt{T}(\hat{\beta}_{OLS} - \beta) = N\left(0, \left[E\left(\tilde{x}_t \tilde{x}_t' \right)\right]^{-1}E\left(\tilde{x}_t \Sigma \tilde{x}_t' \right)\left[E\left(\tilde{x}_t \tilde{x}_t' \right)\right]^{-1}\right)$$

and

$$\sqrt{T}(\hat{\beta}_{GLS} - \beta), \sqrt{T}(\hat{\beta}_{FGLS} - \beta), \sqrt{T}(\hat{\beta}_{MD} - \beta) = N\left(0, \left[E\left(\tilde{x}_t \Sigma^{-1} \tilde{x}_t' \right)\right]^{-1}\right) = N\left(0, \left[G' \Sigma^{-1} \otimes E(\tilde{x}_t \tilde{x}_t')G\right]^{-1}\right).$$

It is straightforward to show that the SUR estimator using the information in the system is more efficient (has a smaller
variance) than the estimator of the individual equations. By using the above distributional results, it is straightforward to
construct statistics to test general nonlinear hypotheses.

Finite sample properties of SURE have been studied extensively either analytically in some restrictive cases (Zellner, 1963;
1972; Kakwani, 1967), by asymptotic expansions (Phillips, 1977; Srivastava and Maekawa, 1995) or by simulation (Kmenta
and Gilbert, 1968). Most work has focused on the two-equation case. The above approximations appear to be good descriptions
of the finite-sample behaviour of the estimators analysed when the number of observations, $T$, is large relative to the number of
equations, $N$. In particular, efficient methods provide an efficiency gain in cases where the correlation among disturbances
across equations is high and when correlation among regressors across equations is low. Non-normality of disturbances has also
been found to deteriorate the quality of the above approximations. Bootstrap methods have also been proposed to remedy these
documented departures from normality and improve the size of tests.

Extensions

In this section we discuss several extensions of the classical linear SUR model where the assumption on the error terms is no
longer satisfied.

Autocorrelation and heteroskedasticity

As in standard univariate models, non-spherical disturbances can be accommodated by either modelling the residuals or
computing robust covariance matrices. In addition to standard dynamic effects, serial correlation can arise in this environment
due to the presence of individual effects (see Baltagi, 1980). One could define the equivalent of White (in the case of
heteroskedasticity) or HAC (in the case of serial correlation) standard errors to conduct inference with the OLS estimator as in
the single-equation framework.

For efficiency in estimation some parametric assumption on the disturbance process is often imposed (see Greene, 2003). For
example, in the case of heteroskedasticity, Hodgson, Linton, and Vorkink (2002) propose an adaptive estimator that is efficient
under the assumption that the errors follow an elliptical symmetric distribution that includes the normal as a special case. An
intermediate approach is to use a restricted (or parametric) covariance matrix to try to capture some efficiency gains in estimation, and then use a nonparametric heteroskedasticity and autocorrelation (HAC) consistent estimator of the covariance matrix to do inference. This two-tier approach (dubbed quasi-FGLS) has been suggested by Creel and Farell (1996).

Endogenous regressors

When the regressor $X_t$ in the SUR model is correlated with the error term $U_t$, one needs instrumental variables (IVs), say, $Z_t = [z_{1t}', \ldots, z_{N_t}]'$ to estimate $\beta$. We suppose that the IVs satisfy the usual rank condition. The generalized method of moments (GMM) estimator (or the IV estimator), then, utilizes the moment condition

$$E[\text{vec}(Z_t U_t')] = 0.$$

The optimal GMM estimator $\hat{\beta}_{GMM}$ is derived by minimizing the GMM objective function with the optimal choice of weighting matrix given by

$$\left(\Sigma \otimes \left(\sum_{t=1}^{T} Z_t Z_t'\right)^{-1}\right)^{-1},$$

$$Q_{GMM}(\beta) = \left[\sum_{t=1}^{T} \text{vec}\left(Z_t (Y_t - A(\beta)'X_t)'ight)'ight]' \left(\Sigma \otimes \sum_{t=1}^{T} Z_t Z_t'\right)^{-1} \left[\sum_{t=1}^{T} \text{vec}\left(Z_t (Y_t - A(\beta)'X_t)'ight)'ight].$$

Then, we have

$$\hat{\beta}_{GMM} = \left(C' \left(\Sigma \otimes \left(\sum_{t=1}^{T} X_t Z_t\right)\left(\sum_{t=1}^{T} Z_t Z_t'\right)^{-1}\left(\sum_{t=1}^{T} Z_t X_t'\right)^{-1}\right)^{-1} C\right)^{-1} \times C' \left(\Sigma \otimes \left(\sum_{t=1}^{T} X_t Z_t\right)\left(\sum_{t=1}^{T} Z_t Z_t'\right)^{-1}\left(\sum_{t=1}^{T} Z_t X_t'\right)^{-1}\right)^{-1} \text{vec}(\hat{A}_{2SLS}),$$

where

$$\hat{A}_{2SLS} = \left(\sum_{t=1}^{T} X_t Z_t\right)\left(\sum_{t=1}^{T} Z_t Z_t'\right)^{-1} \left(\sum_{t=1}^{T} Z_t X_t'\right)^{-1} \times \left(\sum_{t=1}^{T} X_t Z_t\right)\left(\sum_{t=1}^{T} Z_t Z_t'\right)^{-1} \left(\sum_{t=1}^{T} Z_t Y_t\right)$$

is the two-stage least squares estimator of $A(\beta)$. When $X_t$ is exogenous, so that $X_t = Z_t$, the GMM objective function $Q_{GMM}(\beta)$ and minimum distance objective function $Q_{MD}(\beta)$ are identical, and in this case $\hat{\beta}_{GMM} = \hat{\beta}_{MD}$. 

Vector autoregressions
Seemingly unrelated regressions: The New Palgrave Dictionary of Economics

When the index $t$ in the SUR model denotes time and the regressors $x_{it}$ include lagged dependent variables, the classical linear SUR model becomes a vector autoregression model (VAR) with exclusion restrictions. In this case, the regressors $X$ are no longer strictly exogenous, and the assumption in the previous section is violated. A special case is when the order of the lagged dependent variables is one. In this case, for $\{y_{it}\}_t$ to be stationary, it is necessary that the absolute value of the coefficient of $y_{i,t-1}$ is less than one. If the coefficient of $y_{i,t-1}$ is one, $\{y_{it}\}_t$ is non-stationary. Non-stationary SUR VAR models have been used in developing tests for unit roots and cointegration in panels with cross-sectional dependence: see for example Chang (2004), Groen and Kleibergen (2003) and Larsson, Lyhagen, and Lothgren (2001).

Seemingly unrelated cointegration regressions

When the non-constant regressors in $X_t$ are integrated non-stationary variables but the errors in $U_t$ are stationary, we call model (1) (or equivalently (2)) a seemingly unrelated cointegration regression model; see Park and Ogaki (1991), Moon (1999), Mark, Ogaki and Sul (2005), and Moon and Perron (2004). These papers showed that for efficient estimation of $\hat{\beta}$, an estimator of the long-run variance of $U_t$, not of the spontaneous covariance $\Sigma$ as in the previous section, should be used in FGLS. In addition, some modification of the regression is necessary when the integrated regressors and the stationary errors are correlated. Empirical applications in the main references include tests for purchasing power parity, the relation between national saving and investment, and tests of the forward rate unbiasedness hypothesis.

Nonlinear SUR (NSUR)

An NSUR model assumes that the conditional mean of $y_{it}$ given $x_{it}$ is nonlinear, say $h_l(\beta, x_{it})$, that is, $y_{it} = h_l(\beta, x_{it}) + u_{it}$. Defining $H(\beta, X_t) = (h_1(\beta, X_{1t}), \ldots, h_N(\beta, X_{Nt}))$, we write the NSUR model in a multivariate nonlinear regression form,

$$y_t = H(\beta, X_t) + U_t.$$

In this case, we may estimate $\hat{\beta}$ using (quasi) MLE assuming that $Y_t$ are Gaussian conditioned on $X_t$ or GMM utilizing the moment condition that $E[g(X_t)U'_t] = 0$ for any measurable transformation $g$ of $X_t$.

selection bias and self-selection

James J. Heckman
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This entry defines the problems of selection bias and presents the conditions required to solve them. It gives examples of common sampling frames, presents economic selection mechanisms, and discusses the assumptions required to use selected samples to determine features of the population distribution.

The analytical framework developed to understand selection bias problems is also fruitful in understanding the economics of self-selection. The prototypical model of choice theoretic self-selection is the Roy model, in which agents choose among a variety of discrete ‘occupational’ opportunities. The Roy model is presented and its fruitful extension to a variety of settings is demonstrated.

Keywords
censored regression model; choice-based sampling; general stratified sampling; length-biased sampling; random sampling; Roy model; selection bias and self-selection; size-biased sampling

Article

The problem of selection bias in economic and social statistics arises when a rule other than simple random sampling is used to sample the underlying population that is the object of interest. The distorted representation of a true population as a consequence of a sampling rule is the essence of the selection problem. Distorting selection rules may be the outcome of decisions of sample survey statisticians, self-selection decisions by the agents being studied, or both.

A random sample of a population produces a description of the population distribution of characteristics that has many desirable properties. One attractive feature of a random sample generated by the known rule that all individuals are equally likely to be sampled is that it produces a description of the population distribution of characteristics that becomes increasingly accurate as sample size expands.

A sample selected by any rule not equivalent to random sampling produces a description of the population distribution of characteristics that does not accurately describe the true population distribution of characteristics no matter how big the sample size. Unless the rule by which the sample is selected is known or can be recovered from the data, the selected sample cannot be used to produce an accurate description of the underlying population. For certain sampling rules, even knowledge of the rule generating the sample does not suffice to recover the population distribution from the sampled distribution.

This entry defines the problem of selection bias and presents conditions required to solve the problem. Examples of various types of commonly encountered sampling frames are given and specific economic selection mechanisms are presented. Assumptions required to use selected samples to determine features of the population distribution are discussed.

The analytical framework developed to understand the inferential problems raised by selection bias is also fruitful in understanding the economics of self-selection. The prototypical choice theoretic model of self-selection is that of Roy (1951). In his model, agents choose among a variety of discrete ‘occupational’ opportunities. Agents can pursue only one ‘occupation’ at a time. While every person can, in principle, do the work in each ‘occupation’, at least at some level of competence, self-interest drives individuals to choose that ‘occupation’ which produces the highest income (utility) for them. As in the statistical
selection bias and self-selection: The New Palgrave Dictionary of Economics

...selection bias problem, there is a latent population (of skills). Observed (utilized) skill distributions are the outcome of a selection rule by agents. The relationship between observed and latent skill distributions is of considerable interest and underlies recent work on worker hierarchies (see Willis and Rosen, 1979). The 'occupations' can be: (a) market work or non-market work (b) unemployed and searching or working at the offered wage (c) working in one province or working in another, or (d) any choice among a set of mutually exclusive opportunities.

Because the insights in the Roy model underlie much recent research, we present a brief exposition of it and demonstrate how it can be or has been fruitfully extended to a variety of settings. An important issue, closely linked to the problem of identifying population parameters from selected sample distributions, is the empirical content of economic models of self-selection and worker hierarchies. Are they artefacts of distributional assumptions for unobservable skills or are they genuine behavioural hypotheses?

1. A definition and some examples of selection bias

Any selection bias model can be described by the following set-up. Let \( Y \) be a vector of outcomes of interest and let \( X \) be a vector of 'control' or 'explanatory' variables. The population distribution of \((Y,X)\) is \( F(y,x) \). To simplify the exposition we assume that the density is well defined and write it as \( f(y,x) \).

Any sampling rule can be interpreted as producing a non-negative weighting function \( \omega(Y,X) \) that alters the population density. Let \((Y^*,X^*)\) denote the sampled random variables. The density of the sampled data \( g(y^*,x^*) \) may be written as

\[
g(y^*, x^*) = \frac{\omega(y^*, x^*) f(y^*, x^*)}{\int \omega(y^*, x^*) f(y^*, x^*) dy^* dx^*}
\]

(1.1)

where the denominator of the expression is introduced to make the density \( g(y^*,x^*) \) integrate to one as is required for proper densities.

Alternatively, the weight may be defined as

\[
\omega^*(y^*, x^*) = \frac{\omega(y^*, x^*)}{\int \omega(y^*, x^*) f(y^*, x^*) dy^* dx^*}
\]

so that

\[
g(y^*, x^*) = \omega^*(y^*, x^*) f(y^*, x^*).
\]

(1.2)

Sampling schemes for which \( \omega(Y,X) = 0 \) for some values of \((Y,X)\) create special problems. For such schemes, not all values of \((Y,X)\) are sampled. Let indicator variable \( i(Y,X) = 0 \) if a potential observation at values \( y,x \) cannot be sampled and let \( i(Y,X) = 1 \) otherwise. Let \( \Delta = 1 \) record the occurrence of the event 'a potential observation is sampled, i.e. the value of \( y,x \) is observed' and let \( \Delta = 0 \) if it is not. In the population, the proportion that is sampled is

\[
\Pr(\Delta = 1) = \int i(y,x) f(y,x) dy dx.
\]
For samples in which $\omega(Y, X) = 0$ for a non-negligible proportion of the population ($Pr(\Delta = 0) > 0$) it is clarifying to consider two cases. A truncated sample is one for which $Pr(\Delta = 1)$ is not known and cannot be consistently estimated. For such a sample, (1.1) is the density of all of the sampled $Y$ and $X$ values. A censored sample is one for which $Pr(\Delta = 1)$ is known or can be consistently estimated. The sampling rule in this case is such that values of $y*, x*$ for which $\omega(y, x) = 0$ are not known but it is known whether or not $i(y, x) = 0$ for all values of $Y*, X*$. In this case it is notationally convenient to define $\Delta^* = (0, 0)$ for values of $y*, x*$ such that $\omega(y, x) = i(y, x) = 0$. Such a definition is innocuous provided that in the population there is no point mass (concentration of probability mass) at $(0, 0)$. (Any value other than $(0, 0)$ can be selected provided that there is no point mass at that value.) Given $\Delta = 0$ the distribution of $Y*, X*$ is

$$g(y*, x*) = 1 \text{ for } \Delta = 0$$

at

$$Y^* = 0 \text{ and } X^* = 0.$$  

The joint density of $Y*, X*, \Delta$ for the case of a censored sample is obtained by combining (1.1) and (1.3). Thus

$$g(y*, x*, \delta) = \left[ \frac{\omega(y*, x*) f(y*, x*)}{\int\omega(y*, x*) f(y*, x*) dy* dx*} \right] \delta \left[ \int i(y, x) f(y, x) dy dx \right]^{\delta} \times [1 - \delta \left[ \int (1 - i(y, x)) f(y, x) dy dx \right]]^{1 - \delta}.$$  

The first term on the right-hand side of (1.4) is the conditional density of $Y*, X*$ given $\Delta = 1$. The second term is the probability that $\Delta = 1$. The third term is the conditional density of $Y*, X*$ given $\Delta = 0$. This density assigns unit mass to $Y^* = 0$, $X^* = 0$ when $\Delta = 0$. The fourth term is the probability that $\Delta = 0$. Notice that in the case in which $\omega(y, x) > 0$ for all $y, x, \Delta = 1$ and (1.4) is identical to (1.1).

In a random sample $\omega(Y*, X*) = 1$ (and so $\omega^*(Y^*, X^*) = 1$). In a selected sample, the sampling rule weights the data differently. Values of $(Y, X)$ are over-sampled or under-sampled relative to their occurrence in the population. In the case of truncated samples, the weight is zero for certain values of the outcome.

In many problems in economics, attention focuses on $f(Y|X)$, the conditional density of $Y$ given $X = x$. In such problems knowledge of the population distribution of $X$ is of no direct interest. If samples are selected solely on the $x$ variables (selection bias and self-selection: The New Palgrave Dictionary of Economics)
selection bias and self-selection: The New Palgrave Dictionary of Economics

on the exogenous variables'), \( \omega(\mathbf{y}, \mathbf{x}) = \omega(\mathbf{x}) \) and there is no problem about using selected samples to make valid inference about the population conditional density. This is so because in the case of selection on the exogenous variables

\[
g(\mathbf{y}^*, \mathbf{x}^*) = f(\mathbf{y}^* | \mathbf{x}^*) \frac{\omega(\mathbf{x}^*) f(\mathbf{x}^*)}{\int \omega(\mathbf{x}^*) f(\mathbf{x}^*) d\mathbf{x}}
\]

and

\[
g(\mathbf{x}^*) \frac{\omega(\mathbf{x}^*) f(\mathbf{x}^*)}{\int \omega(\mathbf{x}^*) f(\mathbf{x}^*) d\mathbf{x}^*}.
\]

Thus

\[
g(\mathbf{y}^* | \mathbf{x}^*) = \frac{g(\mathbf{y}^*, \mathbf{x}^*)}{g(\mathbf{x}^*)} = f(\mathbf{y}^* | \mathbf{x}^*).
\]

For such problems, sample selection distorts inference only if selection occurs on \( \mathbf{y} \) (or \( \mathbf{y} \) and \( \mathbf{x} \)). Sampling on both \( \mathbf{y} \) and \( \mathbf{x} \) is termed \textit{general stratified sampling}.

From a sample of data, it is not possible to recover the true density \( f(\mathbf{y}^* | \mathbf{x}) \) without knowledge of the weighting rule. On the other hand, if the weighting rule is known \( (\omega(\mathbf{y}^*, \mathbf{x}^*)) \) the density of the sampled data is known \( (g(\mathbf{y}^*, \mathbf{x}^*)) \), the support of \( (\mathbf{y}^*, \mathbf{x}^*) \) is known and \( \omega(\mathbf{y}^*, \mathbf{x}^*) \) is non-zero, then \( f(\mathbf{y}^* | \mathbf{x}) \) can always be recovered because

\[
\frac{g(\mathbf{y}^*, \mathbf{x}^*)}{\omega(\mathbf{y}^*, \mathbf{x}^*)} = \frac{f(\mathbf{y}^*, \mathbf{x}^*)}{\int \omega(\mathbf{y}^*, \mathbf{x}^*) f(\mathbf{y}^*, \mathbf{x}^*) d\mathbf{y}^* d\mathbf{x}^*} = 1.
\]

Integrating the left-hand side of (1.5) it is possible to determine \( \int \omega(\mathbf{y}^*, \mathbf{x}^*) f(\mathbf{y}^*, \mathbf{x}^*) d\mathbf{y}^* d\mathbf{x}^* \) and hence to use (1.5) to recover the population density of the data.

The requirements that (a) the support of \( (\mathbf{y}, \mathbf{x}) \) is known and (b) \( \omega(\mathbf{y}, \mathbf{x}) \) is nonzero are not innocuous. In many important problems in economics requirement (b) is not satisfied: the sampling rule excludes observations for certain values of \( \mathbf{y}, \mathbf{x} \) and
hence it is impossible without invoking further assumptions to determine the population distribution of \((Y, X)\) at those values. If neither the support nor the weight is known, it is impossible, without invoking strong assumptions, to determine whether the fact that data are missing at certain \(y, x\) values is due to the sampling plan or that the population density has no support at those values. We now turn to some specific sampling plans of interest in economics.

**Example 1**

Data are collected on incomes of individuals whose income \(Y\) exceeds a certain value \(c\) (for cut-off value). The rule is to observe \(Y\) if \(Y > c\). Thus \(\omega(y) = 1 \text{ if } Y > c\) and \(\omega(y) = 0 \text{ if } Y \leq c\). Because the weight is zero for some values of \(y\), we know that knowledge of the sampling rule does *not* suffice to recover the population distribution. From a random sample of the entire population, the social scientist knows or can consistently estimate (a) the sample distribution of \(Y\) above \(c\) and (b) the proportion of the original random sample with income below \(c\) \((F(c)\) where \(F\) is the distribution function of \(Y\)). The social scientist does not observe values of \(Y\) below \(c\).

In this example, observed income is a *truncated random variable*. The point of truncation is \(c\). The sample of observed income is said to be *censored*. If the proportion of the original random sample with income below \(c\) is not known and cannot be consistently estimated, the *sample is truncated*. In a truncated sample, nothing is known about the proportion of the underlying population that can appear in the sample. A sample is truncated only if \(\omega(y) = 0\) for some intervals of \(y\) (for \(y\) continuous) or if \(\omega(y) = 0\) at values of \(y\) at which there is finite probability mass. In a censored sample, the proportion of the underlying population that can appear in the sample is known, at least to an arbitrarily high degree of approximation, as sample size increases.

Let \(Y^* = Y\) if \(Y > c\). Define \(Y^* = 0\) otherwise (the choice of the value for \(Y^*\) when \(Y\) is not observed is inessential and any value can be used in place of 0 provided that the true distribution places no mass at the selected value). Define an indicator variable \(\Delta = 1\) if \(Y > c\). \(\Delta = 0\) otherwise. Then the distribution of \(Y^*\) is

\[
G(y^* | Y > 0) = F(y^* | Y > c) = F(y^* | \delta = 1) = \frac{F(y^*)}{1 - F(c)}, \quad y^* > c.
\]

(1.6a)

\[
G(y^* | Y^* > 0) = 1 \text{ for } y^* = 0 (\delta = 0).
\]

(1.6b)

Observe that (1.6a) is obtained from (1.1) by setting \(\omega(y^*) = 1\) if \(Y > c\), and \(\omega(y^*) = 0\) otherwise, and integrating up with respect to \(y^*\). The distribution of \(\Delta\) is

\[
\Pr(\Delta) = [1 - F(c)]^\delta [F(c)]^{1-\delta}.
\]

The joint distribution of \((Y^*, \Delta)\) is
Note that (1.7) is obtained from (1.4) by setting \( \omega(y) = 0 \), \( y < \xi \), \( \omega(y) = 1 \) otherwise, by setting \( \Omega(y) = \omega(y) \) and by integrating up with respect to \( y^* \). For normally distributed \( Y \), (1.7) is the ‘Tobit’ distribution.

The difference between the information in a truncated sample and the information in a censored sample is encapsulated in the contrast between (1.6a) and (1.7). Clearly there is more information in a censored sample than in a truncated sample because one can obtain (1.6a) from (1.7) (by conditioning on \( \Delta = 1 \)) but not vice versa.

Inferences about the population distribution based on assuming that \( F(y^* | y > \xi) \) closely approximates \( F(y) \) are potentially very misleading. A description of population income inequality based on a subsample of high income people may convey no information about the true population distribution.

Without further information about \( F \) and its support, it is not possible to recover \( F \) from \( G(y^*) \) from either a censored or a truncated sample. Access to a censored sample enables the analyst to recover \( F(y) \) for \( y > \xi \) but obviously does not provide any information on the shape of the true distribution for values of \( y \leq \xi \).

This problem is routinely ‘solved’ by assuming that \( F \) is of a known functional form. This solution strategy does not always work. If \( F \) is normal, then it can be recovered from a censored or truncated sample (Pearson, 1901). If \( F \) is Pareto, \( F \) cannot be recovered from either a truncated or a censored sample (see Flinn and Heckman, 1982). If \( F \) is real analytic (i.e. possesses derivatives of all order) and the support of \( Y \) is known, then \( F \) can be recovered (Heckman and Singer, 1985).

**Example 2**

Expand the discussion in the previous example to a linear regression setting. Let

\[
Y = X\beta + U
\]  

(1.8)

be the population earnings function where \( Y \) is earnings, \( X \) is a regressor vector assumed to be distributed independently of mean zero disturbance \( U \). ‘\( \beta \)’ is a suitably dimensioned parameter vector. Conventional assumptions are invoked to ensure that ordinary least squares applied to a random sample of earnings data consistently estimates \( \beta \).

Data are collected on incomes of persons for whom \( Y \) exceeds \( c \). Again the weight depends solely on \( y \), i.e. \( \omega(y, X) = 0 \), \( y \leq \xi \), \( \omega(y, X) = 1 \), \( y > \xi \). The social scientist knows or can consistently estimate (a) the sample distribution of \( Y \) above \( c \) (b) the sample distribution of the \( X \) for \( Y \) above \( c \) and (c) the proportion of the original random sample with income below \( c \). The social scientist does not observe values of \( Y \) below \( c \).

As before, let \( y^* = y \) if \( y > \xi \). Define \( y^* = 0 \) otherwise. \( \Delta = 1 \) if \( y > \xi \), \( \Delta = 0 \) otherwise. The probability of the event \( \Delta = 1 \) given \( X = x \) is

\[
Pr(\Delta = 1 | X = x) = Pr(y > \xi | X = x) = Pr(y > \xi - x\beta | X = x).
\]

Invoking independence between \( U \) and \( X \) and letting \( F_u \) denote the distribution of \( U \),
The distribution of $Y^*$ conditional on $X$ is

$$G(Y^*Y > 0, X = x) = F(Y^*X = x, Y > c) = F(Y^*X = x, \Delta = 1) = \frac{F_U(Y^* - x\beta)}{1 - F_U(c - x\beta)}, \quad Y^* > c.$$  
(1.10a)

$$G(Y^*Y \leq 0) = 1 \text{ for } Y^* = 0(\Delta = 0).$$  
(1.10b)

The joint distribution of $(Y^*, \Delta)$ given $X = x$ is

$$F(Y^*, \delta|X = x) = F(Y^*|\delta, x)\Pr(\delta|x) = \left\{ F_U(Y^* - x\beta) \right\}^\delta \left\{ F_U(c - x\beta) \right\}^{1-\delta}. $$  
(1.11)

In particular,

$$E(Y^*|X = x, \Delta = 1) = x\beta + E(U|X = x, \delta = 1) = x\beta + \int_c^{\infty} \frac{z d F_U(z)}{1 - F_U(c - x\beta)}$$  
(1.12)

where $\delta$ is a dummy variable of integration. In contrast, the population mean regression function is

$$E(Y|X = x) = x\beta.$$  
(1.13)
The contrast between (1.12) and (1.13) is illuminating. Many behavioural theories in social science produce empirical counterparts of (1.8) with population conditional expectations like (1.13). Such theories sometimes restrict the signs, permissible values and other relationships among the coefficients in $\beta$. When the theoretical model is estimated on a selected sample ($\Delta = 1$) the true conditional expectation is (1.12) not (1.13). The conditional mean of $U$ depends on $x$. In terms of conventional omitted variable analysis, $E(U|x, \Delta = 1)$ is omitted from the regression. Since this term is a function of $x$ it is likely to be correlated with $x$. Least squares estimates of $\beta$ obtained on selected samples which do not account for selection are biased and inconsistent.

To illustrate the nature of the bias, it is useful to draw on the work of Cain and Watts (1973). Suppose that $X$ is a scalar random variable (e.g. education) and that its associated coefficient is positive ($\beta > 0$). Under conventional assumptions about $U$ (e.g. mean zero, independently and identically distributed and distributed independently of $X$), the population regression of $Y$ on $X$ is a straight line. The scatter about the regression line and the regression line are given in Figure 1. When $Y > \zeta$ is imposed as a sample inclusion requirement, lower population values of $U$ are excluded from the sample in a way that systematically depends on $x$ ($Y > \text{cor} U > \zeta - x\beta$). As $x$ increases, the conditional mean of $U[E(U|x, \Delta = 1)]$ decreases. Regression estimates of $\beta$ that do not correct for sample selection (that is, include $U$ as a regressor) are downward biased because of the negative correlation between $x$ and $E(U|x, \Delta = 1)$. See the flattened regression line for the selected sample in Figure 1.

Figure 1

In models with more than one regressor, no sharp result on the sign of the bias in the regression estimate that results from ignoring the selected nature of the sample is available except when the $X$ variables are from certain distributions (e.g. normal, see Goldberger, 1983). None the less, the key result – that conventional least squares estimates of $\beta$ obtained from selected samples are biased and inconsistent – remains true.

As in example 1, it is fruitful to distinguish between the case of a truncated sample and the case of a censored sample. In the truncated sample case, no information is available about the fraction of the population that would be allocated to the truncated sample $[\text{Pr}(\Delta = 1)]$. In the censored sample case, this fraction is known or can be consistently estimated. In the censored sample case it is fruitful to distinguish two further cases: (a) the case in which $X$ is not observed when $\Delta = 0$ and (b) the case in which it is. Case (b) is the one most fully developed in the literature (Heckman and MaCurdy, 1981).

Note that the conditional mean $E(U|x, \Delta = 1)$ is a function of $\zeta - x\beta$ solely through $\text{Pr}(\Delta = 1|x)$. Since $\text{Pr}(\Delta = 1|x)$ is monotonically in $\zeta - x\beta$ the conditional mean depends solely on $\text{Pr}(\Delta = 1|x)$ and the parameters $F_u$ i.e. since

$$F_u^{-1}(1 - \text{Pr}(\Delta = 1|x)) = \zeta - x\beta, E(U|x, \Delta = 1) = \int F_u^{-1}(1 - \text{Pr}(\Delta = 1|x)) \frac{zdF_u(z)}{\text{Pr}(\Delta = 1|x)}.$$

This relationship demonstrates that the conditional mean is a function of the probability of selection. As the probability of selection goes to 1, the conditional mean goes to zero. For samples chosen so that the values of $x$ are such that the observations are certain to be included in the sample, there is no problem in using ordinary least squares on selected samples to estimate $\beta$. Thus in Figure 1, ordinary least squares regressions fit on samples selected to have large $x$ values closely approximate the true regression function and become arbitrarily close as $x$ becomes large. The condition mean in (1.12) is a surrogate for $\text{Pr}(\Delta = 1|x)$. As this probability goes to one, the problem of sample selection in regression analysis becomes negligibly small. Heckman (1976) demonstrates that $\beta$ and $F_u$ are identified if $U$ is normally distributed and standard conditions invoked in regression analysis are satisfied. Gallant and Nychka (1984) and Cosselett (1984) establish conditions for identification for non-normal $U$. In their analyses, $F_u$ is consistently non-parametrically estimated.

Example 3

The next example considers censored random variables. This concept extends the notion of a truncated random variable by
letting a more general rule than truncation on the outcome of interest generate the selected sample. Because the sample generating rule may be different from a simple truncation of the outcome being studied, the concept of a censored random variable in general requires at least two distinct random variables.

Let $Y_1$ be the outcome of interest. Let $Y_2$ be another random variable. Denote observed $Y_1$ by $Y_1^*$. If $Y_2 < \zeta$, $Y_1$ is observed. Otherwise $Y_1$ is not observed and we can set $Y_1^* = 0$ or any other convenient value (assuming that $Y_1$ has no point mass at $Y_1 = 0$ or at the alternative convenient value). In terms of the weighting function $\omega$, $\omega(Y_1, Y_2) = 0$ if $Y_2 > \zeta$, $\omega(Y_1, Y_2) = 1$ if $Y_2 \leq \zeta$.

Selection rule $Y_2 < \zeta$ does not necessarily restrict the range of $Y_1$. Thus $Y_1^*$ is not in general a truncated random variable. Define $\Delta = 1$ if $Y_2 < \zeta; \Delta = 0$ otherwise. If $F(y_1, y_2)$ is the population distribution of $(Y_1, Y_2)$, the distribution of $\Delta$ is

$$
\Pr(\Delta = \delta) = [1 - F_2(\zeta)]^{1-\delta} [F_2(\zeta)]^\delta, \delta = 0, 1,
$$

where $F_2$ is the marginal distribution of $Y_2$. The distribution of $Y_1^*$ is

$$
G(Y_1^* = 0) = 1, \Delta = 0.
$$

(1.14a)

(1.14b)

Note that (1.14a) is the distribution function corresponding to the density in (1.1) when $\omega(Y_1, Y_2) = 1$ if $Y_2 \leq \zeta$ and $\omega(Y_1, Y_2) = 0$ otherwise.

The joint distribution of $(Y_1^*, \Delta)$ is

$$
G(Y_1^*, \delta) = [F(Y_1^*, \zeta)]^\delta [1 - F_2(\zeta)]^{1-\delta}.
$$

(1.15)

This is the distribution function corresponding to density (1.4) for the special weighting rule of this example. In a censored sample, under general conditions it is possible to consistently estimate $\Pr(\Delta = \delta)$ and $G(Y_1^*)$. In a truncated sample, only conditional distribution (1.14a) can be estimated. A degenerate version of this model has $Y_1^* = Y_2$. In that case, censored random variable $Y_1$ is also a truncated random variable. Note that a censored random variable may be defined for a truncated or censored sample.

Example 3 and variants of it have wide applicability in economics. Let $Y_1$ be the wage of a woman. Wages of women are observed only if women work. Let $Y_2$ be an index of a woman's propensity to work. In Gronau (1974) and Heckman (1974), $Y_2$
is postulated as the difference between reservation wages (the value of time at home determined from household preference functions) and potential market wages $Y_1$. Then if $Y_2 < 0$, the woman works. Otherwise, she does not. $Y_1^* = Y_1$ if $Y_2 < 0$ is the observed wage.

If $Y_1$ is the offered wage of an unemployed worker, and $Y_2$ is the difference between reservation wages (the return to searching) and offered market wages, $Y_1^* = Y_1$ if $Y_2 < 0$ is the accepted wage for an unemployed worker (see Flinn and Heckman, 1982). If $Y_1$ is the potential output of a firm and $Y_2$ is its profitability, $Y_1^* = Y_1$ if $Y_2 > 0$. If $Y_1$ is the potential income in occupation one and $Y_2$ is the potential income in occupation two, $Y_1^* = Y_1$ if $Y_1 - Y_2 < 0$ while $Y_2^* = Y_2$ if $Y_1 - Y_2 > 0$. We develop this example at length in section 2 where we consider explicit economic models of self-selection. There we discuss the identifiability of this model.

Example 4

This example builds on example 3 by introducing regressors. This produces the censored regression model (Heckman, 1976; 1979). In example 3 set

$$Y_1 = X_1 \beta_1 + U_1$$

(1.16a)

$$Y_2 = X_2 \beta_2 + U_2$$

(1.16b)

where $(X_1, X_2)$ are distributed independently of $(U_1, U_2)$, a mean zero, finite variance random vector. Conventional assumptions are invoked to ensure that if $Y_1$ and $Y_2$ can be observed, least squares applied to a random sample of data on $(Y_1, Y_2, X_1, X_2)$ would consistently estimate $\beta_1$ and $\beta_2$. $Y_1^* = Y_1$ if $Y_2 < 0$. If $Y_2 < 0$, $\Delta = 1$. Then the regression function for the selected sample is

$$E(Y_1^*(X_1 = x_1, Y_2 < 0) = E(Y_1^*(X_1 = x_1, \Delta = 1) = X_1 \beta_1 + E(U_1|X_1 = x_1, \Delta = 1)$$

(1.17)

and the regression function for the population is

$$E(Y_1|X_1 = x_1) = X_1 \beta_1$$

(1.18)

As in the regression analysis of truncated random variables, there is an illuminating contrast between the conditional
expectation for the selected sample (1.17) and the population regression function (1.18). The two functions differ by the conditional mean of $E[U_1|X_1 = x_1, \Delta = 1]$. In the regression analysis of truncated random variables, ordinary least squares estimates of $\hat{\beta}$ (in equation (1.14)) are biased and inconsistent because the conditional mean is improperly omitted from the selected sample regression. The same analysis applies to the regression analysis of censored random variables. The conditional mean is a surrogate for the probability of selection $[\Pr(\Delta = 1|x_2)]$. As $\Pr(\Delta = 1|x_2)$ goes to one, the problem of sample selection bias becomes negligible. However, in the censored regression case, a new phenomenon appears. If there are variables in $X_2$ not in $X_1$, such variables may appear to be statistically important determinants of $Y_1$ when ordinary least squares is applied to data generated from censored samples.

As an example, suppose that survey statisticians use some extraneous (to $X_1$) variables to determine sample enrolment. Such variables may appear to be important determinants of $Y_1$ when in fact they are not. They are important determinants of $Y^*_1$. In an analysis of self-selection, let $Y_1$ be the wage that a potential worker could earn were he to accept a market offer. Let $Y_2$ be the difference between the best non-market opportunity available to the potential worker and $Y_1$. If $Y_2 < 0$, the agent works. The conditional expectation of observed wages ($Y^* = Y$ if $Y_2 < 0$) given $x_1$ and $x_2$ will be a non-trivial function of $x_2$. Thus variables determining non-market opportunities will determine $Y^*_1$, even though they do not determine $Y_1$. For example, the number of children less than six may appear to be significant determinants of $Y_1$ when inadequate account is taken of sample selection, even though the market does not place any value or penalty on small children in generating wage offers for potential workers. Heckman (1976) develops the analysis of this model when $(U_1, U_2)$ is normally distributed. Gallant and Nychka (1984) and Cosslett (1984) demonstrate that under mild restrictions on $F(u_1, u_2)$, if there is one continuous valued variable in $X_2$ not in $X_1$ (so that there is no exact linear dependence between $X_2$ and $X_1$), $\beta_1$, $\beta_2$ and $F(u_1, u_2)$ can be consistently non-parametrically estimated. Heckman and MaCurdy (1986) develop this class of models at length.

Example 5

This example demonstrates how self-selection bias affects the interpretation placed on estimated consumer demand functions when there is self-selection. We postulate a population of consumers with a quasi-concave utility function $U(Z, E)$ which depends on the consumption of goods and preference shock $E$ which represents heterogeneity in preferences among consumers. The support of $E$ is $E$. For price vector $P$ and endowment income $M$, the consumer's problem is to

$$\max U(Z, E) \text{subject to } P'Z \leq M.$$ 

In the population $P$ and $M$ are distributed independently of $E$. First-order conditions for this problem are

$$\frac{\partial U(Z, E)}{\partial Z} \leq \lambda P,$$

(1.19)

where $\lambda$ is the Lagrange multiplier associated with the budget constraint. Focusing on the demand for the first good, $Z_1$, none of it is purchased if at zero consumption of $Z_1$

$$\left.\frac{\partial U(Z, E)}{\partial Z_1}\right|_{Z_1=0} \leq \lambda P_1.$$

(1.20)
that is, marginal valuation is less than marginal cost in utility terms. Conventional interior solution demand functions for \( Z_1 \) are defined for a given \( \mathbf{P}, M \) only for values of \( E \) such that

\[
\frac{\partial U(Z, E)}{\partial Z_1} \bigg|_{Z_1=0} \leq \lambda P_1.
\]  

(1.21)

Let the set of \( E \) for which conventional interior solution consumer demand functions for \( Z_1 \) are defined be denoted by \( \mathbb{E} \). Then

\[
\mathbb{E} = \left\{ E \text{ such that } \frac{\partial U(Z, E)}{\partial Z_1} \bigg|_{Z_1=0} \leq \lambda P_1 \text{ for given } \mathbf{P}, M \right\}.
\]

Let \( \Delta_1 = 0 \) if the consumer does not purchase \( Z_1 \). Let \( \Delta_1 = 1 \) otherwise. If \( F(\varepsilon) \) is the population distribution of \( E \), the proportion purchasing none of good \( Z_1 \) given \( \mathbf{P}, \mathbf{M} \) is

\[
Pr(\Delta_1 = 0|\mathbf{P}, \mathbf{M}) = 1 - \int_{\mathbb{E}} dF(\varepsilon).
\]

Provided inequality (1.21) is satisfied, \( \Delta_1 = 1 \) and interior solution demand function

\[
Z_1 = Z_1(\mathbf{P}, M, E)
\]  

(1.22)

is well defined and \( Z_1 = Z_1^* \). When \( \Delta_1 = 0 \), observed \( Z_1 = Z_1^* = 0 \).

Equation (1.22) is the conventional object of interest in consumer theory. Partial derivatives of that function holding \( E \) and the other arguments constant have well defined economic interpretations. Suppose that some non-negligible proportion of the population buys none of good \( Z_1 \). Regression estimates of the parameters of (1.22) using \( Z_1^* \) approximate the conditional expectation

\[
E(Z_1|\Delta_1 = 1, \mathbf{P}, \mathbf{M}) = \int_{\mathbb{E}} Z_1(\mathbf{P}, M, \varepsilon)dF(\varepsilon).
\]  

(1.23)
The derivatives of (1.23) are different from the derivatives of (1.22). In order to define these derivatives, it is helpful to define \( l_{E}(E) \) as an indicator function for set \( E \) which equals one if \( E \in \bar{E} \) and equals zero otherwise. When prices or income change, the set of values of \( E \) that satisfy inequality (1.21) changes. Let \( \bar{E} + \Delta \bar{E} \) be the set of \( E \) values that satisfy (1.21) when there is a finite price change \( \Delta \bar{P} \). \( l_{E}(E) \) is an indicator function which equals one when \( E \in \bar{E} + \Delta \bar{E} \). Then the derivatives of (1.23) are, for the \( j \)th price

\[
\frac{\partial}{\partial \bar{P}_j} E(Z_{1}\Delta = 1, \bar{P}, \bar{M}) = \int_{\bar{E}} \frac{\partial}{\partial \bar{P}_j} Z_{1}(\bar{P}, \bar{M}, \bar{E}) \, dF(\bar{E}) + \lim_{\Delta \bar{P}_j \to 0} \int_{\bar{E}} \frac{\left[ l_{\bar{E} + \Delta \bar{E}}(E) - l_{\bar{E}}(E) \right] Z(\bar{P}, \bar{M}, \bar{E})}{\Delta \bar{P}_j} \, dF(\bar{E}).
\]

(1.24)

When the limit in the second term does not exist, the derivative does not exist. We assume for expositional convenience that the limit is well defined.

The first expression on the right-hand side of (1.24) is the average effect of price change on commodity demand. The second term on the right-hand side of (1.24) arises from the change in sample composition of \( E \) as the proportion of non-purchasers changes in response to price change. This term generates the selection bias.

Neither term is the same as the price derivative of (1.22) for an arbitrary value of \( E = \varepsilon \) although the first term on the right-hand side of (1.24) approximates the price derivative of (1.22) for some value of \( E = \varepsilon \).

A similar decomposition of the derivatives of the conditional demand function can be performed if it is defined solely for a sample of non-zero purchasers (see Heckman and MaCurdy, 1981; 1986). Just as in the statistical sample selection bias problem, there is a population of interest. In this case, the population parameters of interest are the distribution of \( E \) and the parameters of \( U(Z, \cdot, E) \). Those who buy \( Z \) are a self-selected sample of the population. Estimates of population parameters estimated on self-selected samples are biased and inconsistent. There is a population distribution of \( Z_1(\bar{P}, \cdot, M, \cdot, E) \) generated by the distribution of \( E \). Observations of \( Z_1 \) are obtained only if \( E \in \bar{E} \) and \( \omega(E) = 1 \) if \( E \in \bar{E} \), \( \omega(E) = 0 \) otherwise. Alternatively one can express the inclusion criteria in terms of the latent population distribution of \( Z_1 \) induced by \( E \) (given \( \bar{P} \) and \( M \)) and write \( \omega(Z_1) = 1 \) if \( Z_1 > 0 \), \( \omega(Z_1) = 0 \) if \( Z_1 \leq 0 \).

Heckman (1974) and Heckman and MaCurdy (1981) provide further discussion of this type of model which is widely used in applied economics and consider issues of identifiability for such models.

**Example 6. Length biased sampling**

Let \( T \) be the duration of an event such as a completed unemployment spell or a completed duration of a job with an employer. The population distribution of \( T \) is \( F(t) \) with density \( f(t) \). The sampling rule is such that individuals are sampled at random. Data are recorded on a completed spell provided that at the time of the interview the individual is experiencing the event. Such sampling rules are in wide use in many national surveys of employment and unemployment. In order to have a sampled completed spell, a person must be in the state at the time of the interview. Let ‘0’ be the date of the survey. Decompose any completed spell \( T \) into a component that occurs before the survey \( T_b \) and a component that occurs after the survey \( T_a \). Then \( T = T_a + T_b \). For a person to be sampled, \( T_b > 0 \). The density of \( T \) given \( T_b = t_b \) is

\[
f(t | t_b) = \frac{f(t)}{1 - F(t_b)}, \quad t \geq t_b.
\]

(1.25)

Suppose that the environment is stationary. The population entry rate into the state at each instant of time is $k$. From each vintage of entrants into the state distinguished by their distance from the survey date $t_b$, only $1 - F(t_b) = Pr(T > t_b)$ survive. Aggregating over all cohorts of entrants, the population proportion in the state at the date of the interview is $P$ where

$$P = \int_0^\infty k(1 - F(t_b))dt_b$$

(1.26)

which is assumed to exist. The density of $T_b^*$, sampled pre-survey duration, is

$$g(t_b^* | t_b^* > 0) = \frac{k(1 - F(t_b^*))}{P}.$$  

(1.27)

The density of sampled completed durations is thus

$$g(t^*) = \int_0^{t^*} f(t^* | t_b^* > 0)dt_b^* = \frac{k}{P} \int_0^{t^*} \frac{1 - F(t_b^*)}{1 - F(t_b^*)} \frac{1 - F(t_b^*)}{P} dt_b^* = \frac{k}{P} \int_0^{t^*} f(t^*) dt^*.$$  

Observe from (1.26) that by a standard integration by parts argument

$$P = k\int_0^\infty (1 - F(z))dz = k\int_0^\infty zdF(z) = kE(T).$$

Note that

$$g(t^*) = \frac{t^* f(t^*)}{E(T)}.$$  

(1.28)

In this form (1.28) is equivalent to (1.1) with $\omega(t) = t$. Hence the term 'length biased sampling'. Intuitively, longer spells are oversampled when the requirement is imposed that a spell be in progress at the time the survey is conducted ($T_b > 0$). Suppose, instead, that individuals are randomly sampled and data are recorded on the next spell of the event (after the survey date). As long as successive spells are independent, such a sampling frame does not distort the sampled distribution because no requirement is imposed that the sampled spell be in progress at the date of the interview. It is important to notice that the source of the bias is the requirement that $T_b > 0$, not only that a fraction of the population experiences the event ($P < 1$).
The simple length weight \((\omega(t) = t)\) that produces (1.28) is an artefact of the stationarity assumption. Heckman and Singer (1985) consider the consequences of non-stationarity and un-observables when there is selection on the event that a person be in the state at the time of the interview. They also demonstrate the bias that results from estimating parametric models on samples generated by length biased sampling rules when inadequate account is taken of the sampling plan. Vardi (1983, 1985) and Gill and Wellner (1985) consider nonparametric identification and estimation of models with densities of the form (1.28).

It is unfortunate that the lessons of length biased sampling are not adequately appreciated in economics. Two widely cited studies by Clark and Summers (1979) and Hall (1982) use length biased data to prove, respectively, that unemployment and employment spells are ‘surprisingly long’. Whether their findings are artefacts of sampling plans remains to be determined.

Example 7. Choice based sampling

Let \(D\) be a discrete valued random variable which assumes a finite number of values \(I, D = i, i = 1, \ldots, l\) corresponds to the occurrence of state \(i\). States are mutually exclusive. In the literature the states may be modes of transportation choice for commuters (Domencich and McFadden, 1975), occupations, migration destinations, financial solvency status of firms, schooling choices of students, etc. Interest centres on estimating a population choice model

\[
\Pr(D = i | X = x), i = 1, \ldots, l. \tag{1.29}
\]

The population density of \((D, X)\) is

\[
f(d, x) = \Pr(D = d | X = x) h(x) \tag{1.30}
\]

where \(h(x)\) is the density of the data.

In many problems, plentiful data are available on certain outcomes while data are scarce for other outcomes. For example, interviews about transportation preferences conducted at train stations tend to over-sample train riders and under-sample bus riders. Interviews about occupational choice preferences conducted at leading universities over-sample those who select professional occupations.

In choice based sampling, selection occurs solely on the \(D\) coordinate of \((D, X)\). In terms of (1.1) (extended to allow for discrete random variables), \(\omega(d, X) = \omega(d)\). Then sampled \((D^*, X^*)\) has density

\[
g(d^*, x^*) = \frac{\omega(d^*, x^*) f(d^*, x^*)}{\sum_{i=1}^{l} \omega(i) f(i, x^*) dx^*} \tag{1.31}
\]

Notice that the denominator can be simplified to

\[
\sum_{i=1}^{l} \omega(i) f(i)
\]
where \( f(d^*) \) is the marginal distribution of \( D^* \) so that

\[
g(d^*, x^*) = \frac{\omega(d^*) f(d^*, x^*)}{\sum_{i=1}^{l} \omega(i) f(i)}
\]

(1.32)

Also, integrating (1.31) with respect to \( x \) using (1.32) we obtain

\[
g(d^*) = \frac{\omega(d^*) f(d^*)}{\sum_{i=1}^{l} \omega(i) f(i)}
\]

(1.33)

which makes transparent how the sampling rule causes the sampled proportions to deviate from the population proportions.

Note further that as a consequence of sampling only on \( D \), the population conditional density

\[
h(x^* | d^*) = \frac{f(d^*, x^*)}{f(d^*)}
\]

(1.34)

can be recovered from the choice-based sample. The density of \( x \) in the sample is thus

\[
g(x^*) = \sum_{i=1}^{l} h(x^* | i) g(i).
\]

(1.35)

Then using (1.32)–(1.35) we reach

\[
g(d^* | x^*) = f(d^* | x^*) \left\{ \frac{\omega(d^*)}{\sum_{i=1}^{l} \omega(i) f(i)} \right\} \left\{ \frac{1}{\sum_{i=1}^{l} f(i)} \right\} g(i) \frac{g(i)}{f(i)}
\]

(1.36)

The bias that results from using choice based samples to make inference about \( f(d^* | x^*) \) is a consequence of neglecting the
selection bias and self-selection: The New Palgrave Dictionary of Economics

terms in braces on the right-hand side of (1.36). Notice that if the data are generated by a random sampling rule, \( \omega(d^*) = 1 \), 
\( g(d^*) = f(d^*) \) and the term in braces is one. 

Example 8. Size biased sampling

Let \( N \) be the number of children in a family. \( f(N) \) is the density of discrete random variable \( N \). Suppose that family size is recorded only when at least one child is interviewed. Suppose further that each child has an independent and identical chance \( \beta \) of being interviewed. The probability of sampled family size of \( N^* = n^* \) is

\[
g(n^*) = \frac{\omega(n^*) f(n^*)}{E[\omega(N^*)]} \tag{1.37}
\]

where \( \omega(n^*) = 1 - (1 - \beta)^n^* \) (the probability that at least one child from a family of size \( n^* \) will be sampled) and

\[
E[\omega(N^*)] = \sum_{n^*} \left( 1 - (1 - \beta)^n^* \right) f(n^*)
\]

is the probability of observing a family. In a large population \( \beta \to 0 \) with increasing population size. Using l'Hospital's rule, and assuming that passage to the limit under the summation sign is valid

\[
\lim_{\beta \to 0} g(n^*) = \frac{n^* f(n^*)}{E(N^*)} \tag{1.38}
\]

Thus the limit form of (1.37) is identical to (1.28). Larger families tend to be oversampled and hence a misleading estimate of family size will be produced from such samples. Since the model is formally equivalent to the length biased sampling model, all references and statements about identification given in example 6 apply with full force to this example. See the discussion in Rao (1965).

2 Economic models of self-selection

We begin our analysis by expositing the Roy model of self-selection for workers with heterogeneous skills. The statistical framework for this model has been outlined in examples 3 and 4. Following Roy, we assume that there are two market sectors in which income-maximizing agents can work. Agents are free to enter the sector that gives them the highest income. However, they can work in only one sector at a time.

Each sector requires a unique sector-specific task. Each agent has two skills, \( T_1 \) and \( T_2 \), which he cannot use simultaneously. The model is short run in that aggregate skill distributions are assumed to be given. There are no costs of changing sectors, and
selection bias and self-selection: The New Palgrave Dictionary of Economics

Investment is ignored. Because of this assumption, the model presented here applies to environments with certain or uncertain prices for sector-specific tasks. For simplicity and without any loss of generality (given the preceding assumptions), we assume an environment of perfect certainty.

Let \( T_i \) be the amount of sector \( i \) specific task a worker can perform. The price of task \( i \) is \( \pi_i \). An agent works in sector 1 if his income is higher there, that is

\[
\pi_1 T_1 > \pi_2 T_2
\]

(2.1)

Indifference between sectors is a negligible probability event if the \( T_1 = 1, 2 \) are assumed to be continuous nondegenerate random variables. Throughout we assume that prices are positive (\( \pi_i > 0 \)).

The log wage in task \( i \) of an individual with endowment \( T_i \) is

\[
\ln W_i = \ln \pi_i + \ln T_i
\]

(2.2)

The proportion of the population working at task \( i \) is the proportion of the population for whom

\[
T_1 > \frac{\pi_2}{\pi_1} T_2.
\]

Roy assumes that \( (\ln T_1, \ln T_2) \) is normally distributed with mean \( (\mu_1, \mu_2) \) and covariance matrix \( \Sigma \). Letting \( (U_1, U_2) \) be a mean zero normal vector, agents in the Roy model choose between two possible wages:

\[
\ln W_1 = \ln \pi_1 + \mu_1 + U_1
\]

or

\[
\ln W_2 = \ln \pi_2 + \mu_2 + U_2.
\]

Workers enter sector 1 if \( \ln W_1 > \ln W_2 \). Otherwise they enter sector 2.

Letting

\[
\sigma^* = \sqrt{\text{var}(U_1 - U_2)}
\]
and

\[ c_i = \frac{\ln(\pi_i / \pi_j) + \mu_j - \mu_i}{\sigma^2}, \text{ for } i \neq j, \Pr(i) = P(\ln W_i > \ln W_j) = \Phi(c_i), \text{ for } i \neq j, \text{ for } i, j = 1, 2 \]

where \( \Phi(\cdot) \) is the cumulative distribution function of a standard normal variable. When standard sample selection bias formulae are used (see, e.g., Heckman, 1976), the mean of log wages observed in sector \( i \) is

\[
E(\ln W_i | \ln W_i > \ln W_j) = \ln \pi_i + \mu_i + \frac{\sigma_{ii} - \sigma_{ij}}{\sigma^2}\lambda(c_i), \quad i, j = 1, 2, \quad i \neq j,
\]

(2.3)

where

\[
\lambda(c) = \frac{1}{\sqrt{2\pi}} \exp \left( -\frac{1}{2} c^2 \right) \frac{1}{\Phi(c)}
\]

is a convex monotone decreasing function of \( c \) with \( \lambda(c) \geq 0 \) and

\[
\lim_{c \to \infty} \lambda(c) = 0, \quad \lim_{c \to -\infty} \lambda(c) = \infty.
\]

Convexity is proved in Heckman and Honoré (1986). The variance of log wages observed in sector \( i \)

\[
\text{var}(\ln W_i | \ln W_i > \ln W_j) = \sigma_{ii}\left[ \phi_i^2 \left[ 1 - \frac{1}{2} \lambda^2(c_i) \right] + (1 - \rho_i^2) \right], \quad i \neq j
\]

(2.4)

where \( \rho_i = \text{correl}(U_i, U_j - U_i), \quad i \neq j = 1, 2 \). The variance of the log of observed wages never exceeds \( \sigma_{ii} \), the population variance, because the term in braces in (2.4) is never greater than unity. In general, sectoral variances decrease with increased selection. For example, if \( \rho_1 \) and \( \rho_2 \) do not equal zero, as \( \pi_2 \) increases with \( \pi_1 \) held fixed so that people shift from sector 2 to sector 1, the variance in the log of wages in sector 1 increases while the variance in the log of wages in sector 2 decreases. Using the fact that \( W_i = \pi_i \tilde{T}_i \), we may use (2.3) to write

\[
E(\ln \tilde{T}_1 | \ln W_1 > \ln W_2) = \mu_1 + \frac{\sigma_{11} - \sigma_{12}}{\sigma}\lambda(c_1),
\]
Focusing on (2.5a) and noting that $\lambda$ is positive for all values of $c_1$ (except $c_1 = \infty$), the mean of log task 1 used in sector 1 exceeds, equals, or falls short of the population mean endowment of log task 1 as $\sigma_{11} - \sigma_{12}$ is greater than, equal to, or less than zero. If endowments of tasks are uncorrelated ($\sigma_{12} = 0$) self-selection always causes the mean of $\ln T_1$ employed in sector 1 to be above the population mean $\mu_1$. The opposite case occurs when $\sigma_{11} - \sigma_{12}$ is negative. This case can arise only when values of $\ln T_1$ and $\ln T_2$ are sufficiently positively correlated. If this occurs, the mean of log task 1 used in sector 1 falls below the population mean $\mu_1$. Since covariance matrices must be positive semi-definite, $\sigma_{11} + \sigma_{22} - 2\sigma_{12} \geq 0$. Thus if $\sigma_{11} - \sigma_{12} < 0$, $\sigma_{22} - \sigma_{12} > 0$ so the mean of log task 2 employed in sector 2 necessarily lies above the population mean $\mu_2$.

In the Roy model the unusual case can arise in at most one sector. Notice from (2.5) that only if $\sigma_{11} = \sigma_{12}$ (so $\rho_1 = 0$) is the variance of log task 1 employed in sector 1 identical to the variance of log task 1 in the population. Otherwise, the sectoral variance of observed log task 1 is less than the population variance of log task 1.

To gain further insight into the effect of self-selection on the distribution of earnings for workers in sector 1, it is helpful to draw on some results from normal regression theory. The regression equation for $\ln T_2$ conditional on $\ln T_1$ is

$$\ln T_2 = \mu_2 + \frac{\sigma_{12}}{\sigma_{11}} (\ln T_1 - \mu_1) + \varepsilon_2. \tag{2.6}$$

where $E(\varepsilon_2) = 0$ and $\text{var}(\varepsilon_2) = \sigma_{22}[1 - (\sigma_{12}^2 / \sigma_{11}\sigma_{22})]$.

Figure 2 plots regression function (2.6) for the case $\sigma_{12} < \sigma_{11}$ and $\mu_2 > \mu_1 > 0$. For each value of $\ln T_1$, the population values of $\ln T_2$ are normally distributed around the regression line. Individuals with high values of $\ln T_1$ also tend to have a high value of $\ln T_2$. Assuming $\pi_1 = \pi_2$, individuals with $(\ln T_1, \ln T_2)$ endowments above the $45^\circ$ line of equal income shown in Figure 1 choose to work in sector 2, while those individuals with endowments below this line work in sector 1. Because $\sigma_{12} = \sigma_{11}$, the regression function is parallel to the line of equal income.

The distribution of $\varepsilon_2$ about the regression line is the same for all values of $\ln T_1$. When individuals are classified on the basis of their $\ln T_1$ values the same proportion of individuals work in sector 1 at all values of $\ln T_1$. For this reason the distribution of $\ln T_1$ employed in sector 1 is the same as the latent population distribution. If $\pi_1$ is raised (or $\pi_2$ is lowered) so that the $45^\circ$ equal income line is shifted upward, the same proportion of people enter sector 1 at each value of $\ln T_1 = t_1$. Figure 3 plots regression function (2.6) for the case $\sigma_{12} > \sigma_{11}$ and $\mu_2 > \mu_1 > 0$.

Figure 2

Figure 3

Figure 3
As before we set $\pi_1 = \pi_2$. Individuals with endowments above the 45° line choose to work in sector 2, while those with endowments below this line work in sector 1. When individuals are classified on the basis of their $T_1$ values, the fraction of people working in sector 1 decreases the higher the value of $T_1$. Self-selection causes the mean of log task 1 employed in sector 1 to be less than the mean of log task 1 in the total population. People with high values of $T_1$ are under-represented in sector 1 and low $T_1$ values are over-represented. In the extreme, when $\ln T_1$ and $\ln T_2$ are perfectly positively correlated, all high-income individuals are in sector 2, while all the low-income individuals are in sector 1. The highest-paid sector 1 worker earns the same as the lowest-paid sector 2 worker (Roy, 1951; Willis and Rosen, 1979). In this case there is really only one skill dimension and individuals can be unambiguously ranked along this scale.

If $\pi_1$ is raised (or $\pi_2$ is lowered) so that the line of equal income is shifted upward, the mean of ln $T_1$ employed in sector 1 must rise. The only place left to get $T_1$ is from the high end of the $T_1$ distribution. Unlike the case of $\sigma_{12} = \sigma_{11}$ in which a 10 per cent increase in $\pi_1$ results in a 10 per cent increase in measured average earnings in sector 1, when $\sigma_{12} > \sigma_{11}$ a 10 per cent increase in $\pi_1$ results in a greater than 10 per cent increase in the measured average earnings in sector 1 as the average quality of the sector 1 workforce increases. The variance of log wages in sector 1 increases.

If $\sigma_{11} < \sigma_{12}$ then $\sigma_{12} < \sigma_{22}$ in order for $\Sigma$ to be a covariance matrix. In the population, log task 2 must have greater variability than log task 1. Individuals with high $T_1$ values tend to have high $T_2$ values. But the population distribution of log task 2 has more mass in the tails. The higher an agent's value of $T_1$, the more likely it is that he will be able to get higher income in sector 2. At the lower end of the distribution, the process works in reverse: lower $T_1$ individuals on average have poor $T_2$ values. Self-selection causes the ln $T_1$ distribution in sector 1 to have an evacuated right tail, an exaggerated left tail, and a lower mean than the population mean of ln $T_1$.

If $\sigma_{12} < \sigma_{11}$ (a case not depicted graphically), the proportion of each $T_1$ group working in sector 1 increases, the higher the value of $T_1$. The mean of the log task employed in sector 1 exceeds $\mu_1$. A 10 per cent increase in $\pi_1$ produces an increase of less than 10 per cent in the average earnings of workers in sector 1 as the mean of ln $T_1$ employed in sector 1 declines. In fact if $\sigma_{12} > \sigma_{22}$ it is possible for an increase in $\pi_1$ to cause measured sector 1 wages to decline. Thus through a selection phenomenon it is possible for the average wage of people working in sector 1 to decline even though the price per unit skill increases there.

How robust are these conclusions if the normality assumption is relaxed? Heckman and Sedlacek (1985) show that many propositions derived from assumed normality of skills do not hold up for more general distributions. For example, increasing selection need not decrease sectoral variances. The effects of selection on mean employed skill levels are ambiguous. Heckman and Honoré (1986) demonstrate that in a single cross-section of data, it is possible to identify all of the parameters of the model from the data if the normality assumption is invoked. However, in a single cross-section many other models can explain the data equally well. In particular, intuitive notions about the degree of correlation or dependence among skills have no empirical content and so models of skill ‘hierarchies’ based on the extent of such dependence have no content for single cross-sections of data with all individuals facing common prices.

To show this, write the density of skills as $f(t_1, t_2)$. Let

$$Z_1 = \begin{cases} T_1 & \text{if } T_1 > T_2 \\ 0 & \text{otherwise} \end{cases}$$

$$Z_2 = \begin{cases} T_2 & \text{if } T_2 > T_1 \\ 0 & \text{otherwise} \end{cases}$$

Prices are normalized to unity ($\pi_1 = \pi_2 = 1$). Then the density of $Z_1$ is

$$Q_1' (z_1) = \int_{t_2 \leq z_1} f(t_1, t_2) \, dt_2 = \int_0^{z_1} f(z_1, t_2) \, dt_2.$$
The density of $Z_2$ is

$$Q'_2(z_2) = \int_0^{z_2} f(t_1, z_2) \, dt_1.$$  

Note that $Q'_1(n)$ and $Q'_2(n)$ summarize all of the available data on observed earnings.

Now if $T_1, T_2$ are independent with cdf's $F^*_1$ and $F^*_2$ respectively

$$Q'_1(n) = f^*_1(n) F^*_2(n)$$  
$$Q'_2(n) = F^*_1(n) f^*_2(n).$$

Define

$$\bar{Q}(n) = \int_0^n \left[ Q'_1(l) + Q'_2(l) \right] \, dl = F^*_1(n) F^*_2(n).$$

Then

$$\int_{\psi}^{\infty} \frac{Q'_i(n)}{\bar{Q}(n)} \, dn = \int_{\psi}^{\infty} \frac{f^*_1(n)}{F^*_1(n)} \, dn = - \ln F^*_1(\psi).$$

Thus we can write

$$F^*_i(\psi) = \exp \left( - \int_{\psi}^{\infty} \frac{Q'_i(n)}{\bar{Q}(n)} \, dn \right) \quad i = 1, 2$$

so that we can always rationalize the data on wages in a single cross-section by a model of skill independence, and economic models of skill hierarchies have no empirical content for a single cross-section of data.

Suppose, however, that the observing economist has access to data on skill distributions in different market settings i.e. settings in which relative skill prices vary. To take an extreme case, suppose that we observe a continuum of values of $\pi_1 / \pi_2$ ranging from zero to infinity. Then it is possible to identify $F(t_1, t_2)$ and it is possible to give empirical content to models based on the degrees of dependence among latent skills.
This point is made most simply in a situation in which $Z$ is observed but the analyst does not know $Z_1$ or $Z_2$ (i.e. which occupation is chosen). When $n_1/n_2 = 0$ everyone works in occupation two. Thus we can observe the marginal density of $t_2$. When $n_1/n_2 = \infty$ everyone works in occupation one. As $n_1/n_2$ pivots from zero to infinity it is thus possible to trace out the full joint distribution of $(T_1, T_2)$.

To establish the general result, set $\sigma = n_2/n_1$. Let $F(t_1, t_2)$ be the distribution function of $T_1, T_2$. Then

$$\Pr(Z \leq n) = \Pr(\max(T_1, \sigma T_2) \leq n) = \Pr\left(T_1 \leq n, T_2 \leq \frac{1}{\sigma} n\right) = F\left(n, \frac{n}{\sigma}\right).$$

As $\sigma$ varies between 0 and $\infty$ the entire distribution can be recovered since $N$ is observed for all values in $(0, \infty)$. Note that it is not necessary to know which sector the agent selects.

This proposition establishes the benefit of having access to data from more than one market. Heckman and Honoré (1986) show how access to data from various market settings and information about the choices of agents aids in the identification of the latent skill distributions.

The Roy model is the prototype for many models of self-selection in economics. If $T_1$ is potential market productivity and $T_2$ is non-market productivity (or the reservation wage) for housewives or unemployed individuals, precisely the same model can be used to explore the effects of self-selection on measured productivity. In such a model, $T_2$ is never observed. This creates certain problems of identification discussed in Heckman and Honoré (1986). The model has been extended to allow for more general choice mechanisms. In particular, selection may occur as a function of variables other than or in addition to $T_1$ and $T_2$.

Applications of the Roy model include studies of the union–non-union wage differential (Lee, 1978), the returns to schooling (Willis and Rosen, 1979), and the returns to training (Bjorklund and Moffitt, 1986, and Heckman and Robb, 1985). Amemiya (1984) and Heckman and Honoré (1986) present comprehensive surveys of empirical studies based on the Roy model and its extensions.

Heckman, J. 1976. The common structure of statistical models of truncation, sample selection and limited dependent variables and a simple estimator for such models. Annals of Economic and Social Measurement 5(4), 475–92.

**How to cite this article**

workers' cooperation, mutual training, and tenure longevity is another old idea in economics. A recent neoclassical application, with abundant citations, is that of Oliver E. Williamson (1975), who argues that such institutional devices as implicit contracts, collective bargaining, internal promotion ladders, and seniority rights are economically efficient when jobs and workers are heterogeneous and idiosyncratic.

A fixed structure of wages for jobs, which is emphasized by segmentation economists, is descriptively accurate and useful for analysing short-run behaviour, but even in the short run a human capital model of supply-side productivity traits can explain the match of workers to a hierarchy of wage-fixed jobs. In the long run the human capital model can explain changes in workers' productivity traits, and neoclassical models generally would predict changes in the structure of both jobs and wages.

A discussion of empirical work and policy issues concerning segmented labour markets is beyond the scope of this entry (see the bibliography below). It should be stated, however, that the sometime claim that the neoclassical economists ignore the demand side of the market in policy discussions is unfounded.

That labour market outcomes and processes are complex and controversial is evident in the intellectual legacy of the above-listed five sources of inequality. The criticisms and empirical work of the segmented labour market economists have added to this legacy, but they, like the earlier dissenters, the Marxists and the Institutionals, remain on the bank of the mainstream.

GLEN G. CAIN

BIBLIOGRAPHY

The literature on segmented labour markets is extensive and diversified, and there are disputes about who are the leading theorists and which are the landmark articles. These characteristics make it difficult to provide a brief bibliography. In addition to the items cited in the text, several survey articles and books contain lengthy bibliographies: Taubman and Wachtler (1986); Gordon, Edwards and Reich (1982); Wilkinson (1981); Cain (1976). The application of segmented labour market theories to development economics is not, however, covered in this entry.

population that is the object of interest. The distorted representation of a true population as a consequence of a sampling rule is the essence of the selection problem. Distorting selection rules may be the outcome of decisions of sample survey statisticians, self-selection decisions by the agents being studied or both.

A random sample of a population produces a description of the population distribution of characteristics that has many desirable properties. One attractive feature of a random sample generated by the known rule that all individuals are equally likely to be sampled is that it produces a description of the population distribution of characteristics that becomes increasingly accurate as sample size expands.

A sample selected by any rule not equivalent to random sampling produces a description of the population distribution of characteristics that does not accurately describe the true population distribution of characteristics no matter how big the sample size. Unless the rule by which the sample is selected is known or can be recovered from the data, the selected sample cannot be used to produce an accurate description of the underlying population. For certain sampling rules, even knowledge of the rule generating the sample does not suffice to recover the population distribution from the sampled distribution.

This entry defines the problem of selection bias and presents conditions required to solve the problem. Examples of various types of commonly encountered sampling frames are given and specific economic selection mechanisms are presented. Assumptions required to use selected samples to determine features of the population distribution are discussed.

The analytical framework developed to understand the inferential problems raised by selection bias is also fruitful in understanding the economics of self-selection. The prototypical choice theoretic model of self-selection is that of Roy (1951). In his model, agents choose among a variety of discrete "occupational" opportunities. Agents can pursue only one 'occupation' at a time. While every person can, in principle, do the work in each 'occupation', at least at some level of competence, self-interest drives individuals to choose that 'occupation' which produces the highest income (utility) for them. As in the statistical selection bias problem, there is a latent population (of skills). Observed (utilized) skill distributions are the outcome of a selection rule by agents. The relationship between observed and latent skill distributions is of considerable interest and underlies recent work on worker hierarchies (see Willis and Rosen, 1979). The 'occupations' can be: (a) market work or non-market work (b) unemployed and searching or working at the offered wage (c) working in one province or working in another, or (d) any choice among a set of mutually exclusive opportunities.

Because the insights in the Roy model underly much recent research, we present a brief exposition of it and demonstrate how it can be or has been fruitfully extended to a variety of settings. An important issue, closely linked to the problem of identifying population parameters from selected sample distributions, is the empirical content of economic models of self-selection and worker hierarchies. Are they artefacts of distributional assumptions for unobservable skills or are they genuine behavioural hypotheses?

I. A DEFINITION AND SOME EXAMPLES OF SELECTION BIAS

Any selection bias model can be described by the following set-up. Let \( Y \) be a vector of outcomes of interest and let \( X \) be a vector of 'control' or 'explanatory' variables. The population distribution of \((Y, X)\) is \( f(y, x) \). To simplify the exposition we assume that the density is well defined and write it as \( f(y, x) \).

Any sampling rule can be interpreted as producing a non-negative weighting function \( \omega(y, x) \) that alters the population density. Let \((Y^*, X^*)\) denote the sampled random variables. The density of the sampled data \( g(y^*, x^*) \) may be written as

\[
g(y^*, x^*) = \omega(y^*, x^*) f(y^*, x^*) \int \omega(y^*, x^*)/f(y^*, x^*) \, dy^* \, dx^* \quad (1.1)
\]

where the denominator of the expression is introduced to make the density \( g(y^*, x^*) \) integrate to one as is required for proper densities.

Alternatively, the weight may be defined as

\[
\omega(y^*, x^*) = \omega(y^*, x^*) \int \omega(y^*, x^*)/f(y^*, x^*) \, dy^* \, dx^* \quad (1.2)
\]

so that

\[
g(y^*, x^*) = \omega(y^*, x^*) f(y^*, x^*) \quad (1.2)
\]

Sampling schemes for which \( \omega(y, x) = 0 \) for some values of \((Y, X)\) create special problems. For such schemes, not all values of \((Y, X)\) are sampled. Let indicator variable \( i(y, x) = 0 \) if a potential observation at values \( y, x \) cannot be sampled and let \( i(y, x) = 1 \) otherwise. Let \( \Delta = 1 \) record the occurrence of the event 'a potential observation is sampled, i.e. the value of \( y, x \) is observed' and let \( \Delta = 0 \) if it is not. In the population, the proportion that is sampled is

\[
Pr(\Delta = 1) = \int i(y, x) f(y, x) \, dy \, dx \quad (1.3)
\]

while

\[
Pr(\Delta = 0) = 1 - Pr(\Delta = 1).
\]

For samples in which \( \omega(y, x) = 0 \) for a non-negligible proportion of the population \((Pr(\Delta = 0) > 0)\), it is clarifying to consider two cases. A truncated sample is one for which \( Pr(\Delta = 1) \) is not known and cannot be consistently estimated. For such a sample, (1.1) is the density of all of the sampled \( Y \) and \( X \) values. A censored sample is one for which \( Pr(\Delta = 1) \) is known or can be consistently estimated. The sampling rule in this case is such that values of \( y, x \) for which \( \omega(y, x) = 0 \) are not known but it is known whether or not \( i(y, x) = 0 \) for all values of \( Y, X \). In this case it is notationally convenient to define \( (Y^*, X^*) = (0, 0) \) for values of \( y, x \) such that \( \omega(y, x) = i(y, x) = 0 \). Such a definition is innocuous provided that in the population there is no point mass (concentration of probability mass) at \( (0, 0) \). (Any value other than \( (0, 0) \) can be selected provided that there is no point mass at that value). Given \( \Delta = 0 \), the distribution of \( Y^*, X^* \) is

\[
G(y^*, x^*) = 1 \quad (\Delta = 0)
\]

at

\[
Y^* = 0 \quad \text{and} \quad X^* = 0.
\]

The joint density of \( Y^*, X^*, \Delta \) for the case of a censored sample is obtained by combining (1.1) and (1.3). Thus

\[
g(y^*, x^*, \delta) = \frac{\omega(y^*, x^*) f(y^*, x^*)}{\int [i(y, x) f(y, x) \, dy \, dx]} \times \left[ \int (1 - i(y, x)) f(y, x) \, dy \, dx \right]^{-1} \quad (1.4)
\]
Thus we have

\[ \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f(y, x) \, dy \, dx = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f(y^*, x^*) \omega(y^*, x^*) \, dy^* \, dx^* \]

(1.6a)

As such, the conditional density of \( Y^*, X^* \) given \( \Delta = 1 \) is identical to (1.1).

In a random sample \( \omega(y^*, x^*) = 1 \) (and so \( \omega^*(y^*, x^*) = 1 \)). In a selected sample, the sampling rule weights the data differently. Values of \( (Y, X) \) are over-sampled or under-sampled relative to their occurrence in the population. In the case of truncated samples, the weight is zero for certain values of the outcome.

In many problems in economics, attention focuses on \( f(y|x) \), the conditional density of \( Y \) given \( X = x \). In such problems knowledge of the population distribution of \( X \) is of no direct interest. If samples are selected solely on the \( x \) variables ('selection on the exogenous variables'), \( \omega(y, x) = \omega(x) \) and there is no problem about using selected samples to make valid inference about the population conditional density. This is so because in the case of selection on the exogenous variables

\[ g(y^*, x^*) = f(y^*|x^*) \frac{\omega(x^*)}{f(x^*)} \]

and

\[ g(x^*) = \frac{\omega(x^*)}{\int \omega(x^*) f(x^*) \, dx^*} \]

Thus

\[ g(y^*, x^*) = \frac{g(x^*)}{f(y^*)} = f(y^*|x^*) \]

For such problems, sample selection distorts inference only if selection occurs on \( y \) (or \( y \) and \( x \)). Sampling on both \( y \) and \( x \) is termed general stratified sampling.

From a sample of data, it is not possible to recover the true density \( f(y, x) \) without knowledge of the weighting rule. On the other hand, if the weighting rule is known \( \omega(y^*, x^*) \), the density of the sampled data is known \( g(y^*, x^*) \), the support of \( (y^*, x^*) \) is known and \( \omega(y, x) \) is nonzero, then \( f(y, x) \) can always be recovered because

\[ \frac{g(y^*, x^*)}{\omega(y^*, x^*)} \int g(y^*, x^*) \, dy^* \, dx^* = 1 \]

(1.5)

and by hypothesis both the numerator and denominator of the left-hand side are known. From the requirement that \( g(y^*, x^*) \) has a well defined density

\[ \int (y^*, x^*) \, dy^* \, dx^* = 1 \]

the left-hand side of (1.5) is possible to determine \( \int \omega(y^*, x^*) f(y^*, x^*) \, dy^* \, dx^* \) and hence to use (1.5) to recover the population density of the data.

The requirements that (a) the support of \( y \) is known and \( \omega(y, x) \) is nonzero are not innocuous. In many important problems in economics requirement (b) is not satisfied: the sampling rule excludes observations for certain values of \( y, x \) and hence it is impossible without invoking further assumptions to determine the population distribution of \( (Y, X) \) at those values. If neither the support nor the weight is known, it is impossible, without invoking strong assumptions, to determine whether the fact that data are missing at certain \( x \) values is due to the sampling plan or that the population density has no support at those values. We now turn to some specific sampling plans of interest in economics.

Example 1. Data are collected on incomes of individuals whose income \( Y \) exceeds a certain value \( c \) (for cutoff value). The rule is to observe \( Y \) if \( Y > c \). Thus \( \omega(y) = 1 \) if \( y > c \) and \( \omega(y) = 0 \) if \( y \leq c \). Because the weight is zero for some values of \( y \), we know that knowledge of the sampling rule does not suffice to recover the population distribution. From a random sample of the entire population, the social scientist knows or can consistently estimate (a) the sample distribution of \( Y \) above \( c \) and (b) the proportion of the original random sample with income below \( c \) \( F(c) \) where \( F \) is the distribution function of \( Y \). The social scientist does not observe values of \( Y \) below \( c \).

In this example, observed income is a truncated random variable. The point of truncation is \( c \). The sample of observed income is said to be censored. If the proportion of the original random sample with income below \( c \) is not known and cannot be consistently estimated, the sample is truncated. In a truncated sample, nothing is known about the proportion of the underlying population that can appear in the sample. A sample is truncated only if \( \omega(y) = 0 \) for some intervals of \( y \) (for \( y \) continuous) or if \( \omega(y) = 0 \) at values of \( y \) at which there is finite probability mass. In a censored sample, the proportion of the underlying population that can appear in the sample is known, at least to an arbitrarily high degree of approximation, as sample size increases.

Let \( Y^* = Y \) if \( Y > c \). Define \( Y^* = 0 \) otherwise (the choice of the value for \( y^* \) when \( Y \) is not observed is inessential and any value can be used in place of 0 provided that the true distribution places no mass at the selected value). Define an indicator variable \( \Delta = 1 \) if \( Y > c \). \( \Delta = 0 \) otherwise. Then the distribution of \( Y^* \) is

\[ G(y^*|Y > 0) = F(y^*) \]

(1.6a)

\[ G(y^*|Y > 0) = 1 \quad \text{for} \quad y^* = 0 (\Delta = 0) \]

(1.6b)

Observe that (1.6a) is obtained from (1.1) by setting \( \omega(y^*) = 1 \) if \( y > c \), and \( \omega(y^*) = 0 \) otherwise, and integrating up with respect to \( y^* \). The distribution of \( \Delta \) is

\[ \Pr(\Delta) = [1 - F(c)](F(c))^{-1}. \]

(1.7)

The joint distribution of \( (Y^*, \Delta) \) is

\[ F(y^*, \delta) = F(y^*) \delta \Pr(\delta) \]

\[ = \left\{ \begin{array}{ll}
F(y^*) & \quad \text{if } \delta = 1 \\
[1 - F(c)](1 - \delta) & \quad \text{if } \delta = 0
\end{array} \right. \]

(1.7)

Note that (1.7) is obtained from (1.4) by setting \( \omega(y) = 0, y < c, \omega(y) = 1 \) otherwise, by setting \( i(y) = \omega(y) \), and by integrating up with respect to \( y^* \). For normally distributed \( Y \), (1.7) is the 'Tobit' distribution.

The difference between the information in a truncated sample and the information in a censored sample is encapsulated in the contrast between (1.6a) and (1.7). Clearly there is more information in a censored sample than in a truncated sample because one can obtain (1.6a) from (1.7) (by conditioning on \( \Delta = 1 \)) but not vice versa.

Inferences about the population distribution based on assuming that \( F(y^*|Y > c) \) closely approximates \( F(y) \) are potentially very misleading. A description of population income inequality based on a subsample of high income people may convey no information about the true population distribution.
The joint distribution of \((Y^*, L^*)\) given \(X = x\) is
\[
G(y^*, l^* | X = x) = F(y^* | X = x, Y > c)
\]
where \(l^*\) is a dummy variable of integration. In contrast, the distribution of \(y^*\) conditional on \(X\) is
\[
G(y^* | X = x) = F(y^* | X = x, Y > c)
\]
where \(y^*\) is a dummy variable of integration. In contrast, the distribution of \(U\), \(G(U | X = x, Y > c)\), can be recovered (Heckman and Singer, 1985). If \(F\) is normal, then it can be recovered from a censored or truncated sample (Pearson, 1901). If \(F\) is Pareto, \(F\) cannot be recovered from either a truncated or a censored sample (see Flinn and Heckman, 1982). If \(F\) is real analytic (i.e. possesses derivatives of all order) and the support of \(Y\) is known, then \(F\) can be recovered (Heckman and Singer, 1985).

**Example 2.** Expand the discussion in the previous example to a linear regression setting. Let
\[
Y = \beta X + U
\]
be the population earnings function where \(Y\) is earnings, \(X\) is a regressor vector assumed to be distributed independently of mean zero disturbance \(U\). \(\beta\) is a suitably dimensioned parameter vector. Conventional assumptions are invoked to ensure that ordinary least squares applied to a random sample of earnings data consistently estimates \(\beta\).

Data are collected on incomes of persons for whom \(Y\) exceeds \(c\). Again the weight depends solely on \(y\), i.e. \(w(y, x) = 1, y < c, w(y, x) = 1, y > c\). The social scientist knows or can consistently estimate (a) the sample distribution of \(Y\) above \(c\), (b) the sample distribution of the \(X\) for \(Y\) above \(c\) and (c) the proportion of the original random sample with income below \(c\). The social scientist does not observe values of \(Y\) below \(c\).

As before, let \(Y^* = Y\) if \(Y > c\). Define \(y^* = 0\) otherwise. \(\Delta = 1\) if \(Y > c, \Delta = 0\) otherwise. The probability of the event \(\Delta = 1\) given \(X = x\) is
\[
Pr(\Delta = 1 | X = x) = Pr(Y > c | X = x) = Pr(Y > c - x\beta | X = x).
\]
Invoking independence between \(U\) and \(X\) and letting \(F_\Delta\) denote the distribution of \(U\),
\[
Pr(\Delta = 1 | X = x) = 1 - F_\Delta(c - x\beta)
\]
and
\[
Pr(\Delta = 0 | X = x) = F_\Delta(c - x\beta)
\]
The distribution of \(y^*\) conditional on \(X\) is
\[
G(y^* | Y > 0, X = x) = F(y^* | X = x, Y > c) = F(y^* | X = x, \Delta = 1) = F_\Delta(y^* - x\beta) = 1 - F_\Delta(c - x\beta), \quad y^* > c.
\]
(1.10a)
\[
G(y^* | Y \leq 0) = 1 \text{ for } y^* = 0 (\Delta = 0).
\]
(1.10b)
The joint distribution of \((Y^*, \Delta)\) given \(X = x\) is
\[
F(y^*, \delta | X = x) = F(y^* | \delta, x) Pr(\delta | x) = \{F_\Delta(y^* - x\beta)\}^\delta \{F_\Delta(c - x\beta)\}^{1-\delta}.
\]
(1.11)
In particular,
\[
E(Y^* | X = x, \Delta = 1) = x\beta + E(U | X = x, \delta = 1) = x\beta + \int_{c-x\beta}^{\infty} z dF_\beta(z)
\]
where \(z\) is a dummy variable of integration. In contrast, the population mean regression function is
\[
E(Y | X = x) = x\beta.
\]
(1.13)

The contrast between (1.12) and (1.13) is illuminating. Many behavioural theories in social science produce empirical counterparts of (1.8) with population conditional expectations like (1.13). Such theories sometimes restrict the signs, permissible values and other relationships among the coefficients in \(\beta\).

When the theoretical model is estimated on a selected sample \((\Delta = 1)\), the true conditional expectation is (1.12) not (1.13). The conditional mean of \(U\) depends on \(x\). In terms of conventional omitted variable analysis, \(E(U | X = x, \Delta = 1)\) is omitted from the regression. Since this term is a function of \(x\), it is likely to be correlated with \(x\). Least squares estimates of \(\beta\) obtained on selected samples which do not account for selection are biased and inconsistent.

To illustrate the nature of the bias, it is useful to draw on the work of Cain and Watts (1973). Suppose that \(X\) is a scalar random variable (e.g. education) and that its associated coefficient is positive \((\beta > 0)\). Under conventional assumptions about \(U\) (e.g. mean zero, independently and identically distributed and distributed independently of \(X\)), the population regression of \(Y\) on \(X\) is a straight line. The scatter about the regression line and the regression line are given in Figure 1. When \(Y > c\) is imposed as a sample inclusion requirement, lower population values of \(U\) are excluded from the sample in a way that systematically depends on \(x\). (\(Y > c\) or \(U > c - x\beta\)). As \(x\) increases, the conditional mean of \(U\) \((E(U | X = x, \Delta = 1))\) decreases. Regression estimates of \(\beta\) that do not correct for sample selection (i.e. include \(E(U | X = x, \Delta = 1)\) as a regressor) are downward biased because of the negative correlation between \(x\) and \(E(U | X = x, \Delta = 1)\). See the flattened regression line for the selected sample linear regression line in Figure 1.

In models with more than one regressor, no sharp result on the sign of the bias in the regression estimate that results from ignoring the selected nature of the sample is available except when the \(X\) variables are from certain distributions (e.g. normal, see Goldberger, 1983). None the less, the key result - that conventional least squares estimates of \(\beta\) obtained from selected samples are biased and inconsistent remains true.

As in example 1, it is fruitful to distinguish between the case of a truncated sample and the case of a censored sample. In the truncated sample case, no information is available about the fraction of the population that would be allocated to the truncated sample \(\{Pr(\Delta = 1)\}\). In the censored sample case, this
fraction is known or can be consistently estimated. In the censored sample case it is fruitful to distinguish two further cases: (a) the case in which X is observed when \( \Delta = 0 \) and (b) the case in which it is. Case (b) is the one most fully developed in the literature (Heckman and MacCulloch, 1981).

Note that the conditional mean \( E(U|X = x, \Delta = 1) \) is a function of \( c - X \beta \) solely through \( \Pr(\Delta = 1|x) \). Since \( \Pr(\Delta = 1|x) \) is monotonic in \( c - X \beta \), the conditional mean depends solely on \( \Pr(\Delta = 1|x) \) and the parameters \( F_c \) i.e. since

\[
F_c = (1 - \Pr(\Delta = 1|x)) = c - X \beta .
\]

This relationship demonstrates that the conditional mean is a function of the probability of selection. As the probability of selection goes to 1, the conditional mean goes to zero. For samples chosen so that the values of \( x \) are such that the observations are certain to be included in the sample, there is no problem in using ordinary least squares on selected samples to estimate \( \beta \). Thus in Figure 1, ordinary least squares regressions fit on samples selected to have large \( x \) values closely approximate the true regression function and become arbitrarily close as \( x \) becomes large. The condition mean (1.12) is a surrogate for \( \Pr(\Delta = 1|x) \). As this probability goes to one, the problem of sample selection in regression analysis becomes negligibly small.

Heckman (1976) demonstrates that \( \beta \) and \( F_c \) are identified if \( U \) is normally distributed and standard conditions invoked in regression analysis are satisfied. Gallant and Nychka (1984) and Cosslett (1984) establish conditions for identification of non-normal \( U \). In their analyses, \( F_c \) is consistently non-parametrically estimated.

Example 3. The next example considers censored random variables. This concept extends the notion of a truncated random variable by letting a more general rule than truncation on the outcome of interest generate the selected sample. Because the sample generating rule may be different from a simple truncation of the outcome being studied, the concept of a censored random variable in general requires at least two distinct random variables.

Let \( Y_t \) be the outcome of interest. Let \( Y_t \) be another random variable. Denote observed \( Y_t \) by \( Y_t^* \). If \( Y_t < c \), \( Y_t \) is observed. Otherwise \( Y_t \) is not observed and we can set \( Y_t^* = 0 \) or any other convenient value (assuming that \( Y_t \) has no point mass at \( Y_t = 0 \) or at the alternative convenient value). In terms of the weighting function \( w_t, o_t(y_1, y_2) = 1 \) if \( y_2 < c, o_t(y_1, y_2) = 1 \) if \( y_2 < c \).

Selection rule \( Y_t < c \) does not necessarily restrict the range of \( Y_t \). Thus \( Y_t^* \) is not in general a truncated random variable. Define \( \Delta = 1 \) if \( Y_t < c, \Delta = 0 \) otherwise. If \( F_t(y_1, y_2) \) is the population distribution of \( (Y_t, Y_t^*) \), the distribution of \( Y_t^* \) is

\[
\Pr(\Delta = 1) = 1 - F_t(c)^{-2}F_t(c)^{\Delta}, \quad \delta = 0, 1.
\]

where \( F_t \) is the marginal distribution of \( Y_t \). The distribution of \( Y_t^* \) is

\[
G(y_t^*, \Delta) = \frac{F_t(y_t^*, c)}{F_t(c)} \quad (1.14a).
\]

Note that (1.14a) is the distribution function corresponding to the density in (1.1) when \( o_t(y_1, y_2) = 1 \) if \( y_2 < c \) and \( o_t(y_1, y_2) = 0 \) otherwise.

The joint distribution of \( (Y_t^*, \Delta) \) is

\[
G(y_t^*, \Delta) = [F_t(y_t^*, c)]^\delta[1 - F_t(c)]^{1-\delta} \quad (1.15).
\]

This is the distribution function corresponding to density (1.4) for the special weighting rule of this example. In a censored sample, under general conditions it is possible to consistently estimate \( \Pr(\Delta = 1) \) and \( G(y_t^*) \). In a truncated sample, only conditional distribution (1.14a) can be estimated. A degenerate version of this model has \( Y_t = Y_t^* \). In that case, censored random variable \( Y_t \) is also a truncated random variable. Note that a censored random variable may be defined for a truncated or censored sample.

Example 3 and variants of it have wide applicability in economics. Let \( Y_t \) be the wage of a woman. Wages of women are observed only if women work. Let \( Y_t \) be an index of a woman’s propensity to work. In Gronau (1974) and Heckman (1974), \( Y_t \) is postulated as the difference between reservation wages (the value of time at home determined from household preference functions) and potential market wages \( Y_t^* \). Then if \( Y_t < 0 \), the woman works. Otherwise, she does not. \( Y_t^* = Y_t \) if \( Y_t < 0 \) is the observed wage.

If \( Y_t \) is the offered wage of an unemployed worker, and \( Y_t \) is the difference between reservation wages (the return to searching) and offered market wages, \( Y_t^* = Y_t^* \) if \( Y_t < 0 \) is the accepted wage for an unemployed worker (see Flinn and Heckman, 1982). If \( Y_t \) is the potential output of a firm and \( Y_t \) is its profitability, \( Y_t^* = Y_t \) if \( Y_t > 0 \). If \( Y_t \) is the potential income in occupation one and \( Y_t^* \) is the potential income in occupation two, \( Y_t^* = Y_t \) if \( Y_t > 0 \), \( Y_t^* = Y_t \) if \( Y_t < 0 \). We develop this example at length in section 2 where we consider explicit economic models of self-selection.

There we discuss the identifiability of this model.

Example 4. This example builds on example 3 by introducing regressors. This produces the censored regression model (Heckman, 1976; 1979). In example 3 set

\[
Y_t = X_t \beta + U_t
\]

where \( (X_t, X_0) \) are distributed independently of \( (U_t, U_0) \), a mean zero, finite variance random vector. Conventional assumptions are invoked to ensure that if \( Y_t \) and \( Y_t^* \) can be observed, least squares applied to a random sample of data on \( (Y_t, Y_t^*, X_t, X_0) \) would consistently estimate \( \beta \) and \( \beta \), \( \gamma = Y_t^* \) if \( Y_t < 0 \). If \( Y_t < 0, \Delta = 1 \). Then the regression function for the selected sample is

\[
E(Y_t^*|X_t = x_t, Y_t < 0) = E(Y_t^*|X_t = x_t, \Delta = 1) = X_t \beta + E(U_t|X_t = x_t, \Delta = 1)
\]

and the regression function for the population is

\[
E(Y_t|X_t = x_t) = X_t \beta_0.
\]

As in the regression analysis of truncated random variables, there is an illuminating contrast between the conditional expectation for the selected sample (1.17) and the population regression function (1.18). The two functions differ by the conditional mean of \( U_t[E(U_t|X_t = x_t, \Delta = 1)] \). In the regression analysis of truncated random variables, ordinary least squares estimates of \( \beta \) (in equation (1.14)) are biased and inconsistent because the conditional mean is improperly omitted from the selected sample regression. The same analysis applies to the regression analysis of censored random variables. The conditional mean is a surrogate for the probability of selection [\( \Pr(\Delta = 1|x_t) \)]. As \( \Pr(\Delta = 1|x_t) \) goes to one, the problem of sample selection bias becomes negligible. However, in the censored regression case, a new phenomenon appears. If there are variables in \( X_t \) not in \( X_0 \), such variables may appear to be
statistically important determinants of $Y_i$ when ordinary least squares is applied to data generated from censored samples.

As an example, suppose that survey statisticians use some extraneous (to $X_i$) variables to determine sample enrollment. Such variables may appear to be important determinants of $Y_i$, when in fact they are not. They are important determinants of $Y_i^\star$. In an analysis of self-selection, let $Y_i$ be the wage that a potential worker could earn were he to accept a market offer. Let $Y_i$ be the difference between the best non-market opportunity available to the potential worker and $Y_i$. If $Y_i < 0$, the agent works. The conditional expectation of observed wages ($Y_i^\star = Y_i$ if $Y_i < 0$) given $x_i$ and $x_i$ will be a non-trivial function of $x_i$. Thus variables determining non-market opportunities will determine $Y_i^\star$, even though they do not determine $Y_i$. For example, the number of children less than six may appear to be significant determinants of $Y_i$ when inadequate account is taken of sample selection, even though the market does not place any value or penalty on small children in generating wage offers for potential workers.

Heckman (1976) develops the analysis of this model when $(U_i, U_{ii})$ is normally distributed. Gallant and Nychka (1984) and Cosslett (1984) demonstrate that under mild restrictions on $F(u_i, u_{ii})$, if there is one continuous valued variable in $X_i$ not in $x_i$ (so that there is no exact linear dependence between $x_i$ and $x_{ii}$), $f, f_i$ and $F(u_i, u_{ii})$ can be consistently non-parametrically estimated. Heckman and MaCurdy (1986) develop this class of models at length.

Example 5. This example demonstrates how self-selection bias affects the interpretation placed on estimated consumer demand functions when there is self-selection. We postulate a population of consumers with a quasi-concave utility function $U(Z, E)$ which depends on the consumption of goods and preference shock $E$ which represents heterogeneity in preferences among consumers. The support of $E$ is $E$. For price vector $P$ and endowment income $M$, the consumer’s problem is to

$$\text{Max } U(Z, E) \text{ subject to } P'Z \leq M.$$  

In the population $P$ and $M$ are distributed independently of $E$. First order conditions for this problem are

$$\frac{\partial U(Z, E)}{\partial Z} \leq \lambda P,$$  

where $\lambda$ is the Lagrange multiplier associated with the budget constraint. Focusing on the demand for the first good, $Z_1$, none of it is purchased if at zero consumption of $Z_1$ \[\frac{\partial U(Z, E)}{\partial Z_1} \bigg|_{Z_1 = 0} \geq \lambda P_1.\]

i.e. marginal valuation is less than marginal cost in utility terms. Conventional interior solution demand functions for $Z_1$ are defined for a given $P, M$ only for values of $E$ such that

$$\frac{\partial U(Z, E)}{\partial Z_1} \bigg|_{Z_1 = 0} \geq \lambda P_1.$$  

Let the set of $E$ for which conventional interior solution consumer demand functions for $Z_1$ are defined be denoted by $E$. Then

$$E = \left\{ E \mid \frac{\partial U(Z, E)}{\partial Z_1} \bigg|_{Z_1 = 0} \geq \lambda P_1 \right\} \text{ for given } P, M.$$

Let $A_1 = 0$ if the consumer does not purchase $Z_1$. Let $A_1 = 1$ otherwise. If $F(\epsilon)$ is the population distribution of $E$, the proportion purchasing none of good $Z_1$ given $P, M$ is

$$Pr(\Delta_1 = 0 | P, M) = 1 - \int_{-\infty}^{\infty} dF(\epsilon).$$

Provided inequality (1.21) is satisfied, $\Delta_1 = 1$ and interior solution demand function

$$Z_1 = Z_1(P, M, E)$$  

is well defined and $Z_1 = Z_1^\star$ . When $\Delta_1 = 0$, observed $Z_1 = Z_1^\star = 0$.

Equation (1.22) is the conventional object of interest in consumer theory. Partial derivatives of that function holding $E$ and the other arguments constant have well defined economic interpretations. Suppose that some non-negligible proportion of the population buys none of good $Z_1$. Regression estimates of the parameters of (1.22) using $Z_1^\star$ approximate the conditional expectation

$$E(Z_1 | \Delta_1 = 1, P, M) = \int Z_1(P, M, E) dF(\epsilon).$$  

The derivatives of (1.23) are different from the derivatives of (1.22). In order to define these derivatives, it is helpful to define $L(E)$ as an indicator function for set $E$ which equals one if $E \in E$ and equals zero otherwise. When prices or income change, the set of values of $E$ that satisfy inequality (1.21) changes. Let $E + \Delta E$ be the set of $E$ values that satisfy (1.21) when there is a finite price change $\Delta P$. $L(E + \Delta E)$ is an indicator function which equals one when $E \in E + \Delta E$. Then the derivatives of (1.23) are, for the $j$th price

$$\partial E(Z_1 | \Delta_1 = 1, P, M) \bigg|_{\Delta_1 = 1} = \int \frac{\partial Z_1(P, M, \epsilon)}{\partial P_j} dF(\epsilon)$$

$$+ \lim_{\Delta \epsilon \to 0} \int_{E+\Delta E} \left[ \frac{L(E + \Delta E)}{L(E)} - L(E) \right] Z_1(P, M, \epsilon) dF(\epsilon).$$

When the limit in the second term does not exist, the derivative does not exist. We assume for expositional convenience that the limit is well defined.

The first expression on the right-hand side of (1.24) is the average effect of price change on commodity demand. The second term on the right-hand side of (1.24) arises from the change in sample composition of $E$ as the proportion of non-purchasers changes in response to price change. This term generates the selection bias.

Neither term is the same as the price derivative of (1.22) for an arbitrary value of $E = \epsilon$ although the first term on the right-hand side of (1.24) approximates the price derivative of (1.22) for some value of $E = \epsilon$.

A similar decomposition of the derivatives of the conditional demand function can be performed if it is defined solely for a sample of non-zero purchasers (see Heckman and MaCurdy, 1981, 1986).

Just as in the statistical sample selection bias problem, there is a population of interest. In this case, the population parameters of interest are the distribution of $E$ and the parameters of $U(Z, E)$. Those who buy $Z_1$ are a self-selected sample of the population. Estimates of population parameters estimated on self-selected samples are biased and inconsistent. There is a population distribution of $Z_1(P, M, E)$ generated by the distribution of $E$. Observations of $Z_1$ are obtained only if $E \in E(P, M, E)$ generated by the distribution of $E$. Observations of $Z_1$ are obtained only if $E \in E(P, M, E)$ generated by the distribution of $E$.
Example 6. Length biased sampling. Let $T$ be the duration of an event such as a completed unemployment spell or a completed duration of a job with an employer. The population distribution of $T$ is $F(t)$ with density $f(t)$. The sampling rule is such that individuals are sampled at random. Data are recorded on a completed spell provided that at the time of the interview the individual is experiencing the event. Such sampling rules are in wide use in many national surveys of employment and unemployment.

In order to have a sampled completed spell, a person must be in the state at the time of the interview. Let '0' be the date of the survey. Decompose any completed spell $T$ into a component that occurs before the survey $T_b$ and a component that occurs after the survey $T_s$. Then $T = T_b + T_s$. For a person to be sampled, $T_s > 0$. The density of $T$ given $T_b = t_b$ is

$$f(t(t_b), t > t_b).$$

(1.25)

Suppose that the environment is stationary. The population entry rate into the state at each instant of time is $k$. From each vintage of entrants into the state distinguished by their distance from the survey date $t_b$, only $1 - F(t_b) = P(T > t_b)$ survive. Aggregating over all cohorts of entrants, the population proportion in the state at the date of the interview is $P$ where

$$P = \int_0^\infty k(1 - F(t_b)) dt_b,$$

(1.26)

which is assumed to exist. The density of $T^*_s$, sampled presurvey duration, is

$$g(t^*_s|t^*_s > 0) = k(1 - F(t^*_s)) P.$$  

(1.27)

The density of sampled completed durations is thus

$$g(t^*_s) = \int_0^\infty f(t^*_s|t^*_s > 0) dt^*_s = k \frac{f(t^*_s)}{1 - F(t^*_s)} P \int_0^\infty dt^*_s = k \frac{t^*_s f(t^*_s)}{P}.$$  

Observe from (1.26) that by a standard integration by parts argument

$$P = P \int_0^\infty (1 - F(z)) dz = P \int_0^\infty z dF(z) = P E(T),$$

Note that

$$g(t^*_s) = \frac{t^*_s f(t^*_s)}{E(T)}.$$  

(1.28)

In this form (1.28) is equivalent to (1.1) with $\omega(i) = t$. Hence the term 'length biased sampling'. Intuitively, longer spells are oversampled when the requirement is imposed that a spell be in progress at the time the survey is conducted ($T_s > 0$). Suppose, instead, that individuals are randomly sampled and data are recorded on the next spell of the event (after the survey date). As long as successive spells are independent, such a sampling frame does not distort the sampled distribution because no requirement is imposed that the sampled spell be in progress at the date of the interview. It is important to notice that the source of the bias is the requirement that $T_s > 0$, not that only a fraction of the population experiences the event ($P < 1$).

The simple length weight ($\omega(t) = t$) that produces (1.28) is an artefact of the stationarity assumption. Heckman and Singer (1983) consider the consequences of non-stationarity and unobservable on samples generated by length biased sampling rules when inadequate account is taken of the sampling plan. Vardi (1983, 1985) and Gill and Wellner (1985) consider nonparametric identification and estimation of models with densities of the form (1.28).

It is unfortunate that the lessons of length biased sampling are not adequately appreciated in economics. Two widely cited studies by Clark and Summers (1979) and Hall (1982) use length biased data to prove, respectively, that unemployment and employment spells are surprisingly long. Whether their findings are artefacts of sampling plans remains to be determined.

Example 7. Choice based sampling. Let $D$ be a discrete valued random variable which assumes a finite number of values $1, D = i, i = 1, \ldots, I$ corresponds to the occurrence of state $i$. States are mutually exclusive. In the literature the states may be modes of transportation choice for commuters (Domencich and McFadden, 1975), occupations, migration destinations, financial solvency status of firms, schooling choices of students, etc. Interest centres on estimating a population choice model

$$Pr(D = i|X = x), \quad i = 1, \ldots, I.$$  

(1.29)

The population density of $(D, X)$ is

$$f(d, x) = Pr(D = d|X = x) h(x)$$  

(1.30)

where $h(x)$ is the density of the data.

In many problems, plentiful data are available on certain outcomes while data are scarce for other outcomes. For example, interviews about transportation preferences conducted at train stations tend to over-sample train riders and under-sample bus riders. Interviews about occupational choice preferences conducted at leading universities over-sample those who select professional occupations.

In choice based sampling, selection occurs solely on the $D$ coordinate of $(D, X)$. In terms of (1.1) (extended to allow for discrete random variables), $\omega(d, x) = \omega(d)$. Then sampled $(D^*, X^*)$ has density

$$g(d^*, x^*) = \frac{\omega(d^*)f(d^*, x^*)}{\sum_{i=1}^I \omega(i)f(i, x^*)}$$  

(1.31)

Notice that the denominator can be simplified to

$$\sum_i \omega(i)f(i)$$

and that

$$\omega(d^*)$$

is the marginal distribution of $D^*$ so that

$$g(d^*, x^*) = \frac{\omega(d^*)f(d^*, x^*)}{\sum_{i=1}^I \omega(i)f(i)}$$  

(1.32)

Also, integrating (1.31) with respect to $x$ using (1.32) we obtain

$$g(d^*) = \frac{\omega(d^*)f(d^*)}{\sum_{i=1}^I \omega(i)f(i)}$$  

(1.33)

293

Heckman (1974) and Heckman and MaCurdy (1981) provide further discussion of this type of model which is widely used in applied economics and consider issues of identifiability for such models.
which makes transparent how the sampling rule causes the sampled proportions to deviate from the population proportions. Note further that as a consequence of sampling only on \( D \), the population conditional density

\[
h(x^*|d^*) = \frac{f(d^*, x^*)}{f(d^*)}
\]

(1.34)

can be recovered from the choice based sample. The density of \( x \) in the sample is thus

\[
g(x^*) = \sum_{i=1}^{I} h(x^*) g(i).
\]

(1.35)

Then using (1.32)-(1.35) we reach

\[
g(d^*|x^*) = f(d^*|x^*)
\]

(1.36)

The bias that results from using choice based samples to make inference about \( f(d^*|x^*) \) is a consequence of neglecting the terms in braces on the right-hand side of (1.36). Notice that if the data are generated by a random sampling rule, \( \omega(d^*) = 1, g(d^*) = f(d^*) \) and the term in braces is one. Manski and Lerman (1977), Manski and McFadden (1981) and Cosslett (1981) provide illuminating discussions of choice based sampling.

Example 8. Size biased sampling. Let \( N \) be the number of children in a family. \( f(N) \) is the density of discrete random variable \( N \). Suppose that family size is recorded only when at least one child is interviewed. Suppose further that each child has an independent and identical chance \( \beta \) of being interviewed. The probability of sampled family size of \( N^* = n^* \) is

\[
g(n^*) = \frac{\omega(n^*) f(n^*)}{E(\omega(N^*))}
\]

(1.37)

where \( \omega(n^*) = 1 - (1 - \beta)^n^* \) (the probability that at least one child from a family of size \( n^* \) will be sampled) and

\[
E(\omega(N^*)) = \sum_{n} (1 - (1 - \beta)^n) f(n)
\]

is the probability of observing a family. In a large population \( \beta \to 0 \) with increasing population size. Using Hospital’s rule, and assuming that passage to the limit under the summation sign is valid

\[
\lim g(n^*) = \frac{\gamma f(n^*)}{E(N)}(1.38)
\]

Thus the limit form of (1.37) is identical to (1.28). Larger families tend to be oversampled and hence a misleading estimate of family size will be produced from such samples. Since the model is formally equivalent to the length biased sampling model, all references and statements about identification given in example 6 apply with full force to this example. See the discussion in Rao (1965).

2. ECONOMIC MODELS OF SELF-SELECTION

We begin our analysis by expositing the Roy model of self-selection for workers with heterogeneous skills. The statistical framework for this model has been outlined in examples 3 and 4. Following Roy, we assume that there are two market sectors in which income-maximizing agents can work. Agents are free to enter the sector that gives them the highest income. However, they can work in only one sector at a time.

Each sector requires a unique sector-specific task. Each agent has two skills, \( T_1 \) and \( T_2 \) which he cannot use simultaneously. The model is short run in that aggregate skill distributions are assumed to be given. There are no costs of changing sectors, and investment is ignored. Because of this assumption, the model presented here applies to environments with certain or uncertain prices for sector-specific tasks. For simplicity and without any loss of generality (given the preceding assumptions), we assume an environment of perfect certainty.

Let \( T_i \) be the amount of sector \( i \) specific task a worker can perform. The price of task of \( i \) is \( \pi_i \). An agent works in sector \( i \) if his income is higher there, that is

\[
\pi_i T_i > \pi_j T_j
\]

(2.1)

Indifference between sectors is a negligible probability event if the \( T_i = 1, 2 \) are assumed to be continuous nondegenerate random variables. Throughout we assume that prices are positive (\( \pi_i > 0 \)).

The log wage in task \( i \) of an individual with endowment \( T_i \) is

\[
\ln W_i = \ln \pi_i + \ln T_i
\]

(2.2)

The proportion of the population working at task \( i \) is the proportion of the population for whom

\[
T_i > \frac{\pi_2}{\pi_1} T_j.
\]

Roy assumes that \( (\ln T_1, \ln T_2) \) is normally distributed with mean \( (\mu_1, \mu_2) \) and covariance matrix \( \Sigma \). Letting \( (U_1, U_2) \) be a mean zero normal vector, agents in the Roy model choose between two possible wages:

\[
\ln W_1 = \ln \pi_1 + \mu_1 + U_1
\]

or

\[
\ln W_2 = \ln \pi_2 + \mu_2 + U_2.
\]

Workers enter sector 1 if \( \ln W_1 > \ln W_2 \). Otherwise they enter sector 2.

Letting

\[
\sigma^2 = \text{var}(U_1 - U_2)
\]

and

\[
c_i = (\ln(\pi_i/\pi_j) + \mu_i - \mu_j) e^*. \quad i \neq j,
\]

\[
Pr(i|j) = P(\ln W_i > \ln W_j) = \Phi(c_{ij}), \quad i \neq j, \quad i, j = 1, 2
\]

where \( \Phi(\cdot) \) is the cumulative distribution function of a standard normal variable. When standard sample selection bias formulae are used (see, e.g. Heckman 1976), the mean of log wages observed in sector \( i \) is

\[
E(\ln W_i|\ln W_i > \ln W_j) = \ln \pi_i + \mu_i + \frac{\sigma^2 - \sigma_i^2}{\sigma^2} \lambda(c),
\]

\[
i, j = 1, 2, \quad i \neq j
\]

(2.3)

where

\[
\lambda(c) = \sqrt{\frac{2\pi}{c^2}} \Phi(c)
\]

is a convex monotone decreasing function of \( c \) with \( \lambda(c) \geq 0 \), and

\[
\lim \lambda(c) = 0, \quad \lim \lambda(c) = \infty.
\]

Convexity is proved in Heckman and Honore (1986).
The variance of log wages observed in sector $i$ is:

$$\text{var}(\ln W_i|\ln W_j) = \sigma_i^2 + \frac{\lambda_i}{\sigma_i^2} \left(1 - \rho_i^2 \right), \quad i \neq j \quad (2.4)$$

where $\rho_i = \text{corr}(U_i, U_j), \ i \neq j = 1, 2$. The variance of the log of observed wages never exceeds $\sigma_i^2$, the population variance, because the term in braces in (2.4) is never greater than unity. In general, sectoral variances decrease with increased selection. For example, if $\rho_1$ and $\rho_2$ do not equal zero, as $\pi_i$ increases with $\pi_i$ held fixed so that people shift from sector 2 to sector 1, the variance in the log of wages in sector 1 increases while the variance in the log of wages in sector 2 decreases.

Using the fact that $W_i = \pi_i T_i$, we may use (2.3) to write:

$$E(\ln T_i|\ln W_i > \ln W_j) = \mu_i + \frac{\sigma_{12}}{\sigma_1} \lambda_i (c_i). \quad (2.5a)$$

$$E(\ln T_i|\ln W_i > \ln W_j) = \mu_i + \frac{\sigma_{12}}{\sigma_1} \lambda_i (c_i). \quad (2.5b)$$

Focusing on (2.5a) and noting that $\lambda_i$ is positive for all values of $c_i$, the mean of log task 1 used in sector 1 exceeds, equals, or falls short of the population mean endowment of log task 1 as $\sigma_{11}$ is greater than, equal to, or less than zero. If endowments of tasks are uncorrelated ($\sigma_{12} = 0$), self-selection always causes the mean of $\ln T_1$ employed in sector 1 to be above the population mean $\mu_i$. The opposite case occurs when $\sigma_{11} = \sigma_{12}$ is negative. This case can arise only when values of $\ln T_1$ and $\ln T_2$ are sufficiently positively correlated. If this occurs, the mean of log task 1 used in sector 1 falls below the population mean $\mu_i$. Since covariance matrices must be positive semidefinite, $\sigma_{11} = \sigma_{12} = 0$ is the only solution.

In the Roy model the unusual case can arise in at most one sector. Notice from (2.5) that only if $\sigma_{11} - \sigma_{12} = 0$ (so $\rho_1 = 0$) is the variance of log task 1 employed in sector 1 identical to the variance of log task 1 in the population. Otherwise, the sectoral variance of observed log task 1 is less than the population variance of log task 1.

To gain further insight into the effect of self-selection on the distribution of earnings for workers in sector 1, it is helpful to draw on some results from normal regression theory. The regression equation for $\ln T_2$ conditional on $\ln T_1$ is:

$$\ln T_2 = \mu_2 + \frac{\sigma_{12}}{\sigma_2} (\ln T_1 - \mu_1) + \epsilon_2. \quad (2.6)$$

where $E(\epsilon_2) = 0$ and $\text{var}(\epsilon_2) = \sigma_2^2 \left(1 - \rho_2^2 \right)$.

Figure 2 plots regression function (2.6) for the case $\sigma_{12} = \sigma_{11}$ and $\mu_2 > \mu_1 > 0$. For each value of $\ln T_1$, the population values of $\ln T_2$ are normally distributed around the regression line. Individuals with high values of $\ln T_1$ also tend to have a high value of $\ln T_2$. Assuming $\pi_1 = \pi_2$, individuals with $\ln T_1, \ln T_2$ endowments above the 45° line of equal income in Figure 1 choose to work in sector 2, while those individuals with endowments below this line work in sector 1. Because $\sigma_{12} = \sigma_{11}$, the regression function is parallel to the line of equal income.

The distribution of $\epsilon_2$ about the regression line is the same for all values of $\ln T_1$. When individuals are classified on the basis of their in $\ln T_1$ values the same proportion of individuals work in sector 1 at all values of $\ln T_1$. For this reason the distribution of $\ln T_1$ employed in sector 1 is the same as the latent population distribution. If $\pi_i$ is raised (or $\pi_i$ is lowered) so that the 45° equal income line is shifted upward, the same proportion of people enter sector 1 at each value of $\ln T_1 = t_1$. Figure 3 plots regression function (2.6) for the case $\sigma_{12} > \sigma_{11}$ and $\mu_2 > \mu_1 > 0$.

As before we set $\pi_i = \pi_2$. Individuals with endowments above the 45° line choose to work in sector 2, while those with endowments below this line work in sector 1. When individuals are classified on the basis of their $\ln T_1$ values, the fraction of people working in sector 1 decreases the higher the value of $\ln T_1$. The population mean of log task 1 employed in sector 1 to be less than the mean of log task 1 in the total population. People with high values of $\ln T_1$ are under-represented in sector 1 and low $\ln T_1$ values are over-represented. In the extreme, when $\ln T_1$ and $\ln T_2$ are perfectly positively correlated, all high-income individuals are in sector 2, while all the low-income individuals are in sector 1. The highest-paid sector 1 worker earns the same as the lowest-paid sector 2 worker (Roy, 1951; Willis and Rosen, 1979). In this case there is really only one skill dimension and individuals can be unambiguously ranked along this scale.

If $\pi_1$ is raised (or $\pi_2$ is lowered) so that the line of equal income is shifted upward, the mean of $\ln T_1$ employed in sector 1 must rise. The only place left to get $\ln T_1$ is from the high end of the $\ln T_2$ distribution. Unlike the case of $\sigma_{12} = \sigma_{11}$, in which a 10 per cent increase in $\ln T_1$ results in a 10 per cent increase in measured average earnings in sector 1, when $\sigma_{12} > \sigma_{11}$, a 10 per cent increase in $\ln T_1$ results in a greater than 10 per cent increase in the measured average earnings in sector 1 as the average quality of the sector 1 work-force increases. The variance of log wages in sector 1 increases.

If $\sigma_1 < \sigma_2$, than $\sigma_1 < \sigma_2$ in order for $\Sigma$ to be a covariance matrix. In the population, log task 2 must have greater variability than log task 1. Individuals with high $\ln T_1$ values tend to have high $\ln T_2$ values. But the population distribution of log task 2 has more mass in the tails. The higher an agent's value of $\ln T_1$, the more likely it is that he will be able to get higher income in sector 2. At the lower end of the distribution, the process works in reverse: lower $\ln T_1$ individuals on average have poor $\ln T_2$ values. Self-selection causes the $\ln T_1$ distribution in sector 1 to have an evacuated right tail, an exaggerated left tail, and a lower mean than the population mean of $\ln T_1$. 

295
selection bias and self-selection

If \( \sigma_2 < \sigma_1 \) (a case not depicted graphically), the proportion of each \( T_i \) group working in sector 1 increases, the higher the value of \( \tau_i \). The mean of the log task employed in sector 1 exceeds \( \mu_1 \). A 10 per cent increase in \( \tau_i \) produces an increase of less than 10 per cent in the average earnings of workers in sector 1 as the mean of \( \ln T_i \) employed in sector 1 declines. In fact if \( \sigma_1 > \sigma_2 \) it is possible for an increase in \( \tau_i \) to cause measured sector 1 wages to decline. Thus through a selection phenomenon it is possible for the average wage of people working in sector 1 to decline even though the price per unit skill increases there.

How robust are these conclusions if the normality assumption is relaxed? Heckman and Sédlacek (1985) show that many propositions derived from assumed normality of skills do not hold up for more general distributions. For example, increasing selection need not decrease sectoral variances. The effects of selection on mean employed skill levels are ambiguous. Heckman and Honoré (1986) demonstrate that in a single cross-section of data, it is possible to identify all of the parameters of the model from the data if the normality assumption is invoked. However, in a single cross-section many other models can explain the data equally well. In particular, intuitive notions about the degree of correlation or dependence among skills have no empirical content and so models of skill ‘hierarchies’ based on the extent of such dependence have no content for single cross-sections of data.

To show this, write the density of skills as \( f(t_1, t_2) \). Let

\[
Z = \begin{cases} 
T_1 & \text{if } T_1 > T_2 \\
0 & \text{otherwise}
\end{cases}
\]

\[
Z_2 = \begin{cases} 
T_2 & \text{if } T_2 > T_1 \\
0 & \text{otherwise}
\end{cases}
\]

Prices are normalized to unity \((\pi_1 = \pi_2 = 1)\). Then the density of

\[
Q_1'(z_1) = \int_{|t_2 < q_1|} f(t_1, t_2) dt_2 = \int_0^{q_1} f(t_1, t_2) dt_2.
\]

The density of \( z_2 \) is

\[
Q_2(z_2) = \int_0^{q_2} f(t_1, t_2) dt_1.
\]

Note that \( Q_1(n) \) and \( Q_2(n) \) summarize all of the available data on observed earnings.

Now if \( T_1, T_2 \) are independent with cdf’s \( F_1^* \) and \( F_2^* \) respectively

\[
Q_1(n) = f^*_1(n)F_1^*(n) \quad Q_2(n) = F_1^*(n)f_2(n).
\]

Define

\[
Q(n) = \int_n^\infty Q_1'(t) dt_1 + \int_n^\infty Q_2'(t) dt_2 = F_1^*(n)f_2(n).
\]

Thus we can write

\[
F_1^*(\phi) = \exp \left( -\int_0^\phi \frac{Q_1'(n)}{Q(n)} dn \right) \quad i = 1, 2
\]

so that we can always rationalize the data on wages in a single cross-section by a model of skill independence, and economic models of skill hierarchies have no empirical content for a single cross-section of data.

Suppose, however, that the observing economist has access to data on skill distributions in different market settings i.e. settings in which relative skill prices vary. To take an extreme case, suppose that we observe a continuum of values of \( \tau_1/\tau_2 \) ranging from zero to infinity. Then it is possible to identify \( F(t_1, t_2) \) and it is possible to give empirical content to models based on the degrees of dependence among latent skills.

This point is made most simply in a situation in which \( Z \) is observed but the analyst does not know \( Z_1 \) or \( Z_2 \) (i.e. which occupation is chosen). When \( \pi_1/\pi_2 = 0 \), everyone works in occupation two. Thus we can observe the marginal density of \( t_2 \). When \( \pi_1/\pi_2 = \infty \), everyone works in occupation one. As \( \pi_1/\pi_2 \) pivots from zero to infinity it is thus possible to trace out the full joint distribution of \( (T_1, T_2) \).

To establish the general result, set \( \sigma = \pi_2/\pi_1 \). Let \( F(t_1, t_2) \) be the distribution function of \( T_1, T_2 \). Then

\[
Pr(Z \leq n) = Pr(\max(T_1, T_2) \leq n) = Pr(T_1 \leq n, T_2 \leq \frac{1}{\sigma} n)
\]

\[
= F \left( \frac{n}{\sigma} \right).
\]

As \( \sigma \) varies between 0 and \( \infty \), the entire distribution can be recovered since \( N \) is observed for all values in \((0, \infty)\). Note that it is not necessary to know which sector the agent selects.
This proposition establishes the benefit of having access to data from more than one market. Heckman and Honore (1986) show how access to data from various market settings and information about the choices of agents aids in the identification of the latent skill distributions. The Roy model is the prototype for many models of self-selection in economics. If \( T_2 \) is potential market productivity and \( T_1 \) is non-market productivity (or the reservation wage) for housewives or unemployed individuals, precisely the same model can be used to explore the effects of self-selection on measured productivity. In such a model, \( T_1 \) is never observed. This creates certain problems of identification discussed in Heckman and Honore (1986). The model has been extended to allow for more general choice mechanisms. In particular, selection may occur as a function of variables other than or in addition to \( T_1 \) and \( T_2 \). Applications of the Roy model include studies of the union–non-union wage differential (Lee, 1978); the returns to schooling (Willis and Rosen, 1979); and the returns to training (Bjorklund and Moffitt, 1986) and Heckman and Robb (1985). Amemiya (1984) and Heckman and Honore (1986) present comprehensive surveys of empirical studies based on the Roy model and its extensions.

JAMES J. HECKMAN

BIBLIOGRAPHY

self-interest. Two of the basic questions with which moral philosophers have been concerned are: (a) what are the fundamental principles of morality? (b) why should we obey them? One tempting answer to the second question is: because obeying them is in your own interest. Tempting, because any other answer simply invites a further 'why?' For example, 'why bother about helping others to get what they want?' clearly demands an answer. But 'why bother about getting what you want?', though of course it can be asked, hardly makes sense.

Self-interest as the answer to the second question, however, implies a similar answer to the first. Self-interest can only be a reason for obeying moral principles if those principles do always benefit us as individuals, so that the fundamental one becomes: Do whatever will enable you to satisfy your own desires. And this seems perverse, since most moralists tell us to consider others rather than ourselves. Self-sacrifice, we are told, is noble, and self-seeking base.

Thomas Hobbes answers this objection by pointing out that, while human desires are diverse, so that there is no common end, there is a single means common to all ends. They all require the cooperation of other people, or at least their non-interference. Everyone has an interest in maintaining a peaceful and harmonious society. Moral principles are simply the rules which everyone must follow in order to obtain such a society. We should obey them because obeying them makes for peace and security, and without peace and security no one has much chance of satisfying any desires. If morality requires us to consider others and not ourselves, it is for our own sakes in the long run.

To suppose that men imposed moral restraints on themselves for this reason might suggest a far-sightedness greater than most of us are capable of. Bernard Mandeville suggested that men are motivated less by this consideration than by vanity. Morality, he conjectured, came about through the artifice of a
Self-confirming equilibria are limiting outcomes of purposeful interactions among a collection of adaptive agents, each of whom averages past data to approximate moments of conditional probability distributions. Self-confirming equilibria are powerful tools to investigate dynamic economic problems such as the limiting behaviour of learning systems, the selection of plausible equilibria in games and dynamic macroeconomic models, the incidence and distribution of rare events that occasionally arise as large deviations from self-confirming equilibria, and how agents respond to model uncertainty.

Keywords

adaptive learning; law of large numbers; learning rules; ordinary differential equations; perfect foresight; rational expectations equilibrium; recursive learning algorithms; robust control; self-confirming equilibrium; stochastic approximation algorithms

A self-confirming equilibrium is the answer to the following question: what are the possible limiting outcomes of purposeful interactions among a collection of adaptive agents, each of whom averages past data to approximate moments of the conditional probability distributions of interest? If outcomes converge, a law of large numbers implies that agents’ beliefs about conditional moments become correct on events that are observed sufficiently often. Beliefs are not necessarily correct about events that are infrequently observed. Where beliefs are correct, a self-confirming equilibrium is like a rational expectations equilibrium. But there can be interesting gaps between self-confirming and rational expectations equilibria where beliefs of some important decision makers are incorrect.

Self-confirming equilibria interest macroeconomists because they connect to an influential 1970s argument made by Christopher Sims that advocated rational expectations as a sensible equilibrium concept. This argument defended rational expectations equilibria against the criticism that they require...
that agents ‘know too much’ by showing that we do not have to assume that agents start out ‘knowing
the model’. If agents simply average past data, perhaps conditioning by grouping observations, their
forecasts eventually become unimprovable.
Research on adaptive learning has shown that the glass is ‘half full’ and ‘half empty’ for this clever
1970s argument. On the one hand, the argument is correct when applied to competitive or infinitesimal
agents: by using naive adaptive learning schemes (various versions of recursive least squares), agents
can learn every conditional distribution that they require to play best responses within an equilibrium.
On the other hand, large agents (for example, governments in macro models) who can influence the
market outcome cannot expect to learn everything that they need to know to make good decisions: in a
self-confirming equilibrium, large agents may base their decisions on conjectures about off-equilibrium-
path behaviours that turn out to be incorrect. Thus, a rational expectations equilibrium is a self-
confirming equilibrium, but not vice versa.
While agents’ beliefs can be incorrect off the equilibrium path, the self-confirming equilibrium path still
restricts them in interesting ways. For macroeconomic applications, the government’s model must be
such that its off-equilibrium path beliefs rationalize the decisions (its Ramsey policy or Phelps policy, in
the language of Sargent, 1999) that are revealed along the equilibrium path. The restrictions on
government beliefs required to sustain self-confirming equilibria have only begun to be explored in
macroeconomics, mainly in the context of some examples like those in Sargent (1999). Analogous
restrictions have been more thoroughly analysed in the context of games (Fudenberg and Levine, 1993).
The freedom to specify beliefs off the equilibrium path makes the set of self-confirming equilibria
generally be larger than the set of Nash equilibria, which often admit unintuitive outcomes in extensive
form games (Kreps, 1998). A widely used idea of refining self-confirming equilibrium is to embed the
decision making problem within a learning process in which decision makers estimate unknown
parameters through repeated interactions, and then to identify a stable stationary point of the learning
dynamics (for example, Fudenberg and Kreps, 1993; 1995; Evans and Honkapohja, 2001).
The gap between a self-confirming equilibrium and a rational expectations equilibrium can be vital for a
government designing a Ramsey plan, for example, because its calculations necessarily involve
projecting outcomes of counterfactual experiments. For macroeconomists, an especially interesting
feature of self-confirming equilibria is that, because a government can have a model that is wrong off
the equilibrium path, a policy that it thinks is optimal can very well be far from optimal. Even if a policy
model fits the historical data correctly and is unimprovable, one cannot conclude that the policy is
optimal. As a result, it requires an entirely a priori theoretical argument to diminish the influence of a
good fitting macroeconomic model on public policy (Sargent, 1999).

Formal definitions

An agent \( i \) is endowed with strategy space \( A_i \) and state space \( X_i \). Generic elements of \( A_i \) and \( X_i \) are called
a strategy and a state, respectively. A probability distribution \( \mathcal{P}_i \) over \( A_i \times X_i \) describes how actions and
states are related. A utility function is \( u_i : A_i \times X_i \to \mathbb{R} \). Let \( \mu_i(\cdot : a_i) \) be a probability distribution over \( X_i \),
which represents \( i \)'s belief about the state conditioned on action \( a_i \). Agent \( i \)'s decision problem is to solve

Single person decision problems

Here a self-confirming equilibrium is a simply a pair \((a_i^*, \mu_i^*)\) satisfying

\[
\max_{a_i \in A_i} \int x_i \ u_i(a_i, x_i) \ d\mu_i(x_i; a_i).
\]  

(1)

\[
a_i^* \in \arg \max_{a_i \in A_i} \int x_i \ u_i(a_i, x_i) \ d\mu_i(x_i; a_i)
\]

(2)

\[
\mu_i^*(x_i; a_i^*) = \mathcal{P}_i(x_i; a_i^*).
\]  

(3)

(2) implies that the choice must be optimal given his subjective belief \(\mu_i^*\), while (3) says that the belief must be confirmed, conditioned on his equilibrium action \(a_i^*\). Self-confirming equilibrium has the two key ingredients of rational expectations equilibrium: optimization and self-fulfilling property. The key difference is (3), which imposes a self-confirming property conditioned only on equilibrium action \(a_i^*\).

The decision maker can entertain \(\mu_j(\cdot; a_i) \neq \mathcal{P}(\cdot; a_i)\), conditioned on \(a_i \neq a_i^*\). In this sense, the agent can have multiple beliefs about the state conditioned on his own action.

If we strengthen things to require

\[
\mu_j(\cdot; a_i) = \mathcal{P}(\cdot; a_i) \ \forall a_i
\]

(4)

then we attain a rational expectations equilibrium. As will be shown later, (4) is called the unitary belief condition (Fudenberg and Levine, 1993), which is one of the three key features that distinguishes a self-
self-confirming equilibria: The New Palgrave Dictionary of Economics

confirming equilibrium from a rational expectations equilibrium or Nash equilibrium.

Multi-person decision problems

If we interpret the state space as the set of the strategies of the other players \( X_i = A_{-i} \), we can naturally extend the basic definition to the situation where more than one person is making a decision. A self-confirming equilibrium is a profile of actions and beliefs, \( \{(a_1^*, \mu_1^*), \ldots, (a_n^*, \mu_n^*)\} \) such that (2) and (3) hold for every \( i = 1, \ldots, n \). As we move from single person to multi-person decision problems, however, (3) differs three ways from a Nash equilibrium, in addition to the unitary belief condition (4). (1) If there are more than two players, the belief of player \( i \neq j, k \) about player \( k \)'s strategy can be different from player \( j \)'s belief about player \( k \)'s strategy (failure of consistency). (2) Similarly, player \( i \) can entertain the possibility that player \( j \) and player \( k \) correlate their strategies according to an un-modelled randomization mechanism, leading to correlated beliefs. (3) If we require that a self-confirming equilibrium should admit unitary and consistent beliefs, while excluding correlated beliefs, then the self-confirming equilibrium is a Nash equilibrium (Fudenberg and Levine, 1993).

Dynamic decision problems

Suppose that player \( i \) solves (1) repeatedly. The first step to embed self-confirming equilibria in dynamic contexts is to spell out learning rules that specify how beliefs respond to new observations. We define a learning rule as a mapping that updates belief \( \mu_i \) into a new belief when new data arrive. Define \( Z_i \subset X_i \) as a subspace of \( X_i \) that is observed by a decision maker. Let \( \mathcal{M}_i \) be the set of probability distributions over \( Z_i \times A_i \). These represent player \( i \)'s belief about the state, that is, the model entertained by player \( i \). A learning rule is defined as

\[
T_i: \mathcal{M}_i \times Z_i \rightarrow \mathcal{M}_i
\]

A belief \( \mu_i^* \in \mathcal{M}_i \) is a steady state of the learning dynamics if

\[
a_i^* \in \arg \max_{a_i \in A_i} \int_{Z_i} u_i(a_i, x_i) d\mu_i^*(x_i; a_i)
\]

(5)
for every \( z_i \) in the support of \( P_i(x_i; a_i^*) \).

The steady state of learning dynamics is a self-confirming equilibrium for a broad class of recursive learning dynamics including Bayesian (Fudenberg and Levine, 1993), and least square learning algorithms (Sargent, 1999; Evans and Honkapohja, 2001) are self-confirming equilibria.

**Refinements**

We can study the salience of the self-confirming equilibrium by examining the stability of the associated steady states. The stability property provides a useful foundation for selecting a sensible self-confirming equilibrium (Bray, 1982; Marcet and Sargent, 1989; Woodford, 1990; Evans and Honkapohja, 2001). With a possible exception of the Bayesian learning algorithm, most ad hoc learning rules are motivated by the simplicity of some updating scheme as well as its ability to support sufficiently sophisticated behaviour in the limit. By exploiting the convergence properties of learning dynamics, we can often devise a recursive algorithm to calculate a self-confirming equilibrium, that is, a fixed point of the \( T_i \).

This approach to computing equilibria has occasionally proved fruitful to compute equilibria in macroeconomics (for example, Aiyagari et al., 2002).

In principle, a player need not know the other player's payoff in order to play a self-confirming equilibrium. Self-confirming equilibria allow a player to entertain any belief conditioned on actions not used in the equilibrium. This is one of the main sources of multiplicity. In the game theoretic context, a player can delineate the set of possible actions of the other players, even if he does not have perfect foresight. If each player knows the payoff of the other players, and if it is common knowledge that every player is rational, then a player can eliminate the actions of the other players that cannot be rationalized. By exploiting the idea of sophisticated learning of Milgrom and Roberts, (1990; 1991), Dekel, Fudenberg and Levine (1999) restricted the set of possible beliefs off the equilibrium path to eliminate evidently unreasonable self-confirming equilibrium.

**Applications**

Self-confirming equilibria and recursive learning algorithms are powerful tools to investigate a number of important dynamic economic problems such as (1) the limiting behaviour of learning systems (Evans and Honkapohja, 2001; Fudenberg and Levine, 1998); (2) the selection of plausible equilibria in games and dynamic macroeconomic models (Marcet and Sargent, 1989; Kreps, 1998); (3) the incidence and distribution of rare events that occasionally arise as large deviations from self-confirming equilibria (Cho, Williams and Sargent, 2002; Sargent, 1999); and (4) formulating plausible models of how agents respond to model uncertainty (Cho and Kasa, 2006).
Remarkably, related mathematics tie together all of these applications. The mean dynamics that propel the learning algorithms to self-confirming equilibria (in item (1)) are described by ordinary differential equations (ODE) derived through an elegant stochastic approximation algorithm (for example, Fudenberg and Levine, 1998; Woodford, 1990; Marcet and Sargent, 1989). Because the stationary point of the ODE is a self-confirming equilibrium, the stability of the ODE determines the selection criterion used to make statements about item (2) (Fudenberg and Levine, 1998; Evans and Honkapohja, 2001). Remarkably, by adding an adverse deterministic shock to that same ODE, we obtain a key object that appears in a deterministic control problem that identifies the large-deviation excursions in item (3) away from a self-confirming equilibrium (Cho, Williams and Sargent, 2002). Finally, that same large deviations mathematics is associated with robust control ideas that use entropy to model how agents cope with model uncertainty (Pandit and Meyn, 2006).

Article

Seligman was born in New York City on 25 April 1861 and died on 18 July 1939 at Lake Placid, New York. An economist of unusual erudition, energy and wide-ranging interests, Seligman successfully combined a life of distinguished scholarship with philanthropy and active participation and leadership in a variety of reform causes. Raised in a talented and wealthy New York Jewish business family, Seligman studied privately under Horatio Alger Jr. and at Columbia Grammar School before graduating from Columbia in 1879. After three years’ study in Berlin, Heidelberg (under Karl Knies), Geneva and Paris he returned to Columbia obtaining MA and LLB degrees in 1884, the Ph.D. cum laude in 1885 and a full professorship in political economy at age 30, a post he held until retirement in 1931. Dignified, wise and balanced in outlook, Seligman personified the best in late 19th-century efforts to blend orthodox classical and German historical economics. His original studies of neglected British and American economists, and his compilation of perhaps the world's greatest library of economic works, reveal his lifetime devotion to doctrinal history, while his widely read and durable *Economic Interpretation of History* (1902) testifies to the breadth and sensitivity of his historical knowledge. Like Henry Carter Adams, with whom he created the field of public finance in America, Seligman was influenced by Adolph Wagner. But he was more of a theorist than Adams, and his concepts of ‘faculty’ or ability to pay, and benefit, were the first systematic modern efforts to develop theoretical criteria of taxation. A severe critic of Henry George, Seligman nevertheless favoured taxes on land values and progressive inheritance taxes, and advocated proportional income taxes as early as 1894. Sympathetic to labour unions, federal railroad legislation, effective central banking measures and other moderate reform proposals, including deficit finance and public works during the depression of the 1930s, Seligman also advocated US aid to Europe after 1918 and the cancellation of their debts.

Seligman served on innumerable public bodies as a taxation and financial specialist, and as a social
reformer, for example as Chairman of the Bureau of Municipal Research and with the National Civic Federation. A founder, first Treasurer and later President (1902–4) of the American Economic Association, he was an outstanding champion of academic freedom and co-founder of the American Association of University Professors, of which he was President 1919–20. His success as fund-raiser and Editor in Chief of the *Encyclopaedia of the Social Sciences* 1927–35 was a fitting culmination of an outstanding career of scholarly and public service.

Selten, Reinhard (born 1930)

Eric van Damme

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article describes the main contributions to game theory and boundedly rational economic behaviour of Reinhard Selten, winner, together with John Nash and John Harsanyi, of the Nobel Memorial Prize in Economics in 1994.

Keywords

Article

Reinhard Selten was born in Breslau, then in Germany, and now called Wroclaw, in Poland. His father, who was of Jewish origin, died of illness when he was 12 years old, and the family had a difficult time during the war. After having been refugees for a couple of years, they settled in Hessia, where Selten completed high school in 1951. In that same year, he had his first contact with game theory through a popular article in *Fortune*. From 1951 to 1957, Selten studied mathematics in Frankfurt, where, under the guidance of Ewald Burger, he wrote his Master's thesis on cooperative game theory, aiming to axiomatize a value for extensive form games. He continued to work for his Ph.D. in Frankfurt, in the institute of Professor Heinz Sauermann, where he soon became involved in laboratory experiments. After receiving his Ph.D. in mathematics in 1961, he remained in Frankfurt until 1969, when he moved to the Free University of Berlin. In 1972, he moved to Bielefeld, to the newly established Institute of
Mathematical Economics. In 1984, he moved to the University of Bonn, where he set up the Bonn Experimental Laboratory, to which he is still affiliated. In 1994, he received the Nobel Prize in Economics, which he shared with John Nash and John Harsanyi. For more personal details, see his autobiography for the prize (Selten, 1995).

Selten describes himself as a ‘methodic dualist’: throughout his career, he has investigated both the consequences of ideal rationality in game situations, as well as the limitations of this concept to describe actual observed behaviour, and he has proposed several more descriptive theories. For Selten's perspective on his own work and how it hangs together, see Selten (1993). A selection of his path-breaking contributions has been collected in Selten (1999).

**Perfect equilibria**

John Nash has proposed the fundamental solution concept for non-cooperative games, that is, games in which the players cannot make binding agreements outside of the formal rules. A *Nash equilibrium* has a natural stability property: once having arrived at it, either through introspection, learning or evolution, no player has an incentive to unilaterally deviate. Nash showed that each game has at least one equilibrium, and that a non-self-destroying, single-valued theory of rationality has to prescribe playing such an equilibrium. See strategic and extensive form games for more details for formal definitions of other concepts discussed in this article.

Applying John von Neumann's insight that any extensive form (that is, dynamic) game can be reduced to an equivalent one in which the players move just once and simultaneously, Nash focused mainly on the latter. In his early experiments, Selten was, however, working with dynamic oligopoly games. When calculating the Nash equilibria, to provide a benchmark to compare the actual outcomes with, he soon discovered that there typically were many, including those that could not be considered compatible with rationality. To eliminate these, he proposed the refinement of subgame perfection. The idea underlying this concept is that, once a subgame (a part that constitutes a game in itself) is reached, everything outside of it (the things that could have happened but did not) has become irrelevant, so that the logic underlying the equilibrium should be applied to the subgame as well.

By requiring subgame perfection, one eliminates equilibria that rely on non-credible threats or promises. As an example, suppose that two players have to divide $4. One player, the proposer, $P$, may offer 3, 2 or 1 to the responder, $R$, who can only accept or reject; if he accepts, the division is implemented, otherwise each player gets zero. Assume it is commonly known that each player cares only about his own monetary payoff and prefers more money to less. The game has a Nash equilibrium in which $P$ offers 3 and $R$ rejects any outcome in which he is offered less. The threat to reject any amount, however, is not credible: confronted with offer $m$, by assumption $R$ prefers $m$ to 0, hence, he should accept it. In the unique subgame perfect equilibrium, $P$ offers 1, which $R$ accepts.

Later, Selten discovered that subgame perfection is not sufficient to rule out all ‘non-rational’ equilibria. In Selten (1975), he introduced a further refinement: ‘trembling-hand perfection’, a concept that insists that equilibria be robust with respect to small perturbations of the strategies. Formally, it is assumed that, whenever a player has to move, with a small probability he makes a mistake, and an equilibrium is trembling-hand perfect if, under these circumstances, each player is still willing to play it. Ideal rationality is thus viewed as a limiting case of rationality with small errors.

Selten was the first to refine Nash's concept for analysing dynamic games. In the beginning of the 1970s,
he was also one of the first to successfully apply these refined concepts to dynamic game models of imperfect competition, thus pioneering the use of game theory in industrial organization. Subgame perfection is now routinely applied in situations of strategic interaction involving a time element. The robustness approach proposed in Selten (1975) also turned out to be very fruitful. On the one hand, it gave rise to solution concepts, such as sequential equilibrium, that were easy to use in applications; on the other hand, it induced a search for further refinements and stability concepts that uncovered the deeper mathematical structure of ideal rationality; see Kohlberg and Mertens (1986). We refer to Nash equilibrium, refinements of for further details.

**Equilibrium selection and the cooperation with John Harsanyi**

In 1965, during a workshop in Jerusalem, Selten met John Harsanyi, and they started to cooperate. During the academic year 1967–8, Selten visited Harsanyi in Berkeley to work on two-person bargaining under incomplete information. They decided to take the rationality assumption in situations of strategic interaction to its logical limit, and started a project that would be finished only 20 years later with Harsanyi and Selten (1988). The motivation for this work is that the traditional justification of the Nash equilibrium concept is incomplete: it relies on the assumption that each game has a unique solution, but a game typically has multiple Nash equilibria. The natural question thus is, whether, by strengthening the rationality requirements, a unique selection can be obtained.

An essential ingredient of their selection theory is the notion of risk dominance. The concept tries to assess whether, in a situation in which players are a priori uncertain about which equilibrium should be played, they can still coordinate on a single equilibrium and, if so, which one. The stag hunt game may illustrate the concept and can show that there may be a conflict between payoff dominance and risk dominance. Assume two players that each can choose between a safe action, $S$, and a risky one, $R$. $S$ yields 1 for sure, while $R$ gives payoff $X$, with $X>1$, if the other player also chooses $R$, but it yields 0 otherwise. Both $(R,R)$ and $(S,S)$ are equilibria and the former Pareto dominates the latter. If $X$ is not too large, however, one can gain only little by playing $R$ and the downward risk is considerable. In Harsanyi and Selten (1988), risk dominance is formalized by means of the tracing procedure, a theoretical model of the thinking process that converts any mixed strategy profile into an equilibrium of the game. In our example, $(S,S)$ is the risk dominant equilibrium if $X<2$ and there is a conflict between risk dominance and payoff dominance if $1<X<2$. The concept has found applications also in other domains of game theory. For example, in an evolutionary setting, where players repeatedly play the game in a myopic fashion, adjusting strategies through time, it was found that risk dominance is related to the long-run stochastic stability of the equilibrium (see learning and evolution in games: an overview).

For extensive form games, Harsanyi and Selten propose subgame consistency, a natural extension of subgame perfection, as an important selection principle: if $g$ is a subgame of $G$, then in $g$ the solution of $G$ should prescribe the solution of $g$. Again the idea is that, once $g$ is reached, everything else has become irrelevant. To illustrate, let $g$ be the stag hunt game with $X=1.8$, and let $G$ be the game in which player 1 first chooses whether to take up an outside option yielding both players 1.5 or to play $g$. A selection theory incorporating subgame consistency and risk dominance implies that player 1 should take up the outside option. On the other hand, the strategy ‘go to $g$ and play $S$’ is a dominated strategy in the overall game, so that repeated elimination of dominated strategies, or forward induction, produces
the outcome \((R,R)\). The example shows that several desirable properties easily conflict. The conclusion is that it is possible to construct a single valued theory of rationality in non-cooperative games, but that an ideal theory does not exist.

Bounded rationality and experiments

When, after finishing his Master's thesis in 1957, Selten started to work in the institute of Professor Heinz Sauermann on a project on the ‘Theory of the Firm’, under the influence of Herbert Simon's ideas he very quickly became convinced that it was necessary to model economic behaviour as boundedly rational. (Also see rationality, bounded.) In Selten's view, bounded rationality (defined as the rationality exhibited by actual human behaviour) differs fundamentally from the ideal rationality that we have been discussing in this article thus far. Bounded rationality, hence, is not viewed as an approximation to full rationality; it simply is something different. Furthermore, since actual behaviour cannot be invented in the armchair, the development of theories of bounded rationality needs an empirical basis. Consequently, laboratory experimentation becomes an important source of empirical evidence, also because of the possibility of gathering data under controlled circumstances. See also experimental economics. Selten's first experimental paper, co-authored with Sauermann, had already appeared in 1959. Given the sharp distinction drawn between ideal rationality and bounded rationality, it is not too surprising that the work was not directed at testing a theory; rather, it was an explorative piece, trying to uncover regularities. Ever since that first paper, Selten's work in this area has tried to uncover the structure of boundedly rational decision making, with an emphasis on individual data.

Selten distinguishes between cognitive bounds on rationality and motivational bounds. The former arise from the limited human ability to think and compute. Motivational bounds are different: even when the standard rational solution appears obvious, and is fully understood, as in the finitely repeated Prisoner's Dilemma game, a player may not have the incentive to implement it. In his paper on the chain store game, Selten argued that we lack a ‘behavioural trust’ in abstract subgame perfection arguments, and he proposed a theory of decision making in which decisions can arise at three different levels: the routine level, using past experience and analogies; the imagination level, involving various scenarios; and the reasoning level in which the individual makes a conscious effort to analyse the situation in rational, logical way. Since different levels involve different decision costs, not all levels may be activated, and even if they are, then, in Selten's view, there is no reason why the decision at the higher level should be selected. This brief description may make clear why boundedly rational behaviour may indeed be very different from normative rationality.

An important tool in the uncovering of the structure of boundedly rational decision making has been the use of the strategy method: in experiments, subjects are asked not just to make decisions as the game goes along, but also to specify or programme strategies for the entire game. In this way more of the strategic reasoning of the subject is revealed. Selten game theory and biology. Originally, the fundamental solution concept in evolutionary game theory, that of evolutionarily stable strategies (ESS), had been defined only for symmetric static games; Selten extended it to dynamic games and to asymmetric games, thus expanding the range of applicability. It is important to note that evolutionary game theory is not normative but descriptive, with equilibrium being thought of as the result of a dynamic process. Even in games arising in economics and social situations, equilibrium is increasingly
Selten has often worked in areas away from the mainstream. As he has written: ‘Since I am slow, I have to try to be early.’ In the areas that he pioneered in the first part of his career, many others have meanwhile joined him.

semiparametric estimation

James L. Powell
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Semiparametric estimation methods are used for models which are partly parametric and partly nonparametric; typically the parametric part is an underlying regression function which is assumed to be linear in the observable explanatory variables, while the nonparametric component involves the distribution of the model’s ‘error terms’. Semiparametric methods are particularly useful for limited dependent variable models (for example, the binary response or censored regression models), since fully parametric specifications for those models yield inconsistent estimators if the parametric distribution of the errors is misspecified.

Keywords

binary response models; censored regression (‘Tobit’) models; fixed effects; identification; kernel estimators; limited dependent variable models; linear regression models; maximum likelihood; maximum score estimation; nonparametric estimation; panel data models; propensity score; sample selection models; selectivity bias; semiparametric estimation; semiparametric regression models

Article

Introduction

Semiparametric estimation methods are used to obtain estimators of the parameters of interest – typically the coefficients of an underlying regression function – in an econometric model, without a complete parametric specification of the conditional distribution of the dependent variable given the explanatory variables (regressors). A structural econometric model relates an observable dependent variable \( y \) to some observable regressors \( x \); some unknown parameters \( \beta \), and some unobservable ‘error term’ \( \epsilon \), through some functional form \( y=g(x, \beta, \epsilon) \); in this context, a semiparametric estimation problem does not restrict the distribution of \( \epsilon \) (given the regressors) to belong to a parametric family determined by a finite number of unknown parameters, but instead imposes only broad restrictions on the distribution of \( \epsilon \) (for example, independence of \( \epsilon \) and \( x \)), or symmetry of \( \epsilon \) about zero given \( x \)) to obtain identification of \( \beta \) and construct consistent estimators of it.

Thus the term ‘semiparametric estimation’ is something of a misnomer; the same estimator can be considered a parametric, semiparametric or nonparametric estimator depending upon the restrictions imposed upon the economic model. For example, if a random sample of dependent variables \( \{y_i\} \) and regressors \( \{x_i\} \) are assumed to satisfy a linear regression model \( y_i = x_i'\beta + \epsilon_i \) the classical least squares estimator can be considered a ‘parametric’ estimator of the regression coefficient vector \( \beta \) if the error terms \( \{\epsilon_i\} \) are assumed to be normally distributed and independent of \( \{x_i\} \). It could alternatively be considered a ‘nonparametric estimator’ of the best linear predictor coefficients \( \hat{\beta} = \left[ E(x_ix'_i) \right]^{-1} E(x_iy_i) \) if only the weak condition \( E(x_i\epsilon_i) = 0 \) is imposed (implying that \( \hat{\beta} \) is a unique function of the joint distribution of the observations). And the least squares estimator would be ‘semiparametric’ under the intermediate restriction \( E(\epsilon_i | x_i)=0 \), which imposes a parametric (linear) form for the conditional mean \( E(y_i|x_i)=x'_i \beta \) of the dependent variable but imposes no further restrictions on the conditional distribution. So the term
'semiparametric' is a more suitable adjective for models which are partly (but not completely) parametrically specified than it is for the estimators of those parameters.

Nevertheless, while most econometric estimation methods that do not explicitly specify the likelihood function of the observable data (for example, least squares, instrumental variables, and generalized method-of-moments estimators) could be considered semiparametric estimators, ‘semiparametric’ is sometimes used to refer to estimators of a finite number of parameters of interest (here, ) that involve explicit nonparametric estimators of unknown nuisance functions (for example, features of the distribution of the errors ). Such ‘semiparametric estimators’ use nonparametric estimators of density or regression functions as inputs to second-stage estimators of regression coefficients or similar parameters. Occasionally terms like ‘semi-nonparametric’, ‘distribution-free’ and even ‘nonparametric’ have been used to describe such estimation methods, with the latter terms referring to the treatment of the error terms in an otherwise-parametric structural model.

The primary objective of semiparametric methods is to identify and consistently estimate the unknown parameter of interest by determining which combinations of structural functions and weak restrictions on the distribution of the errors permit this. Given identification and consistent estimation, the next step in the statistical theory is determination of the speed with which the estimator converges to its probability limit . The rate of convergence for estimators for standard parametric problems is the square root of the sample size , while nonparametric estimators of unknown density and regression functions (with continuously distributed regressors) generically converge at a slower rate; if a semiparametric estimator can be shown to converge at the parametric rate, that is, if it is ‘root- consistent’, then its relative efficiency to a parametric estimator (for a correctly specified parametric model) will not tend to zero as increases. For inference, it is also useful to demonstrate the asymptotic (that is, approximate) normality of the distribution of in large samples, so that asymptotic confidence regions and hypothesis tests can be constructed using normal sampling theory. Finally, for problems where existence of root- consistent, asymptotically normal semiparametric estimators can be shown, the question of efficient estimation arises. The solution to this question has two parts – determination of the efficiency bound for the semiparametric estimation problem and construction of a feasible estimator that attains that bound.

Econometric applications

In econometrics, most of the attention to semiparametric methods dates from the late 1970s and early 1980s, which saw the development of parametric models for discrete and limited dependent variable (LDV) models. Unlike the linear regression model, those models are not additive in the underlying error terms, so the validity (specifically, the consistency) of maximum likelihood and related estimation methods depends crucially on the assumed parametric form of the error distribution. As shown for particular examples by Arabmazar and Schmidt (1981; 1982) and Goldberger (1983), failure of the standard assumption of normally distributed error terms makes the corresponding likelihood-based estimators inconsistent. This is in contrast to the linear regression model, where the maximum likelihood (classical least squares) estimator is consistent under much weaker assumptions than normally (and identically) distributed errors.

Much of the early literature on semiparametric estimation concentrated on a particular limited dependent variable model, the binary response model, which arguably presents the most challenging setting for identification and estimation of the underlying regression coefficients. Early examples of semiparametric identification assumptions and estimation methods for this model give a flavour of the approaches used for other econometric models, among them the censored regression and sample selection models. The discussion here treats only selected assumptions and estimators for these models, and not their numerous variants; more complete surveys of semiparametric models and estimation methods are given by Manski (1989), Powell (1994), Newey (1994), and Pagan and Ullah (1999).

Semiparametric binary response models

The earliest semiparametric estimation methods in the econometrics literature on LDV models concerned the binary response model, in which the dependent variable assumed the values zero or 1 depending upon the sign of some underlying latent (unobservable) dependent variable which satisfies a linear regression model ; that is,

\[ y_i = 1\{x_i'\beta - \varepsilon_i > 0\}, \]
where ‘1{A}’ denotes the indicator function of the event A; that is, it is 1 if A occurs and is zero otherwise. For a parametric model, in which the errors ε_i are assumed to be independent of x_i and distributed with a known marginal cumulative distribution function F(ε_i), the average log-likelihood function takes the form

\[ L_n(\beta) = \frac{1}{n} \sum_{i=1}^{n} [y_i \ln F(x_i' \beta) + (1 - y_i) \ln (1 - F(x_i' \beta))] \]

for a random sample of size n, and consistency of the corresponding maximum likelihood estimator \( \hat{\beta}_{ML} \) requires correct specification of F unless the regressors satisfy certain restrictions (as discussed by Ruud, 1986). When F is unknown, a scale normalization on \( \beta \) is required, and a constant (intercept) term will not be identified no normalization on the location of ε is imposed.

Manski (1975; 1985) proposed a semiparametric alternative, termed the 'maximum score' estimator, which defined the estimator to maximize the number of correct matches of the value of y_i with an indicator function \( 1\{x_i' \beta > 0\} \) of the positivity of the regression function. That is, the maximum score estimator \( \hat{\beta}_{MS} \) maximizes the average 'score' function

\[ S_n(\beta) = \frac{1}{n} \sum_{i=1}^{n} [ y_i : 1\{x_i' \beta > 0\} + (1 - y_i) : 1\{x_i' \beta < 0\}] \]

over \( \beta \). Unlike the maximum likelihood estimator \( \hat{\beta}_{ML} \), consistency of \( \hat{\beta}_{MS} \) requires only that the median of the error terms was zero given the regressors, that is, the conditional cumulative F(ε |x) of given x_i=x had F(λ |x)=1/2 when λ > 0, and F(λ |x)<1/2 when λ <0. However, the estimation approach is generally not root-n consistent (as shown by Chamberlain, 1986). A variant of the maximum score estimator, proposed by Horowitz (1992), essentially 'smoothed' the indicator functions for positivity of \( x_i' \beta \) in the minimand \( S_n(\beta) \) using a continuous approximation to it, similar to the smoothing used in nonparametric kernel estimators of regression and density functions. The rate of convergence of the resulting 'smoothed maximum score' estimator can be made arbitrarily close to the root-n rate if the distribution of the regressors is sufficiently smooth.

To obtain root-n consistent estimators of the unknown θ, the assumption on the error term ε can be strengthened to independence of θ and x. Han (1987) proposed an alternative to the maximum score estimator, termed the ‘maximum rank correlation’ estimator, which compared the sign of the difference \( y_i - y_j \) of the dependent variable to the corresponding difference \( (x_i - x_j)' \beta \) in the regression functions across all distinct pairs of observations i and j. The estimator \( \hat{\beta}_{MR} \) maximizes

\[ M_n(\beta) = \binom{n}{2}^{-1} \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} \text{sgn}(y_i - y_j) \cdot \text{sgn}((x_i - x_j)' \beta) \]

⇔ over \( \beta \), where \( \text{sgn}(u) \equiv 1\{u>0\} - 1\{u<0\} \). The rationale for this estimator is based upon the monotonicity of \( \Pr\{y_i = 1|x\} = F(x_i' \beta) \) in \( x_i' \beta \) so that, given \( y_i \neq y_j, \Pr\{y_i>y_j|x_i, x_j\} \) exceeds 1/2 when \( x_i' \beta > x_j' \beta \). Han's article gave conditions under which \( \hat{\beta}_{MR} \) was shown to be consistent, and Sherman (1993) showed that this estimator was root-n consistent and asymptotically normal.
An alternative estimation approach for \( \beta \) under the assumption of independence of \( u \) and \( x \) combines estimation of the parameter vector \( \beta \) with nonparametric estimation of the unknown distribution function \( F \). Cosslett (1983) proposed a 'nonparametric maximum likelihood' estimator \( \hat{\beta}_{NPM} \) obtained by simultaneously maximizing the likelihood function \( L_n(\beta) = L_n(\beta; F) \) over both \( \beta \) and \( F \), where the latter function is restricted to be nondecreasing with values in the unit interval. While consistency of this estimator could be established, its rate of convergence could not. An alternative estimation method, proposed by Klein and Spady (1993), used kernel regression methods to estimate the unknown distribution function \( F \) in the likelihood function. The resulting estimator was shown to be root-\( n \) consistent and asymptotically normally distributed under additional regularity conditions; furthermore, the estimator was shown to achieve the semiparametric efficiency bound for this problem, that is, its asymptotic covariance matrix is the smallest possible among regular estimators of \( \beta \) which impose only the independence restriction between \( x \) and \( u \).

Still other estimators for \( \beta \) when \( u \) and \( x \) are independent exploit the single index regression structure of this model, since the conditional expectation of \( y_i \) given \( x_i \) only depends upon the 'single index' \( x_i' \beta \):

\[
E[ y_i|x_i ] = g(x_i) = F(x_i' \beta).
\]

If the vector of regressors \( x_i \) is continuously distributed with joint density function \( f_X(x) \) which is continuous for all \( x \), Stoker (1986) noted that the vector of slope parameters \( \beta \) is proportional to the expectation of the derivative of \( g(x) \),

\[
E\left[ \frac{\partial g(x_i)}{\partial x} \right] = E\left[ F'(x_i' \beta) \right] : \beta.
\]

Using integration-by-parts, this 'average derivative' can in turn be expressed as the expected value of the product of \(-y_i\) and the derivative of the logarithm of the density \( f_X \) of the regressors,

\[
E\left[ \frac{\partial g(x_i)}{\partial x} \right] = - E\left[ y_i \frac{\partial \log [ f_X(x_i) ]}{\partial x} \right].
\]

Härdle and Stoker (1989) proposed a semiparametric estimator of this representation of \( \beta \) (up to scale) using nonparametric (kernel) estimators of \( f_X \) and its gradient, while Powell, Stock and Stoker (1989) constructed a similar estimator of the 'density-weighted average derivative'

\[
E\left[ f_X(x_i) \frac{\partial g(x_i)}{\partial x} \right] = E[ f_X(x_i) F'(x_i' \beta) ] : \beta = - 2 E\left[ y_i \frac{\partial f_X(x_i)}{\partial x} \right],
\]

which is also proportional to \( \beta \) under the single index restriction.

Though the motivation given here was based upon the binary response model under independence of the errors and regressors, the average derivative and weighted average derivative estimators apply to other models with a single index structure, for example, any transformation model with
for $T$ a nondegenerate function (possibly unknown) and with $\varepsilon_i$ continuously distributed and independent of $x_i$. The same is true for the ‘single index regression’ estimator proposed by Ichimura (1993), defined to minimize

$$R_n(\beta) = \frac{1}{n} \sum_{i=1}^{n} \left( y_i - \hat{F}(x_i'; \beta) \right)^2 t_n(x_i);$$

in this expression, $\hat{F}(u; \beta)$ represents a nonparametric regression estimator of $E[y|x_i'\hat{=}u]$ and $t_n(x_i)$ represents a ‘trimming’ term which is zero whenever $x_i$ lies outside a set for which $F$ is sufficiently precisely estimated. Unlike the average derivative $\hat{\theta}_{AD}$ and weighted average derivative $\hat{\theta}_{WAD}$ estimators, which require the regressors to be jointly continuously distributed, root-$n$ consistency and asymptotic normality of the single index regression estimator $\hat{\theta}_{SIR}$ require only that $x_i'\hat{=}\hat{\theta}$ has a continuous distribution, so that some of the regressors can be discrete. The criterion function $R_n(\beta)$ is the nonlinear least squares analogue of the maximand for the Klein and Spady (1993) estimator (which also involved a similar trimming term $t_n(x_i)$). The asymptotic covariance matrices for both estimators have the same general form as the corresponding nonlinear least squares and maximum likelihood estimators with $F$ known, except for the replacement of the cross product of the regressors $x_i$ with the cross product of $x_i - E[x_i|x_i'\hat{=}\hat{\theta}]$, adjusting the asymptotic covariance matrices upward to account for the nonparametric estimation of the unknown function $F$.

The problem of consistent estimation of $\beta$ in binary response models is compounded for panel data models with fixed effects (that is, individual-specific intercept terms), written as

$$y_{it} = 1\{x_i'\hat{=}\hat{\theta} + \alpha_i - \varepsilon_{it} > 0\}$$

for individuals $i$ ranging from 1 to $n$ and time periods $t$ from 1 to $T$. For this model, even if the distribution function $F$ of the error terms $\varepsilon_{it}$ is known, the maximum likelihood estimators of $\beta$ and the fixed effects $\{\alpha_i\}$ will generally be inconsistent if the number of time periods $T$ is fixed as $N$ increases. A consistent semiparametric estimation strategy using a variant of the maximum rank correlation estimator was proposed by Manski (1987); for the special case $T=2$ (that is, two time periods), the estimator $\hat{\beta}_{BFD}$ can be defined as the maximizer of the criterion

$$P_{(\alpha)}(\beta) = \frac{1}{n} \sum_{i=1}^{n} \text{sgn}(y_{i2} - y_{i1}) \cdot \text{sgn}((x_{i2} - x_{i1})'\beta),$$

which is analogous to $M_{(\beta)}$, except that the differencing is across time periods rather than across individuals. While consistency of $\hat{\beta}_{BFD}$ was established under weak conditions on the error terms, it is not possible to obtain a root-$n$ consistent estimator unless the errors are logistic (Chamberlain, 1993) or other restrictive assumptions (for example, independence of the fixed effect $\alpha_i$ and the regressors $x_{it}$, or the conditions in Honoré and Lewbel, 2002; Lee, 1999) are imposed.
semiparametric estimation: The New Palgrave Dictionary of Economics

Other semiparametric econometric models

Many of the identifying assumptions imposed on semiparametric binary response models give identification and yield consistent estimators for other limited dependent variable models, though these models can sometimes be identified and consistently estimated using assumptions that are uninformative for binary response. Consider, for example, the censored regression (‘Tobit’) model, in which the dependent variable \( y_i \) satisfies a linear regression model if it is nonnegative, and is zero otherwise:

\[
y_i = \max \left\{ 0, x_i' \beta + \epsilon_i \right\}.
\]

For this model, as for the binary response model, the dependent variable is a monotonic function of the error term \( \epsilon_i \); since monotone transformations by definition preserve orderings, the median (or any other percentile) of this monotonic transformation of \( \epsilon_i \) is the monotonic transformation evaluated at the median. Thus the assumption that the errors \( \epsilon_i \) have conditional median zero given \( x_i \) implies that the conditional median of \( y_i \) given \( x_i \) takes the form

\[
\max \left\{ 0, x_i' \beta \right\},
\]

depending only on the unknown coefficients \( \beta \) and not on the shape of the distribution of \( \epsilon_i \). Using this fact, and the characterization of medians as minimizers of a least absolute deviations criterion, Powell (1984) proposed estimation of the unknown \( \beta \) vector by the minimizer \( \hat{\beta}_{CLAD} \) of

\[
Q_n(\beta) = \frac{1}{n} \sum_{i=1}^{n} |y_i - \max \left\{ 0, x_i' \beta \right\}|
\]

for this model; it is analogous to the maximum score estimator \( \hat{\beta}_{MS} \) for the binary response model, which can be defined as the minimizer of the sample average absolute deviation of \( y_i \) from its conditional median function \( 1 \{ x_i' \beta > 0 \} \) for binary response with median zero errors. (The maximum rank correlation estimator \( \hat{\beta}_{MRC} \) and binary panel data estimator \( \hat{\beta}_{BPD} \) can also be expressed as solutions to least absolute deviations problems.) Unlike \( \hat{\beta}_{MS} \), though, the censored median estimator \( \hat{\beta}_{CLAD} \) is root-\( n \) consistent and asymptotically normally distributed under weak regularity conditions, without need for a scale normalization. An alternative estimator for this model, which involved a nonparametric estimator of the probability that \( y_i \) equals zero given \( x_i \), was proposed by Buchinsky and Hahn (1998).

A stronger restriction on the error distribution is conditional symmetry about zero given the regressors; while this restriction is no more informative than the implied zero median restriction for binary response, it yields different identification approaches for censored regression. Specifically, the ‘symmetrically censored’ residual

\[
u_i(\beta) = \min \{ y_i - x_i' \beta, x_i' \beta \} = \min \{ \max \left\{ - x_i' \beta, \epsilon_i \right\}, x_i' \beta \}\]

is an even function of \( \epsilon_i \) when the regression function \( x_i' \beta \) is positive, and thus is itself conditionally symmetric about zero. This implies a population moment restriction

\[
0 = E \left[ 1 \{ x_i' \beta > 0 \} \psi(\delta_i(\beta)) \cdot x_i \right].
\]
for $\psi(u) = -\psi(-u)$ an odd function of its argument. Powell (1986) proposed a 'symmetrically censored least squares' estimator of $\beta$ based upon this restriction with $\psi(u)=u$; like the censored median estimator $\hat{\beta}_{CML}$ which exploits the same moment condition with $\psi(u)=sgn(u)$ – the estimator $\hat{\beta}_{SCLS}$ is root-$n$ consistent and asymptotically normally distributed under weak assumptions. Neither estimator involves explicit nonparametric estimation of the error distribution, a feature shared by the maximum score estimator $\hat{\beta}_{MS}$ and its relatives $\hat{\beta}_{MRC}$ and $\hat{\beta}_{BP}$ for binary response.

As for the binary response model or most limited dependent variable models, consistent estimation of slope coefficients using panel data with fixed effects is challenging, with maximum likelihood estimators for $\beta$ being inconsistent when the number of time periods is fixed and the number estimated fixed effects increases. For the special case $T=2$, writing

$$\nu_{it} = \max\{0, x_{it}'\beta + \alpha_i + \epsilon_{it}\},$$

Honoré (1992) noted that the difference in 'identically trimmed' residuals

$$\delta_i(\beta) = \max\{-x_{i1}'\beta, \nu_{i2} - x_{i2}'\beta\} - \max\{-x_{i2}'\beta, \nu_{i1} - x_{i1}'\beta\} = \max\{-x_{i1}'\beta, -x_{i2}'\beta, \alpha_i + \epsilon_{i2}\} - \max\{-x_{i1}'\beta, -x_{i2}'\beta, \alpha_i + \epsilon_{i2}\}$$

would be symmetrically distributed about zero if the error terms $\epsilon_{i1}$ and $\epsilon_{i2}$ were identically distributed given $x_{i1}$ and $x_{i2}$ and value of the fixed effect $\alpha_i$. This implies population moment conditions of the form

$$0 = E[\psi(\delta_i(\beta)) \cdot (x_{i2} - x_{i1})],$$

again with $\psi(u)$ an odd function of its argument. Setting $\psi(u)=sgn(u)$ and $\psi(u)=u$ yields root-$n$ consistent and asymptotically normal estimators which are similar to the censored least absolute deviations estimator $\hat{\beta}_{CML}$ and symmetrically-censored least squares estimator $\hat{\beta}_{SCLS}$ respectively.

Other estimation approaches for censored regression involve explicit nonparametric estimation of features of the distribution of the error terms, which is common for other semiparametric econometric models. One such model is the semiparametric regression (or semilinear regression) model, for which some regressors enter linearly while others enter nonparametrically. The model can be written algebraically as

$$\nu_i = x_i'\beta + \lambda(w_i) + \epsilon_i \equiv x_i'\beta + u_i,$$

where the error terms $\epsilon_i$ are restricted to satisfy $E[\epsilon_i|x_i,w_i]=0$, or, equivalently, $E[u_i|x_i,w_i]=E[u_i|w_i] \equiv \lambda(w_i)$; the regressors $x_i$ and $w_i$ thus enter parametrically (linearly) or nonparametrically in the conditional mean of $y_i$. Robinson (1988) exploited the fact that

$$\nu_i - E[\nu_i|w_i] = (x_i - E[x_i|w_i])'\beta + \epsilon_i$$
to construct a root-$\sqrt{n}$ consistent, asymptotically-normal estimator of $\beta$ by applying least squares estimation to this equation, replacing the unknown quantities $E[y_i|w_i]$ and $E[x_i|w_i]$ by nonparametric (kernel) estimators. For the parameters $\beta$ to be identified for this model, the covariance matrix of the 'residual regressors' must be nonsingular, ruling out functional dependence of $x_i$ on $w_i$. Though the semilinear regression model is not itself a limited dependent variable model, it arises as a consequence of 'selectivity bias' in a bivariate limited dependent variable model, the censored selection model, in which a linear latent 'outcome' variable $y_i^* = x_i^* \beta + \varepsilon_i$ is observed only if some related binary 'selection' variable $d_i$ equals 1:

$$d_i = 1\{w_i^* \delta - \eta_i > 0\},$$

$$y_i = d_i \cdot (x_i^* \beta + \varepsilon_i),$$

where the regressors $x_i$ and $w_i$ are observed and the unobserved error terms $\eta_i$ and $\varepsilon_i$ need not be mutually independent. Heckman (1979) showed that, for the uncensored ($d_i=1$) subsample from this model, the dependent variable satisfied a semilinear regression model, since

$$E[y_i|d_i=1, x_i, w_i] = x_i^* \beta + \lambda(w_i^* \delta);$$

when the errors are jointly normal, as Heckman assumed, the function $\lambda(u)$ has a known parametric form, but is nonparametric if the error distribution is not in a parametric family. Cosslett (1991) developed a consistent two-step estimator for the regression parameters $\beta$ in the outcome equation, computing a binary nonparametric maximum likelihood estimator $\delta_{NPM}$ of $\delta$ in the first step and using a step-function approximation to $\lambda(u)$ in a least squares fit of the outcome equation for the uncensored observations. Ahn and Powell (1993) proposed a root-$\sqrt{n}$ consistent two-step estimator of $\beta$ for the related semilinear model

$$E[y_i|d_i=1, x_i, w_i] = x_i^* \beta + \lambda''(p(w_i)),$$

where the 'propensity score' $p(w_i) \equiv E[d_i|w_i]$ is first estimated by a nonparametric regression method; this semilinear model is implied by a generalization of the original censored selection model, replacing the linear form of the regression function $w_i^* \delta$ in the selection equation with an unknown function of the regressors $w_i$.

Some variations of the censored selection model admit other semiparametric identification strategies. For example, if the selection equation is censored rather than binary, for example, if

$$d_i = \max\{0, w_i^* \delta + \eta_i\},$$

$$y_i = 1\{d_i > 0\} \cdot (x_i^* \beta + \varepsilon_i),$$

then Honoré, Kyriazidou and Udry (1997) construct a root-$n$ consistent two-step estimator of $\beta$ under the assumption that the
errors $\eta_i$ and $\varepsilon_i$ are jointly symmetric about zero given the regressors $w_i$ and $x_i$, using a symmetrically censored least squares estimator of $\delta$ in the first step and exploiting the symmetry of $v_i - x_i'\beta$ about zero given that $0 < d_i < 2w_i'\delta$ in the second step. In contrast, estimation of censored selection models for panel data with fixed effects is no less challenging than for binary panel data models; Kyriazidou (1997) proposes a consistent (but not root-$n$ consistent) two-step estimator for the panel data selection model using Manski's (1987) binary panel data estimator to estimate $\delta$ in the first step and a semilinear regression estimator similar to the Ahn and Powell (1993) approach in the second step.

Sen, Amartya (born 1933)

Sudhir Anand
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract
Amartya Sen has made fundamental contributions to social choice theory, welfare economics, economic measurement, axiomatic choice theory, rationality and economic behaviour, development economics, poverty and famines, gender inequalities and family economics, among many other areas. His contributions to the field of welfare economics were cited for his award of the 1998 Nobel Memorial Prize in Economics. Sen's work combines foundational and theoretical originality, and the willingness to reconsider basic assumptions. His approach is unusual for its breadth of concern coupled with an uncompromising rigour of analysis. His writings address some of the most important human and ethical issues of our time.

Article
Amartya Sen was born in Santiniketan, Bengal in 1933 on the campus of Rabindranath Tagore's Viswa Bharati (both a school and a college) where his maternal grandfather taught Sanskrit and where both his mother and he had been students. At Santiniketan he concentrated on Sanskrit, mathematics and physics, before studying economics (with mathematics minor) at Presidency College, Calcutta and then at Trinity College, Cambridge. His Ph.D. thesis at Cambridge University on the ‘choice of techniques’ was the basis of his election to a competitive Prize Fellowship at Trinity, and this allowed him time to pursue his interests in logic, epistemology, and moral and political philosophy – in addition to economics. Some of his later work in social choice theory and welfare economics would draw on the intersection of these interests, but he has also made major contributions to many of these fields separately.
Sen, Amartya (born 1933) : The New Palgrave Dictionary of Economics

Sen has taught at several universities: Trinity College, Cambridge; Jadavpur University in Calcutta; the Delhi School of Economics; the London School of Economics; Oxford, where he was Drummond Professor of Political Economy and Fellow of All Souls College; and Harvard, where he is Lamont University Professor, Professor of Economics and Philosophy, and Senior Fellow of the Society of Fellows. He has also held visiting appointments at MIT, Stanford, Berkeley and Cornell. During 1998–2003 Sen was back at Cambridge—as Master of Trinity College. (For further details of his personal and academic life, see Sen, 1999a.) He is widely regarded as one of the finest teachers anywhere, with his lectures and classes always overflowing or oversubscribed. Amartya Sen has been president of the Econometric Society, the American Economic Association, the Indian Economic Association, and the International Economic Association – and he holds more than 90 honorary doctorates. He has won innumerable awards including the Agnelli International Prize in Ethics, the Feinstein World Hunger Award, the Nobel Memorial Prize in Economics, the Bharat Ratna (highest civilian award in India), the Eisenhower Medal, Companion of Honour, UK, and the George C. Marshall Award. His research output is prodigious, and as of 2007 he had published more than 25 books (his works have been translated into more than 30 languages) and about 400 articles. Details of his publications (as well as honorary fellowships and awards) may be found in his CV, at http://www.economics.harvard.edu/faculty/sen/cv.pdf. A list of his publications up to 1998 is available in the Scandinavian Journal of Economics (1999).

Sen has made fundamental contributions to several areas in economics including social choice theory, economic measurement, and welfare economics. He has also worked in many other areas, such as axiomatic choice theory, rationality and economic behaviour, development economics, gender and feminist economics, famines and hunger, economic methodology, project evaluation and cost–benefit analysis, and so on. In this brief review of his contributions to economics, I will concentrate on the first three areas, and will also have to overlook his major work in philosophy, history, and on India's economy, society, culture and politics (his CV lists 20 separate areas, of which this review considers just three).

As one reviewer put it, Sen is as comfortable writing in the Journal of Philosophy or Philosophy and Public Affairs as he is in Econometrica or the Economic Journal. His writings outside economics address some of the most important issues and theories in ethics, justice, and legal and moral philosophy.

In the space available for this review, some areas within economics where Sen's research has had a major impact can only be flagged. These, in general, are more accessible and have been the subject of several other accounts of his work. Thus, in development economics Sen's research began with his Ph.D. thesis, published as Choice of Techniques (1968, 3rd edition). It made rigorous a series of arguments that had often been advanced casually concerning the need for ‘appropriate’ (labour-intensive) technology in poor and populous countries. Further work developed the idea of ‘labour surplus’ in a framework that brought the division of labour within the household to economists’ attention. The game-theoretic concepts used in this work were also applied to explain low rates of saving in developing countries. He has also studied important qsts of policy, with research on cost–benefit analysis and accounting prices, including ‘shadow wages’. A summary of his contributions to employment and technological choice in different institutional and labour market contexts may be found in his monograph Employment, Technology and Development (1975). A more extensive collection of his writings on development economics, covering many other topics, is available in Resources, Values and Development (1984). Another major contribution was his work on the understanding of famine, drawn together in his book Poverty and Famines: An Essay on Entitlement and Deprivation (1981a). He introduced the notion that famines may be due to a decline not in the overall supply of food but in the purchasing power, more generally ‘entitlements’, of vulnerable people – in particular, the poor. The real incomes of a section of the population can decline radically for a variety of reasons (unemployment, relative price changes, production failure, and so on) which can lead to a collapse of their command over food even without any change in overall food production and supply. This analysis can provide both a better explanation of famines as well as a more effective approach to the remedying of starvation and hunger – through the regeneration of ‘food entitlements’ (see Drèze and Sen, 1989).
In the area of gender and family economics, Sen (1990) has highlighted the deprivation suffered by females both inside and outside the household. In traditionally unequal societies, gender bias in nutrition, health care and medical attention – as well as women often having to work harder than men – has led Sen to broaden the information base in assessing relative female disadvantage. He has used mortality and survival information to draw attention to the coarsest aspects of gender-related inequality, and has estimated the number of ‘missing women’ by comparing the female–male ratio with what would be expected in the absence of gender bias in mortality (including female foeticide) (see Sen, 1992b; 2003).

Sen has been instrumental in the recharacterization of development away from the metric of gross national product per capita and its growth. In his book *Development as Freedom* (1999b), he argues that development can be seen as a process of expanding the real freedoms that people enjoy. Freedoms depend not only on individual incomes but on other determinants such as social and economic arrangements, and political and civil rights. He argues that substantive freedoms are not only the primary ends of development but also among its principal means. His related work on ‘capabilities’ has directly influenced the assessment of development by the United Nations Development Programme in its *Human Development Reports*.

Sen's work in economics combines foundational and theoretical originality, and the willingness to reconsider basic assumptions. His approach is unusual for its breadth of concern coupled with an uncompromising rigour of analysis. It is important to stress the range of his scholarship in an age when the profession is becoming increasingly specialized. For all its diversity there is considerable harmony in his work, with research in one area informing that in another. In this academic biography I shall review his contributions in the areas cited by the Royal Swedish Academy of Sciences in its press release on 14 October 1998 for his award of the 1998 Bank of Sweden Prize in Economic Sciences in Memory of Alfred Nobel. Under the general heading of ‘welfare economics’, the citation lists three specific areas: social choice, welfare distributions, and poverty.

**Contributions to social choice theory**

Sen's book *Collective Choice and Social Welfare* (1970a) is a classic work in the theory of social choice. It is a magisterial study that contains profound and original theorems, including the famous ‘liberal paradox’ that has spawned a secondary literature of hundreds of articles in learned journals. His analysis of the causes of the various paradoxes of collective choice, including voting and other decision-making procedures, has been central in the economics, philosophy and political theory literatures. His deep insights into Arrow's impossibility theorem, particularly concerning its informational base, have greatly enhanced our understanding of the entire subject of social choice theory. Sen's seminal papers in social choice, including many written after 1970, are reprinted in his book *Choice, Welfare and Measurement* (1982), and later papers are reprinted in his collection *Rationality and Freedom* (2002).

As Arrow (1999, p. 163) states,

> ...we cannot do justice to Sen's work in social welfare on the basis of one or two seminal papers, although there have been several such, as I will point out. Rather it is the work as a whole and the way the various parts interplay that must be understood to see the importance of Sen's contribution. His exploration of the notions of social welfare takes place at every level of analysis, formal-mathematical, conceptual, and empirical. It is by far the most comprehensive study of its kind, drawing on profound understanding of both economics and moral philosophy.

Some formal notation is needed to help understand Sen's contributions in social choice theory. Let $X$ be the set of social states, and $n$ the number of individuals in the society. Each individual $i (i=1, 2, ..., n)$ has a weak preference relation $R_i$ over the set $X$, where $R_i$ is assumed to be an ordering, that is, reflexive, complete and
transitive. $P_i$ denotes the corresponding strict preference relation. The social weak preference relation is denoted by $R$, with $P$ its asymmetric factor.

An Arrow social welfare function (SWF) is a functional relation that specifies one social ordering for any given $n$-tuple of individual orderings $\{R_i\}$, one ordering for each person:

$$R = f(\{R_i\}) = f(R_1, R_2, \ldots, R_n).$$

Arrow was concerned with the case in which the value of the function $f(\cdot)$, viz. $R$, is required to be an ordering, that is, reflexive, complete and transitive.

Four conditions are imposed on the function $f(\cdot)$.

- (U) (*unrestricted or universal domain*). The domain of $f(\cdot)$ includes all possible $n$-tuples of individual orderings of $X$.
- (P) (*weak Pareto principle*). For any pair of social states $\{x, y\}$, if for all $i$: $x P_i y$, then $x P y$.
- (I) (*pairwise independence of irrelevant alternatives*). The social preference between two alternatives $x$ and $y$ depends only on the individual preferences between $x$ and $y$ (and not on individual preferences over other, ‘irrelevant’, alternatives).
- (ND) (*non-dictatorship*). There is no individual $i$ such that for all preference $n$-tuples in the domain of $f(\cdot)$, for each ordered pair $(x, y)$,

$$x P_i y \rightarrow x P y.$$

Denoting the set of individuals in the society as $H$, Arrow's impossibility theorem can be stated as follows. 

*Theorem (Arrow):* If $H$ is finite and the number of alternatives is at least three, there is no SWF satisfying conditions (U), (P), (I) and (ND).

In other words, a SWF satisfying conditions (U), (P) and (I) must be dictatorial.

This result has turned out to be very robust, and nobody has done more to enhance our understanding of it than Sen. He suggested weakening the requirement of transitivity of the social preference relation $R$ in Arrow's theorem as a way out of the dilemma (Sen, 1969, theorem V). If we demand only *quasi-transitivity* of $R$, that is, transitivity of the strict preference relation $P$, it turns out to generate not dictatorship but (still) an oligarchy. Combined with conditions (U), (P) and (I), a reflexive, complete and quasi-transitive social preference relation yields an oligarchy (Sen, 1970a, attributes this result to Allan Gibbard in an unpublished paper). An oligarchy is a group of individuals $G$ who are together decisive (whenever $x P_i y$ for all $i$ in $G$ then $x P y$) and every member of $G$ has a veto (for any $i$, $x P_i y$ implies not $y P x$). Thus the replacement of transitivity by quasi-transitivity translates the possibility of dictatorship to an oligarchy with veto powers (that is, a group that is decisive with each person in the group having a veto).

One extreme case of an oligarchy is a dictator (one-person oligarchy). The other extreme makes the oligarchy group include every individual in the society. In that case, the fact that all individuals taken together happen to be decisive is not remarkable; it follows immediately from the Pareto principle. But it also gives every member
The consequences of further weakening of quasi-transitivity of the social preference relation \( R \) to acyclicity, admitting no cycle of strict preference, have also been explored as a way out of the Arrow problem. Acyclicity is sufficient if we are interested simply in choosing the best element(s) of a subset \( S \) of \( X \) – called the choice set \( C(S) \). Sen shows (1970a, lemma 1*1) that if \( R \) is reflexive and complete, and \( X \) is finite, then a necessary and sufficient condition for \( C(S) \) to be non-empty for every non-empty subset \( S \) of \( X \) is that \( R \) be acyclical.

A social decision function (SDF) is defined as a function \( f(\cdot) \) that maps \( n \)-tuples of individual orderings \( \{R_i\} \), one ordering for each person, into reflexive, complete and acyclic social preference relations \( R \). It turns out that, even without quasi-transitivity, the ‘veto’ result continues to be obtained for an SDF – by supplementing the weaker demand of acyclicity with some other conditions (a variety of such results is discussed in Sen, 1977a). While the existence of vatoers may be less unattractive than that of a dictator, it is, according to Sen (1986, p. 1085), ‘unappetizing enough not to provide a grand resolution of the Arrow problem’.

As Sen (1993, p. 507) states,

> … these and other weakenings [of the ‘consistency’ requirement of the social preference relation \( R \)] cannot avoid the ‘spirit’ of Arrow's impossibility theorem. The impossibility can be regenerated through balancing the weakening of ‘social preference’ by corresponding strengthenings, which are plausible enough, of other conditions, in particular, the non-dictatorship requirement (avoiding not just a dictator, but also an oligarchy, or a vetoer, or a partial vetoer, and so on).

There is a detailed review and assessment of such theorems in Sen (1986).

The discussion so far has imposed some sort of consistency or rationality condition on the social preference relation \( R \), for example, transitivity, quasi-transitivity or acyclicity. However, as Sen (1993; 1995) notes, the idea of consistency or rationality applied to ‘social preferences’ is more difficult to defend than in the case of an individual’s preferences. The question thus arises whether dropping the requirement that social choice be based on a (transitive) binary preference relation negates Arrow’s theorem reformulated in ‘choice-functional’ terms. A functional collective choice rule (FCCR) makes the value of the function \( f(\{R_i\}) \) not a social preference relation \( R \) but a choice function \( C(S) \), which specifies for every non-empty set \( S \) of social states a non-empty subset \( C(S) \) of states chosen from \( S \):
For a FCCR the Arrow conditions (U), (P), (I) and (ND) can be translated in different ways, but the typical translation has taken the form of restricting choices over pairs only. The consistency conditions for the choice function $C(\cdot)$, which are analogous to rationality conditions for the social preference relation $R$, can be classified or factorized into requirements of two essentially different types – contraction consistency and expansion consistency. (Sen, 1971, has shown that standard contraction consistency – Property $\alpha$ – and standard expansion consistency – Property $\gamma$ – are necessary and sufficient for the choice function to be binary – in that its informational content can be exactly captured by a binary relation defined on $X$.) A series of choice-functional impossibility theorems has been established using alternative forms of such consistency conditions, together with (U), (P), (I) and (ND) translated into choice-functional terms. As in the social-relational case, the conditions imposed on the FCCR (apart from non-dictatorship) can lead it to be dictatorial, oligarchic, or have a vetoer (the results are reviewed in Sen, 1977a; 1986).

In the choice-functional context the robustness of Arrow's impossibility is demonstrated in a remarkable theorem by Sen (1993). He shows (1993, theorem 3) that, without imposing any inter-menu consistency condition on the choice function, the Arrow result survives in the form of a dictator who is decisive in rejecting any dispreferred alternative from a given set $S$, irrespective of the preferences of others. The condition (P) is translated in the choice context as the rejection of Pareto-inferior states; (U) as unrestricted domain applying to the FCCR; (I) as the rejection decisiveness of a group of individuals over any ordered pair $(x, y)$ in $S$ not being affected by individual preferences over pairs other than $(x, y)$, that is, over ‘irrelevant’ alternatives; and (ND) as there being no individual who is rejection-decisive over a given set $S$ of social states.

Since Sen's proof invokes only one set (or menu) of social states $S$, no inter-menu consistency condition for social choice is considered. By the same token, the dictator that emerges from combining the modified conditions (U), (P) and (I) with the FCCR is a rejection dictator for the given set $S$ – and not necessarily for another set of social states, which could have a different individual as rejection dictator. The non-dictatorship condition in Sen's theorem is thus stronger than requiring the absence of a single individual who is a rejection dictator across all sets of social states. His theorem identifies exactly how far it is possible to go down the route of weakening and finally eliminating any consistency requirement for the social choice mechanism without escaping Arrow's problem. With no consistency condition on social choice, it is still not possible to avoid an individual who dictates the rejection of every state in a given set $S$, no matter what the other individuals prefer. Sen's theorem demonstrates just how robust is Arrow's impossibility. The source of Arrow's problem seems to lie elsewhere than in the consistency conditions imposed on the choice function $C(\cdot)$ or the social preference relation $R$ (see above).

**Interpersonal comparisons and social welfare functionals**

Sen has argued that the real source of the Arrow impossibility problem is ‘the tension between the informational eschewal implicitly imposed by Arrow’s set of axioms and the demands of discriminating social choice also entailed by the same axioms. The positive possibilities lie, therefore, in making more room for use of information (both utility and non-utility information) in social choice’ (1993, p. 514, n. 38). Thus, in the original (social-relational) form of Arrow's theorem, the domain of the social welfare function (SWF) consists of $n$-tuples of individual orderings $\{R_i\}$ only, with no information on valuation of intensity of preferences, or interpersonal comparisons of utility. Sen (1970a) formulated a framework to enrich the informational base to allow different assumptions of measurability and comparability of individual utilities. This has opened up an entire new field
The informational base of the Arrovian approach can be improved by making the social preference relation $R$ not a function of the $n$-tuple of individual orderings $\{R_i\}$, but the $n$-tuple of individual utility functions $\{u_i(\cdot)\}$. For example, the classical utilitarian characterization of social welfare is a special case of such a form. However, the difficulty with this way of formalizing the functional relations arises from the fact that, given the measurability and comparability assumptions of individual utilities, the utility function has to be represented not by one $n$-tuple of individual utilities, but by a set of $n$-tuples of individual utilities which are informationally identical (for the given assumptions of measurability and interpersonal comparability). For example, utility functions can be nominally varied through alternative representations without involving any ‘real’ change (for instance, doubling all the utility numbers), and such informationally equivalent representations should lead to the same social ordering $R$. This problem is met in Sen's (1970a) approach of social welfare functionals through imposing a class of invariance requirements, which demand the same outcome for each of the $n$-tuples of utility functions in the class that could reflect the same underlying reality – given the chosen characterization of measurability and comparability of utilities.

A social welfare functional (SWFL) specifies exactly one social ordering $R$ over the set $X$ of social states for any given $n$-tuple $\{u_i(\cdot)\}$ of individual utility functions defined over $X$, that is, $R=F(\{u_i\})$. The invariance requirement takes the general form of specifying that, for any two $n$-tuples of utility functions $\{u_i\}, \{u_i'\}$ that are related in a particular way (reflecting the assumptions that are made of measurability and interpersonal comparability of individual utilities), the social ordering generated must be the same, that is, $F(\{u_i\})=F(\{u_i'\})$.

Thus Arrow's SWF corresponds to a SWFL where the invariance class permits monotonic increasing transformations of the individual utility functions $u_i(\cdot)$; these transformations can be different for each $i$ – thus incorporating ordinal non-comparability of the utility functions $\{u_i\}$ which represent the orderings $\{R_i\}$ in Arrow's SWF.

Using this SWFL framework, Sen (1970a, theorem 7*1) showed that utilitarianism requires cardinal ‘unit’ but not ‘level’ comparability (that is, comparability of utility differences but not of levels). He also showed that cardinality of individual utilities without interpersonal comparability does not avoid Arrow's impossibility (1970a, theorem 8*2). He noted that Rawls's maximin criterion only required ordinal interpersonal comparisons ‘to discover who is the worst-off person’, and then the ‘minimal element in the set of individual welfares is maximized’ (Sen, 1970a, pp. 136–7). Many other results were presented by him using the SWFL framework, including several concerning ‘partial comparability’ (Sen, 1970c). The field he opened up has generated a great number of important results, including axiomatic characterizations of utilitarianism, and the maximin (or its lexicographic version, leximin) criterion as a positional dictatorship rule which requires only ‘level’ comparability of ordinal utility functions. Hammond (1976), d'Aspremont and Gevers (1977), Maskin (1978) and Roberts (1980a), among others, have derived many of the results in this area (individual references for other contributions can be found in Sen, 1986). Roberts (1980b) has presented a comprehensive characterization of the welfare functions that result from assuming different degrees of measurability and comparability of individual utilities, including cardinal full comparability and ratio-scale full comparability.

The impossibility of the Paretian liberal

Apart from Arrow's impossibility theorem, perhaps the most well-known result in social choice theory is Sen's (1970b) impossibility of a Paretian liberal. Sen (1979, p. 539) has argued that the Arrow impossibility can be ‘seen as resulting from combining a version of welfarism ruling out the use of non-utility information with making the utility information rmkably poor (particularly in ruling out interpersonal utility comparisons)’. Welfarism entails that two social states are ranked exclusively on the basis of the individual utilities in the
It turns out that the impossibility of the Paretian liberal is closely related to the difficulties with welfarism. Paretianism can be seen as essentially a weak form of welfarism, which makes non-utility information redundant in the special case where everyone's utility rankings of two social states coincide. Considerations of liberty require the use of non-utility information, viz. the specification of an individual's 'protected sphere' with the social ranking respecting the individual's ranking of states that fall within it. Sen (1970a, theorem 6*) shows that this use of non-utility information goes not only against welfarism but it can go even against Paretianism. Sen introduces a condition called 'minimal liberalism' as follows.

- (L) (minimal liberalism). There are at least two individuals such that for each such individual $i$, there is a personal domain with at least one pair of social states $\{x, y\}$ such that:

$$x \not\in P_i y \rightarrow x \not\in P y \quad \text{and} \quad y \not\in P_i x \rightarrow y \not\in P x.$$

**Theorem (Sen):** There is no social decision function $f(\cdot)$ that satisfies (U), (P) and (L).

Arrow (1999) was greatly impressed by this result, stating that it ‘brilliantly combines simplicity and depth’. He added that he found it very surprising [because] both the Pareto judgment and the idea that each individual has some private domain of choice, even if others would make different choices over that domain, are hard to deny; and independence, which on the whole is central to most variations of the Impossibility Theorem, is not assumed here. The paradox arises because ‘nosy’ preferences of others about choices that are in an individual's domain of private choice enter into the Pareto judgment. The result is not only surprising analytically but also addresses profound ethical qsts on the relation between even the vestigial remnant of utilitarianism contained in the Pareto principle and the existence of individual ‘rights’, a scope (however small) over which the individual has complete control. (Arrow, 1999, pp. 165–6)

Sen's ‘impossibility of the Paretian liberal’ is rightly seen as a seminal result in social choice theory. (The choice-functional version of the ‘impossibility of the Paretian liberal’ was originally presented in Sen, 1970a, pp. 81–2, with conditions (U), (P) and (L) translated for a FCCR and with no consistency condition imposed on the choice function. A formal proof is also given in Sen, 1993, theorem 2.)

**Contributions to economic measurement**

**Inequality and welfare**

The contributions of Sen to the literature on inequality and welfare measurement go back to his classic monograph *On Economic Inequality* (1973a) (*OEI-1973*). This book has been re-issued after a quarter century with a substantial annexe written jointly with James Foster. In the annexe there is a review of the themes in Sen (1973a) that have motivated a great deal of subsequent work in the area and also an acknowledgement that a 'significant part of OEI-1973 was, in fact, Atkinson-inspired’ (Sen and Foster, 1997, p. 114). Indeed, the
literature on inequality measurement has been much influenced by Atkinson's celebrated paper on the ranking of income distributions (see also Kolm, 1969). Atkinson (1970) demonstrated the equivalence of three different rankings of income distributions – according to Lorenz dominance, the principle of transfers, and social welfare for all additively separable concave welfare functions.

Formally, let the vector \( y = (y_1, y_2, \ldots, y_n) \) denote an income distribution among \( n \) individuals with person \( i \) receiving income \( y_i \), for \( i = 1, 2, \ldots, n \). Let the vector \( x = (x_1, x_2, \ldots, x_n) \) denote a different income distribution among the \( n \) individuals with the same total income. Atkinson's theorem then shows that the following statements are equivalent:

1. (i) \( x \) Lorenz dominates \( y \);
2. (ii) \( x \) can be obtained from \( y \) by a sequence of income transfers from richer to poorer individuals;
3. (iii) \( \sum_i U(x_i) \geq \sum_i U(y_i) \) for any non-decreasing concave function \( U(\cdot) \), that is \( x \) yields as much welfare as \( y \) for any additively separable, symmetric, non-decreasing, concave social welfare function \( (\sum_i U(y_i)) \).

In fact, a slightly stronger theorem than this can be proved by adopting a weaker criterion for the welfare ranking (iii). The welfare function \( \sum_i U(y_i) \) can be replaced by a symmetric, non-decreasing, quasi-concave function of individual incomes \( W(y_1, y_2, \ldots, y_n) \) (Dasgupta, Sen and Starrett, 1973). The quasi-concavity restriction on the welfare function can be weakened still further. For the theorem to go through, it is clear that the weakest requirement on the function is that welfare does not decrease by a transfer of income from a richer to a poorer individual. Such a function may be called egalitarian or, as in the literature, S-concave – a property that is weaker than quasi-concavity (Rothschild and Stiglitz, 1973). Thus we consider two further welfare rankings of the income distributions \( x \) and \( y \):

1. (iv) \( x \) yields as much welfare as \( y \) for all symmetric, non-decreasing, quasi-concave welfare functions;
2. (v) \( x \) yields as much welfare as \( y \) for all symmetric, non-decreasing, egalitarian or S-concave welfare functions.

As shown in Anand (1983, p. 338), the stronger theorem establishing equivalence of (iii) with (iv) and (v) follows as an immediate corollary to Atkinson's theorem. Since the class of additively separable concave functions is contained in the class of quasi-concave functions, which in turn is contained in the class of egalitarian or S-concave functions, it follows that (v) implies (iv), and (iv) implies (iii). But from Atkinson's theorem, (iii) implies (ii), and by the very definition of an egalitarian welfare function, (ii) implies (v); therefore, (iii) implies (v). Hence the chain of implications is complete, with (v)\( \rightarrow \) (iv)\( \rightarrow \) (iii)\( \rightarrow \) (v), and there is no information loss in ranking by welfare functions from the more restrictive additively separable class. It is enough to check that distribution \( x \) yields as much welfare as distribution \( y \) for all members of the class of additively separable concave functions, and it will automatically do so for all members of the more general class of S-concave functions too. Hence, Atkinson's theorem in fact establishes the equivalence of (i), (ii) and (v).

Sen's own wide-ranging contributions to the measurement of inequality and welfare begin with On Economic Inequality (1973a) and are followed inter alia by Sen (1974; 1976a; 1978; 1992a). In OEI-1973 he argues for inequality to be seen as a ‘quasi-ordering’ (or partial ordering) without insisting that it must be a complete ordering; he has in fact defended such assertive incompleteness in many different evaluative contexts. Sen (1973a, pp. 72–4) shows that when there are multiple criteria each of which yields a complete ordering (for example, welfare functions or inequality indices in a given class), then their intersection generates a partial ordering. Thus the Lorenz ranking of distributions \( x \) and \( y \) (with the same mean income) is their intersection quasi-ordering generated by all welfare functions in the class of additively separable concave functions. Sen
initially used the intersection (or unanimity) quasi-ordering approach to measure relative inequality in a positive or descriptive sense by employing different statistical measures of inequality, which avoids ‘exclusive reliance on any particular measure and on the complete ordering generated by it’ (1973a, p. 72). Consider the class of inequality indices that satisfy mean and population-size independence, and the Pigou–Dalton condition (viz. a transfer of income from a richer to a poorer person reduces the value of the inequality index). Then all indices from this class will show less inequality for a Lorenz dominant distribution (Anand, 1983, pp. 339–40), and the intersection quasi-ordering generated by all measures in this class is the Lorenz partial ordering (Sen and Foster, 1997, pp. 142–5).

When Lorenz curves cross, further structure has to be imposed on our social values (or relative inequality indices) – in terms of agreement about sub-classes of welfare functions (inequality indices) or choice of a specific one. Sen provides an axiomatic derivation for a welfare function by drawing on his definition of the Gini coefficient as an affine transformation of the rank-order weighted sum of individual income levels. With individuals labelled in non-descending order of income so that \( y_1 \leq y_2 \leq \ldots \leq y_n \), and \( \mu \) their mean income, Sen (1973a, p. 31) expresses the Gini coefficient as:

\[
G = \frac{n+1}{n} \left( 1 - \frac{2}{n^2(n+1)} \sum_{i=1}^{n} y_i \right)
\]

so that the poorest person receives a weight of \( n \), the \( i \)th poorest person a weight of \( (n+1-i) \), and the richest (or \( n \)th poorest) person a weight of unity. Hence the weights on incomes are based on the ranking of individual welfare (assumed to be monotonic in income) levels, which leads to a social welfare ordering of distributions of the same total income by the negative of the Gini coefficient.

The social welfare function behind the Gini coefficient has been used by Sen in different contexts, and has been defended by him in that it ‘makes much use of [ordinal] level comparability without bringing in interpersonally comparable cardinal welfare functions, but at the same time shuns Rawlsian extremism’ (Sen, 1974, p. 398). The rank-order weighting scheme leads him to a distributionally-adjusted measure of real national income (Sen, 1976a), which is the country's mean income \( \mu \) multiplied by \((1 - G)\), where \( G \) is the Gini coefficient. The real income, or ‘welfare’ in the space of income, measure \( \mu (1 - G) \), was the motivation for the development of the generalized Lorenz curve, and Sen's measure is simply twice the area under the generalized Lorenz curve – just as \((1 - G)\) is twice the area under the ordinary Lorenz curve.

**Poverty measurement**

Expressing dissatisfaction with the earlier literature on poverty measurement, Sen (1976b) proposed a new index of poverty which he derived axiomatically. Two types of indices have been used to measure the extent of poverty once the poverty line has been chosen. The most common index is the headcount ratio \( H \), which simply counts the proportion of people below the poverty line. The other index is the income-gap ratio \( I \), which measures the proportionate average income shortfall of the poor from the poverty line. The former index ignores the amounts by which the incomes of the poor fall below the poverty line, while the latter is independent of the number actually in poverty. Both, moreover, are insensitive to a transfer of income from the poor to the very poor. In other words, neither measure is sensitive to the distribution of income among the poor. Sen's measure of poverty incorporates all these three concerns into a single index.

The index is derived axiomatically after the general form for the poverty measure is taken to be a ‘normalized weighted sum of the income gaps of the poor’. Two axioms then suffice to derive the index. The first specifies
the weights on the income gaps of the poor, and the second the normalization of the index. Sen argues for weights based on the rank order of the poor below the poverty line, and normalizes his index such that when all the poor have the same income the index is simply $H \cdot I$. The weight on the income gap of the $i$th poorest person is the number of poor people with incomes at least as large as that of person $i$. From the definition of the Gini coefficient above, this weighting scheme will yield the Gini coefficient of the income distribution among the poor, $G_p$.

For an ordered income distribution $y$ (with $y_1 \leq y_2 \leq \ldots \leq y_n$), let $z$ be the poverty line, $q$ the number of people with income less than or equal to $z$, and $\nu$ the mean income of the poor. Then $H=(q/n)$, $I=(z-\nu)/z$, and Sen's poverty measure

$$P = \frac{(q / n) \cdot [z - \nu + \{q / (q + 1)\} \nu G_p]}{z} = \frac{(q / n) \cdot [z - \nu(1 - G_p)]}{z} \text{ for large } q = H \cdot [1 + (1 - l) G_p].$$

The effect of the weighting scheme is to augment the average income gap $(z - \nu)$ by the Gini coefficient $G_p$ times the mean income $\nu$ of the poor. Thus, the equivalent of an additional income loss arises when inequality among the poor is taken into account. The correction for this loss involves deflating the mean income $\nu$ of the poor by $(1 - G_p)$, which yields the familiar equally distributed equivalent income corresponding to the rank-order welfare function. Hence the weighted income gap is calculated by taking the difference not between the poverty line and the mean income of the poor, but between the poverty line and the equally distributed equivalent income of the poor.

Weighting schemes based on welfare functions different from the rank-order function will produce different expressions for equally distributed equivalent income and, by the same token, different measures of inequality. Hence, Sen's approach will generate a different index of poverty for each different welfare function.

Sen's pioneering article has led to an enormous theoretical and empirical literature on poverty measurement. There have been different normalizations of the Sen index, and authors have used different weights on the income gaps of the poor, for example, those that depend on the size of a poor person’s income gap rather than on the number of poor people with higher incomes (as with rank-order weights). The huge theoretical literature that has been generated by the original article is surveyed in Sen and Foster (1997).

Contributions to welfare economics

Utility, income and capability

Sen has criticized utilitarianism from many points of view – among them that it is welfarist and concerned solely with the sum-total of individual utilities, not with the interpersonal distribution of that sum. Consider the pure distribution problem for two people in which person 1 derives exactly twice as much utility as person 2 from any given level of income, say, because person 2 has some handicap (for example, being a cripple). In this case the utilitarian solution is to give person 1 a higher income than person 2. Even if income were equally divided, person 1 would have enjoyed more utility than person 2 (twice as much); but instead of reducing this inequality the utilitarian rule compounds it – by giving more income to person 1 who is already better off.

The perverse consequences of utilitarianism on inequality in both income and utility spaces led Sen (1973a) to formulate the Weak Equity Axiom (WEA) – which, according to Arrow (1999, p. 167), is another ‘ex of Sen’s seminal role in the area of formal theories of social choice’. WEA states that, in distributing a given total
income, an individual getting less utility from any level of income should get a higher income. This axiom is in general inconsistent with utilitarianism, and its consequences have been much explored in the social choice literature; for example, similar equity axioms over the set of social states $X$ have been used to characterize the leximin rule (the results are discussed in Sen, 1977b; 1986). WEA highlights interest in equality as a criterion independent of utility or income. But equality of what?

What is missing in the utility or income framework is some notion of ‘basic capabilities’: a person being able to do certain basic things. The ability to move about is relevant for a cripple, but there are others such as ‘the ability to meet one’s nutritional requirements, the wherewithal to be clothed and sheltered, the power to participate in the social life of the community’ (Sen, 1980, p. 218).

Sen is critical of the use of both income (or commodity possession) and utility as measures of well-being, arguing that they constitute the wrong space in which to make such assessments. He argues that ‘well-being’ has to do with being well, which must take into account the capability to live long, be well-nourished, be literate, and so on. As he puts it, the ‘value of the living standard lies in the living, and not in the possessing of commodities, which has derivative and varying relevance’ (Sen, 1987, p. 25). What is valued intrinsically are people’s achievements – their ‘beings’ and ‘doings’ – or their ‘capabilities to function’. Income can have importance as an instrument for expanding capabilities, while utility may provide evidence of achievement. But Sen's argument is that the space in which well-being should be assessed has to be more directly linked to what matters most – not its instrumental antecedents (income) nor its evidential correlates (utility).

**Poverty as capability deprivation**

The conversion of income into achieved well-being is subject to great variation. The mapping of income into basic capabilities is significantly affected by personal heterogeneities (such as age, disability and illness), gender and social roles, environmental and epidemiological conditions, among many other factors. There is thus an important need to go beyond income information in poverty analysis, in particular to see poverty as capability deprivation.

Apart from the basic capabilities involved in leading a minimally acceptable life, such as avoiding hunger or undernourishment or preventable morbidity, there are elementary social functionings, such as ‘appearing in public without shame’ or ‘taking part in the life of the community’. The commodity or income requirements of such capability fulfillment will vary between communities within a country, and between countries. Indeed, as Sen (1983, p. 161) has argued convincingly, ‘poverty is an absolute notion in the space of capabilities’ but it often takes ‘a relative form in the space of commodities’. For example, to avoid shame from the inability to meet the demands of custom or convention in a society, the relative income requirements will typically be higher in richer countries. These requirements vary with what others in the community standardly have (for example, in 18th century Europe, according to Adam Smith, ‘a creditable day-labourer would be ashamed to appear in public without a linen shirt’ – cited in Sen, 1983, p. 161). *Relative* deprivation in the space of incomes can thus lead to *absolute* deprivation in the space of capabilities (Sen, 1992a, p. 115).

As Atkinson (1999, p. 186) notes, ‘[i]n this way, Sen exposes the popular confusion that an absolute approach implies a constant real income standard when measuring poverty. Rising living standards in the community as a whole may lead to a poverty line that increases in real terms, even when our concern is limited to absolute deprivation in the space of capabilities.’

**A concluding remark**

The importance of the subject of welfare economics cannot be overemphasized. Welfare judgements lie at the heart of economic policy analysis and prescription. Yet there has been a tendency to avoid examining welfare
Sen, Amartya (born 1933) : The New Palgrave Dictionary of Economics

Statements critically or the assumptions underlying them. Sen's work in welfare economics is of far-reaching significance. His critique of utilitarianism and the Pareto principle, and his insistence on embodying distributional judgements and non-utility information (for example, personal liberty, rights and capabilities), have dramatically shifted the focus of the subject. Sen has done more than anyone else to investigate, scrutinize and develop the foundations of welfare economics and social choice theory. He has used formal analysis, conceptual elucidation, measurement theory, philosophical reasoning, and empirical work to advance the subject – as no one has done before him. The range and reach of Sen's contributions to welfare economics are truly formidable. Their totality essentially defines the present subject matter of this critical branch of economics.

N. De Marchi
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Early 19th-century English political economists divided on method. Some, Senior among them, favoured Smith's approach: observe behaviour and try to tie it to likely motives. Others, such as Ricardo and the Mills, preferred to build models based on strong assumptions, then qualify the conclusions while still insisting on their basic truth. On policy questions, and on the basic motives behind economic behaviour, they often agreed, but Smith's approach allowed for more than one answer to questions such as: what is value? Much ink was spilt and much muddle resulted, clarification (on value) being achieved only with Jevons and Marshall.

Article

Born at Compton Beauchamp in Berkshire, the eldest son of John Raven Senior, Vicar of Durnford, Nassau Senior studied for the Bar in London, was the first Drummond Professor of Political Economy at Oxford, 1825–30, and was elected to a second term, 1847–52. In 1831 he was appointed Professor of Political Economy at King's College, London, but was soon forced to resign over his controversial recommendation that some of the revenues of the established Church in Ireland be turned over to the Roman Catholics. Senior became a respected adviser: he served on the Commission for inquiring into the Administration and Operation of the Poor Laws (1832–4), being mainly responsible for the writing of its report, and was consulted by Lord John Russell on Irish Poor Law Reform in 1836. In 1841 Senior drew up the Report of the Commission on the condition of the Unemployed Hand-loom Weavers (on
Senior, Nassau William (1790–1864) : The New Palgrave Dictionary of Economics

Two years after it was founded in 1821 Senior was elected to membership of the Political Economy Club and remained a member, except for the years 1848–53, until his death.

Senior first came to the notice of those conversant with political economy through an article on the Corn Laws in the Quarterly Review (1821), and he was a regular contributor to the Edinburgh Review from 1841 to 1855. He was at home in both literary and political circles in London and cultivated an interest in Continental affairs via frequent travels and the company of men of influence, among whom were Guizot and De Tocqueville. Conversations with such men in France and Italy and in Ireland were assiduously recorded (and checked for accuracy) and, together with a traveller's observations on these and other countries, filled many journals. Several of these were published, including conversations with De Tocqueville spanning the years 1834–59.

It was Senior's intention to publish a systematic account of political economy, collecting the ideas that were largely scattered in periodicals, lectures, official reports and pamphlets into a major treatise. The plan was not fulfilled and his main printed legacy is his 1836 Outline of the Science of Political Economy, plus a collection of pamphlets and public letters published by Augustus Kelley, entitled Selected Writings on Economics (1966) and his Three Lectures on the Rate of Wages (1830a).

S. Leon Levy undertook the work Senior never brought to fruition, in a volume entitled Industrial Efficiency and Social Economy (1928). This is a composite, organized by a plan of the editor's own making, and comprising selections from periodical articles, reports and – mainly – manuscript lectures from Senior's second term as Drummond Professor. The work is supposed to represent Senior's 'mature' thoughts, but the manner of its composition makes it of very limited value from a scholar's point of view.

Senior belonged to the band of eminent political economists of the second quarter of the 19th century who may be called respectful dissenters from Ricardo's doctrines. He did not dissent on methodological grounds, as did Whewell and Richard Jones (De Marchi and Sturges, 1973; Hollander, 1985, vol. 1, chs 1–3), but on value and distribution he followed Smith and Say more closely than Ricardo. Thus 'value' to Senior meant value in exchange rather than cost of production or labour cost (1836, pp. 13–14). And distribution he preferred to treat as a question of factor incomes rather than of functional shares. The expression 'high wages', for example, Senior used to stand for high nominal or real wages rather than for a large share of labour's product actually received by labour (1830a, pp. 2–3). This is not to say that he anticipated the marginal productivity theory of distribution, although at least as far as labour and capital are concerned he liked to think of the incomes attributable to each as payment for services rendered or, even more especially, as a 'reward … [for] conduct' (1836, p. 89).

Senior's approach to distribution displays tensions that are unavoidable in trying to combine a Ricardian concern with macro-issues such as capital and population growth and the time-path of wages with a Smithian predilection to treat value and distribution as the outcome of voluntary exchanges entered into by individuals. To illustrate: Senior retained the Ricardian theory of rent, whereby rent is an intra-marginal surplus. This surplus accrues to ownership. Where, however, there is competitive access to the powers of nature, the price of the product equals the sum of wages, a reward for labour services, and profit, a return for waiting or 'abstinence' (1836, p. 89). This falls short of an integrated theory of distribution, reflecting as it does the institutional fact of appropriation, on the one hand, and economic conduct by free agents, on the other. Similarly, in discussing the time-path of wages, Senior reverted to a wages-fund approach: given labour productivity, 'the rate of wages depends on the extent of the fund for the maintenance of labourers, compared with the number of labourers to be maintained' (1830a, p. xii).
This refers to the average wage; but we are not told how individual contracts struck between worker and employer upon the value of labour services relate to this average. The problem is familiar to modern theorists wanting to make explicit the microfoundations of macroeconomics; though the major difficulty, changing relative wages, Senior neatly sidestepped by following Smith in the conviction that, once established, relative wage scales remained fixed (1830b, p. 15).

Senior's Ricardianism is perhaps most evident in his views on trade and on the international aspects of money. In Three Lectures on the Transmission of the Precious Metals, delivered at Oxford in June 1827 and printed the following year, on an issue he felt to be ‘next to the Reformation, next to the question of free religion, the most momentous that has ever been submitted to human decision’ (1828, p. 88), Senior employed Hume's doctrine (and Ricardo's) to show that no country can have a permanently favourable or unfavourable balance of trade or exchange rate, then used this against the mercantilist view. His main concern is the efficient allocation of labour, and this leads him to the Ricardian conclusion that, if a domestic tax on one industry hurts its international competitiveness, then a ‘countervailing duty’ on the competing import is ‘not a departure from the principles of free trade but an application of them’ (1828, p. 70; compare Ricardo 1822, vol. 4, p. 217). In another set of three lectures, this time On the Cost of Obtaining Money (1830b), Senior addressed the question of international comparisons of wages and argued that the productivity of labour measured in the goods required to import precious metals (in a non-mining country) determines whether wages are high or low. In both sets of lectures Senior discusses paper money and reaches the basic Ricardian conclusion that variations in the amount of the currency, whether metal or paper, may cause sudden disturbances but these will be transitory.

It is worth stressing that the Stoic tradition so evident in Smith's writings – self-respect issuing from prudent behaviour, most notably self-restraint – also infuses Senior's discussions of distribution and related social issues. Senior takes it as given that men tend to be myopic and to prefer taking their ease to working (Senior, 1827, p. 8; 1836, pp. 26 ff.). He therefore considered the supply of goods to be a result of prudential exertions to overcome these obstacles (1836, pp. 15–16). There is no such exertion attached to mere ownership. Hence the income of a landlord is a transfer and categorically distinct from wages and profits, which are properly considered rewards. They are like the good which results from confronting and overcoming unavoidable evil (pain). Although Senior is properly extolled for having glimpsed marginal utility, his contribution on the side of supply and the overcoming of obstacles is at least as interesting.

Marx, it need hardly be added, saw Senior as ‘a mere apologist of the existing order’ (Marx, 1905–10, vol. 3, p. 353). This in part refers to Senior's view that profit is the reward of ‘abstinence’. Senior's sacrifice–reward approach to the sharing out of the price of product at the margin, however, was adopted fully by the later Ricardians, John Stuart Mill (1848, p. 400) and John Elliott Cairnes (1874, p. 74).

Senior's views on method too are indistinguishable in all but two details from John Stuart Mill's. One reasons in political economy from true premises known by introspection (the desire for wealth, subject to a preference for least effort and present enjoyment) or from observation (the laws of return and of population). Being true these premises will, upon correct reasoning, yield true principles. In the science of political economy, therefore, there resides as much certainty as in any science outside axiomatic logic (Senior, 1827, p. 11). Nonetheless, the psychological drives for wealth, leisure and present satisfaction produce counteracting conduct, so that it is difficult to assign motives (causes) to or predict behaviour (1827, p. 9).

Mill tended to bundle the three psychological motives together and make the wealth motive do most of
the work. He also chose to reason hypothetically, as if the desire for wealth were the sole motivation of an individual. This meant that his results could be true only in the abstract, or to the degree to which that assumption was in fact true. In later years Senior, despite his early warning that counteracting motives could not readily be disentangled (1827, p. 9), argued against Mill's simplifying approach. His Four Introductory Lectures from the second period of his tenure of the Drummond Professorship (1847–52) lamented the slow progress made in political economy. He found reason in the Millian manner of dealing with the science. Hypothetical reasoning, in Senior's view, rendered the subject unattractive, because unrealistic, and laid the reasoner open to error, either from forgetting some relevant additional cause or from forgetting that the reasoning itself was based on arbitrary assumptions and was not directly transferable to real world situations (Senior, 1852, pp. 63–5). In more recent discussion, T.W. Hutchison has kept Senior's objections alive, protesting in particular a tendency to confuse tautological with empirical propositions, and to leap straight from abstract models to policy conclusions (Hutchison, 1938). While Senior's concern is understandable, to the extent to which his earlier judgement was well-founded – ‘that we are liable to the greatest mistakes when we endeavour to assign motives [causes] to … conduct’ (1827, p. 9) – it is not clear that he gains anything by his later modified approach, and there is in that case less practical difference between his position and Mill's than some modern commentators have made out (Bowley, 1937, pp. 59–62).

Both Senior and Mill cautioned against applying the principles of political economy without the utmost care and a broad and detailed knowledge of the facts applying to any case in question. Senior, however, nonetheless confidently offered advice on the great issues of the 1830s and 1840s: Poor Law reform; the Factory Act (Ten Hours Bill); agricultural unrest, overpopulation and emigration; free trade and the role of banks in commercial crises. In few of the views he expressed is there anything very remarkable – an exception is noted below in connection with the Ten Hours Bills – but he had a striking ability to cut through to the heart of complex issues, and he had a persuasive pen. To illustrate, his overriding criterion for judging all schemes of relief to the able-bodied poor was whether they destroyed incentives by separating effort from reward (1830a, preface; 1834, pp. 126 ff.). In a particular argument against reducing factory hours, he held that if capital replenishment is, say, 11/12ths of gross turnover, then interest plus profits depend essentially on the last hour of a 12-hour day. A ten-hour day, therefore, would spell ruin (1837, pp. 12–13). This not only presupposed constant returns to hours worked, but confused stocks and flows in the calculation of returns (Johnson, 1969).

separability

Charles Blackorby, Daniel Primont and R. Robert Russell
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Given a smooth increasing function, two variables are separable from a third if the marginal rate of substitution between the first two variables is independent of the third. In this case it is possible to construct an aggregator function over the first two variables that is independent of the third. This is much weaker than additive separability or additivity. We show that separability is equivalent to decentralization and that additive separability is closely related to two-stage budgeting.

Article

1 Introduction

Separability, as discussed here, refers to certain restrictions on functional representations of consumer (or social) preferences or producer technologies. These restrictions add structure to the decision-making tasks undertaken by economic agents. They also allow the economic researcher to study the behaviour of these agents in a more effective manner.

To keep things simple we will focus on consumers. Consumers must make choices among a large number of goods – both consumption and leisure, both present and future. The apparent complexity of their decision-making problems may lead consumers to engage in simplified budgeting practices. Are these procedures consistent with rational behaviour? In modelling consumer behaviour, economists – theoretical and empirical – employ models that consider only a subset or several subsets of the complete
list of goods and services consumed. Can these practices be justified? And, if so, what kinds of restrictions do these rationalizations place on the preferences and the behaviour of the consumer? In what follows, we discuss several proposals that address this class of problems and present their solutions.

One way to think about reducing the complexity of the allocation decision is to imagine that the consumer receives a lump sum of money that he or she first allocates to broad classes of commodities, such as food, shelter and recreation. Detailed decisions about how to spend the money that has been allocated to the food budget are postponed until one is actually in the store buying specific food items. More formally, if the correct amount of money to spend on food commodities, for example, has been allocated, under what circumstances is the consumer able to dispense the food budget among food commodities knowing only the food prices? If the consumer can arrive at an optimal pattern of food expenditures in this way, preferences are said to be *decentralizable*. It is fairly obvious that, if food commodities were separable from all other commodities, decentralization would be possible. What is somewhat surprising, however, is that separability is necessary as well as sufficient for this practice to be rationalized. We first present more formally the concepts of decentralization and separability and then discuss their equivalence.

Consumption bundles are $N$-tuples, $x=(x_1, \ldots, x_N)$, that are elements of a consumption space, $\Omega$. We take $\Omega$ to be a closed and convex subset of $\mathbb{R}^N_+$. Thus we begin with a consumer with a well-defined, neoclassical utility function, $U: \Omega \to \mathbb{R}$. Partition the set of variable indices, $I=\{1, 2, \ldots, N\}$, into two subsets $\{I_1, I_2\}$. This divides the set of goods into two groups, one and two, and we can write the consumption space as $\Omega = \Omega_1 \times \Omega_2$ and the consumption vector as $x=(x^1, x^2)$. The consumer faces commodity prices given by $p=(p_1, \ldots, p_N)$ and allocates income $y$ among the $N$ goods. The price vector can also be written as $p=(p^1, p^2)$.

The consumer's utility maximization problem,

$$\max \ U(x) \text{ subject to } p \cdot x = y,$$

\hspace{1cm} (1)

can be rewritten as

$$\max \ U(x^1, x^2) \text{ subject to } p^1 \cdot x^1 + p^2 \cdot x^2 = y.$$  

\hspace{1cm} (2)

The solution to (1) [or (2)] is denoted by
Expenditure on goods in group two is denoted by $y_2$. Group two expenditure is optimal if $y_2 = p_2 \Phi^2(y, p)$.

### 2 Decentralization and separability

The consumer's utility maximization problem may be decentralized if the consumer is able to optimally allocate expenditure on group-two commodities knowing only group-two optimal expenditure and group-two prices. More formally, the utility maximization problem is *decentralizable* (for group two) if there exists a function $\Phi^2$ such that

$$\Phi^2(y_2, p^2) = \Phi^2(y, p) \text{if } y_2 = p^2 \cdot \Phi^2(y, p).$$

Now the question is: what restriction on the consumer's utility function allows for decentralizability of the utility maximization problem? As it turns out, decentralizability for group-two goods is possible if and only if group-two goods are separable from group-one goods. We turn to the formal definition of separability.

According to the original Leontief–Sono definition of separability, the goods in group two are *separable* from the goods in group one if

$$\frac{\partial}{\partial x_k} \left( \frac{\partial U(x)}{\partial x_i} \right) \equiv 0,$$

for all $i, j \in I^2$, $k \in I^1$ (see Leontief, 1947a; 1947b; Sono, 1945; 1961).

The condition (4) says that marginal rates of substitution between pairs of goods in group two are independent of quantities in group one and hence that an aggregator function exists for group-two goods. Under fairly mild conditions, this aggregator function may be defined by

$$U^2(x^2) = U(O^1, x^2)$$
for any choice of a fixed vector, $O^1 \in \Omega^1$; that is, $(O^1, x^2) \in \Omega$. Different choices of $O^1$ give rise to different aggregator functions that are ordinally equivalent. Having accomplished this, we also define a macro function, $u$, that is defined by

$$U(x^1, x^2) = u(x^1, U^2(x^2)).$$

(5)

Example: Let $I = \{1,2,3,4\}$, $I^1 = \{1,2\}$, and $I^2 = \{3,4\}$. Consider the utility function given by

$$U(x_1, x_2, x_3, x_4) = \frac{x_1^{1/3}x_2^{1/3}x_3^{1/3} + x_2^{1/2}x_3^{1/4}x_4^{1/4}}.$$

By defining $u_2 = U^2(x_3, x_4) = x_3^{1/3}x_4^{1/3}$ and $u(x_1, x_2, u_2) = x_1^{1/3}u_2 + x_2^{1/2}u_2^{3/4}$, we observe that

$$U(x_1, x_2, x_3, x_4) = u(x_1, x_2, u_2),$$

and hence that group two is separable from group one. One may also confirm this fact using the Leontief–Sono conditions. The reader should notice that the choice of the aggregator and macro function is not unique. An alternative choice would be $u_2 = U^2(x_3, x_4) = x_3^{1/2}x_4^{1/2}$ and

$$u(x_1, x_2, u_2) = x_1^{1/3}u_2^{2/3} + x_2^{1/2}u_2^{1/2}.$$ In this case, the aggregator function is chosen to be homogeneous of degree one. The reader should also notice that group one is not separable from group two; separability is not a symmetric concept.

The formal result on decentralizability can now be stated. The consumer's utility maximization problem is decentralizable for group two if and only if group two is separable from group one – that is, if and only the utility function can be written as

$$U(x^1, x^2) = u(x^1, U^2(x^2)).$$
The implication of this result is that the consumer utility maximization problem may be broken up into two parts:

1. Solve

$$\max_{x^2} U^2(x^2) \text{subject to } p^2 x^2 \leq y_2$$

(6)

to get the conditional demand function, $\phi^2(y_2, p^2)$, for group two.

2. Solve

$$\max_{x^1, y_2} u(x^1, U^2(\psi^2(y_2, p^2))) \text{subject to } p^1 x^1 + y_2 \leq y$$

(7)

to get the optimal demands for group one and the optimal income allocation for group two.

While separability is inherently an asymmetric concept, we may want to consider the symmetric case. We may also want to extend the analysis to consider $R$ groups of goods. To this end, let $\{I^1, \ldots, I^R\}$ be a partition of the original set of variable indices $I$. The goods vector and the price vector can be written as $x=(x^1, \ldots, x^R)$ and $p=(p^1, \ldots, p^R)$, respectively. Then the utility function is separable in the partition $\{I^1, \ldots, I^R\}$ if and only if the utility function may be written as

$$U(x^1, \ldots, x^R) = z^1(u^1(x^1), \ldots, u^R(x^R)).$$

(8)

Expenditure on goods in group $r$ is denoted by $y_r$, $r=1,\ldots,R$. Group $r$ expenditure is optimal if $y_r = p^r \cdot \Phi^r(y, p)$.

The consumer's utility maximization problem may be decentralized if the consumer is able to optimally allocate expenditure on group $r$ commodities knowing only group $r$ optimal expenditure and group $r$ prices. More formally, the utility maximization problem is *decentralizable* for the partition $\{I^1, \ldots, I^R\}$ if there exist functions $\Phi^r$, $r=1,\ldots,R$, such that
A useful device for explicating the necessary and sufficient conditions for decentralizability of the utility maximization problem is the conditional indirect utility function. For the $R$ group case it is defined as

$$
\varphi^r(y_r, p^r) = \Phi^r(y, p) \text{if } y_r = p^r \cdot \Phi^r(y, p), \ r = 1, \ldots, R.
$$

This function yields the maximum utility conditional on an income allocation, $(y_1, \ldots, y_R)$, among the $R$ groups. In a second stage one can solve for the optimal income allocation by solving

$$
\max_{y_1, \ldots, y_R} H(y_1, \ldots, y_R, p) \text{subject to } \sum_{r=1}^{R} y_r^r \leq y.
$$

Denote the solution to (10) by the expenditure-allocation functions

$$
y_r = \theta^r(y, p), \ r = 1, \ldots, R.
$$

A remarkable feature of the conditional indirect utility function is that

$$
H(\theta^1(y, p), \ldots, \theta^R(y, p), p) = W(y, p) = \max_{x} \{U(x) : p \cdot x \leq y\}.
$$

Thus, the overall consumer utility maximization may always be performed in the two steps given in (9) and (10) even in the absence of separability restrictions on the utility function.
The results for decentralizability in the $R$-group symmetric case can be stated in two parts. First, the utility function is separable in the partition \( \{I^1,\ldots, I^R\} \) as in (8) if and only if the conditional indirect utility function may be written as

\[
H(y_1, \ldots, y_R, p) = U^1(y_1, p^1), \ldots, U^R(y_R, p^R)
\]

where

\[
\psi^r(y_r, p^r) = \max_{x^r} \left\{ U^r(x^r) : p^r x^r \leq y_r \right\}, \quad r = 1, \ldots, R,
\]

are the conditional indirect utility functions for the aggregator functions, \( U^r(x^r), r=1,\ldots,R \). Second, the consumer's utility maximization problem is decentralizable for the partition \( \{I^1,\ldots, I^R\} \) if and only if the utility function is separable in the partition \( \{I^1,\ldots, I^R\} \).

Separability in the partition \( \{I^1,\ldots, I^R\} \) allows the following two-step budgeting procedure. In the first step the consumer solves the problem in (12), which yields conditional demand functions

\[
x^r = \psi^r(y_r, p^r), \quad r = 1, \ldots, R.
\]

In the second step, the consumer solves (10), which yields the optimal income allocation. While the first step economizes the informational requirements – knowledge of only in-group prices are needed – the second step requires the entire vector of prices. However, additional restrictions on the utility function will reduce both the computational and informational burden of the second step; these restrictions will be discussed shortly.

Decentralization may be possible in more than one partition of the set of commodities. Moreover, the separable sectors might well overlap. Suppose, for example, that \( U \) is a social welfare function and \( x^r \) is the consumption vector of consumers in group \( r \). As some policies affect only a subset of the population, one might want to analyse separately the social welfare of, say, two subgroups of the population: (1) a particular ethnic group and (2) those in a particular geographical region. Clearly, the two groups could overlap. A deep result of Gorman (1968) indicates that the existence of such overlapping separable groups has powerful implications for the structure of the welfare function.

3 Additive structures

Let \( I^r \) and \( I^c \) be the two (separable) groups of interest and suppose that

\[
I^1 = I^r \setminus I^c \neq \emptyset, \quad I^2 = I^r \cap I^c \neq \emptyset, \quad \text{and} \quad I^3 = I^c \setminus I^r \neq \emptyset.
\]

Let \( I^4 \) be the complement of \( I^r \cup I^c \) in \( I \).
One of the important aspects of Gorman's overlapping theorem is that this structure is equivalent to the following representation of $U$:

$$U(x) = U(U^1(x^1) + U^2(x^2) + U^3(x^3), x^4).$$

(Additional regularity conditions on the ‘essentiality’ of each group are required for this result; see Gorman, 1968; Blackorby, Primont and Russell, 1978; 1998.)

Note that what drives this result on (groupwise) additive structures is not simply separability of each of the sectors, $I^1, I^2$ and $I^3$, from their complements but also separability of arbitrary unions of these sectors. This observation suggests the general result on groupwise-additive structures (see Debreu, 1959; Gorman, 1968):

$$U(x) = \left( \sum_{r=1}^{R} U^r(x^r) \right), \quad R > 2,$$

if and only if arbitrary unions of subsets of the partition $\{I^1, \ldots, I^R\}$ are separable from their complements. Note that a special case of (14) is when each element of the partition $I$ is a singleton ($R=n$), in which case,

$$U(x) = \left( \sum_{j=1}^{N} U^j(x^j) \right), \quad N > 2.$$

That is, $u$ is additive in the variables themselves.

Another example in the context of social welfare functions illustrates the power of Gorman's overlapping theorem. Suppose that the social decision rule satisfies the anonymity condition: only the individuals’ utilities and not their names should matter in social evaluation. This standard social choice assumption is equivalent to symmetry of the social welfare function: permuting the names of individuals does not affect the value of the function. Let $\{1, 2\}$ be the subset of individuals who are affected by some set of policies, and suppose that these policies are judged solely by their effects on these two individuals. This implies that $\{1, 2\}$ is separable from its complement in the set of citizens and hence that
The fact that $W$ is symmetric means that it can be written as

$$W(u_1, ..., u_R) = J(F(u_1, u_2), u_3, ..., u_R).$$

This in turn implies that $\{1,3\}$ is separable from its complement in the set of citizens. However, these sets have a non-empty intersection, $\{2\}$, and the overlapping theorem implies that the social welfare function can be written as

$$W(u_1, ..., u_R) = J(F(u_1, u_3), u_2, u_4, ..., u_R).$$

Proceeding by induction yields a strong implication: the social welfare function must be additive:

$$W(u_1, ..., u_R) = \psi(f^1(u_1) + f^2(u_2) + f^3(u_3), u_4, ..., u_R).$$

The Gorman overlapping argument establishing the groupwise additive structure (13) requires the existence of at least two overlapping separable sets resulting in at least three separable sets. Put differently, separability of arbitrary unions of non-overlapping sets in a binary partition $\{I^1, I^2\}$ adds no restriction to separability of the two sets from their complements. But two-group additivity arises in many contexts. One example is the typical additive utility function in overlapping-generations models where each generation's finite lifetime is divided into two periods (often a 'work' period and a 'retirement' period). A special case of two-group additivity is the quasi-linear utility function that is so critical to the analysis of public goods and incentive compatibility. The stronger conditions required for two-group additivity are based on Sono's (1945; 1961) independence condition. A set of variables, $I^1$, is said to be Sono independent of $I^2$ if there exist functions $\psi^i, i, j \in I^1$, such that
That is, the effect of changing the consumption of a commodity in sector 1 on the marginal rates of substitution between pairs of variables, one in sector $I_1$ and the other in sector $I_2$, depends only on the values of consumption levels in sector 1.

The necessary and sufficient condition for two-group additivity is as follows: $U$ can be written as

$$U(x) = U^1(x^1) + U^2(x^2)$$

if and only if $I_1$ is independent of $I_2$ and is separable from $I_2$. (This version of the two-group additivity result is attributable to Blackorby, Primont and Russell, 1978. A somewhat weaker version was proved by Sono, 1945; 1961, who maintained separability of $I_2$ from $I_1$ as well.) Although this structure is commonly referred to as ‘separable’, it is clearly stronger than separability as the term has historically been used.

4 Two-stage budgeting

It was emphasized in Section 2 that the principal motivation for separability is that it rationalizes decentralizability of the (possibly complex) expenditure-constrained maximization problem. But, since separability only guarantees that sectoral expenditure is optimally allocated within the sector, full rationalization requires in addition that the optimal amount of money be allocated to each sector. This is accomplished by solving the allocation problem (10).

But solving this problem is tantamount to solving the overall optimization problem and does not seem to reduce the informational requirements. For this reason, Strotz (1957) and Gorman (1959) emphasized the existence of sectoral price aggregates (indexes) that can be used to simplify the first stage of the two-stage optimization problem. Formally, we say that price aggregation is possible if the allocation functions in (11) can be written as

$$y_r = \Theta^r(y, p^1, ..., p^R), \quad r = 1, ..., R$$

(18)
(where the price-index functions, $\Pi^r, r=1, \ldots, R$, are not assumed to be homogeneous of degree one or even homothetic).

Price aggregation is equivalent to the following structure for the direct utility function (in an appropriate permutation of the sectoral indices, $1, \ldots, R$):

$$U(x) = \left\{ \sum_{r=1}^{D} f^r(x^r) + G(f^{D+1}(x^{D+1}), \ldots, f^R(x^R)) \right\},$$

(19)

where each $f^r, r = D + 1, \ldots, R$, is homothetic and hence can be normalized to be homogeneous of degree one and the sectoral indirect utility functions dual to the first $D$ aggregator functions, defined by

$$v^r(y^r, p^r) = \max_{x^r} \left\{ U^r(x^r): p^r x^r \leq y^r \right\}, r = 1, \ldots, R,$$

(20)

have the structure,

$$v^r(y^r, p^r) = v^r\left(\frac{y^r}{\Pi^r(p^r)}\right) + w^r(p^r), r = 1, \ldots, D, $$

(21)

where each $w^r$ is homogeneous of degree zero in $p^r$ and $\Pi^r$ is homogeneous of degree 1 in $p^r$. (Gorman, 1959, assuming away the troublesome two-group case, proved a restricted version of this result. Exploiting Sono independence and some newer results not available to Gorman in 1959, Blackorby and Russell, 1997, proved the general result, showing that the entire structure needed for two-stage budgeting is, in fact, imbedded in the two-group case.)

An interesting special case of (19) is obtained if $D=0$:

$$U(x) = F(f^1(x^1), \ldots, f^R(x^R)).$$

(22)
In this case, the first stage of the budgeting algorithm can be expressed as choosing $X^1,\ldots,X^R$ to maximize $F(X^1,\ldots,X^R)$ subject to the budget constraint, $\Sigma r^i (r^i) X^i = y$. This structure allows the two-stage budgeting to be accomplished using only price and quantity aggregates in the first stage.

5 Closing remarks

We have chosen consumer demand theory as a way to illustrate the use of separability in economic analysis. However, separability assumptions, either explicit or implicit, are found in numerous areas in economics. For references to the literature, the reader can consult Blackorby, Primont and Russell (1978; 1998).

A ‘sequence economy’ is a general equilibrium model including markets at a sequence of dates, reopening over time. It is alternative to the Arrow–Debreu model with a full set of futures markets where all exchanges for current and future goods are transacted without transaction cost at a single market date. Sequence economy markets reopen and may be incomplete (some markets, particularly futures, may be inactive) because of transaction costs. The model can provide a microeconomic general equilibrium foundation for the store-of-value function of money, since markets reopening over time create an incentive to carry money and debt intertemporally.

Keywords

Arrow–Debreu model; budget constraint; fiat money; futures markets; general equilibrium; incomplete markets; infinite horizons; intertemporal transfers; overlapping generations models; sequence economies; spot markets; store-of-value function of money; sunspot equilibrium; temporary equilibrium; transaction costs

Article

A ‘sequence economy’ is a general equilibrium model in discrete time including specific provision for the availability of markets at a sequence of dates (Hicks, 1939; Radner, 1972). Markets reopen over time, and at each date firms and households act so that plans and prospects for actions on markets available in the future significantly affect their current actions.

This model is in contrast to the Arrow–Debreu model with a (complete) full set of futures markets (Debreu, 1959). There, all exchanges for current and future goods (including contingent commodities, futures contracts contingent on the realization of uncertain events) are transacted on a market at a single point in time. In the Arrow–Debreu model, there is no need for markets to reopen in the future; economic activity in the future consists simply of the execution of the contracted plans. The Arrow–
Debreu model with a full set of futures markets appears unsatisfactory in that it denies commonplace observation: futures markets for goods and Arrow securities (contingent contracts payable in money) are not generally available for most dates or a sufficiently varied array of uncertain events; markets do reopen over time. The sequence economy model is an alternative that allows formalization and explanation of these observations.

Several major classes of theoretical model are set in the sequence economy framework: overlapping generations (Balasko and Shell, 1980; 1981; Geanakoplos and Polemarchakis, 1991; Wallace, 1980); temporary equilibrium (Grandmont, 1977; Lucas, 1978), sunspot equilibrium (Chiappori and Guesnerie, 1991), incomplete markets (Geanakoplos, 1990; Magill and Quinzii, 1996). These are general equilibrium models over sequential time emphasizing monetary and financial structure. Each of these areas has a large literature of its own. Typically these models assume a given (incomplete) structure of active financial markets without a detailed foundation for how markets come to be incomplete. This contrasts with the statement of the sequence economy model presented below, which derives market activity and incompleteness endogenously as an equilibrium outcome reflecting transaction costs. The sequence economy model is particularly suitable to provide a microeconomic foundation for the store-of-value function of money (Hahn, 1971; Starrett, 1973). It is precisely because markets reopen over time that agents may find it desirable to carry abstract purchasing power from one date to succeeding dates. Typically, this will take the form of transactions on spot markets at a succession of dates with money or other financial assets held over time to reflect the (net) excess value of prior sales over purchases. This may occur simply because the model does not provide for futures markets or because futures markets, though available in principle, are in practice inactive. Endogenously determined inactivity of futures markets is the result of transaction costs which tend to make the use of futures markets disproportionately costly compared with spot markets.

There are three principal reasons for the excess cost of futures markets:

1. The necessarily greater complexity of futures contracts may require use of more resources (for example, for record keeping or enforcement) than spot markets.
2. The transaction costs of a futures contract are incurred (partly) at the transaction date, those of an equivalent spot transaction are incurred in the future. The present discounted value of the spot transaction costs incurred in the distant future may be lower than the futures market transaction cost incurred in the present, simply because of time-discounting.
3. Use of a full set of futures markets under uncertainty implies that most contracts transacted become otiose and are left unfulfilled as their effective dates pass and the events on which they were contingent do not occur. There is a corresponding saving in transaction costs associated with reducing the number of transactions required by use of a single spot transaction instead of many contingent commodity contracts, though this reduction may imply a different and inferior allocation of risk-bearing.

We now present a formal pure exchange sequence economy model with transaction costs (Kurz, 1974; Heller and Starr, 1976).

Commodity \( i \) for delivery at date \( \tau \) may be bought spot at date \( \tau \) or futures at any date \( t, 1 \leq t < \tau \). The complete system of spot and futures markets is available at each date (although some markets may be
inactive). The time horizon is date \( K \); each of \( H \) households is alive at time 1 and cares nothing about consumption after \( K \). There are \( n \) commodities deliverable at each date; in the monetary interpretation of the model spot money is one of the goods. At each date and for each commodity, the household has available the current spot market, and futures markets for deliveries at all future dates. Spot and futures markets will also be available at dates in the future and prices on the markets taking place in the future are currently known. Thus in making his purchase and sale decisions, the household considers without price uncertainty whether to transact on current markets or to postpone transactions to markets available at future dates. There is a sequence of budget constraints, one for the market at each date. That is, for every date, the household faces a budget constraint on the spot and futures transactions taking place at that date, (4) below. The value of its sales to the market at each date (including delivery of money) must balance its purchases at that date.

In addition to a budget constraint, the agent's actions are restricted by a transaction technology. This technology specifies for each complex of purchases and sales at date \( t \), what resources will be consumed by the process of transaction. It is because transaction costs may differ between spot and futures markets for the same good that we consider the reopening of markets allowed by the sequence economy model. Specific provision for transaction cost is introduced to allow an endogenous determination of the activity or inactivity of markets. In the special case where all transaction costs are nil, the model is unnecessarily complex; there is no need for the reopening of markets, and the equilibrium allocations are identical to those of the Arrow–Debreu model. Conversely, in the case where some futures markets are prohibitively costly to operate and others are costless, then there is an incomplete array of spot and futures markets and the model is an example of that of Radner (1972).

All of the \( n \)-dimensional vectors below are restricted to be non-negative.

- \( x^h_\tau(t) \) = vector of purchases for any purpose at date \( t \) by household \( h \) for delivery at date \( \tau \).
- \( y^h_\tau(t) \) = vector of sales analogously defined.
- \( z^h_\tau(t) \) = vector of inputs necessary to transactions undertaken at time \( t \). The index \( \tau \) again refers to the date at which these inputs are actually delivered.
- \( \omega^h(t) \) = vector of endowments at \( t \) for household \( h \).
- \( s^h(t) \) = vector of goods coming out of storage at date \( t \).
- \( r^h(t) \) = vector of goods put into storage at date \( t \).
- \( p^\tau(t) \) = price vector on market at date \( t \) for goods deliverable at date \( \tau \).

With this notation, \( p_{it}(t) \) is the (scalar) spot price of good \( i \) at date \( t \), and \( p_{i\tau}(t) \) for \( \tau > t \) is the futures price (for delivery at \( \tau \)) of good \( i \) at date \( t \).

The (non-negative) consumption vector for household \( h \) is

\[
\mathbf{c}^h(t) = \omega^h(t) + \sum_{\tau=1}^{t} \left[ x^h_\tau(\tau) - y^h_\tau(\tau) - z^h_\tau(\tau) \right] + s^h(t) - r^h(t) \geq 0, \ (t = 1, \ldots, K).
\]

(1)
That is, consumption at date $t$ is the sum of endowments plus all purchases past and present with delivery date $t$ minus all sales for delivery at $t$ minus transaction inputs with date $t$ (including those previously committed) plus what comes out of storage at $t$ minus what goes into storage. We suppose that households care only about consumption and not about which market consumption comes from. The household is constrained by its transaction technology, $T^h(t)$, and by its storage technology, $S^h(t)$. $T^h(t)$ specifies the resources, for example, how much leisure time and shoeleather, must be used to carry out a transaction. Let $x^h(t)$ denote the vector of $x^h_t$'s [and similarly for $y^h(t)$ and $z^h(t)$]. We insist

$$[x^h(t), y^h(t), z(t)] \in T^h(t), \ (t = 1, \ldots, K).$$

(2)

Naturally, storage input and output vectors must be feasible, so

$$[r^h(t), s^h(t + 1)] \in S^h(t), \ (t = 1, \ldots, K - 1).$$

(3)

The budget constraints for household $h$ are then:

$$p(t) \cdot x^h(t) \leq p(t) \cdot y^h(t), \ (t = 1, \ldots, K).$$

(4)

Households may transfer purchasing power forward in time by using futures markets and by storage of goods that will be valuable in the future. Purchasing power may be carried backward by using futures markets. But these may be very costly transactions. In a monetary interpretation of the model, where money and promissory notes are present, the household can either hold money as a store of wealth, or it can buy or sell notes.

Let household $h$'s action at date $t$ be denoted $a^h(t) \equiv [x^h(t), y^h(t), z^h(t), r^h(t), s^h(t)]$. Let $a^h$ be a vector of the $a^h(t)$'s, and define $x^h, y^h, z^h, r^h$ and $s^h$ similarly. Define $B^h(p)$ as the set of $a^h$'s which satisfy constraints (1)–(4). The household chooses $a^h(t)$ to maximize $U^h(c^h)$ over $B^h(p)$. Denote the demand correspondence (i.e. the set of maximizing $a^h$'s) by $\gamma^h(p)$. 
The model can be interpreted as monetary or non-monetary. We think of money as simply a 0th good that does not enter household preferences. Futures contracts in money are discounted promissory notes. $x_{ht}(t)$ is $h$’s monetary receipts at $t$, $x_{0t}(t)$ is $h$’s note purchase at $t$ due at $\tau$. Money is not treated as numeraire – positivity of its value cannot be assumed – it has a price $p_{0t}(t)$.

The correspondences $Y_t(p)$ are always homogeneous of degree zero in $p(t)$, as is seen from the definition of $B^h(p)$. We can therefore restrict the price space to the simplex. Let $S^t$ denote the unit simplex of dimensionality, $n(K-t+1)$. Let $P = x_{t=1}^K S^t$, where $X$ denotes a Cartesian product.

An equilibrium of the economy is a price vector $p^* \in P$ and an allocation $\alpha^h$, for each $h$, so that $\alpha^h \in Y^h(p^*)$ for all $h$ and

$$\sum_{h=1}^H x^h = \sum_{h=1}^H y^h$$

(the inequality holds coordinate-wise), where for any good $i$, $t$, $\tau$ such that the strict inequality holds in (5) it follows that $p_{i\tau}^* = 0$. The equilibrium of a monetary economy is said to be non-trivial (that is, the economy is really monetary) if $p_{i\tau}^* \neq 0$ for all $t$. Sufficient conditions for existence of equilibrium are continuity and convexity requirements typical of an Arrow–Debreu model appropriately extended. Transaction costs are often thought to be non-convex, leading to approximate equilibrium rather than full equilibrium results (Heller and Starr, 1976).

In the case of fiat (unbacked) money, existence of non-trivial monetary equilibrium requires additional structure designed to maintain positivity of the price of money (boundedness of the price level expressed in monetary terms). This may take a variety of forms: the model may arbitrarily require that fiat money be held or turned in at a finite horizon; households may expect fiat money to be valuable in the future sustaining its value in the present; there may be taxes payable in fiat money. Alternatively, the model may assume an infinite horizon (typical of the overlapping generations model) so that the lack of backing for fiat money need not be experienced (though a nil value of fiat money in equilibrium is still a logical possibility).

In contrast to the Arrow–Debreu economy, a sequence economy equilibrium allocation is not generally Pareto efficient. This is not due simply to the presence of transaction costs; transaction costs technically necessary to a reallocation must be incurred, and they represent no inefficiency. The Arrow–Debreu model, however, uses a lifetime budget constraint. The corresponding constraint here is the sequence of budget constraints in (4). Transfer of purchasing power intertemporally – costless in the Arrow–Debreu model – is here a resource using activity; it requires purchase and sale of assets with resultant transaction cost. But the intertemporal transfer of purchasing power, unlike reallocation of goods among households, is needed not to satisfy technical or consumption requirements but rather to satisfy the
administrative requirements of sequential budget constraint embodied in (4). Hence technically feasible Pareto-improving reallocations may be prevented in equilibrium by prohibitive transaction costs which would have to be incurred to satisfy the purely administrative requirements of crediting and debiting agents’ budgets intertemporally (Hahn, 1971). If trade in monetary instruments is costless, however, then an equilibrium allocation is Pareto efficient (Starrett, 1973). Thus the sequence economy model provides a value-theoretic foundation for the store-of-value role of money.

sequential analysis

James O. Berger
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Data often arrives sequentially, rather than as a collection. When this occurs – or when the experiment can be designed so that this occurs – there can be a considerable advantage in using statistical methods, called sequential analysis, that are tailored to such situations. Classical frequentist statistical methods require analysis with a pre-specified collection of data, and hence cannot be used in such sequential settings. Interestingly, Bayesian methods can be directly used in sequential settings.

Keywords

Bayesian statistics; dynamic programming; Friedman, M.; sequential analysis; stopping rules; Wald, A.; Wallis, W. A.

Article

Statistical experiments are of either fixed sample or sequential design. A fixed sample size experiment is one in which the sample size taken for experimentation is predetermined, while a sequential experiment involves monitoring incoming data to help determine an appropriate time to stop experimentation. To formalize these notions, suppose the data can be observed one-at-a-time; let $X_1, X_2, \ldots$ denote this possible stream of data. Examples include a series of products coming off an assembly line, a series of missiles being tested for accuracy, and a series of patients participating in a clinical trial.

A key concept is that of a stopping rule, $R$, which is a description of the manner in which the data stream will be used to determine cessation of the experiment.

Example 1: Consider the stopping rule $R_1$: stop experimentation after $n$ observations have been taken. This stopping rule effectively defines what we earlier called a fixed sample size experiment, since we will take precisely $n$ observations.

Example 2: Consider the stopping rules (where $\bar{X}_j = \sum_{i=1}^{j} X_i / j$) $R_2$: stop experimentation if
or (failing that) when \(n=100\); \(R_3\): after each new observation, \(X_j\), check whether or not
\[
\bar{X}_j \geq 0.5 + 0.823 / \sqrt{j}
\]
if so, stop experimentation and otherwise take the next observation. Note that \(R_2\) allows experimentation to stop only after 50 or 100 observations have been taken (this is often called ‘group sequential’ analysis), while \(R_3\) gives rise to the possibility of stopping after any observation. To see why stopping rules such as \(R_2\) and \(R_3\) can be desirable, consider a clinical trial investigating a new treatment in which, for the \(j\)th participating patient, the observation is a Bernoulli (\(\theta\)) random variable, \(X_j\), which can assume the values 1 (denoting treatment success) or 0 (denoting treatment failure). Thus \(\theta\) is the probability of the treatment being successful. Suppose that the standard (old) treatment is known to have a success probability of \(\frac{1}{2}\), so it is desired to test the hypothesis \((H_0)\) that
\[
\theta \leq \frac{1}{2}
\]
(the old treatment is better) versus the hypothesis \((H_a)\) that
\[
\theta > \frac{1}{2}
\]
(the new treatment is better).

A typical fixed sample size test of these hypotheses would proceed by choosing a sample size, say \(n = 100\), observing \(X_1, \ldots, X_{100}\) from \(n = 100\) independent patients, and then rejecting if \(\bar{X}_{100} \geq 0.582\). This is an \(\alpha = 0.05\) level test. (We make no judgement here concerning the appropriateness of formulating this problem as a statistical hypothesis test.) Suppose now that the experimenters happen to look at the data after 50 patients have participated in the trial, and observe that, for all 50, the treatment proved successful. This would appear to be overwhelming evidence that the new treatment is better, and would lead reasonable people to stop the clinical trial and recommend adoption of the new treatment. It is a rather surprising fact that this conclusion would be forbidden by classical statistics, because the original design called for a sample of size 100. (Classical analyses do not allow deviation from original experimental protocol.) It would have been possible, however, to plan for such a possible eventuality by adopting a sequential design, whereby after every observation (or every few observations) the possibility of stopping is allowed. Indeed, \(R_2\) and \(R_3\) are two such stopping rules, and had either been employed, the above-mentioned clinical trial would certainly have stopped by the time the overwhelming evidence had accumulated.

As indicated in the above example, the advantage of a sequential experimental design is that it allows one to stop the experiment precisely when sufficient evidence has accumulated. The disadvantages of a sequential design are that it can be more expensive (often it is cheaper per observation if the data is collected all at once or in large batches), and that it is harder to analyse from the classical perspective. This last point has to do with the fact that the stopping rule can significantly affect classical statistical measures.

Example 2 (continued): Suppose the stopping rule \(R_2\) had been employed in the clinical trial (that is, an interim analysis at the halfway point in the trial had been performed). Also, suppose that, if one did stop after 50 observations (that is, if \(\bar{X}_{50} > 0.62\), then \(H_0\) would be rejected, and that, if the trial lasted for all 100 observations (that is, if \(\bar{X}_{50} < 0.62\), so that the experiment did not stop at the halfway point), then \(H_0\) would be rejected when \(\bar{X}_{100} > 0.582\). It can be shown that, for a fixed sample of 50 observations, rejecting \(H_0\) when \(\bar{X}_{50} > 0.62\) is an \(\alpha = 0.05\) level test, as is rejecting \(H_0\) if \(\bar{X}_{100} > 0.582\) for a fixed sample size experiment with \(n = 100\). For the experiment using \(R_2\), however, it can be shown that the level is \(\alpha = 0.095\). (One obtains an error probability larger than each of the
sequential analysis: The New Palgrave Dictionary of Economics

Because use of $R_2$ gives ‘two chances’ to reject $H_0$.) Thus, if $R_1$ had been used and $ar{X}_{100} = 0.582$ had been observed, one could claim significant evidence against $H_0$ at the $\alpha = 0.05$ level, while if $R_2$ had been used, one could not claim significance at the $\alpha = 0.05$ level.

It should be mentioned that there is considerable controversy over the issue of whether use of stopping rules should affect statistical conclusions. When classical measures are used, there is no typically a substantial effect. But, interestingly, for certain other statistical measures, such as Bayesian measures, the stopping rule has no effect. Thus, employment of the Bayesian approach to statistics allows one to collect data without having to pre-specify a rigid initial stopping rule, greatly increasing the flexibility of experimentation. For discussion of this issue, and support for the Bayesian viewpoint, see Berger and Wolpert (1984) and Berger (1985).

The founder of sequential analysis is generally acknowledged to be Abraham Wald, with Milton Friedman and W. Allen Wallis providing substantial motivational and collaborative support. Early history of sequential analysis is given in Wald (1947), which developed the basic formulation of the problem in terms of stopping rules and analysed a number of basic situations, such as the sequential probability ratio test (for testing between two simple hypotheses). Most of the subsequent work in sequential analysis has focused on either (a) evaluating classical measures, such as error probabilities, for special stopping rules (see Siegmund, 1985), or (b) determining optimal stopping rules. This last problem is very difficult, and can be rephrased as the problem of deciding if enough information is already available to reach a decision, or if another (or several) observations should be taken. The mathematics of this problem is essentially that of dynamic programming. For general reviews of sequential analysis, see DeGroot (1970), Ghosh (1970), Ghosh, Sen and Mukhopadhyay (1997), Govindarajulu (1981), Berger (1985), Lai (2001), Sen and Ghosh (1991), and Siegmund (1985).

serial correlation and serial dependence

Yongmiao Hong
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

In this article we discuss serial correlation in a linear time series regression context and serial dependence in a nonlinear time series context. We first discuss various tests for serial correlation for both estimated regression residuals and observed raw data. Particular attention is paid to the impact of parameter estimation uncertainty and conditional heteroskedasticity on the asymptotic distribution of test statistics. We discuss the drawback of serial correlation in nonlinear time series models and introduce a number of measures that can capture nonlinear serial dependence and reveal useful information about serial dependence.

Keywords

ARMA models; Durbin–Watson statistic; efficient market hypothesis; entropy; generalized spectral density; homoskedasticity; heteroskedasticity; kernel estimators; Lagrange multipliers; rational expectations; serial correlation; serial dependence; spectral density; statistical inference; time series analysis

Article

1 Introduction

Serial correlation and serial dependence have been central to time series econometrics. The existence of serial correlation complicates statistical inference of econometric models; and in time series analysis, inference of serial correlation, or more generally, serial dependence, is crucial to characterize the dynamics of time series processes. Lack of serial correlation is also an important implication of many economic theories and economic hypotheses. For example, the efficient market hypothesis implies that asset returns are a martingale difference sequence \((m.d.s.)\), and so are serially uncorrelated. More generally, rational expectations theory implies that the expectational errors of the economic agent are serially uncorrelated. In this article we first discuss various tests for serial correlation, for both estimated model residuals and observed raw data, and we discuss their relationships. We then discuss serial dependence in a nonlinear time series context, introducing related measures and tests for serial dependence.

2 Testing for serial correlation

Consider a linear regression model

\[
Y_t = X_t' \beta^0 + \epsilon_t, \quad t = 1, \ldots, n, \tag{2.1}
\]

where \(Y_t\) is a dependent variable, \(X_t\) is a \(k\times1\) vector of explanatory variables, \(\beta^0\) is an unknown \(k\times1\) parameter vector, and \(\epsilon_t\) is an unobservable disturbance with \(E(\epsilon_t | X_t) = 0\). Suppose \(X_t\) is strictly exogenous such that \(\text{cov}(X_t, \epsilon_s) = 0\) for all \(t, s\). Then (2.1) is called a
static correlation and serial dependence: The New Palgrave Dictionary of Economics

For a linear dynamic regression model, serial correlation in \( \{ \varepsilon_t \} \) will generally render inconsistent the OLS estimator. To see this, we consider an AR(1) model

\[
Y_t = \beta_0^0 + \beta_1^0 Y_{t-1} + \varepsilon_t = X'_t \beta_0^0 + \varepsilon_t,
\]

where \( X_t = (1, Y_{t-1})' \). If \( \{ \varepsilon_t \} \) also follows an AR(1) process, we will have \( E(X_t \varepsilon_t) \neq 0 \), rendering inconsistent the OLS estimator for \( \beta_0 \). It is therefore important to check serial correlation for estimated model residuals, which serves as a misspecification test for a linear dynamic regression model. For a static linear regression model, it is also useful to check serial correlation. In particular, if there exists no serial correlation in \( \{ \varepsilon_t \} \) in a static regression model, then there is no need to use a long-run variance estimator of the OLS estimator \( \hat{\beta} \) (for example, Andrews, 1991; Newey and West, 1987).

### 2.1 Durbin–Watson test

Testing for serial correlation has been a longstanding problem in time series econometrics. The most well known test for serial correlation in regression disturbances is the Durbin–Watson test, which is the first formal procedure developed for testing first order serial correlation

\[
\varepsilon_t = \rho \varepsilon_{t-1} + \varepsilon_t, \quad \{ \varepsilon_t \} \sim i.i.d. (0, \sigma^2)
\]

using the OLS residuals \( \{ \varepsilon_t \} \) in a static linear regression model. Durbin and Watson (1950; 1951) propose a test statistic

\[
d = \frac{\sum_{t=2}^{n} (\varepsilon_t - \varepsilon_{t-1})^2}{\sum_{t=1}^{n} \varepsilon_t^2}.
\]

Durbin and Watson present tables of bounds at the 0.05, 0.025 and 0.01 significance levels of the \( d \) statistic for static regressions with an intercept. Against the one-sided alternative that \( \rho > 0 \), if \( d \) is less than the lower bound \( d_L \), the null hypothesis that \( \rho = 0 \) is rejected; if \( \rho \) is greater than the upper bound \( d_U \), the null hypothesis is accepted. Otherwise, the test is equivocal. Against the one-sided alternative that \( \rho < 0 \), \( 4 - d \) can be used to replace \( d \) in the above procedure. The Durbin–Watson test has been extended to test for lag 4 autocorrelation by Wallis (1972) and for autocorrelation at any lag by Vinod (1973).

### 2.2 Durbin's h test

The Durbin–Watson \( d \) test is not applicable to dynamic linear regression models, because parameter estimation uncertainty in the OLS estimator \( \hat{\beta} \) will have nontrivial impact on the distribution of \( d \). Durbin (1970) developed the so-called \( h \) test for first-order autocorrelation in \( \{ \varepsilon_t \} \) that takes into account parameter estimation uncertainty in \( \hat{\beta} \). Consider a simple dynamic linear regression model

\[
Y_t = \beta_0^0 + \beta_1^0 Y_{t-1} + \beta_2^0 X_t + \varepsilon_t,
\]
where $X_t$ is strictly exogenous. Durbin's $h$ statistic is defined as:

$$h = \hat{\rho} \left( \frac{n}{1 - n\text{var}(\hat{\beta}_1)} \right),$$

where $\text{var}(\hat{\beta}_1)$ is an estimator for the asymptotic variance of $\hat{\beta}_1$, $\hat{\rho}$ is the OLS estimator from regressing $e_t$ on $e_{t-1}$ (in fact, $\hat{\rho} \approx 1 - d/2$). Durbin (1970) shows that $h \to N(0, 1)$ as $n \to \infty$ under null hypothesis that $\rho = 0$.

2.3 Breusch–Godfrey test

A more convenient and generally applicable test for serial correlation is the Lagrange multiplier test developed by Breusch (1978) and Godfrey (1978). Consider an auxiliary autoregression of order $p$:

$$\varepsilon_t = \sum_{j=1}^{p} \alpha_j \varepsilon_{t-j} + z_t, t = p + 1, \ldots, n. \quad (2.2)$$

The null hypothesis of no serial correlation implies $\alpha_j = 0$ for all $1 \leq j \leq p$. Under the null hypothesis, we have $nR_{UC}^2 \stackrel{d}{\to} \chi_p^2$, where $R_{UC}^2$ is the uncentred $R^2$ of (2.2). However, the autoregression (2.2) is infeasible because $\varepsilon_t$ is unobservable. One can replace $\varepsilon_t$ with the OLS residual $e_t$:

$$e_t = \sum_{j=1}^{p} \alpha_j e_{t-j} + v_t, t = p + 1, \ldots, n. \quad (2.3)$$

Such a replacement, however, may contaminate the asymptotic distribution of the test statistic because $e_t = \varepsilon_t - (\hat{\beta} - \beta)'X_t$ contains the estimation error $(\hat{\beta} - \beta)'X_t$ where $X_t$ may have nonzero correlation with the regressors $e_{t-j}$ for $1 \leq j \leq p$ in dynamic regression models. This correlation affects the asymptotic distribution of $nR_{UC}^2$ so that it will not be $\chi_p^2$. To purge this impact of the asymptotic distribution of the test statistic, one can consider the augmented auxiliary regression

$$e_t = X_t'Y + \sum_{j=1}^{p} \alpha_j e_{t-j} + v_t, t = p + 1, \ldots, n. \quad (2.3)$$

The inclusion of $X_t$ will capture the impact of estimation error $(\hat{\beta} - \beta)'X_t$. As a result, the test statistic $nR_{UC}^2 \stackrel{d}{\to} \chi_p^2$ under the null
serial correlation and serial dependence: The New Palgrave Dictionary of Economics

hypothesis, where, assuming that $X_t$ contains an intercept, $R^2$ is the centred squared multi-correlation coefficient in (2.3). For a static linear regression model, it is not necessary to include $X_t$ in the auxiliary regression, because $\{X_t\}$ and $\{\varepsilon_t\}$ are uncorrelated, but it does not harm the size of the test if $X_t$ is included. Therefore, the $nR^2$ test is applicable to both static and dynamic regression models. We note that Durbin's $h$ test is asymptotically equivalent to the $nR^2$ test of (2.3) with $p=1$.

2.4 Box–Pierce–Ljung test

In time series ARMA modelling, Box and Pierce (1970) propose a portmanteau test as a diagnostic check for the adequacy of an ARMA model

$$Y_t = \psi_0 + \sum_{j=1}^{r} \psi_j Y_{t-j} + \sum_{j=1}^{q} \theta_j \varepsilon_{t-j} + \varepsilon_t \sim \{0, \sigma^2\}.$$  

(2.4)

Suppose $\varepsilon_t$ is an estimated residual obtained from a maximum likelihood estimator. One can define the residual sample autocorrelation function

$$\hat{\rho}(j) = \frac{\hat{\gamma}(j)}{\hat{\gamma}(0)}, \quad j = 0, \pm 1, \ldots, \pm (n-1),$$

where $\hat{\gamma}(j) = \frac{1}{n} \sum_{t=1}^{n} \varepsilon_{t} \varepsilon_{t-j}$ is the residual sample autocovariance function. Box and Pierce (1970) propose a portmanteau test

$$Q = n \sum_{j=1}^{p} \rho^2(j) \sim \chi^2_{p-(r+q)},$$

where the asymptotic $\chi^2$ distribution follows under the null hypothesis of no serial correlation, and the adjustment of degrees of freedom $r+q$ is due to the impact of parameter estimation uncertainty for the $r$ autoregressive coefficients and $q$ moving average coefficients in (2.4).

To improve small sample performance of the $Q$ test, Ljung and Box (1978) propose a modified $Q$ test statistic:

$$Q^* = n(n+2) \sum_{j=1}^{p} (n-j)^{-1} \rho^2(j) \sim \chi^2_{p-(r+q)}.$$

The modification matches the first two moments of $Q^*$ with those of the $\chi^2$ distribution. This improves the size in small samples, although not the power of the test.

The $Q$ test is applicable to test serial correlation in the OLS residuals $\{e_t\}$ of a linear static regression model, with $Q \sim \chi^2_{p}$ under the null hypothesis. Unlike for ARMA models, there is no need to adjust the degrees of freedom for the $\chi^2$ distribution because the
estimation error \((\hat{\beta} - \beta)^t X_t\) has no impact on it, due to the fact that \(\text{cov}(X_t, \varepsilon_s) = 0\) for all \(t, s\). In fact, it could be shown that the \(nR^2\) and \(Q\) statistics are asymptotically equivalent under the null hypothesis. However, when applied to the estimated residual of a dynamic regression model which contains both endogenous and exogenous variables, the asymptotic distribution of the \(Q\) test is generally unknown (Breusch and Pagan, 1980). One solution is to modify the \(Q\) test statistic as follows:

\[
\hat{Q} = \hat{\rho} \left( 1 - \hat{\Phi} \right) - 1 \hat{\rho} + \chi^2_p \quad \text{as} \quad n \to \infty,
\]

where \(\hat{\rho} = [\hat{\rho}(1), \ldots, \hat{\rho}(p)]\) and \(\hat{\Phi}\) captures the impact caused by nonzero correlation between \(\{X_t\}\) and \(\{\varepsilon_s\}\). See Hayashi (2000, Section 2.10) for more discussion.

### 2.5 Spectral density-based test

Much criticism has been levelled at the possible low power of the Box–Pierce–Ljung portmanteau tests, which also applies to the \(nR^2\) test, due to the asymptotic equivalence between the \(Q\) test and the \(nR^2\) test for a static regression. Moreover, there is no theoretical guidance on the choice of \(p\) for these tests. A fixed lag order \(p\) will render inconsistent any test for serial correlation of unknown form. To test serial correlation of unknown form in the estimated residuals of a linear regression model, which can be static or dynamic, Hong (1996) uses a kernel spectral density estimator

\[
\hat{h}(\omega) = \frac{1}{2\pi} \sum_{j=1}^{n-1} k(j/p) \hat{\gamma}(j) e^{-i\omega j}, \quad \omega \in [-\pi, \pi),
\]

and compares it with the flat spectrum implied by the null hypothesis of no serial correlation:

\[
\hat{h}_0(\omega) = \frac{1}{2\pi} \hat{\gamma}(0), \quad \omega \in [-\pi, \pi).
\]

Under the null hypothesis, \(\hat{h}(\omega)\) and \(\hat{h}_0(\omega)\) are close. If \(\hat{h}(\omega)\) is significantly different from \(\hat{h}_0(\omega)\) there is evidence of serial correlation. A global measure of the divergence between \(\hat{h}(\omega)\) and \(\hat{h}_0(\omega)\) is the quadratic form

\[
L^2(\hat{h}, \hat{h}_0) = \int_{-\pi}^{\pi} \left[ \hat{h}(\omega) - \hat{h}_0(\omega) \right]^2 d\omega = \sum_{j=1}^{n-1} k^2(j/p) \hat{\gamma}^2(j).
\]

The test statistic is a normalized version of the quadratic form:

\[
M_\omega = \left[ \sum_{j=1}^{n-1} k^2(j/p) \hat{\rho}_j^2 - \hat{\gamma}_0(p) \right] / \sqrt{\sum_{j=1}^{n-1} k^2(j/p) \hat{\gamma}_0^2(p)} \overset{d}{\to} N(0, 1).
\]
where the centring and scaling factors

\[ \hat{c}_o(p) = \sum_{j=1}^{n-1} (1 - j/n) k^2(j/p), \]

\[ \hat{D}_o(p) = 2 \sum_{j=1}^{n-2} (1 - j/n) [1 - (j+1)/n] k^4(j/p). \]

This test can be viewed as a generalized version of Box and Pierce's (1970) portmanteau test, the latter being equivalent to using the truncated kernel \( k(z) = 1(|z| \leq 1) \), which gives equal weighting to each of the first \( p \) lags. In this case, \( M_o \) is asymptotically equivalent to

\[ M_T = \frac{n\sum_{j=1}^{p} \hat{\rho}^2(j) - p}{\sqrt{2p}} \to \frac{\chi^2_p - p}{\sqrt{2p}} \sim N(0, 1) \text{ as } p \to \infty. \]

However, uniform weighting to different lags may not be powerful when a large number of lags is employed. For any weakly stationary process, the autocovariance function \( \gamma(j) \) typically decays to 0 as lag order \( j \) increases. Thus, it is more efficient to discount higher order lags. This can be achieved by using non-uniform kernels. Most commonly used kernels, such as the Bartlett, Pazren and quadratic-spectral kernels, discount higher order lags. Hong (1996) shows that the Daniell kernel \( k(z) = \frac{\sin(\pi z)}{\pi z}, -\infty < z < \infty \), maximizes the power of the \( M \) test over a wide class of the kernel functions when \( p \to \infty \). The optimal kernel for hypothesis testing differs from the optimal kernel for spectral density estimation.

It is important to note that the spectral density test \( M \) applies to both static and dynamic regression models, and no modification is needed when applied to a dynamic regression model. Intuitively, parameter estimation uncertainty causes some adjustment of degrees of freedom, which becomes asymptotically independent when the lag order \( p \to \infty \) as \( n \to \infty \). This differs from the case where \( p \) is fixed.

For similar spectral density-based tests for serial correlation, see Paparoditis (2000), Chen and Deo (2004), and Fan and Zhang (2004).

### 2.6 Heteroskedasticity–robust tests

All the aforementioned tests assume conditional homoskedasticity or even \( i.i.d. \) on \( \{\varepsilon_t\} \). This rules out high frequency financial time series, which have been documented to have persistent volatility clustering. Some effort has been devoted to robustifying tests for serial correlation. Wooldridge (1990; 1991) proposes a two-stage procedure to robustify the \( nR^2 \) test for serial correlation in estimated residuals \( \{e_t\} \) of a linear regression model (2.1): (i) regress \( (e_{t-1}, \ldots, e_{t-p}) \) on \( X_t \) and save the estimated \( p \times 1 \) residual vector \( \hat{\varepsilon}_t \); (ii) regress 1 on \( \hat{\varepsilon}_t \) and obtain SSR, the sum of squared residuals; (iii) compare the \( n-SSR \) statistic with the asymptotic \( \chi^2_p \) distribution.

The first auxiliary regression purges the impact of parameter estimation uncertainty in the OLS estimator \( \hat{\beta} \) and the second auxiliary regression delivers a test statistic robust to conditional heteroskedasticity of unknown form.

Whang (1998) also proposes a semiparametric test for serial correlation in estimated residuals of a possibly nonlinear regression model. Assuming that \( \varepsilon \sim \sigma[Z_t(\alpha)z_t] \), where \( \{z_t\} \sim i.i.d. (0, 1) \), \( \var(\varepsilon \mid I_{t-1}) = \sigma^2[Z_t(\alpha)] \) depends on a random vector with fixed dimension (for example, \( Z_t(\alpha) = (\varepsilon_{t-1}^2, \ldots, \varepsilon_{t-K}^2) ' \) for a fixed \( K \)), but the functional form \( \sigma(\cdot) \) is unknown. This covers a variety of conditionally heteroskedastic processes, although it rules out non-Markovian processes such as Bollerslev's (1986) GARCH model.
Whang (1998) first estimates $\sigma^2[Z_t(\alpha)]$ using a kernel method, and then constructs a Box–Pierce type test for serial correlation in the estimated regression residuals standardized by the square root of the nonparametric variance estimator. The assumption imposed on $\text{var}(\varepsilon_t | I_{t-1})$ in Whang (1998) rules out GARCH models, and both Wooldridge (1991) and Whang (1998) test serial correlation up to a fixed lag order only. Hong and Lee (2007) have recently robustified Hong's (1996) spectral density-based consistent test for serial correlation of unknown form:

$$\hat{M} = \left[ n^{-1} \sum_{j=1}^{n-1} k^2(j/p) \hat{\gamma}^2(j) - \hat{c}(p) \right] / \sqrt{\hat{D}(p)},$$

where the centring and scaling factors

$$\hat{c}(p) = \hat{\gamma}^2(0) \sum_{j=1}^{n-1} (1 - j/n) k^2(j/p) + \sum_{j=1}^{n-1} k^2(j/p) \hat{\gamma}_{22}(j),$$

$$\hat{D}(p) = 2\hat{\gamma}^4(0) \sum_{j=1}^{n-2} (1 - j/n) [1 - (j+1)/n] k^4(j/p) + 4\hat{\gamma}^2(0) \sum_{j=1}^{n-2} k^4(j/p) \hat{\gamma}_{22}(j) + 2 \sum_{j=1}^{n-2} \sum_{l=1}^{n-2} k^2(j/p) k^2(l/p) \hat{\gamma}^2(0, j, l),$$

with $\hat{\gamma}_{22}(j) = n^{-1} \sum_{t=j+1}^{n-1} \{ \varepsilon_t^2 - \hat{\gamma}(0) \} \{ \varepsilon_{t-j}^2 - \hat{\gamma}(0) \}$ and $\hat{c}(0, j, l) = n^{-1} \sum_{t=max(j,l)+1}^{n} \{ \varepsilon_t^2 - \hat{\gamma}(0) \} \varepsilon_{t-j} \varepsilon_{t-l}$. Intuitively, the centring and scaling factors have taken into account possible volatility clustering and asymmetric features of volatility dynamics, so the $\hat{M}$ test is robust to these effects. It allows for various volatility processes, including GARCH models, Nelson's (1991) EGARCH, and Glosten, Jagannathan and Runkle's (1993) Threshold GARCH models.

**Martingale tests**

Several tests for serial correlation are motivated for testing the $m.d.s.$ property of an observed time series $\{Y_t\}$, say asset returns, rather than estimated residuals of a regression model. We now present a unified framework to view some martingale tests for observed data. Extending an idea of Cochrane (1988), Lo and MacKinlay (1988) first rigorously present an asymptotic theory for a variance ratio test for the $m.d.s.$ hypothesis of $\{Y_t\}$. Because the $m.d.s.$ hypothesis implies $\gamma(j)=0$ for all $j>0$, one has

$$\frac{\text{var}\left(\sum_{j=1}^{p} Y_{t-j}\right)}{p \cdot \text{var}(Y_t)} = \frac{\rho \gamma(0) + 2 \rho \sum_{j=1}^{p} (1 - j/p) \gamma(j)}{\rho \gamma(0)} = 1.$$

This unity property of the variance ratio can be used to test the $m.d.s.$ hypothesis because any departure from unity is evidence against the $m.d.s.$ hypothesis. The variance ratio test is essentially based on the statistic
where \( \hat{f}(0) \) is a kernel-based normalized spectral density estimator at frequency 0, with the Bartlett kernel \( k(z) = (1 - |z|) 1 (|z| \leq 1) \) and a lag order \( p \). In other words, \( \text{VR}_0 \) is based on a spectral density estimator of frequency 0, and because of this, it is particularly powerful against long memory processes, whose spectral density at frequency 0 is infinity (see Robinson, 1994, for an excellent survey).

Under the m.d.s. hypothesis with conditional homoskedasticity, Lo and MacKinlay (1988) show that for any fixed \( p \),

\[
\text{VR}_0 \overset{d}{\rightarrow} N \left[ 0, 2 (2p - 1)(p - 1) / 3p \right] \text{ as } n \rightarrow \infty.
\]

Lo and MacKinlay (1988) also consider a heteroskedasticity-consistent variance ratio test:

\[
\text{VR} = \sqrt{n / p} \sum_{j=1}^{p} (1 - j / p) \hat{\gamma}(j) / \sqrt{\hat{\gamma}_2(j)},
\]

where \( \hat{\gamma}_2(j) \) is a consistent estimator for the asymptotic variance of \( \hat{\gamma}(j) \) under conditional heteroskedasticity. Lo and MacKinlay (1988) assume a fourth order cumulant condition that

\[
E[(Y_t - \mu)^2 (Y_{t-1} - \mu) (Y_{t-1} - \mu)] = 0, \; j > 0, \; j \neq l.
\]

Intuitively, this condition ensures that the sample autocovariances at different lags are asymptotically uncorrelated; that is, \( \text{cov} \left[ \sqrt{\hat{\gamma}_2(j)}, \sqrt{\hat{\gamma}_2(l)} \right] \rightarrow 0 \) for all \( j \neq l \). As a result, the heteroskedasticity-consistent VR has the same asymptotic distribution as \( \text{VR}_0 \).

However, the condition in (2.5) rules out many important volatility processes, such as EGARCH and Threshold GARCH models. Moreover, the variance ratio test only exploits the implication of the m.d.s. hypothesis on the spectral density at frequency 0; it does not check the spectral density at nonzero frequencies. As a result, it is not consistent against serial correlation of unknown form. See Durlauf (1991) for more discussion.

Durlauf (1991) considers testing the m.d.s. hypothesis for observed raw data \{Y_t\}, using the spectral distribution function

\[
H(\lambda) = 2 \int_0^{\pi \lambda} h(\omega) \, d\omega = \gamma(0) \lambda + \sum_{j=1}^{\infty} \gamma(j) \frac{\sqrt{2} \sin(j \pi \lambda)}{j \pi}, \; \lambda \in [0, 1],
\]

where \( h(\omega) \) is the spectral density of \{Y_t\}:

\[
H(\lambda) = 2 \int_0^{\pi \lambda} h(\omega) \, d\omega = \gamma(0) \lambda + \sum_{j=1}^{\infty} \gamma(j) \frac{\sqrt{2} \sin(j \pi \lambda)}{j \pi}, \; \lambda \in [0, 1],
\]
Under the m.d.s. hypothesis, \( H(\lambda) \) becomes a straight line:

\[
H_0(\lambda) = \gamma(0)\lambda, \quad \lambda \in [0, 1].
\]

An m.d.s. test can be obtained by comparing a consistent estimator for \( H(\lambda) \) and \( \hat{H}_0(\lambda) = \hat{\gamma}(0)\lambda \).

Although the periodogram (or sample spectral density function)

\[
\hat{I}(\omega) = \frac{1}{2\pi n} \left| \sum_{t=1}^{n} (Y_t - \bar{Y}) e^{i\omega t} \right|^2 = \frac{1}{2\pi} \sum_{j=1}^{n-1} \hat{\gamma}(j) e^{-ij\omega}
\]

is not consistent for the spectral density \( h(\omega) \), the integrated periodogram

\[
\hat{I}_H(\lambda) = 2 \int_{0}^{\lambda \pi/n} \hat{I}(\omega) d\omega = \hat{\gamma}(0)\lambda + \sqrt{2} \sum_{j=1}^{n-1} \hat{\gamma}(j) \frac{\sqrt{2} \sin(jn\lambda)}{jn}
\]

is consistent for \( H(\lambda) \), thanks to the smoothing provided by the integration. Among other things, Durlauf (1991) proposes a Cramer–von Mises type statistic

\[
CVM = \frac{1}{2n} \int_{0}^{\pi/n} \left[ \hat{I}_H(\lambda) / \hat{\gamma}(0) - \lambda \right]^2 d\lambda = n \sum_{j=1}^{n-1} \rho^2(j) / (jn)^2.
\]

Under the m.d.s. hypothesis with conditional homoskedasticity, Durlauf (1991) shows

\[
CVM \overset{d}{\to} \sum_{j=1}^{\infty} \chi_j^2 (1) / (jn)^2,
\]

where \( \left\{ \chi_j^2 (1) \right\}_{j=1}^{\infty} \) is a sequence of i. i. d. \( \chi^2 \) random variables with one degree of freedom. This asymptotic distribution is nonstandard, but it is distribution-free and can be easily tabulated or simulated. An appealing property of Durlauf's (1991) test is its consistency against serial correlation of unknown form, and there is no need to choose a lag order \( p \).

Deo (2000) shows that under the m.d.s. hypothesis with conditional heteroskedasticity, Durlauf's (1991) test statistic can be robustified as follows:
serial correlation and serial dependence: The New Palgrave Dictionary of Economics

where $\hat{\gamma}_2(j)$ is a consistent estimator for the asymptotic variance of $\hat{\gamma}(j)$ and the asymptotic distribution remains unchanged. Like Lo and MacKinlay (1988), Deo (2000) also imposes the crucial fourth order joint cumulant condition in (2.5).

3 Serial dependence in nonlinear models

The autocorrelation function $\gamma(j)$, or equivalently, the power spectrum $h(\omega)$, of a time series $\{Y_t\}$, is a measure for linear association. When $\{Y_t\}$ is a stationary Gaussian process, $\gamma(j)$ or $h(\omega)$ can completely determine the full dynamics of $\{Y_t\}$. It has been well documented, however, that most economic and financial time series, particularly high-frequency economic and financial time series, are not Gaussian. For non-Gaussian processes, $\gamma(j)$ and $h(\omega)$ may not capture the full dynamics of $\{Y_t\}$. We consider two nonlinear process examples:

- Bilinear (BL) autoregressive process:

$$Y_t = \alpha \varepsilon_{t-1} Y_{t-2} + \varepsilon_t \{\varepsilon_t\} \sim i.i.d. (0, \sigma^2). \quad (3.1)$$

- Nonlinear moving average (NMA) process:

$$Y_t = \alpha \varepsilon_{t-1} \varepsilon_{t-2} + \varepsilon_t \{\varepsilon_t\} \sim i.i.d. (0, \sigma^2). \quad (3.2)$$

For these two processes, there exists nonlinearity in conditional mean: $E(Y_t|Y_{t-1}) = \alpha \varepsilon_{t-1} Y_{t-2}$ under (3.1) and $E(Y_t|Y_{t-1}) = \alpha \varepsilon_{t-1} Y_{t-2}$ under (3.2). However, both processes are serially uncorrelated. If $\{Y_t\}$ follows either a BL process in (3.1) or a NMA process in (3.2), $\{Y_t\}$ is not m.d.s. but $\gamma(j)$ and $h(\omega)$ will miss it. Hong and Lee (2003a) document that indeed, for foreign currency markets, most foreign exchange changes are serially uncorrelated, but they are all not m.d.s. There exist predictable nonlinear components in the conditional mean of foreign exchange markets.

Serial dependence may also exist only in higher order conditional moments. An example is Engle's (1982) first order autoregressive conditional heteroskedastic (ARCH (1)) process:

$$\begin{align*}
\{Y_t\} &= \sigma_t \varepsilon_t, \\
\sigma_t^2 &= \alpha_0 + \alpha_1 Y_{t-1}^2, \\
\{\varepsilon_t\} &\sim i.i.d. (0, 1). \quad (3.3)
\end{align*}$$

serial correlation and serial dependence: The New Palgrave Dictionary of Economics

For this process, the conditional mean $E(Y_t | I_{t-1}) = 0$; which implies $\gamma(j) = 0$ for all $j > 0$.

However, the conditional variance, $\sqrt{\sigma^2(Y_t | I_{t-1})} = \alpha_0 + \alpha_1 Y_{t-1}$, depends on the previous volatility. Both $\gamma(j)$ and $h(\omega)$ will miss such higher order dependence.

In nonlinear time series modelling, it is important to measure serial dependence, that is, any departure from i.i.d., rather than merely serial correlation. As Priestley (1988) points out, the main purpose of nonlinear time series analysis is to find a filter $h(\cdot)$ such that

$$h(Y_t, Y_{t-1}, \ldots) = \epsilon_t \sim i.i.d.(0, \sigma^2).$$

In other words, the filter $h(\cdot)$ can capture all serial dependence in $\{Y_t\}$ so that the ‘residual’ $\{\epsilon_t\}$ becomes an i.i.d. sequence. One example of $h(\cdot)$ in modelling the conditional probability distribution of $Y_t$ given $I_{t-1}$, is the probability integral transform

$$Z_t(\beta) = \int_{-\infty}^{Y_t} f(Y_t | I_{t-1}, \beta) \, dY,$$

where $f(Y_t | I_{t-1}, \beta)$ is a conditional density model for $Y_t$ given and $I_{t-1}$, and $\beta$ is an unknown parameter. When $f(Y_t | I_{t-1}, \beta)$ is correctly specified for the conditional probability density of $Y_t$ given $I_{t-1}$, that is, when the true conditional density coincides with $f(Y_t | I_{t-1}, \beta_0)$ for some $\beta_0$, the probability integral transforms becomes

$$\{Z_t(\beta_0)\} \sim i.i.d. U[0,1]. \tag{3.4}$$

Thus, one can test whether $f(Y_t | I_{t-1}, \beta)$ is correctly specified by checking the i.i.d. $U[0,1]$ for the probability integral transform series.

3.1 Bispectrum and higher-order spectra

Because the autocorrelation function $\gamma(j)$ and the spectral density $h(\omega)$ are rather limited in nonlinear time series analysis, various alternative tools have been proposed to capture nonlinear serial dependence (for example, Granger and Terasvirta, 1993; Tjøstheim, 1996). For example, one often uses the third-order cumulant function

$$C(j, k) \equiv E[(Y_t - \mu)(Y_{t-j} - \mu)(Y_{t-k} - \mu)], \, j, k = 0, \pm 1, \ldots.$$

This is also called the biautocovariance function of $\{Y_t\}$. It can capture certain nonlinear time series, particularly those displaying asymmetric behaviours such as skewness. Hsieh (1989) proposes a test based on $C(j, k)$ for a given pair of $(j, k)$ which can detect some predictable nonlinear components in asset returns.

The Fourier transform of $C(j, k)$,

$$b(\omega_1, \omega_2) = \frac{1}{(2 \pi)^2} \sum_{j = -\infty}^{\infty} \sum_{k = -\infty}^{\infty} C(j, k) e^{-i(\omega_1 j + \omega_2 k)}, \, \omega_1, \omega_2 \in [ -\pi, \pi].$$
is called the bispectrum of \( \{ Y_t \} \). When \( \{ Y_t \} \) is i.i.d., \( b(\omega_1, \omega_2) \) becomes a flat bispectral surface:

\[
b_0(\omega_1, \omega_2) = \frac{E(Y_t^3)}{(2\pi)^2}, \quad \omega_1, \omega_2 \in [-\pi, \pi].
\]

Any deviation from a flat bispectral surface will indicate the existence of serial dependence in \( \{ Y_t \} \). Moreover, \( b(\omega_1, \omega_2) \) can be used to distinguish some linear time series processes from nonlinear time series processes. When \( \{ Y_t \} \) is a linear process with i.i.d. innovations, that is, when

\[
Y_t = \alpha_0 + \sum_{j=1}^{\infty} \alpha_j \varepsilon_{t-j} + \varepsilon_t, \quad \{ \varepsilon_t \} \sim i. i. d. \sim (0, \sigma^2),
\]

the normalized bispectrum

\[
|\hat{b}(\omega_1, \omega_2)|^2 = \frac{|b(\omega_1, \omega_2)|^2}{h(\omega_1)h(\omega_2)h(\omega_1 + \omega_2)} = \frac{|E(\varepsilon_t^3)|^2}{2\pi \sigma^6}
\]

is a flat surface. Any departure from a flat normalized bispectral surface will indicate that \( \{ Y_t \} \) is not a linear time series with i.i.d. innovations.

The bispectrum \( b(\omega_1, \omega_2) \) can capture the BL and NMA processes in (3.1) and (3.2), because the third order cumulant \( C(j, k) \) can distinguish them from an i.i.d. process. However, it may still miss some important alternatives. For example, it will easily miss ARCH (1) with i.i.d. \( N(0,1) \) innovation \( \{ \varepsilon_t \} \). In this case, \( b(\omega_1, \omega_2) \) becomes a flat bispectrum and cannot distinguish ARCH (1) from an i.i.d. sequence. One could use higher order spectra or polyspectra (Brillinger and Rosenblatt, 1967a; 1967b), which are the Fourier transforms of higher order cumulants. However, higher-order spectra have met with some difficulty in practice: Their spectral shapes are difficult to interpret, and their estimation is not stable in finite samples, due to the assumption of the existence of higher order moments. Indeed, it is often a question whether economic and financial data, particularly high-frequency data, have finite higher order moments.

3.2 Nonparametric measures of serial dependence

Nonparametric measures for serial dependence have been proposed in the literature, which avoid assuming the existence of moments. Granger and Lin (1994) propose a nonparametric entropy measure for serial dependence to identify significant lags in nonlinear time series. Define the Kullback–Leibler information criterion

\[
l(j) = \int \ln \left[ \frac{f_j(x, y)}{g(x)g(y)} \right] f_j(x, y) dx dy, \quad j = 1, 2, \ldots
\]

where \( f_j(x, y) \) is the joint probability density of \( Y_t \) and \( Y_{t-j} \), and \( g(x) \) is the marginal probability density of \( \{ Y_t \} \). The Granger–Lin
normalized entropy measure is defined as follows:

\[ e^2(j) = 1 - \exp \left[ -2l(j) \right], \]

which enjoys some appealing features. For example, \( e(j) = 0 \) if and only if \( Y_t \) and \( Y_{t-j} \) are independent, and it is invariant to any monotonic continuous transformation. Because \( f_j(x, y) \) and \( g(x) \) are unknown, Granger and Lin (1994) use nonparametric kernel density estimators. They establish the consistency of their entropy estimator (say \( \hat{I}(j) \)) but do not derive its asymptotic distribution, which is important for confidence interval estimation and hypothesis testing.

In fact, Robinson (1991) has elegantly explained the difficulty of obtaining the asymptotic distribution of \( \hat{I}(j) \) for serial dependence, namely it is a degenerate statistic so that the usual root-\( n \) normalization does not deliver a well-defined asymptotic distribution. Robinson (1991) considers a modified entropy estimator

\[ \hat{I}_\gamma(j) = 1 - \frac{1}{n} \sum_{t=j+1}^{n} C_t(\gamma) \ln \left( \frac{\hat{f}(Y_t, Y_{t-j})}{\hat{g}(Y_t) \hat{g}(Y_{t-j})} \right), \]

where \( \hat{f}(\cdot, \cdot) \) and \( \hat{g}(\cdot) \) are nonparametric kernel density estimators, \( C_t(\gamma) = 1 - \gamma \) if \( t \) is odd, \( C_t(\gamma) = 1 + \gamma \) if \( t \) is even, and \( \gamma \) is a pre-specified parameter. The weighting device \( C_t(\gamma) \) does not affect the consistency of \( \hat{I}_\gamma(j) \) to \( I(j) \) and affords a well-defined asymptotic \( \text{N}(0,1) \) distribution under the i.i.d. hypothesis.

Skaug and Tjøstheim (1993a; 1996) use a different weighting function to avoid the degeneracy of the entropy estimator for serial dependence:

\[ \hat{I}_w(j) = 1 - \frac{1}{n} \sum_{t=1}^{n} w(Y_t, Y_{t-j}) \ln \left( \frac{\hat{f}(Y_t, Y_{t-j})}{\hat{g}(Y_t) \hat{g}(Y_{t-j})} \right), \]

where \( w(Y_t, Y_{t-j}) \) is a weighting function of observations \( X_t \) and \( X_{t-j} \). Unlike using Robinson’s (1991) weighting device, \( \hat{I}_w(j) \) is not consistent for the population entropy \( I(j) \), but it also delivers a well-defined asymptotic \( \text{N}(0,1) \) distribution after a root-\( n \) normalization.

Intuitively, the use of weighting devices slows down the convergence rate of the entropy estimators, giving a well-defined asymptotic \( \text{N}(0,1) \) distribution after the usual root-\( n \) normalization. However, this is achieved at the cost of an efficiency loss, due to the slower convergence rate. Moreover, this approach breaks down when \( \{Y_t\} \) is uniformly distributed, as in the case of the probability integral transforms of the conditional density in (3.4). Instead of using a weighting device, Hong and White (2005) exploit the degeneracy of \( \hat{I}(j) \) and use a degenerate \( U \)-statistic theory to establish its asymptotic normality. Specifically, Hong and White (2005) show

\[ nh\hat{I}(j) + h^2c_{R}^0 \to N(0, V), \]

where \( h=h(n) \) is the bandwidth, and \( c_{R}^0 \) and \( V \) are nonstochastic factors. This approach preserves the convergence rate of the unweighted entropy estimator, giving sharper confidence interval estimation and more powerful hypothesis tests. It is applicable
When \( \{Y_t\} \) is uniformly distributed.

Skaug and Tjøstheim (1993b) also use an Hoeffding measure to test serial dependence (see also Delgado, 1996; Hong, 1998; 2000). The empirical Hoeffding measures are based on the empirical distribution functions, which avoid smoothed nonparametric density estimation.

### 3.3 Generalized spectrum

Without assuming the existence of higher order moments, Hong (1999) proposes a generalized spectrum as an alternative analytic tool to the power spectrum and higher order spectra. The basic idea is to transform \( \{Y_t\} \) via a complex-valued exponential function

\[ Y_t \rightarrow \exp(iuY_t), \ u \in (-\infty, \infty), \]

and then consider the spectrum of the transformed series. Let \( \psi(u) \equiv \mathbb{E}(e^{iutY_t}) \) be the marginal characteristic function of \( \{Y_t\} \) and let \( \psi_j(u, v) \equiv \mathbb{E}[e^{i(uY_t + vY_{t-|j|})}], \ j = 0, \pm 1, \ldots \) be the pairwise joint characteristic function of \( \{Y_t, Y_{t-|j|}\} \). Define the covariance function between transformed variables \( e^{iutY_t} \) and \( e^{ivY_{t-|j|}} \):

\[ \sigma_j(u, v) \equiv \text{Cov}(e^{iutY_t}, e^{ivY_{t-|j|}}), \ j = 0, \pm 1, \ldots. \]

Straightforward algebra yields \( \sigma_j(u, v) = \psi_j(u, v) - \psi(u) \psi(v) \), which is zero for all \( u, v \) if and only if \( Y_t \) and \( Y_{t-|j|} \) are independent. Thus \( \sigma_j(u, v) \) can capture any type of pairwise serial dependence over various lags, including those with zero autocorrelation. For example, \( \sigma_j(u, v) \) can capture the BL, NMA and ARCH (1) processes in (3.1)−(3.3), all of which are serially uncorrelated.

The Fourier transform of the generalized covariance \( \sigma_j(u, v) \):

\[ f(\omega, u, v) \equiv \frac{1}{2\pi} \sum_{j=-\infty}^{\infty} \sigma_j(u, v)e^{-i\omega j}, \ \omega \in [-\pi, \pi], \]

is called the ‘generalized spectral density’ of \( \{Y_t\} \). Like \( \sigma_j(u, v) \), \( f(\omega, u, v) \) can capture any type of pairwise serial dependencies in \( \{Y_t\} \) over various lags. Unlike the power spectrum and higher order spectra, \( f(\omega, u, v) \) does not require any moment condition on \( Y_t \). When \( \text{var}(Y_t) \) exists, the power spectrum of \( \{Y_t\} \) can be obtained by differentiating \( f(\omega, u, v) \) with respect to \((u, v)\) at \((0, 0)\):

\[ h(\omega) \equiv \frac{1}{2\pi} \sum_{j=-\infty}^{\infty} \gamma_j e^{-i\omega j} = -\frac{\partial^2}{\partial u \partial v} f(\omega, u, v)|_{(u, v) = (0, 0)}, \ \omega \in [-\pi, \pi]. \]

This is the reason why \( f(\omega, u, v) \) is called the ‘generalized spectral density’ of \( \{Y_t\} \).

When \( \{Y_t\} \) is i.i.d., \( f(\omega, u, v) \) becomes a flat generalized spectrum as a function of \( \omega \);
Any deviation of \( f(\omega, u, v) \) from the flat generalized spectrum \( f_0(\omega, u, v) \) is evidence of serial dependence. Thus, \( f(\omega, u, v) \) is suitable to capture any departures from \( i.i.d \). Hong and Lee (2003b) use the generalized spectrum to develop a test for the adequacy of nonlinear time series models by checking whether the standardized model residuals are \( i.i.d \). Tests for \( i.i.d. \) are more suitable than tests for serial correlation in nonlinear contexts. Indeed, Hong and Lee (2003b) find that some popular EGARCH models are inadequate in capturing the full dynamics of stock returns, although the standardized model residuals are serially uncorrelated. Insight into the ability of \( f(\omega, u, v) \) can be gained by considering a Taylor series expansion

\[
f(\omega, u, v) = \sum_{m=0}^{\infty} \sum_{l=0}^{\infty} \frac{(iu)^m (iv)^l}{m!l!} \left[ \frac{1}{2\pi} \sum_{j=-\infty}^{\infty} \text{Cov}(X_t^m, X_{t-j}^l) e^{-ij\omega} \right].
\]

Although \( f(\omega, u, v) \) has no physical interpretation, it can be used to characterize cyclical movements caused by linear and nonlinear serial dependence. Examples of nonlinear cyclical movements include cyclical volatility clustering, and cyclical distributional tail clustering (for example, Engle and Manganelli's (2004) CAVaR model). Intuitively, the supremum function

\[
s(\omega) = \sup_{-\infty < u, v < \infty} \left| f(\omega, u, v) \right|, \omega \in [-\pi, \pi],
\]

can measure the maximum dependence at frequency \( \omega \) of \( \{Y_t\} \). It can be viewed as an operational frequency domain analogue of Granger and Terasvirta's (1993) maximum correlation measure

\[
mmp(j) = \max_{g(\cdot), h(\cdot)} |\text{Corr}[g(Y_t), h(X_{t-j})]|.
\]

Once generic serial dependence is detected using \( f(\omega, u, v) \) or any other dependence measure, one may like to explore the nature and pattern of serial dependence. For example, one may be interested in the following questions:

- Is serial dependence operative primarily through the conditional mean or through conditional higher order moments?
- If serial dependence exists in conditional mean, is it linear or nonlinear?
- If serial dependence exists in conditional variance, does there exist linear or nonlinear and asymmetric ARCH?

Different types of serial dependence have different economic implications. For example, the efficient market hypothesis fails if and only if there is no serial dependence in conditional mean. Just as the characteristic function can be differentiated to generate various moments, generalized spectral derivatives, when they exist, can capture various specific aspects of serial dependence, thus providing information on possible types of serial dependence. Suppose \( E[(Y_t)^{2m+n}g^\omega] < \infty \) for some nonnegative integers \( m, l \). Then the following generalized spectral derivative exists:

\[
f^{(m, n)}(\omega, u, v) = \frac{\partial}{\partial u^m} \frac{\partial}{\partial v^n} f(\omega, u, v) = \frac{1}{2\pi} \sum_{j=-\infty}^{\infty} \sigma_j^{(m, n)}(u, v) e^{-ij\omega},
\]
where \( \sigma_{(m,l)}^{(j)}(u, v) = \partial^{m+l} \sigma_{j}(u, v) / \partial u^m \partial v^l \). As an illustrative example, we consider the generalized spectral derivative of order \((m, l) = (1, 0)\): 

\[
\sigma_{(1,0)}^{(j)}(u, v) = \frac{1}{2\pi} \sum_{j=-\infty}^{\infty} \sigma_{j}(u, v) e^{-ij\omega}. 
\]

Observe \( \sigma_{(1,0)}^{(j)}(0, v) = \text{cov}(Y_t, e^{ivY_{t-j}}) = 0 \) for all \( v \in (-\infty, \infty) \) if and only if \( E(Y_t | Y_{t-j}) = E(Y_t) \) a.s. The function \( E(Y_t | Y_{t-j}) \) is called the autoregression function of \( \{Y_t\} \) at lag \( j \). It can capture a variety of linear and nonlinear dependencies in conditional mean, including the BL and NMA processes in (3.1) and (3.2). (The use of \( \sigma_{(1,0)}^{(j)}(0, v) \), which can be easily estimated by a sample average, avoids smoothed nonparametric estimation of \( E(Y_t | Y_{t-j}) \).) Thus, the generalized spectral derivative \( \sigma_{(0,1,0)}^{(j)}(u, v) \) can be used to capture a wide range of serial dependence in conditional mean. In particular, the function 

\[
\sigma_{(0,1,0)}^{(j)}(0, 0, v) = \sup_{-\infty < \nu < +\infty} \left| \sigma_{(0,1,0)}^{(j)}(\omega, 0, \nu) \right|
\]

can be viewed as an operational frequency domain analogue of Granger and Terasvirta's (1993) maximum mean correlation measure 

\[
\mm(j) = \max_{h(\cdot)} \text{corr}(Y_t, h(Y_{t-j})).
\]

See Hong and Lee (2005) for more discussion. Suppose one has found evidence of serial dependence in conditional mean using \( \sigma_{(0,1,0)}^{(j)}(\omega, u, v) \) or any other suitable measure, one can go further to explore whether there exists linear serial dependence in mean. This can be done by using the \((1,1)\)-th order generalized derivative 

\[
\sigma_{(0,1,1)}^{(j)}(0, 0, 0) = -h(\omega),
\]

which checks serial correlation. Moreover, one can further use \( \sigma_{(0,1,l)}^{(j)}(\omega, u, v) \) for \( l \geq 2 \) to reveal nonlinear serial dependence in mean. In particular, these higher-order derivatives can suggest that there exist: (i) an ARCH-in-mean effect (for example, Engle, Lilien and Robins, 1987) if \( \text{cov}(Y_t, Y_{t-j}^2) \neq 0 \), (ii) a skewness-in-mean effect (for example, Harvey and Siddique, 2000) if \( \text{cov}(Y_t, Y_{t-j}^3) \neq 0 \), and (iii) kurtosis-in-mean effect (for example, Brooks, Burke and Persand, 2005) if \( \text{cov}(Y_t, Y_{t-j}^4) \neq 0 \). These effects may arise from the existence of a time-varying risk premium, asymmetry of market behaviours, and inadequate account for large losses, respectively.

Shackle, George Lennox Sharman (1903–1992)

Peter Earl

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

kaleidics; possibility; Post Keynesian economics; probability; rational expectations; Shackle, G. L. S.

Article

Shackle was born in Cambridge. Financial circumstances compelled him to take an external degree while working first as a bank clerk and then as a schoolmaster; it was only in 1935 that he was able to study under Hayek at the London School of Economics. This was an exciting time to be starting out and later, in one of his best-loved books, The Years of High Theory (1967), Shackle was to look back at the problem-solving activities responsible for the interwar theoretical breakthroughs. Within two years, and very much influenced by the latest work of Myrdal and Keynes, he completed his first doctorate (published as Shackle, 1938). By 1940 he was employed in wartime official service, having completed a second thesis that drew on material from his work as assistant to E.H. Phelps Brown at Oxford. Despite the demands of official work, he produced a series of articles on uncertain, crucial choices, whose outcomes may define, for good or bad, the chooser's future possibilities (see especially Shackle, 1942; 1943). These were reworked into his (1949) book and he rose rapidly, after returning to academia as Reader in Economics at Leeds University in 1950, to become Brunner Professor of Economic Science in the University of Liverpool in 1951. His retirement from Liverpool in 1969 saw no easing in his industry or in his desire to see economists deal with knowledge problems as analytical rudiments rather than refinements (see Shackle, 1972).

Although Shackle's (1949) analysis of crucial choices attracted immediate attention, it won few adherents. In this book, as in many of his subsequent works, Shackle argued that probabilistic notions are questionable if choice experiments can destroy any possibility of their own replication. (Post-Keynesians have extended his view in criticizing the rational expectations hypothesis.) Shackle suggested that, in such situations, choosers would come to focus on particularly attention-arresting pairs of possibilities (one pair for each scheme of action). A possibility is not something which a chooser would expect to happen, given enough tries, with a particular frequency, but something whose taking place looks ex ante surprising (unsurprising) because potentially fatal obstacles to it can (cannot) be
envisaged. Shackle insisted that possibility is not in general distributive: thoughts about a possible outcome not previously imagined need not affect assignments of potential surprise to its rivals, since potential surprise ratings do not sum to any fixed, bounded value. Despite this, many theorists found his ‘potential surprise curves’ difficult to distinguish from inverted probability distributions; they also took issue with his view that it is not rational for choosers to weigh together values for possibilities that are mutually exclusive. Behaviouralists were ill-disposed to the large role played by indifference surfaces in his analysis of how ascendant gain/loss pairings were focused upon and then ranked; whereas orthodox theorists (for example, Ford, 1983) argued that it would be irrational for choosers to focus in the way he proposed, and that his selection device – the ‘gambler preferences’ map – produced the questionable result that an investor will choose a portfolio consisting of no more than two types of financial asset. Much of his noteworthy retirement output (especially his 1974 book) tried to make economists recognize that the incompatibility of speculators’ expectations and changes in the ‘state of the news’ will make the relative demands for durable assets prone to kaleidoscopic instability. To many orthodox model-builders, his kaleidic conception of economic systems had unacceptably nihilistic implications, but it led some Post Keynesians to examine how institutions and policies might be designed to constrain explosive and implosive forces whose precise timings and strengths may be impossible to anticipate.

shadow pricing

Ravi Kanbur
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

border prices; decentralization; distribution of income; lump sum taxes; market prices; shadow pricing; social cost

Article

When a businessman evaluates a project, he does it with a view to calculating the prospective profit from it. These calculations can be seen as taking place in two steps. At the first step, all the physical consequences of relevance to the businessman – the inputs to and outputs from the project – are assessed. At the second stage, these inputs and outputs are converted into costs and revenues, using *market prices*. It is natural that a private businessman should use the ruling market prices for costing inputs and for valuing sales, since these are the prices at which transactions take place and hence profit generated.

Consider now the evaluation of a project by a government. Such evaluation will differ at each of the two steps referred to above. At the first step, the government will be interested in *all* of the repercussions of the project, however indirect. This is because it is the government rather than a private businessman concerned with his own narrowly defined activities. At the second step, the government will wish to use not the ruling market prices but prices which reflect social costs and social benefits, in order to calculate what might be termed social profit. These prices are referred to as *shadow prices*, or accounting prices (see Little and Mirrlees, 1974), and the name suggests that they are to be used in lieu of the actual market prices.

Market prices are what they are. But how are shadow prices to be calculated? Clearly they depend on the government's objective function and on the constraints it faces. The shadow prices should be such that the social profit from the project is positive if and only if the project increases the value of the government's objective function. In a general competitive equilibrium, if the government's objective is economic efficiency, then it can be argued that for a small project the shadow prices do in fact coincide with market prices. If the government's objective includes the pursuance of equity, but it has lump sum instruments to carry this out, then shadow prices still coincide with market prices. Basically the
shadow pricing: The New Palgrave Dictionary of Economics

The government should use redistributive lump sum taxation to pursue equity and the project to pursue increases in aggregate economic welfare. But if the government does not have a sufficient range of instruments to pursue effective redistribution without distortion it may be the case that, even with a full competitive equilibrium, shadow prices may differ from market prices. In addition to this, if the economy is not in a full competitive equilibrium, then the case for using shadow prices different from market prices can be argued strongly. In programming terms, shadow prices are simply dual to the changes in the government's objective function. One justification for their use is the benefits of decentralization: local project evaluators are better equipped to analyse the physical consequences of a project, and this localized knowledge should be used in conjunction with centrally determined shadow prices to evaluate the social profitability of projects. But the real difficulties arise in specifying the objectives of the government and in specifying its constraints, and this is in turn related to who is thought of as doing the project evaluation. The standard assumption is one of a unitary government with a given social welfare function – a benevolent dictator. But the reality is one where either the project evaluator is part of a government which is a coalition of interests, or the project evaluation is being done by an international agency which faces a government made up of conflicting and competing objectives. The logical procedure for an international agency should be clear – in evaluating a project it should incorporate a model of the political process to clarify the responses of various government instruments to the project. Sen (1972) gives an illuminating discussion of a project which requires importing an input on which there is already a quota – so that the border price of the input is very different from its domestic scarcity value. The Little and Mirrlees (1974) method of using border prices is predicated on the assumption that it is these prices which represent the transformation possibilities for the economy as a whole. But if the assessment of the political realities is such that this quota will not be removed by the government – because of the overriding influence of interest groups that benefit from the rents generated by the quota – then the domestic scarcity value should be used in costing the input.

Similarly, any project which alters significantly the distribution of income will have repercussions on the political process – and there will be attempts by groups who are adversely affected to restore their standard of living. Project evaluation in general, and shadow pricing in particular, should take these into account. Consider, for example, the shadow cost of labour. If the labour used on the project comes from the agricultural sector, and if this labour is a constraint on output, then agricultural output will fall. If government revenue depends on taxation of this output, this will fall too. If, in turn, government expenditure is a major source of non-agricultural (urban) incomes, then at constant fiscal deficit urban incomes will fall. This change in the distribution of income will be an important element in the shadow cost of labour. But suppose now that the political processes are such as to not allow a decline in urban living standards. Rather, government expenditure remains constant and the fiscal deficit increases. Now it is the increased burden on future generations which has to be taken into account. Either way, it should be clear that a model of the political process is crucial in specifying shadow prices even if the project evaluator (be it an international agency or a project evaluation unit within the government) is clear about what the objectives are.

Shapley value

Sergiu Hart
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The Shapley value is an a priori evaluation of the prospects of a player in a multi-person game. Introduced by Lloyd S. Shapley in 1953, it has become a central solution concept in cooperative game theory. The Shapley value has been applied to economic, political, and other models.

Keywords

Banzhaf index; coalitions; competitive equilibrium; cooperative game theory; cost allocation; games in coalitional form; large games; market games; perfect competition; political power; Shapley value; Shapley–Shubik index; side payments; transferable utility; value equivalence principle

Article

The value of an uncertain outcome (a ‘lottery’) is an a priori measure, in the participant's utility scale, of what he expects to obtain (this is the subject of ‘utility theory’). The question is, how would one evaluate the prospects of a player in a multi-person interaction, that is, in a game?

This question was originally addressed by Lloyd S. Shapley (1953a). The framework was that of n-person games in coalitional form with side-payments, which are given by a set $N$ of 'players', say 1, 2, …, $n$, together with a 'coalitional function' $\nu$ that associates to every subset $S$ of $N$ ('coalition') a real number $\nu(S)$, the maximal total payoff the members of $S$ can obtain (the ‘worth’ of $S$). An underlying assumption of this model is that there exists a medium of exchange ('money') that is freely transferable in unlimited amounts between the players, and moreover every player's utility is additive with respect to it (that is, a transfer of $x$ units from one player to another decreases the first one's utility by $x$ units and increases the second one's utility by $x$ units; the total payoff of a coalition can thus be meaningfully defined as the sum of the payoffs of its members). This requirement is known as existence of 'side payments' or 'transferable utility'. In addition, the game is assumed to be adequately described by its coalitional function (that is, the worth $\nu(S)$ of each coalition $S$ is well defined, and the abstraction from...
Shapley value: The New Palgrave Dictionary of Economics

The extensive structure of the game to its coalitional function leads to no essential loss; such a game is called a ‘c-game’). These assumptions may be interpreted in a broader and more abstract sense. For example, in a voting situation, a ‘winning coalition’ is assigned worth 1, and a ‘losing’ coalition, worth 0. The essential feature is that the prospects of each coalition may be summarized by one number. The Shapley value associates to each player in each such game a unique payoff – his ‘value’. The value is required to satisfy the following four axioms. (EFF) Efficiency or Pareto optimality: The sum of the values of all players equals \( v(N) \), the worth of the grand coalition of all players (in a superadditive game \( v(N) \) is the maximal amount that the players can jointly get); this axiom combines feasibility and efficiency. (SYM) Symmetry or equal treatment: If two players in a game are substitutes (that is, the worth of no coalition changes when replacing one of the two players by the other one), then their values are equal. (NUL) Null or dummy player: If a player in a game is such that the worth of every coalition remains the same when he joins it, then his value is zero. (ADD) Additivity: The value of the sum of two games is the sum of the values of the two games (equivalently, the value of a probabilistic combination of two games is the same as the probabilistic combination of the values of the two games; this is analogous to ‘expected utility’). The surprising result of Shapley is that these four axioms uniquely determine the values in all games.

Remarkably, the Shapley value of a player in a game turns out to be exactly his expected marginal contribution to a random coalition. The marginal contribution of a player \( i \) to a coalition \( S \) (that does not contain \( i \)) is the change in the worth when \( i \) joins \( S \), that is, \( v(S \cup \{i\}) - v(S) \). To obtain a random coalition \( S \) not containing \( i \), arrange the \( n \) players in a line (for example, 1, 2, …, \( n \)) and put in \( S \) all those that precede \( i \) in that order; all \( n! \) orders are assumed to be equally likely. The formula for the Shapley value is striking, first, since it is a consequence of very simple and basic axioms and, second, since the idea of marginal contribution is so fundamental in much of economic analysis.

It should be emphasized that the value of a game is an a priori measure, that is, an evaluation before the game is actually played. Unlike other solution concepts (for example, core, von Neumann–Morgenstern solution, bargaining set), it need not yield a ‘stable’ outcome (the probable final result when the game is actually played). These final stable outcomes are in general not well determined; the value – which is uniquely specified – may be thought of as their expectation or average. Another interpretation of the value axioms regards them as rules for ‘fair’ division, guiding an impartial ‘referee’ or ‘arbitrator’. Also, as suggested above, the Shapley value may be understood as the utility of playing the game (Shapley, 1953a; Roth, 1977).

In view of both its strong intuitive appeal and its mathematical tractability, the Shapley value has been the focus of much research and many applications. We can only briefly mention some of these here (together with just a few representative references). The reader is referred to the survey of Aumann (1978) and, for more extensive coverage, to the Handbook of Game Theory (Aumann and Hart, vol 1: 1992 [HGT1], vol 2: 1994 [HGT2], vol 3: 2002 [HGT3]), especially Chapters 53–58, as well as parts of Chapters 32–34 and 37.

Variations

Following Shapley's pioneering approach, the concept of value has been extended, modified and generalized.
Weighted values

Assume that the players are of unequal ‘size’ (for example, a player may represent a ‘group’, a ‘department’, and so on), and this is expressed by given (relative) weights. This setup leads to ‘weighted Shapley values’ (Shapley, 1953b); in unanimity games, for example, the values of the players are no longer equal but, rather, proportional to their weights [HGT3, Ch. 54].

Semi-values

Abandoning the efficiency axiom (EFF) yields the class of ‘semi-values’ (Dubey, Neyman and Weber, 1981). An interesting semi-value is the Banzhaf index (Penrose, 1946; Banzhaf, 1965; Dubey and Shapley, 1979), originally proposed as a measure of power in voting games. Like the Shapley value, it is also an expected marginal contribution, but here all coalitions not containing player $i$ are equally likely [HGT3, Ch. 54].

Other axiomatizations

There are alternative axiomatic systems that characterize the Shapley value. For instance, one may replace the additivity axiom (ADD) with a marginality axiom that requires the value of a player to depend only on his marginal contributions (Young, 1985). Another approach is based on the existence of a potential function together with efficiency (EFF) (Hart and Mas-Colell, 1989) [HGT3, Ch. 53].

Consistency

Given a solution concept which associates payoffs to games, assume that a group of players in a game have already agreed to it, are paid off accordingly, and leave the game; consider the ‘reduced game’ among the remaining players. If the solution of the reduced game is the same as that of the original game, then the solution is said to be consistent. It turns out that consistency, together with some elementary requirements for two-player games, characterizes the Shapley value (Hart and Mas-Colell, 1989) [HGT3, Ch. 53], [HGT1, Ch. 18].

Large games

Assume that the number of players increases and individuals become negligible. Such models are important in applications (such as competitive economies and voting), and there is a vast body of work on values of large games that has led to beautiful and important insights (for example, Aumann and Shapley, 1974) [HGT3, Ch. 56].

NTU games
These are games ‘without side payments’, or ‘with non-transferable utility’ (that is, the existence of a medium of utility exchange is no longer assumed). The simplest such games, two-person pure bargaining problems, were originally studied by Nash (1950). Values for general NTU games, which coincide with the Shapley value in the side payments case, and with the Nash bargaining solution in the two-person case, have been introduced by Harsanyi (1963), Shapley (1969), Maschler and Owen (1992) [HGT3, Ch. 55].

Non-cooperative foundations

Bargaining procedures whose non-cooperative equilibrium outcome is the Shapley value have been proposed by Gul (1989) (see Hart and Levy, 1999; Gul, 1999) and Winter (1994) for strictly convex games, and by Hart and Mas-Colell (1996) for general games [HGT3, Ch. 53].

Other extensions

This includes games with communication graphs (Myerson, 1977), coalition structures (Aumann and Drèze, 1974; Owen, 1977; Hart and Kurz, 1983), and others [HGT2, Ch. 37], [HGT3, Ch. 53].

Economic applications

Perfect competition

In the classical economic model of perfect competition, the commodity prices are determined by the requirement that total demand equals total supply; this yields a competitive (or Walrasian) equilibrium. A different approach in such setups looks at the cooperative ‘market game’ where the members of each coalition can freely exchange among themselves the commodities they own. A striking phenomenon occurs: various game-theoretic solutions of the market games yield precisely the competitive equilibria. In particular, in perfectly competitive economies every Shapley value allocation is competitive and, if the utilities are smooth, then every competitive allocation is also a value allocation. This result, called the value equivalence principle, is remarkable since it joins together two very different approaches: competitive prices arising from supply and demand on the one hand, and marginal contributions to trading coalitions on the other. The value equivalence principle has been studied in a wide range of models (for example, Shapley, 1964; Aumann, 1975). While it is undisputed in the TU case, its extension to the general NTU case seems less clear (it holds for the Shapley NTU value, but not necessarily for other NTU values) [HGT3, Ch. 57].

Cost allocation

Consider the problem of allocating joint costs in a ‘fair’ manner. Think of the various ‘tasks’ (or ‘projects’, ‘departments’, and so on) as players, and let \( v(S) \) be the total cost of carrying out the set \( S \) of tasks (Shubik, 1962). It turns out that the axioms determining the Shapley value are easily translated into
Shapley value: The New Palgrave Dictionary of Economics

postulates appropriate for solving cost allocation problems (for example, the efficiency axiom becomes ‘total-cost-sharing’). Two notable applications are airport landing fees (a task here is an aircraft landing; Littlechild and Owen, 1973) and telephone billing (each time unit of a phone call is a player; the resulting cost allocation scheme was put into actual use at Cornell University; Billera, Heath and Raanan, 1978) [HGT2, Ch. 34].

Other applications

The value has been applied to various economic models; for example, models of taxation where a political power structure is given in addition to the economic data (Aumann and Kurz, 1977). Further references to economic applications can be found in Aumann (1985) [HGT3, Ch. 58], [HGT2, Ch. 33].

Political applications

What is the ‘power’ of an individual or a group in a voting situation? A trivial observation – though not always remembered in practice – is that the political power need not be proportional to the number of votes (see Shapley, 1981, for some interesting examples). It is therefore important to find an objective method of measuring power in such situations. The Shapley value (known in this setup as the Shapley–Shubik index; Shapley and Shubik, 1954) is, by its very nature, a most appropriate candidate. Indeed, consider a simple political game, described by specifying whether each coalition is ‘winning’ or ‘losing’. The Shapley value of a player $i$ turns out to be the probability that $i$ is the ‘pivot’ or ‘key’ player, namely, that in a random order of all players those preceding $i$ are losing, whereas together with $i$ they are winning. For example, in a 100-seat parliament with simple majority (that is, 51 votes are needed to win), assume there is one large party having 33 seats and the rest are divided among many small parties; the value of the large party is then close to 50%, considerably more than its voting weight (that is, its 33% share of the seats). In contrast, when there are two large parties each having 33 seats and a large number of small parties, the value of each large party is close to 25% – much less than its voting weight of 33%. To understand this, think of the competition between the two large parties to attract the small parties to form a winning coalition; in contrast, when there is only one large party, the competition is between the small parties (to join the large party).

The Shapley value has also been used in more complex models, where ‘ideologies’ and ‘issues’ are taken into account (thus, not all arrangements of the voters are equally likely; an ‘extremist’ party, for example, is less likely to be the pivot than a ‘middle-of-the-road’ one; Owen, 1971; Shapley, 1977). References to political applications of the Shapley value may be found in Shapley (1981); these include various parliaments (USA, France, Israel), the United Nations Security Council, and others [HGT2, Ch. 32].

The Shapley–Folkman theorem places an upper bound on the size of the non-convexities (loosely speaking, openings or holes) in a sum of non-convex sets in Euclidean $N$-dimensional space, $\mathbb{R}^N$. The bound is based on the size of non-convexities in the sets summed and the dimension of the space. When the number of sets in the sum is large, the bound is independent of the number of sets summed, depending rather on $N$, the dimension of the space. Hence the size of the non-convexity in the sum becomes small as a proportion of the number of sets summed; the non-convexity per summand goes to zero as the number of summands becomes large. The Shapley–Folkman theorem can be viewed as a discrete counterpart to the Lyapunov theorem on non-atomic measures (Grodal, 2002).

large economies; Lyapunov th; non-convexity; Shapley–Folkman th

Article

The theorem is used to demonstrate the following properties:

- existence of approximate competitive general equilibrium in large finite economies with non-convex preferences (increasing marginal rate of substitution) or non-convex technology (bounded increasing returns; the U-shaped cost curve case);
- convergence of the core to the set of competitive equilibria (Arrow and Hahn, 1972; Anderson, 1978).

It may also be used to characterize the solution of non-convex programming problems (Aubin and Ekeland, 1976).
For $S \subset \mathbb{R}^n$, $S$ compact, define $\text{rad}(S)$, the radius of $S$, as a measure of the size of $S$. Define $r(S)$, the inner radius of $S$, and $\rho(S)$ inner distance of $S$, as measures of the non-convexity (size of holes) of $S$. Let $\text{con}S$ denote the closed convex hull of $S$ (smallest closed convex set containing $S$ as a subset).

\[
\text{rad}(S) = \inf_{x \in \mathbb{R}^n} \sup_{y \in S} |x - y|;
\]
\[
r(S) = \sup_{x \in \text{con}S} \inf_{T \subset \mathbb{R}^n} \text{rad}(T);
\]
\[
\rho(S) = \sup_{x \in \text{con}S} \inf_{y \in S} |x - y|.
\]

rad$(S)$ is the radius of the smallest closed ball centred in $\text{con}S$ containing $S$. A set of points $T$ is said to span a point $x$, if $x$ can be expressed as a convex combination (weighted average) of elements of $T$. $r(S)$ is the smallest radius of a ball centred in the convex hull of $S$, so that the ball is certain to contain a set of points of $S$ that span the ball's centre. Hence $r(S)$ represents a measure of breadth of non-convexities in $S$. $\rho(S)$ is the maximum distance from a point in $\text{con}S$ to (the nearest point of) $S$. Hence it represents the smaller of breadth or depth of non-convexities of $S$.

Let $S_1, S_2, \ldots, S_m$ be a (finite) family of $m$ compact subsets of $\mathbb{R}^N$. The vector sum of $S_1, S_2, \ldots, S_m$, denoted $W$ is a set composed of representative elements of $S_1, S_2, \ldots, S_m$ summed together. $W$ is defined as

\[
W \equiv \sum_{i=1}^m S_i \equiv \left\{ w \mid w = \sum_{i=1}^m x^i, x^i \in S_i \right\}
\]

where the sum in the brackets is taken over one element of each $S_i$.

**Theorem:** (Shapley–Folkman): Let $S_1, \ldots, S_m$ be a family of $m$ compact subsets of $\mathbb{R}^N$. $W = \sum_{i=1}^m S_i$. Let $l \geq \text{rad}(S_i)$ for all $S_i$; let $n = \min(N, m)$. Then for any $x \in \text{con}W$

1. (i) $x = \sum_{i=1}^m x^i$, where $x^i \in \text{con}S_i$ and with at most $N$ exceptions, $x^i \in S_i$;
2. (ii) there is $y \in W$ so that $|x - y| \leq l\sqrt{n}$.

**Corollary:** (Starr): Let $S_1, \ldots, S_m$ be a finite family of compact subsets of $\mathbb{R}^N$. $W = \sum_{i=1}^m S_i$. Let $l \geq r(S_i)$ for all $S_i$, $n = \min(m, N)$. Then for any $x \in \text{con}W$ there is $y \in W$ so that
Shapley–Folkman theorem: The New Palgrave Dictionary of Economics

Corollary: (Heller): Let \( S_1, \ldots, S_m \) be a finite family of compact subsets of \( \mathbb{R}^N \). \( W = \sum_{i=1}^{m} S_i \). Let \( L \geq \rho(S_i) \) for all \( S_i, n = \min(m, N) \). Then for any \( x \in \text{con} W \) there is \( y \in W \) so that

\[
|x - y| \leq Ln.
\]

Statements and proofs of the theorem and corollaries along with applications are available in Arrow and Hahn (1972) and Green and Heller (1981). Development of the theorem is due to L.S. Shapley and J.H. Folkman (private correspondence) with publication in Starr (1969). Extensions, alternative proofs, and applications appear in the other references.

Sharecropping is a form of land leasing contract between a tenant and a landlord who share the production. It has a variety of forms and is sometimes linked with credit, lending, or insurance. The apparent inefficiency of sharecropping due to the fact that the tenant receives only a share of the marginal productivity of his labour has attracted economists’ attention since Adam Smith. Within the principal–agent paradigm, sharecropping is now thought of as trading off incentives and risk sharing or as reducing transaction costs for a landlord willing to lend out a piece of land.

Article

Sharecropping is a form of land leasing contract in which the tenant shares the final product with the landlord as a partial or total payment of the rent. A landowner leasing his land to a tenant may use several forms of land renting contracts. ‘Sharecropping’ usually designates all particular forms of land tenancy contracts in which the landlord allows the tenant to cultivate his land in return for a stipulated fraction of the product (the ‘share’), possibly combined with other side payments. This institutional contractual agreement prevailed in many parts of the world and many different periods in the history of agriculture, from antiquity (Egypt, Mesopotamia and Greece), the Middle Ages and Renaissance in Europe, through to contemporary economies. Sharecropping is currently most commonly found in less developed countries where
agriculture and land rental markets are more active, but it also still exists in many developed countries. The sharecropping relationship assumes a variety of forms and is sometimes linked to agreements involving not only land and labour transactions but also credit, lending, insurance or marketing agreements. Indeed, within sharecropping arrangements landlords may also determine the crops to be grown, may choose to monitor some of the key moments of the agricultural process, and may defray a greater or lesser share of the costs of some inputs (other than labour) with a pre-specified fraction that may not necessarily be equal to the fraction of output retained by the landlord in the payment rule.

Is sharecropping inefficient?

Since Adam Smith, economists have taken an interest in sharecropping because of its apparent inefficiency based on the simple observation that the sharecropper receives only a share of the marginal productivity of his labour but bears its full marginal cost. The persistence of such institutions has thus puzzled many economists. More recently, sharecropping has also constituted the typical example of the principal–agent model, the basic paradigm of contract theory. Similar economic relationships occur in both developed and less developed countries when some party (the principal) delegates the use of some capital to another party in exchange for compensation depending on the returns obtained by the other party (the agent). Examples abound in capital markets (stock markets) where investors may let others use their capital in return for a share of the profits, in vertical relationships between producers and retailers in many industries (food and other consumption goods, or rental services), and in some labour contracts within firms where wages may depend on some measure of performance. Researchers working on the theory of rural organization have attempted to explain not only the persistence of sharecropping but also the particular features it exhibits.

Sharecropping as an efficient risk-sharing contract

Concerns about the efficiency of sharecropping relationships have gone through several stages in the history of economic thought. While it was first thought to be an inefficient institutional arrangement, since Stiglitz (1974) it has been understood as possibly representing an efficient risk-sharing mechanism in environments where production is risky and other forms of insurance are not available. Sharecropping has the advantage over fixed-rent land leasing contracts of relieving the tenant of some of the risk. By sharing the product, the landlord and tenant also share its fluctuations due to risks related to the weather, diseases and other unpredictable factors affecting agricultural production. Through the payment of a rent contingent on agricultural production, the risk associated with variations in prices of marketed commodities is also shared by both parties. However, if the landlord is less risk averse, he should further protect the risk-averse peasant by simply using wage contracts. Moreover, the same risk-sharing opportunities could be provided without sharecropping simply by having workers combine wage contracts and rental contracts.

However, the landlord’s ability to monitor the tenant’s labour has also been also called into question. In most places where absentee landlords delegate the use of land to a tenant, it seemed implausible that a contract precisely specifying the labour to be applied could be enforceable. Stiglitz (1974) shows that sharecropping could be an institutional arrangement designed both to share risks and to provide
incentives in a situation where monitoring effort (labour supply) is costly. Sharecropping results, then, from a trade-off between incentives and risk sharing. Fixed-rent contracts provide ‘perfect’ incentives by giving the full marginal product to the tenant but at the cost of shifting all the risk on to the tenant, while fixed-wage contracts protect the tenant against production risk but also remove direct incentives to provide effort.

However, the two necessary ingredients of this trade-off have been successively challenged. Cheung (1969) criticizes the need to provide incentives through contracted remuneration, arguing that contracts could simply specify the optimal level of labour that the tenant should provide. Wage contracts would not then imply any inefficiency in the provision of effort and would completely insure tenants against income fluctuations. However, this reasoning implicitly assumes that monitoring is not costly, and empirical tests have shown in some contexts that input provision was actually lower under share contracts than under fixed-rent contracts (see, among others, Shaban, 1987). Conversely, the other side of the trade-off was also challenged by the apparent paucity of evidence as to the effect of risk on contractual forms. In fact, until recently a great deal of empirical work had failed to present evidence as to the effect of risk on the contract incentives that would be consistent with the alleged trade-off. This was mostly due to the significance of other trade-offs determining the choice of contracts (which we examine below) but also to the failure to recognize that the choice of contracts had to be modelled within a more general understanding of how land rental markets function. Dubois (2002) shows that taking into account the endogeneity of the choice to delegate use of land was important in the empirical analysis of contractual choices in order to avoid problems of selection bias in econometric estimates. Ackerberg and Botticini (2002) show that not taking into account the endogenous matching of landlords and tenants could also lead to an apparent absence of correlation between the incentive power of contracts and the crop risk. Referring to direct evidence on risk sharing in village economies using consumption data linked to contract choices, Dubois (2000) demonstrates that the sharecropping institution could actually play a role in consumption risk sharing.

Thus, in order to reduce shirking, the landlord could either expend resources in monitoring the worker or prefer to resort to a sharecropping contract. The persistence of sharecropping can thus be explained by this argument together with a number of other observed features. For example, the landlord has an incentive to encourage the tenant to use inputs (such as fertilizer or manure) which raise the worker’s marginal product, therefore resulting in higher worker effort. This explains why, as is often observed in sharecropping contracts, the landlord may be prepared to bear a fraction of the costs of inputs that exceeds the fraction of the product received. Obviously, to implement cost sharing, costs have to be observable and verifiable. Why then does the landlord not simply enforce a specific level of input provision by the tenant? This relates to the information structure as to the appropriate level of input, about which the tenant may have better knowledge given the conditions of production. Sharing costs thus remains a useful incentive.

Another argument against interpreting sharecropping as a risk-sharing contract is that the terms of the contracts should logically vary with the level of risk represented by the specific environment, the crops grown, and both parties’ degree of risk aversion. Empirical observation, however, shows that in practice the terms of sharecropping contracts exhibit little variation, especially when it comes to the share of the product, which is often one-half and sometimes one-third or two-thirds. This could be seen to be the result of an approximation process of optimal contracts, but Allen (1985) provides an interesting
explanation of this phenomenon. In a model where landlords initially screen tenants with heterogeneous abilities before entering into fixed-rent contracts with only the more able farmers, a sharecropping contract emerges endogenously in a state of equilibrium. Interestingly, the optimal share of production for the tenant in this case has to be a trade-off between the gains accrued from shirking and leaving the relationship after a given period and the gains from not shirking and being taken on again with a fixed-rent contract following a period of screening. This trade-off clearly depends on the farmers’ time preferences. Allen (1985) shows that, given the usual interest rates that apply in less developed countries, the optimal share has to be close to one-half.

Another argument calling into question the aforementioned rationale for sharecropping is that the theory of contracts predicts that optimal incentive contracts should depend on output in general in a nonlinear way. However, nonlinear contracts imply that different tenants would face different marginal prices for their production, giving opportunities for arbitrage and incentives to collude among farmers. Linear contracts may then be a way to avoid this problem in environments where monitoring harvest and trade between tenants may be difficult. Moreover, the gains represented by the use of nonlinear contracts may not be worth the potential additional costs of implementing them.

In addition to such attempts to determine the rationale of sharecropping, the expected effect of this kind of rural organization on agricultural innovation and development has been investigated. The adoption of innovations in agriculture in developing countries in particular has been a major preoccupation. Whether the contractual form affects the adoption of innovations, and if so how, have been the subjects of much investigation.

Sharecropping within the principal–agent paradigm

Most theoretical analysis of sharecropping contracts has been cast within the principal–agent paradigm, in which the landlord is generally considered to be the principal having the bargaining power to make a take-it-or-leave-it offer to the agent (the tenant). This analysis does not explain the decision of the landlord to delegate the use of land and the way landlords and tenants meet in the land rental market. It is only recently that these decisions have been taken into account in the analysis of sharecropping contracts, from both empirical and theoretical points of view. In this light, let us consider a model where the agricultural production function is linearly homogenous in land area (as generally admitted: see Stiglitz, 1974, and Otsuka, Chuma and Hayami, 1992) because agriculture is a spatial activity and induces constant returns to scale in the cultivated area. For a fixed amount of land, denote \( y \) the agricultural output of the next crop period, \( e \) the tenant's work effort (which can be considered as a measure of efficient labour time), \( x \) a state variable as, for example, land fertility at the beginning of the agricultural period, and define an agricultural production function \( f \) such that \( y = \varepsilon f(x, \theta) \) where \( \varepsilon \) is a multiplicative positive random variable with mean one representing weather uncertainty. The effort \( e \) can represent labour tasks or other agricultural inputs and can be multidimensional. Its cost is \( C(e) \).

Assume also that an investment function controls land fertility dynamics such that the next period land fertility is \( g(x, \theta) \) (adding a multiplicative positive random variable with mean one to represent the influence of the weather or other externalities on land fertility or ground quality would not change the following results). According to the contract signed, the principal pays the agent \( T(y) = \alpha y + \beta \). The contract parameters \( (\alpha, \beta) \) allow the landlord to propose different kinds of contact, from a fixed-wage
contract where $\alpha = 0$, $\beta = w$ with $w$ the wage, to a fixed-rent contract where $\alpha = 1$, $\beta = -R$ with $R$ the rent paid to the landlord, through sharecropping contracts where $0 < \alpha < 1$ and $\beta$ can be zero or not. Concerning preferences, we define $U(T(y)) - C(e)$ and $-T(y)$ the agent's and principal's utility functions. We assume that $U$ is increasingly concave because of risk aversion, while we treat the principal as risk neutral.

**Moral hazard in sharecropping**

When the agent's actions are unobservable to the principal or monitoring costs are prohibitively high, a moral hazard problem arises leading to effort shirking by the agent. The worker chooses his effort level to maximize his expected utility, given the terms of the contract and his outside wage opportunities. Thus, for a crop season, the principal proposes a contract to maximize his welfare given the agent's incentive compatibility ($IC$) constraint and its individual rationality ($IR$) constraint guaranteeing him an exogenous reservation utility denoted $U$. The maximization programme of the landlord can thus be written as

$$\max_{\alpha, \beta} \mathbb{E}[(1 - \alpha) y - \beta]$$

subject to

$$e^* \in \arg \max_e EU(\alpha y + \beta) - C(e)$$

(1)

$$EU(\alpha y + \beta) - C(e^*) \geq \bar{U}$$

(2)

Denoting $f_e$ and $f_{ee}$ the first and second derivatives of the production function with respect to effort, we can show that the solution to this programme is such that the individual rationality constraint ($IR$) is binding and the optimal share of production $\alpha^*$ satisfies the following equation
where $\varepsilon_\alpha$ is the derivative of effort with respect to the share of output $\alpha$ received by the tenant and that satisfies $0 < \frac{\varepsilon U'_{\varepsilon}}{U'} < 1$. Moreover, with concavity of production with effort and convexity of cost of effort, the optimal share $\alpha^*$ is strictly lower than 1, thus corresponding to a sharecropping contract.

The exact form of the contract depends on both the properties of $U$ and $f$, and the magnitude of uncertainty. First, the greater the (compensated) labour supply elasticity, that is, the more sensitive the worker is to incentives, the greater is the optimal share $\alpha^*$, that is, the closer is the optimal contract to a rental contract. Second, the trade-off between incentives and risk sharing depends on the riskiness of production through $\varepsilon$ and on on risk preferences through $U$. With some assumptions on the distribution of $\varepsilon$ or on the shape of $U$, it can be shown that the optimal share is lower for more risk-averse agents or more risky environments (Stiglitz, 1974). At the limit, if the tenant is risk neutral, then $\alpha^* = 1$ and a pure rental contract will be used. Conversely, the greater the risk aversion and the greater the risk, the closer the optimal contract is to a pure wage contract ($\alpha^* = 0, \beta^* > 0$). These predictions constituted the focus of many empirical tests that involved examining the determinants of the choice between sharecropping and fixed-rent contracts. A large number of empirical tests (Braido, 2005) have failed to provide evidence that the risk-sharing trade-off could explain the choice between fixed rent and sharecropping.

Also, these optimal sharecropping contracts ($0 < \alpha^* < 1, \beta^*$) involve a fixed payment $\beta^*$ (either to or from the landlord). In practice, many contractual relations may have an implicit or explicit provision calling for such fixed payments. For example, payments from the landlord to the worker to finance stipulated inputs, like fertilizer, can be interpreted in this manner. However, the empirical observation and measurement of such fixed transfers is generally difficult, which explains why they have not been used for empirical testing of the theory.

In some contexts, given the relative paucity of evidence that the risk-sharing trade-off could explain the determinants of contract choice between fixed rent and sharecropping, other explanations related to transaction costs inherent to landlord–tenant relationships have been offered. One of the most significant transaction costs that seem to plague land rental contracts is linked to the question of land quality maintenance and investment. The risk-sharing argument remains completely silent about investment and land-maintenance problems that were often raised in transaction cost approaches with respect to land-rental contracts. Moreover, as already pointed out by Johnson (1950) and even Adam Smith, the problem of land-fertility maintenance and land overuse can also be cited to explain the choice of contract by landlords. In fact, although observable, land fertility may not be contractible. It may also elude verification due to the complexity of specifying the agricultural tasks related to land-quality maintenance and to difficulties in objectively measuring land quality. A moral hazard problem in land maintenance may thus appear. Delegating farming may lead to land overuse if the landlord and tenant do
not have the same opportunity cost of usage of land (Allen and Lueck, 1993). A share contract may then curb the farmer's incentive to exploit land attributes. One way to see this in the previous model is to take into account the value of the land in the landlord's objective. The landlord will then anticipate the consequences of delegating the use of land for the future returns obtained, since the tenant's actions may affect the future land value. The land value $v(z)$, an increasing function of the land fertility index $z$, can be seen as the result of the expected discounted sum of all future profits obtained by the landlord for a given plot of land of quality $z$. Then, if the objective of the landlord is now

$$\max_{\alpha, \beta} \mathbb{E}[(1 - \alpha) y - \beta + v(z)]$$

subject to $(IC)$ and $(IR)$, the optimal share of output between the landlord and tenant (Dubois, 2002) is the solution to

$$\alpha^* = 1 + v'(z) \frac{g_e}{f_e} - \left(1 - \frac{E \epsilon U'}{EU'}\right) \frac{f}{E \alpha f e}$$

where $z = g(x, e)$. With risk neutrality of the tenant, the optimal share is thus below 1 if the effort of production reduces land fertility ($g_e < 0$) because

$$\alpha^* = 1 + v'(z) \frac{g_e}{f_e}.$$

The contract here shows low-powered incentives and generally corresponds to a sharecropping contract even if there is no risk-sharing issue.

**Multitasks and contract repetition in sharecropping**

But other features of agricultural activity and contractual relationships have been used to explain the observation of sharecropping. Several forms of multitask moral hazard models and dynamic considerations provide interesting insights into this form of contracting. First, the multitask moral hazard model of Holmström and Milgrom (1987), applied to sharecropping for example by Luporini and Parigi (1996), shows that low-powered incentives can be obtained as a way to mitigate the substitution of effort across tasks that cannot be monitored by the landlord even without risk.
aversion of the tenant. Luporini and Parigi (1996) consider the two distinct production tasks of subsistence crops and cash crops. In another kind of multitask model, with limited liability of the tenant instead of risk aversion, Ghatak and Pandey (2000) show that a sharecropping contract can be optimal when there is joint moral hazard in effort and in risk factor for output. Other quite different models with multiple labour inputs explain sharecropping differently according to a number of features that can be observed from time to time. In Bardhan and Srinivasan (1971) or Eswaran and Kotwal (1985), both the landowner and the tenant provide labour input. In Roumasset and Uy (1987), a model with an investment task, a production task and two periods provides a study in the reduction of agency costs by monitoring. Bardhan (1989, ch. 7) and Braverman and Stiglitz (1986) have a sharecropping model with a fertilizer input and non-observable labour effort. They determine the efficient incentives on both separable inputs through production sharing and cost sharing.

The other significant dimension of the landlord–tenant relationship that may explain the form of contracts is the fact that these contracts are often repeated and may have variable duration. The repetition of relationships between a landlord and a tenant actually called into question the rationale of supposedly short-term contracts of sharecropping generally observed empirically. Bardhan (1989, ch. 8) uses a two-period model to show the trade-off between production incentives, enhanced in the initial period by the threat of dismissal by the landowner, and land improvement incentives that decrease with a more powered contract. Dutta, Ray and Sengupta (1989) and Bose (1993) study a number of long-term contracts between landowners and landless peasants where infinitely repeated relationships with threats of eviction are examined. Eviction threats can actually serve as an incentive device in repeated sharecropping contracts (Banerjee, Gertler and Ghatak, 2002; Banerjee and Ghatak, 2004). Moreover, in a repeated moral hazard relation, spot-contract sequences may allow the outcomes of long-term contracts, which are Pareto-superior to short-term agreements, to be implemented (Fudenberg, Holmström and Milgrom, 1990; Malcomson and Spinnewyn, 1988).

Sharecropping is also sometimes considered to be part of a ‘tenancy ladder’ in agriculture allowing landless wage workers to become farmers before they become landlords. The farmer's financial constraints and limited liability may then play a significant role in explaining access to land rental markets and contractual forms (sharecropping with variable share or fixed-rent contracts) proposed by the landlord (Shetty, 1988; Ray and Singh, 2001; Laffont and Matoussi, 1995). In Laffont and Matoussi (1995), risk-neutral farmers are offered a sharecropping contract with more or fewer incentives rather than a fixed-rent contract, due to financial constraints that restrict the amount of working capital the tenant can use as affected by the rent and the share of inputs to be paid at the beginning of the crop season.

Finally, many other forms of sharecropping contracts, including some side transfers or those interlinked with credit (Mitra, 1983; Braverman and Stiglitz, 1982) or involving state contingent informal gifts and transfers (Sadoulet, Fukui and de Janvry, 1994), exist and may sometimes completely change the efficiency properties of such contracts. Thus, considerable care and attention should be devoted to describing contractual agreements so as to study such organizations and possibly recommend policy reforms for land rental markets.

Sharpe, William F. (born 1934)

Steven N. Durlauf
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

William Sharpe, 1990 co-winner of the Nobel Prize in economics, is one of the founders of the modern theory of finance. His most famous work involves the development of the capital asset pricing model (CAPM), which is now one of the fundamental tools for understanding equilibrium risk–return relationships for different assets.

Keywords

capital asset pricing model; Euler equations; finance; Markowitz, H. M.; mean variance analysis; Miller, M.; risk and return; Sharpe, W. S.; Sharpe ratio; single factor models; single index models

Article

William F. Sharpe is one of the founders of the modern theory of finance. Born in Boston in 1934, Sharpe received his BA in economics from UCLA in 1955. After graduation and military service, Sharpe joined the Rand Corporation and simultaneously pursued his Ph.D. from UCLA, which he received in 1961. He joined the department of economics at the University of Washington–Seattle in 1961, remaining until 1968. After a two-year stint at UC Irvine, he joined the Stanford Business School, where he remained for the rest of his career. In addition to his scholarly pursuits, he has been an active consultant for financial firms as well as textbook writer.

Sharpe's most famous contribution to economics is his development of the capital asset pricing model (CAPM). This work developed in two stages (Varian, 1993, provides a very clear discussion of the evolution of Sharpe's work on CAPM). First, mentored by Harry Markowitz, who was also at Rand, Sharpe studied the question of the construction of efficient portfolios in the presence of a riskless asset. This led to Sharpe's study of what he dubbed ‘single factor’ models but which are now more often called ‘single index’ models, in which the holding return on a given asset is a linear function of the return on the market portfolio. The single factor approach provides important computational advantages in
constructing optimal portfolios of the type studied by Markowitz. This doctoral dissertation research was subsequently published in *Management Science* in 1963 as ‘A Simplified Model for Portfolio Analysis’. The analysis of single factor asset return models as a short cut to efficient portfolio construction was followed by Sharpe's investigation of what equilibrium risk–return relationships will emerge in a market of rational agents with mean/variance preferences, leading to his celebrated 1964 *Journal of Finance* paper ‘Capital Asset Prices – A Theory of Market Equilibrium Under Conditions of Risk’. The demonstration that the riskiness of an asset is determined not by the variance of its holding return but rather by the now celebrated 'beta' of the asset, defined as the covariance of that holding return with the holding return on the market portfolio as a whole divided by the standard deviation of the market portfolio, is now a canonical idea in economics and is the basis for much of the modern theory of asset pricing. The underlying economic ideas of the CAPM find modern analogs in the use of Euler equations to characterize equilibrium expected asset returns. The main difference in Euler equation approaches from Sharpe's original formulation in this later work is the relaxation of the assumption that market participants have mean variance preferences with respect to asset returns; in its place explicit consumption-based utility functions are used. It is interesting to note that Sharpe's single factor model embodied the CAPM risk–return relationship by construction. Sharpe's Nobel Prize acceptance speech, published as Sharpe (1991b), is interesting for encapsulating his assessment of the model. See capital asset pricing model for discussion of the model in detail as well as its intellectual history; as Sharpe notes in his Nobel autobiography, a number of researchers were working on similar ideas to his. Sharpe's subsequent research has spanned a wide range of issues in finance. Perhaps most noteworthy, Sharpe's interest in understanding risk and return relationships led to his development, initially in the context of mutual fund evaluation, of what is now called the Sharpe ratio, first discussed in his 1966 *Journal of Business* paper ‘Mutual Fund Performance’. (Sharpe called it the reward to variability ratio.) The ratio is measured by taking the difference between the expected return on an asset (or portfolio) and a benchmark security and dividing by the standard deviation of this difference. When the benchmark security is riskless, the Sharpe ratio provides a simple characterization of the return to risk. Sharpe (1994) gives a nice summary of the statistic and its interpretation. These achievements led to Sharpe's receipt, with Merton Miller and Harry Markowitz, of the 1990 Nobel Memorial Prize in economics as one of the ‘pioneers in the theory of financial economics and corporate finance’. Varian (1993) provides a lovely discussion of why this joint award was so merited.

Shephard, Ronald William (1912–1982)

W.E. Diewert
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

cost functions; distance function; duality; homothetic production function; index numbers; production functions; Shephard, R. W.; Shephard's lemma

Article

Shephard was born in Portland, Oregon, on 22 November 1912 and died in Berkeley, California, on 22 July 1982.
He received his BA in Mathematics and Economics in 1935 and his Ph.D. in Mathematics and Statistics in 1940 at the University of California at Berkeley.
During the years 1943–6 he was a statistical consultant at the Bell aircraft corporation. In the years 1949–51 he worked under the direction of Oskar Morgenstern of Princeton University, producing his path-breaking work, Cost and Production Functions (1953). During 1950–2, he was a senior economist at the RAND Corporation and during 1952–6 he was the manager of the systems analysis department at the Sandia Corporation. From 1957 to 1980 he was a Professor of Industrial Engineering and Operations Research at the University of California at Berkeley.
Shephard made several fundamental contributions to economics. He was the first to rigorously derive a duality between cost and production functions; that is, given a knowledge of either function, the other may be derived from it. He also introduced the distance function to the economics literature in the course of establishing his duality theorems; the distance function is used to define a theoretical index number concept due to Malmquist. Shephard was also the first to derive the derivative property of the cost function (or Shephard's Lemma) starting from the cost function (the derivations by Hicks and Samuelson started from the production or utility function). Shephard also appreciated the econometric implications of Shephard's Lemma.
Shephard also defined the concept of a homothetic production or utility function: a function is homothetic if it is a monotonic transform of a linearly homogeneous function. He also deduced the implications of a homothetic function for its dual cost function.
Shephard also realized the importance of the assumption of homogeneous weak separability for index
number and aggregation theory. Finally, Shephard postulated an ingenious system of axioms or properties for a production function and then was able to deduce the classical law of diminishing returns to a subset of the factors as a theorem.

shrinkage-biased estimation in econometrics

George G. Judge
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The maximum likelihood estimation principle, unbiasedness and hypothesis testing serve as foundation stones for much that goes on in the lives of theoretical and applied econometricians. In this context, the purpose of these words and other symbols is to review the statistical implications of pursuing these estimation and inference goals and to suggest superior alternatives.

Keywords

estimation; Gauss–Markov theorem; inference; James and Stein estimator; least squares; linear models; maximum likelihood estimator; maximum likelihood; multivariate estimation; pretest estimation; semiparametric estimation; shrinkage-biased estimation in econometrics; Stein rule estimator; testing in econometrics

Article

In economics much empirical research proceeds in the context of incomplete subject matter theories and data based on sampling designs not devised by or known to the researcher. This leads to economic or econometric models in the form of ill-posed inverse problems, and partial or incomplete data, and brings a range of uncertainty to the data-processing and information-recovery process in general and the estimation and inference process in particular. In practice, procedures such as preliminary test statistics, tuning parameters and perhaps a bit of magic are invoked to identify a particular econometric-statistical model on which to base estimation and inference process. Given the uncertainty surrounding the model-discovery and post-data estimation and inference tasks, one basis for coping with or reducing the entropy level is to focus on the statistical implications of shrinkage estimation and the possibilities for combining competing estimation problems. The objective is to demonstrate estimation and inference methods that are free of subjective choices and tuning parameters and that have superior risk performance. In the process we demonstrate simple estimators that are uniformly and non-trivially superior over the unknown parameter space to conventional parametric and pretest estimators used by most applied econometrics researchers.

1 The conventional statistical model and estimator base

In econometrics the most widely used estimation and inference techniques are based on linear statistical models and maximum likelihood (ML) and least squares concepts. These estimation and inference methods are supported by a body of theory that dates back over two centuries to Gauss and Legendre and includes the often cited Gauss–Markov theorem with its best linear unbiased estimator conclusion – a conclusion that appears to be generally accepted by
applied econometricians. However, for the economic researcher who is interested in parameter estimation this statistical property, which is right on average, may have limited usefulness and also negative statistical implications. It is to these questions that we now turn.

In econometrics, many multivariate estimation problems can be reduced to the canonical form where \[ \mathbf{b} = (b_1, b_2, \ldots, b_K)' \] is a K variate normal random vector with \( \mathbf{b} \sim N_K(\mathbf{b}, \Sigma_b) \). The mean vector \( \beta \) is unknown and the covariance \( \Sigma_b \) is usually assumed to be known up to a constant of proportionality. One common problem that gives rise to the above is estimating the location vector \( \beta \) for the linear statistical model when we observe a vector \( y \) such that \( y = \mathbf{X}\beta + \mathbf{e} \), where \( \mathbf{e} \sim N(0, \sigma^2 I_T) \) and \( \delta(b) = \left( \mathbf{X}' \mathbf{X} \right)^{-1} \mathbf{X}' y \) is the maximum likelihood estimator (MLE) with covariance \( \Sigma_b = \sigma^2 \left( \mathbf{X}' \mathbf{X} \right)^{-1} \). The objective is to estimate the unknown vector \( \beta \) by an estimator \( \delta(b) \) under the sum of squares of error loss measure

\[
L(\beta, \delta(b)) = \|\beta - \delta(b)\|^2 = \sum_{i=1}^{K} (\beta_i - \delta(b_i))^2
\]

where the unknown loss is a function of both parameters and data. The usual evaluation of the estimator \( \delta(b) \) makes use of the risk function.

\[
\rho(\beta, \delta(b)) = E^b [L(\beta, \delta(b))] = E^b [\|\beta - \delta(b)\|^2]
\]

(1.1a)

where superscripts denote the random quantity over which the expectation is to be taken for fixed \( \beta \). Under (1.1), the maximum likelihood estimator \( \delta(b) = b \) is minimax and has constant risk \( \rho(\beta, \delta(b)) = tr\Sigma_b = \sigma^2 tr\left( \mathbf{X}' \mathbf{X} \right)^{-1} \).

1.1 The Stein alternative

The first hint of difficulty for the MLE \( \delta(b) \) in estimating the multivariate normal mean under quadratic loss (1.1) was when Stein (1955) demonstrated for the orthonormal symmetric case, \( \Sigma_b = \sigma^2 \left( \mathbf{X}' \mathbf{X} \right)^{-1} = I_K \), that the conventional estimator \( \delta(b) \) is inadmissible when \( K \geq 3 \). This means there exists another estimator, say \( \delta^S(b) \), where \( \rho\left( \delta^S(b), \beta \right) \leq \rho(\delta(b), \beta) = K \) for all \( \beta \) and \( \rho\left( \delta^S(b), \beta \right) < \rho(\delta(b), \beta) = K \), for some \( \beta \). In other words, under the usual measure of statistical performance, there is a superior estimator. Stein's inadmissibility proof did not go on to suggest the components of a risk dominating alternative estimator.

1.1.1 The James and Stein shrinkage estimator

Given the inadmissibility result that suggested there may be under quadratic loss other estimators that risk dominate
the MLE, \( b \), James and Stein (1961) demonstrated the estimator

\[
\delta^S(b) = \left( 1 - \frac{K - 2}{||b||^2} \right) b
\]

that has uniformly smaller risk than \( b \). This estimator makes the adjustment in the MLE, \( b \), a smooth and known function of the data. The mean of (1.2) is

\[
E[\delta^S(b)] = b - (K - 2)E\left[ \frac{1}{\chi^2_{(K+2, \lambda)}} \right] b
\]

(1.2a)

with risk

\[
\rho(\delta^S(b), \beta) = K - (K - 2)^2E\left[ \frac{1}{\chi^2_{(K, \lambda)}} \right]
\]

(1.2b)

where \( \chi^2_{(K+2, \lambda)} \) is a non-central chi square random variable with non centrality parameter \( \lambda = \beta' \beta / 2 \) (see Judge and Bock, 1978). When \( \beta = 0 \) the risk of (1.2) is 2 and increases to \( K \), the risk of the MLE, \( b \), as \( \beta' \beta \rightarrow \infty \). Consequently, for the values of \( \beta \) close to the origin the risk gain may be considerable.

The James and Stein estimator (1.2) combines the MLE, \( b \), and the restricted-fixed vector, \( \beta = 0 \), and shrinks \( b \) toward the null mean vector, \( \beta = 0 \). A more general formulation that introduces explicitly an arbitrary origin, considers a fixed mean vector \( r \), and an estimator of the form

\[
\delta^S_F(b) = \left( 1 - \frac{(K - 2)}{||b - r||^2} \right) (b - r) + r
\]

(1.3)

which shrinks \( b \) toward the target vector \( r \in \mathbb{R}^K \). This estimator has bias and risk characteristics in line with the James and Stein estimator (1.2).

If \( \sigma^2 \) is unknown, the optimal James and Stein estimator may be written as
where \( s^2 / \sigma^2 = (T - K) \hat{\sigma}^2 / \sigma^2 \) has a \( \chi^2_{T-K} \) random variable distribution that is independent of \( b \). Since \( b' \hat{b} / \sigma^2 \) is distributed as a \( \chi^2_K \), the optimal James and Stein estimators (1.4) may be rewritten as

\[
\delta^s(b) = \left[ 1 - \frac{(K - 2)}{(T - K + 2)} \right] \left( s / b' b \right) b
\]

(1.5)

where \( \bar{u} = b' \hat{b} / \left( K \hat{\sigma}^2 \right) \) is the likelihood ratio statistic which has an F distribution with \( K \) and \( (T - K) \) degrees of freedom and non-centrality parameter \( \lambda = b' \hat{b} / 2 \sigma^2 \). Thus the shrinkage of the MLE is determined by the data and the hypothesis vector, which in this case is, \( \bar{b} = 0 \). The larger the value of the F test statistic, the smaller is the adjustment made in the MLE. It will be useful to keep in mind this continuous likelihood ratio shrinkage estimator when we discuss pretest estimators in Section 2.

Some of the Stein-like shrinkage estimators have desirable properties from both sampling theory and Bayesian inference points of view. For examples, when \( \sigma^2 \) is unknown the empirical Bayes counterpart is

\[
\delta^B(b) = \left[ 1 - \frac{(K - 2)}{(T - K)} \right] \left( s / b' b \right) b
\]

(1.6)

This estimator is dominated by (1.4).

1.1.2 A positive Stein shrinkage rule

Although under quadratic loss Stein rules improve on the minimax MLE and are themselves minimax, they are not admissible and other superior shrinkage rules exist. One such estimator is the positive Stein rule estimator.

\[
\delta^{+s}(b) = \left( 1 - \frac{c}{||b||^2} \right) b I_{[c, \infty)} (||b||^2) = b - \left( 1 \wedge \frac{c}{||b||^2} \right) b
\]

(1.7)

where \( a \wedge b = \min(a, b) \). Under this formulation, Baranchik (1964) demonstrated that for \( (K - 2) \leq c < 2(K - 2) \) the positive rule estimator (1.7) uniformly improves on the James and Stein estimator (1.2) and thus proves its
inadmissibility. There is no one value of $c$ that is optimal, but Efron and Morris (1973) have demonstrated that rules that restrict $c$ to $[(K-2), 2(K-2)]$, dominate shrinkage rules of $c$ in $[(0,(K-2))]$. Although the positive rule estimator (1.7) is minimax under quadratic loss, it too is inadmissible.

For the more general non-symmetric case where $\Sigma_b$ is just some positive definite symmetric matrix, the class of pseudo Stein–Bayes rules, $\delta^*(b)$, having uniformly smaller risk than the MLE, $\delta(b)$, is very large. For example, if we let $(K-2) / (T-K+2) = a$ and $s = (T-K)^2$, we have the following Stein-type estimator proposed by Judge and Bock (1978, p. 240):

$$\delta(b, s) = \left(1 - \frac{as}{b'X'Xb}\right)b$$

(1.8)

which, under squared loss is minimax if

$$0 \leq a \leq 2 \left(\text{tr}\left(X'X\right)^{-1}d_L^{-1} - 2\right) / (T-K+2)$$

and

$$\text{tr}\left(X'X\right)^{-1} > 2d_L,$$

where $d_L$ is the smallest characteristic root of $X'X$. To prevent overshrinking, the positive rule estimator $\delta(b, s)^+ = c^+b$, which dominates $\delta(b, s) = cb$, where $c^+ = \max\{c, 0\}$, should be used (Judge and Bock, 1978, p. 246).

1.1.3 Implications

In the previous subsections we have considered the problem where the econometrician wishes to estimate the parameters of a $K$ dimensional vector $\beta = (\beta_1, \beta_2, \ldots, \beta_K)'$, where $\beta$ is the mean of an independent normal random vector $b \sim N(\beta, I_K)$ and $\beta$ is unknown. For this problem James and Stein (1961) have demonstrated for $K \geq 3$ that the estimator

$$\delta^*(b) = \left(1 - (K-2) / \|b\|^2\right)b$$

(1.9)

is uniformly better than the MLE, $b$, under quadratic loss. This result holds for a range of linear statistical models and corresponding ML estimators. Given the high esteem in which the MLE is held, this seems at first blush to be impossible. In this estimator the estimate of each $\beta_i$ depends not only on $b_i$, but also on the other $b_j$ whose distributions are apparently independent of $b_i$. The result is a risk improvement in the MLE regardless of the values of $\beta_i$. The reaction of statisticians and econometricians to this seeming magic has been less than overwhelming. However, after a half century, using this shrinkage idea as one way of dealing with model uncertainty seems to be firmly established and, as we see in the next section, has led to the more general idea of combining estimation problems (Efron and Morris, 1973).

1.2 Combining estimation problems
The variants of the James and Stein estimators discussed in section 1.1 achieve their risk advantages by shrinking to a fixed vector. Another alternative is shrinking to a random vector and in this context Lindley (1962) suggested the estimator

\[
\delta^2(b) = \bar{b} + \left\{ 1 - (K - 3) / \|b\|^2 \right\} (b - \bar{b})
\]  

(1.10)

that shrinks toward the grand mean \( \bar{b} \). This estimator dominates the MLE competitor when \( K \geq 4 \) and does especially well risk-wise when the \( b_j \) are near each other. Shrinking toward a random vector suggests consideration of two estimation problems and two corresponding estimators that may have different sampling characteristics. Moving in this direction, Green and Strawderman (1991), in the spirit of the James and Stein estimator, proposed an estimator that involves the best weighted linear combination of two estimation problems, where ‘best’ is defined in terms of quadratic loss. An important point in their formulation is that the quadratic loss criterion is introduced up front and not considered as a result of the estimation process.

Although the Stein-rules of Section 1.1 may be developed from an empirical Bayes base (Judge and Bock, 1978, pp. 173–5), how the shrinkage rule (1.2) came about is a mystery. To make the combining rule transparent we develop the weighted linear combination estimator in some detail. For expository purposes, we continue to consider the orthonormal statistical model

\[
y = X\beta + e; \quad e \sim \left( 0, \sigma^2 I_n \right) \text{ and } X'X = I_K
\]  

(1.11)

and the following ML estimator \( \hat{b} = \hat{\beta} = \left( X'X \right)^{-1} X'y \sim \left( \beta, \sigma^2 I_K \right) \), and a biased competitive estimator, \( \tilde{b} \sim \left( \beta + \delta, \tau^2 I_K \right) \), where \( \delta \) is a bias vector and \( \tau^2 < \sigma^2 \). For convenience assume \( \sigma^2 \) and \( \tau^2 \) are known. The objective is to determine the best linear combination of \( \hat{\beta} \) and \( \tilde{\beta} \) where performance is evaluated in terms of quadratic loss. Under quadratic loss the risk of \( \hat{\beta} \) is \( \sigma^2 K \) and the risk of \( \tilde{\beta} \) is \( \tau^2 K + \delta'\delta \). This suggests that over the parameter space \( \hat{\beta}, \tilde{\beta} \) the risk functions of the two estimators may cross.

Given this situation, the question is whether there exists a weighted linear combination of the two estimators that leads to a combined estimator

\[
\gamma(\hat{\beta}, \tilde{\beta}) = \alpha\hat{\beta} + (1 - \alpha)\tilde{\beta}
\]  

(1.12)

that risk dominates \( \hat{\beta} \). The risk of the linear combination of the two estimators \( \gamma(\hat{\beta}, \tilde{\beta}) \) is
\[ p(\hat{\beta}, \tilde{\beta}, \beta) = \alpha^2 \sigma^2 K + (1 - \alpha)^2 (\tau^2 K + \delta \delta) \]

(1.13)

and the value of the mixing parameter \( \alpha \) that minimizes (1.13) must satisfy

\[ \frac{dp(\hat{\beta}, \tilde{\beta}, \beta)}{d\alpha} = -\alpha \left( \sigma^2 K + \tau K + \delta \delta \right) + (\tau^2 K + \delta \delta) = 0 \]

(1.14)

such that

\[ \alpha = \frac{\tau^2 K + \delta \delta}{\sigma^2 K + \tau^2 K + \delta \delta} \]

(1.15)

Consequently, we may write the minimum risk combination of the two estimators in (1.12) as

\[ \gamma(\hat{\beta}, \tilde{\beta}, \beta) = \frac{(\tau^2 K + \delta \delta)}{\sigma^2 K + \tau^2 K + \delta \delta} \hat{\beta} + \frac{\sigma^2 K}{\sigma^2 K + \tau^2 K + \delta \delta} \tilde{\beta} \]

(1.16)

Since

\[ \mathbb{E} \left[ \left\| \hat{\beta} - \tilde{\beta} \right\|^2 \right] = \sigma^2 K + \tau^2 K + \delta \delta \]

if we substitute \( \left\| \hat{\beta} - \tilde{\beta} \right\|^2 \) for its expected value (Judge and Bock, 1978, p. 175), we may rewrite (1.16) as

\[ \gamma(\beta, \tilde{\beta}, \beta) = \tilde{\beta} + \left( 1 - \sigma^2 K / \left\| \hat{\beta} - \tilde{\beta} \right\|^2 \right) (\hat{\beta} - \tilde{\beta}) \]

(1.17)

which is in the form of a shrinkage estimator, where \( \hat{\beta} \) is shrunk toward the biased estimator \( \tilde{\beta} \), with \( K \) as an approximation for the best linear combination of \( \hat{\beta} \) and \( \tilde{\beta} \).
In the context of Section 2 it is straightforward to demonstrate that \( \gamma(\hat{\beta}, \beta, \beta) \) risk dominates the MLE, \( \hat{\beta} \), with \( K - 2 \) as the uniformly best combination. Building on this work, Judge and Mittelhammer (2004) generalized the orthonormal independent estimator combining problem and developed natural adaptive semiparametric estimation and inference methods for dependent estimators. The resulting semiparametric estimators are free of parametric choices and tuning parameters, and have good asymptotic and finite sample properties and superior risk performance. Extending Stein-like estimation to include a random shrinkage vector greatly extends the applicability of combining type estimators for a range of problems in econometric theory and practice.

2 Traditional pretest estimation

When there is uncertainty about the econometric model and thus the appropriate restrictions or hypothesis to impose, a traditional way to proceed is by statistical hypotheses testing based on the data at hand. The econometric literature abounds with exact and approximate tests for identifying sins of omission or commission relative to a variety of possibly false models. Although the two-stage estimation rule that results is used routinely in applied work, the econometric literature is strangely silent as to the statistical properties of the resulting two-stage estimator, or its sequential counterpart. To see the possible statistical significance of this two-stage process, continue with the orthonormal linear statistical model and notation used in Section 1.2 and follow Judge and Bock (1978; 1983). Under the statistical model and a fixed vector \( r \) and the MLE, \( \hat{\beta} \) we may use likelihood ratio procedures to test the null hypothesis \( H_0: \beta = r \) against the hypothesis \( \beta \neq r \), by using the test statistic

\[
\mathbf{u} = \left( \hat{\beta} - r \right) / K \hat{\sigma}^2, \quad (2.1)
\]

which, if the hypotheses (restrictions) are correct, is distributed as a central F random variable with \( K \) and \( T - K \) degrees of freedom. Of course if the restrictions are incorrect \( \mathbb{E} \left[ \hat{\beta} - r \right] = (\beta - r) = \delta \neq 0 \), and \( u \) is distributed as a non-central F with non-centrality parameter \( \lambda = \left( \beta - r \right)' (\beta - r) / 2\sigma^2 = \delta' \delta / 2\sigma^2 \). As a test mechanism the null hypothesis is rejected if \( u \geq F_{\alpha}(K, T - K) = c \), where \( c \) is determined for a given level of the test \( \alpha \) by

\[
\int_{c}^{\infty} dF(\kappa, T - K) = F_{\alpha}(\kappa, T - K) \geq c = \alpha. \]

This means that by accepting the null hypothesis we use the restricted least squares estimator \( \hat{\beta}^* = r \) as our estimate of \( \beta \), and by rejecting the null hypothesis \( \beta - r = \delta = 0 \) we use the unrestricted least squares estimator, \( \hat{\beta} \). The estimate that results is dependent upon a preliminary test of significance and this means the estimator used by many applied workers is of the form

\[
\hat{\beta}^* = \begin{cases} 
\hat{\beta}^* & \text{if } u < c, \\
\hat{\beta} & \text{if } u \geq c. 
\end{cases} \quad (2.2)
\]

Alternatively the estimator may be written as

\[
\hat{\beta}^* = I_{(0, c)}(u) \beta^* + I_{[1, \infty)}(u) (\hat{\beta} - I_{(0, c)}(u) (\hat{\beta} - r)) \\
(2.3)
\]

where \(I_A(u)\) is an indicator function that takes the value 1 when \(u \in A\) and takes the value 0 otherwise. This specification means that in a repeated sampling context the data, the linear hypotheses, and the selected level of statistical significance determine the combination of the two estimators that is chosen. From (2.3) the mean of the pretest estimator is

\[
E[\hat{\beta}^*] = \beta - E[I_{(0, c)}(u) (\hat{\beta} - r)] \\
(2.4)
\]

which by theorem 2.1 in Judge and Bock (1978, p. 71) may be expressed as

\[
E[\hat{\beta}^*] = \beta - \delta P\left[ \frac{\chi^2_{(K+2, \lambda)}}{\chi^2_{(T-K)}} \leq \frac{cK}{(T-K)} \right] \\
(2.5)
\]

Consequently, if \(\delta = 0\), the pretest estimator is unbiased. This fortunate outcome aside, the size of the bias is affected by the probability of a random variable with a non-central F distribution being less than a constant, which is determined by the level of the test, the number of hypotheses, and the degree of hypothesis error, \(\delta\) or \(\lambda\). Since the probability is always equal to or less than one, the bias of the pretest estimator is equal to or less than the bias of the restricted estimator \(\beta^*\). Following Judge and Bock (1978, p. 70) and using the discontinuous estimator rule (2.3), we may express the risk function for the pretest estimator, \(\hat{\beta}^*\), as

\[
\rho(\beta, \hat{\beta}^*) = E\left[ (\hat{\beta}^* - \beta)'(\hat{\beta}^* - \beta) \right] = \sigma^2 K + (2 \delta' \delta - \sigma^2 K) P\left[ \frac{\chi^2_{(K+2, \lambda)}}{\chi^2_{(T-K)}} \leq \frac{cK}{(T-K)} \right] - \delta' \delta P\left[ \frac{\chi^2_{(K+4, \lambda)}}{\chi^2_{(T-K)}} \leq \frac{cK}{(T-K)} \right] \\
(2.6)
\]

Defining the terms in brackets as L(2) and L(4), we may write (2.6) compactly as

\[
\rho(\beta, \hat{\beta}^*) = \sigma^2 K + (2 \delta' \delta - \sigma^2 K) L(2) - \delta' \delta L(4) \\
(2.6)
\]
where $1 > L(2) > L(4) > 0$. From the risk function (2.6) the following characteristics of the pretest estimator $\hat{\beta}^*$ emerge: (i) if the restrictions are correct and $\delta = 0$, the pretest estimator has a smaller risk than the ML estimator $\hat{\beta}$ at the origin, $\delta = 0$, and the risk depends on the level of significance $\alpha$ and correspondingly the critical value of the test $c$; (ii) as the hypothesis error $\delta$ or $\lambda$ grows, the risk of the pretest estimator $\hat{\beta}^*$ increases, obtains a maximum after exceeding the risk of the MLE, $\hat{\beta}$, and then monotonically decreases to approach $\sigma^2 K$, the risk of the MLE; (iii) as the hypothesis error $\hat{\beta} - r = \delta$ increases and approaches infinity, the risk of the pretest estimator approaches $\sigma^2 K$, the risk of the MLE, from above; and (iv) the risk of the pretest estimator, $\hat{\beta}^*$, varies with $\alpha$ the chosen level of significance. Thus, if one is to use the estimator $\hat{\beta}^*$, the question as to the optimal level of significance $\alpha$ remains. Finally, we note that Sclove, Morris and Radhakrishman (1972) demonstrated that the Stein-rule estimator

$$\delta U^*(\hat{\beta}) = I_{[c, \infty)}(u) \left( 1 - c^* / u \right) (\hat{\beta} - r) + r$$

where $c^* = (T - K)(K - 2)K^{-1}(T - K + 2)^{-1}$ and $u$ is the likelihood ratio statistic defined in (2.1), is under quadratic loss uniformly superior to the pretest estimator, $\hat{\beta}^*$, thus proving its inadmissibility.

3 Concluding remarks

Post-data evaluation procedures constitute a rejection of the concept of a true econometric model for which econometric theory provides a basis for estimation and inference. In this context, if a researcher is willing to forgo the property of unbiasedness, the Stein family of nonlinear biased estimation rules provides, under quadratic loss and conditions normally found in practice, a uniformly superior alternative. These estimators that shrink maximum likelihood estimates towards zero or some predetermined coordinate enjoy good statistical properties from both sampling theory and Bayesian points of view. Extension of the Stein-rule idea to weighted linear combining estimation problems leads to estimators that can be recommended from the standpoint of simplicity, generalizability and efficiency, and robustness over distribution assumptions and loss functions. If, in an information-theoretic context, one wishes to leave the parametric Stein-rule family, minimum divergence estimators that involve reference and subject distributions and a choice of distance measures offer attractive semiparametric estimation and inference alternatives (Mittelhammer et al., 2005).

Estimators that evolve by a two-stage estimation and then hypothesis-testing process lead to estimation rules that are (i) risk inferior, over a large range of the parameter space, to the data-based maximum likelihood estimator, and (ii) uniformly risk-inferior to Stein-rule alternatives. Recognizing this unfortunate situation, one of my colleagues once remarked that pretest estimation (single or repeated hypothesis tests) is the biggest unreported scandal in inferential statistics. My only quibble with this statement is that the statistical implications of pretesting have been reported for over a half-century. Hypothesis testing is like an addictive drug and has led econometricians to produce a plethora of...
conditional test statistics, to higher consumption of old and new hypothesis tests, and to model-discovery processes that lead to pretest estimators with negative and unknown sampling performance. Perhaps it is time for econometricians to just say ‘no’!

Sidgwick, Henry (1838–1900)

Barton Schultz
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Henry Sidgwick is usually regarded as the third greatest classical utilitarian, after Jeremy Bentham and John Stuart Mill, and his masterpiece *The Methods of Ethics* (1874) is a classic of philosophical ethics. But Sidgwick was a many-sided late Victorian intellectual who should also be counted, with Alfred Marshall, as one of the leading figures in the Cambridge School of economics.

S.; Palgrave, R.; Palgrave's Dictionary of Political Economy; Pigou, A.; public goods; Sidgwick, E. (née Balfour); Sidgwick, H.; socialism; utilitarianism; welfare economics

Article

Henry Sidgwick was a Victorian-era philosopher, ethicist, classicist, economist, political and legal theorist, parapsychologist, educational reformer, and literary critic who spent his entire working life at Cambridge University, becoming a central figure in the early Cambridge School of economics. Educated at Rugby and Cambridge, where he studied classics and mathematics and joined the secret discussion society known as the Apostles, he eventually, in 1883, achieved the status of Knightbridge Professor of Moral Philosophy. With his wife, Eleanor Mildred Sidgwick (née Balfour), he helped found both the Society for Psychical Research and Newnham College, Cambridge, one of England's first colleges for women.

Sidgwick published widely, but his major books during his lifetime were *The Methods of Ethics* (first edition 1874), *The Principles of Political Economy* (first edition 1883), and *The Elements of Politics*.
Sidgwick, Henry (1838–1900) : The New Palgrave Dictionary of Economics (first edition 1891). Best known as an ethical philosopher, he was also very influential in other areas, particularly economics. He worked extensively with the Cambridge and London Charity Organization Societies, and in 1885 he was elected president of the economics and statistics section of the British Association; he also contributed to the first *Dictionary of Political Economy*, edited by R. Palgrave, advised his university on economic policy, and appeared as an expert witness for various government committees on economic policy matters.

**The Cambridge School**

Sidgwick's importance as an economic thinker has often been underestimated, in part because of his stormy relationship with Alfred Marshall, who is generally regarded as the founder of the Cambridge School (Groenewegen, 1995). Marshall harshly opposed Sidgwick as a ‘University politician’ and criticized his economic work, but Sidgwick clearly played a vital role in shaping both Marshall and their Cambridge context (Backhouse, 2006; Schultz, 2004). He was, as much as Marshall, caught up in the so-called marginalist revolution:

> as Jevons had admirably explained, the variations in the relative market values of different articles express and correspond to variations in the comparative estimates formed by people in general, not of the total utilities of the amounts purchased of such articles, but of their final utilities; the utilities, that is, of the last portions purchased. (Sidgwick, 1901, p. 82)

But Sidgwick was more involved than Marshall in the methodological debates of the time, seeking to balance both deductive and inductive approaches, and he was also wary of the evolutionary metaphors and talk of ‘economic biology’ to which Marshall was given. Much the better philosopher, Sidgwick's reflective, qualified utilitarianism and analysis of public goods and the role of the state anticipated early 20th-century welfare economics. Indeed, the welfare economics of Marshall's designated successor, A. C. Pigou, was more in line with Sidgwick's views than with Marshall's (O'Donnell, 1979; Backhouse, 2006). As early as 1913, J.S. Nicholson noted that, not only did Pigou 'apply the same general principle of utility, but the main trend of the argument is the same' (Nicholson, 1913, p. 420). Baumol (1965) complained that Sidgwick's overall approach and 'penetrating discussion' of the 'Pigouvian problem' (the possible divergence between private and social benefits and costs) was 'largely unrecognized', and quoted from book III of the *Principles*, where Sidgwick argues that 'there is no general reason' for supposing that it will always be the case that 'the individual can always obtain through free exchange adequate remuneration for the services he is capable of rendering to society' since, among other things, 'there are some utilities which, from their nature, are practically incapable of being appropriated by those who produce them or who would otherwise be willing to purchase them’ (for example, lighthouses, improvements in climate).

Yet even the accounts of Sidgwick's work that recognize his significance often tend to stress different accomplishments. Blaug (1985, p. 479) suggests that the *Principles* may have been the first work ‘to question the traditional idea that technical change is necessarily capital-using’. Stigler (1982, p. 41), when discussing how Edgeworth, Sidgwick and Marshall gave currency to the work of Cournot and
Dupuit on monopoly and oligopoly, remarked that Sidgwick's *Principles* ‘has two chapters (bk II, ch. IX and X) which are among the best in the history of microeconomics, dealing with the theories of human capital and noncompetitive behavior’. Chapter IX concludes that:

> the possessors of capital, real and personal, as well as persons endowed with rare natural gifts, are likely to have – by reason of their limited numbers – important advantages in the competition that determines relative wages; in consequence of which the remuneration of such persons may – and in England often does – exceed the wages of ordinary labour by an amount considerably larger than is required to compensate them for additional outlay or other sacrifices; such excess tending to increase as the amount of capital owned by any individual increases, but in a ratio not precisely determinable by general considerations. (Sidgwick, 1901, p. 337)

Chapter X investigates how and when self-interested action will lead to combination, and it provocatively argues – beyond Mill and against ‘any economist of repute’ – that in many ordinary cases it is possible for workers to combine and win higher wages without such gain having ‘any manifest tendency to be counterbalanced by future loss’. More generally, and anticipating current analyses of labour markets as involving bargaining processes, Sidgwick argues that, when it comes to wage controversies:

> Economic science cannot profess to determine the normal division of the difference remaining, when from the net produce available for wages and profits in any branch of production we subtract the minimum shares which it is the interest of employers and employed respectively to take rather than abandon the business and seek employment for their labour and capital elsewhere. (1901, p. 355)

**Economics and ethics**

This fine-grained (but qualitative) analysis, attentive to expert opinion and the line between description and prescription, but yielding conclusions that for the times were quite sceptical or subversive in their implications, is characteristic of Sidgwick's scholarly work in general. Even his work in ethics mostly sought to set aside preaching and polemics, proceeding instead by a painstaking comparative investigation of the rational grounds for the major systematic ethical positions. His celebrated *Methods* sought, with something akin to scientific open-mindedness, ‘to consider simply what conclusions will be rationally reached if we start with certain ethical premises, and with what degree of certainty and precision’ (Sidgwick, 1907, p. viii). Sidgwick concluded that, although commonsense moral rules – do not lie, do not murder, do not break promises – could be largely derived from utilitarianism, there was a ‘dualism of the practical reason’ when it came to egoism (pursue one's own greatest good) and utilitarianism (pursue the greatest good in general), each of which was as ‘rational’ as the other. The dualism of practical reason was in key respects a philosophical representation of collective action problems, and the conception of ultimate good or happiness figuring in both egoism and utilitarianism was a subtle hedonistic account of pleasurable or desirable consciousness that made it clear how difficult
yet unavoidable interpersonal comparisons of utility could be. This conception would form the basis for Edgeworth's attempted 'hedonometry', or quantification of hedonism, revived in recent years by Kahneman (for example, Edgeworth, 1877; Kahneman, 1999).

Sidgwick himself favoured utilitarianism, though he was haunted by his inability to defend it fully. His utilitarianism nonetheless clearly (and admittedly) informed his economic views, especially when it came to the 'art' of political economy, which concerned the normative considerations that came to be called welfare economics. When it came to such normative political theory, Sidgwick largely assumed the utilitarian principle as the normative bottom line (Sidgwick, 1901). Despite their differences, Marshall was willing to give Sidgwick credit for his 'art', calling the third book of Sidgwick's *Principles* by 'far the best thing of its kind in any language' (in Pigou, 1925, p. 7). He also expressed an admiration for a broader orientation they shared: ‘that we are not at liberty to play chess games, or exercise ourselves upon subtleties that lead nowhere’ (Whitaker, 1996). Neither Sidgwick nor Marshall was enthusiastic about formalization for formalization's sake.

Still, it is not clear precisely what Marshall admired about Sidgwick's welfare economics. Although both stressed the role of education in helping to overcome poverty and economic inequality, Sidgwick arguably went beyond Marshall (and Mill) in setting out the cases of market failure, the limits of laissez-faire, and the limitations of economic analysis in general, both descriptive and normative. Backhouse (2002, p. 271) urges that the truly ‘fundamental part of Sidgwick's argument’ was distinguishing between wealth as ‘as the sum of goods produced, valued at market prices’ and wealth as ‘the sum of individuals’ utilities – what we would now term welfare’. This distinction ‘made it possible, arguably for the first time, to conceive of welfare economics as something distinct from economics in general’, while greatly complicating comparisons of utilities. Analogous arguments are evident in Sidgwick's sceptical account of the possibilities for comparing wealth in cross-cultural or trans-historical contexts. And the notion of unpurchased utilities, not measured by exchange values, allowed that, as Backhouse puts it, ‘if the marginal utility of a particular good were higher for one person than for another, total utility could be raised by redistributing goods to those who valued them most. This would leave wealth at market prices unchanged.’ Such views, conjoined with a belief in declining marginal utility, suggest serious redistributivist possibilities that both Sidgwick and Marshall downplayed:

Marshall is much more aware of the quantitative side of the problem than is Sidgwick … but no nearer a way to thinking quantitatively about how to achieve the best use of resources. They share both a philosophical viewpoint that inclines them towards egalitarianism and a conservatism that will not risk any interference with incentives, lest output be reduced. (Backhouse, 2006, p. 33)

**Economics and politics**

Perhaps Sidgwick was overly impressed by the idea that incentives were crucial to production and that complete communism would lead to splendidly equal destitution. Still, he took more gradualist forms of (market) socialism very seriously – so much so that the libertarian Hayek (1960, p. 419) could complain that Sidgwick's *Elements of Politics* scarcely ‘represents what must be regarded as the British liberal tradition and is already strongly tainted with that rationalist utilitarianism which led to socialism’. The
Elements and the Principles take the laissez-faire principle of individualism – that ‘what one sane adult is legally compelled to render to others should be merely the negative service of non-interference, except so far as he has voluntarily undertaken to render positive services’ – only as a starting point, from which to run a very long course of qualifications and exceptions: education, child care, poor relief, disease control, public works or goods (the famous lighthouse, pure research, the environment and defence), monopoly, collective bargaining, and others. Sidgwick emphasizes two cases that sharply point up the limitations of economic individualism – the ‘humane treatment of lunatics, and the prevention of cruelty to the inferior animals’ – because such restrictions hardly aim at securing the freedom of the lunatics or the animals, but are ‘a one-sided restraint of the freedom of action of men with a view to the greatest happiness of the aggregate of sentient beings’ (Sidgwick, 1919, p. 141). These are only the most conspicuous of the many difficulties with a principle that betrays a naive faith in ‘the psychological proposition that every one can best take care of his own interest’ and the ‘sociological proposition that the common welfare is best attained by each pursuing exclusively his own welfare and that of his family in a thoroughly alert and intelligent manner’.

Cautious as he was, Sidgwick (1903) was ultimately persuaded that the growth of federalism and large-scale state organizations was likely to continue, though he doubted that the social sciences were anywhere near to discovering actual laws of historical development. Moreover, even if he was cautious about economic or political socialism, he was relatively enthusiastic about ethical socialism, that is, about the possibility of humanity growing more altruistic and compassionate, regarding their labour as their contribution to the common good. He was under no illusions whatsoever, not only about the market failing to reflect claims of desert or merit, but also about the limitations of that abstraction, ‘economic man’, since historical and cultural or national context could dramatically alter the possibilities for moving beyond economic individualism. Perhaps the most disturbing and problematic aspect of his economic and political work was the way in which it lent itself to the racist and imperialistic tendencies of the British Empire (Schultz, 2004). Although he was more sceptical about claims of inherent racial differences than many of his contemporaries, he too often countenanced the possibility of such differences, accepting stereotypes about the varying fitness for physical versus mental labour of different peoples (Schultz and Varouxakis, 2005). And although on the economic side he tended to follow Turgot in doubting the material benefits of colonies, he allowed that there were other forms of remuneration involved:

> there are sentimental satisfactions, derived from justifiable conquests, which must be taken into account, though they are very difficult to weigh against the material sacrifices and risks. Such are the justifiable pride which the cultivated members of a civilised community feel in the beneficent exercise of dominion, and in the performance by their nation of the noble task of spreading the highest kind of civilization. (1919, p. 313)

It was in this highly Eurocentric manner that Sidgwick embraced the global leadership of the ‘civilised’ nations in (supposedly) spreading international law and morality and limiting the possibility of war (Sidgwick, 1898).

Sidrauski, Miguel (1939–1968)

Stanley Fischer

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

adaptive expectations; Sidrauski, M.; steady state capital intensity; superneutrality; Tobin's q; two-sector models

Article

Sidrauski was born and educated in Buenos Aires. He entered the University of Chicago Ph.D. programme in 1963, completed his dissertation in 1966, and accepted an assistant professor appointment at MIT. He died of cancer in September 1968, leaving his wife, Martha, and two-month old daughter, Carmela.

Sidrauski is best known in economics for his article ‘Rational Choice and Patterns of Growth in a Monetary Economy’ (1967a), based on his dissertation written under the supervision of Hirofumi Uzawa and Milton Friedman. The model is one of an economy with a representative intertemporally maximizing household, which derives instantaneous utility from both consumption and the holding of real balances. The thesis contains a careful discussion of the device of putting money in the utility function. The household can hold capital as well as money. Sidrauski derives necessary conditions for a maximum, and then studies the dynamics and steady states of inflation and capital accumulation in the model.

The key result is that steady state capital intensity is invariant to the rate of monetary expansion, and thus that money is superneutral between steady states. Sidrauski indicates in his thesis, which extends the paper in several directions, that the superneutrality result changes if money is given a productive role in the economy. In the dynamic analysis he assumes that expectations of inflation are adaptive.

In a non-maximizing money-and-growth model (1967b) Sidrauski confirms the Tobin result that an increase in the growth rate of money increases steady state capital intensity. This is based on the effects of an increase in the growth rate of money in reducing consumption. Sidrauski shows also in this paper that, with adaptive expectations, an increase in the growth rate of money first causes capital accumulation to fall and only later to increase, taking capital intensity above its initial level.

He published four other articles, including one on exchange rate determination, and a book, Monetary...

The book, written jointly with Duncan Foley and published posthumously in 1970, develops a three-asset (money, bonds and capital) two-sector Tobinesque growth model. The two sector structure gives a key role in the investment process to the relative price of capital, $p_k$, which is Tobin's $q$. The authors succeed in making the model answer questions about the effects on growth and inflation of policy changes such as fiscal expansion, increases in the growth rate of all outside assets, and open market operations. The model has not been widely used despite its usefulness and versatility; this may be because the full employment assumption makes it unattractive for use as a cyclical model, and the absence of explicit maximizing assumptions makes it unattractive to many who study long-term growth.

In his two years at MIT Sidrauski established himself as an excellent teacher and adviser, and as an economist of outstanding promise. Milton Friedman's eulogy (1969) speaks not only of his technical skill and promise, but also of his personal warmth and generosity. It concludes:

The death of this young man is a grievous loss to our profession and to the world. Here was a man who would have pushed out the frontiers of our subject, would have changed and added to economic analysis, would have enlightened and informed generations of students – struck down at the very beginning of his career, full of promise but as yet almost bereft of fulfillment.

sieve extremum estimation

Xiaohong Chen
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Semi-nonparametric models are more flexible and robust than parametric models, but are more complex due to the presence of infinite dimensional unknown parameters. This article describes the method of sieve extremum estimation of semi-nonparametric models, which is a general method of optimizing an empirical criterion function over a sequence of approximating parameter spaces (that is, sieves). Widely used sieve spaces and criterion functions are presented as examples, including the sieve M-estimation, series estimation, and sieve minimum distance estimation as special cases. Existing results are cited on asymptotic properties and applications of the method.

Keywords

ARCH models; artificial neural networks; chaos; Engel curve; generalized method of moments; polynomials; maximum likelihood; measurement error models; nonparametric models; semi-nonparametric models; series estimation; sieve extremum estimation; sieve minimum distance; simultaneous equations; splines; spurious regressions; treatment effect; wavelets

Article

1 Introduction

In econometrics literature, a model is called parametric if all of its parameters belong to finite-dimensional parameter spaces, and a model is semiparametric if its parameters of interests belong to finite-dimensional spaces but its nuisance parameters are in infinite-dimensional spaces. For example, a parameterized joint distribution model (such as logit or probit) is a parametric one and can be estimated by the method of maximum likelihood (ML). A model that only parameterizes some moment restrictions is a semiparametric one and can be estimated by the generalized method of moments (GMM). Since economics problems are complicated, researchers often find parametric likelihood models too restrictive and sensitive to deviations from the parametric specification. Moment-based semiparametric models are less restrictive yet still subject to misspecification of parametric moments.

Due to growing availability of large economic data-sets and computational advances, nonparametric and semi-nonparametric models have become increasingly popular in both theoretical and applied econometrics. A model is nonparametric if all of its parameters are in infinite-dimensional parameter spaces, and a model is semi-nonparametric if it contains both finite-dimensional and infinite-dimensional unknown parameters of interests. For example, estimation of a conditional mean function $E[Y|X, W]$ without specifying its functional form is a nonparametric problem. If $E[Y|X, W]$ is specified as a partially linear form, $\beta^\prime X + h(W)$, with $\beta$ being unknown finite-dimensional parameter and $h()$
being unknown function, then it becomes a semi-nonparametric problem. Nonparametric and semi-nonparametric models are more flexible and robust. However, they involve infinite-dimensional parameter spaces; hence it can be computationally difficult to estimate such models using finite data sets. Moreover, even if one could solve the problem of optimizing a sample criterion over an infinite-dimensional parameter space that may not be compact, the resulting estimator may have undesirable large sample properties such as inconsistency and/or a very slow rate of convergence. To tackle the difficulties encountered in semi-nonparametric problems, the method of sieves (Grenander, 1981) optimizes an empirical criterion over a sequence of approximating parameter spaces (that is, sieves); the sieves are less complex, but their complexity grows with the sample size so as to be dense in the original space. The resulting sieve estimator is consistent under very mild regularity conditions, and can generally reach optimal rate of convergence by balancing the bias part (which diminishes as sieve complexity grows), and the standard derivation part (which grows with sieve complexity). Most commonly used sieves in economics are finite dimensional (compact) approximating parameter spaces; when such sieves are used to estimate a semi-nonparametric model, the computation is as easy as to estimate a parametric model. The sieve method is particularly convenient when unknown functions enter the criterion function (or moment condition) nonlinearly, and/or when semi-nonparametric models contain complicated endogeneity and latent heterogeneity. It can easily incorporate prior information and constraints, often derived from economic theory, such as monotonicity, convexity, additivity, multiplicity, exclusion and non-negativity. It can simultaneously estimate the parametric and nonparametric parts in semi-nonparametric models, typically with optimal convergence rates for both parts.

The method of sieves consists of two key ingredients: a criterion function and sieve parameter spaces. Both the criterion functions and the sieve spaces can be very flexible, and we shall present some examples in the next two sections.

2 Examples of sieve spaces

The infinite-dimensional unknown parameter in a semi-nonparametric model can often be viewed as a member of some function space with certain regularities (for example, having bounded derivatives, monotone, concave). Thus, many deterministic approximation results developed in mathematics can be used to suggest sieves that provide good and computable approximations to an unknown function. Here we present some commonly used sieves in economics applications. Additional ones can be found in Judd (1998), DeVore and Lorentz (1993) and Chen (2006).

2.1 Finite-dimensional linear sieves with bounded support

A sieve is called a ‘(finite-dimensional) linear sieve’ if it is a linear span of finitely many known basis functions. Linear sieves, including power series, Fourier series, splines and wavelets, form a large class of sieves that have been widely used in econometrics and statistics. We now provide some commonly used linear sieves for univariate functions with support \( \chi = [0, 1] \).

Polynomials. \( \text{Pol}(J_n) \) is the space of polynomials on \( [0, 1] \) of degree \( J_n \) or less:

\[
\text{Pol}(J_n) = \left\{ \sum_{k=0}^{J_n} a_k x^k, \ x \in [0, 1] : a_k \in \mathbb{R} \right\}.
\]

Trigonometrics. \( \text{TriPol}(J_n) \) is the space of trigonometric polynomials on \( [0, 1] \) of degree \( J_n \) or less:
CosPol\((J_n)\) is the space of cosine polynomials on \([0,1]\) of degree \(J_n\) or less:

\[
\text{CosPol}(J_n) = \left\{ a_0 + \sum_{k=1}^{J_n} a_k \cos(k \pi x), x \in [0, 1] : a_k \in \mathbb{R} \right\}.
\]

SinPol\((J_n)\) is the space of sine polynomials on \([0,1]\) of degree \(J_n\) or less:

\[
\text{SinPol}(J_n) = \left\{ \sum_{k=1}^{J_n} a_k \sin(k \pi x), x \in [0, 1] : a_k \in \mathbb{R} \right\}.
\]

We note that the classical trigonometric sieve, \(\text{TriPol}(J_n)\), is well suited for approximating periodic functions on \([0,1]\), while the cosine sieve, \(\text{CosPol}(J_n)\), is well suited for approximating aperiodic functions on \([0,1]\) and the sine sieve, \(\text{SinPol}(J_n)\), can approximate functions vanishing at the boundary points (that is, when \(h(0)=h(1)=0\)).

Splines. Let \(J_n\) be a positive integer, and let \(t_0, t_1, \ldots, t_{J_n}, t_{J_n+1}\) be real numbers with \(0 = t_0 < t_1 < \cdots < t_{J_n} < t_{J_n+1} = 1\). Partition \([0,1]\) into \(J_n+1\) subintervals \(I_j = [t_j, t_{j+1}), j=0, \ldots, J_n-1, \) and \(I_{J_n} = [t_{J_n}, t_{J_n+1}]\). We assume that the knots \(t_1, \ldots, t_{J_n}\) have bounded mesh ratio:

\[
\frac{\max_{0 \leq j \leq J_n} (t_{j+1} - t_j)}{\min_{0 \leq j \leq J_n} (t_{j+1} - t_j)} \leq \epsilon \text{ for some constant } \epsilon > 0.
\]

(2.1)

Let \(r \geq 1\) be an integer. A function on \([0,1]\) is a spline of order \(r\), equivalently, of degree \(m \equiv r - 1\), with knots \(t_1, \ldots, t_{J_n}\) if the following hold: (i) it is a polynomial of degree \(m\) or less on each interval \(I_j, j=0, \ldots, J_n\); and (ii) (for \(m \geq 1\)) it is \((m-1)\)-times continuously differentiable on \([0,1]\). Such spline functions constitute a linear space of dimension \(J_n + r\). For detailed discussions of univariate splines, see de Boor (1978) and Schumaker (1981). For a fixed integer \(r \geq 1\), we let \(\text{Spl}(r, J_n)\) denote the space of splines of order \(r\) (or of degree \(m \equiv r - 1\)) with \(J_n\) knots satisfying (2.1). Since

\[
\text{Spl}(r, J_n) = \left\{ \sum_{k=0}^{r-1} a_k x^k + \sum_{j=1}^{J_n} b_j \max\{x - t_j, 0\}^{r-1}, x \in [0, 1] : a_k, b_j \in \mathbb{R} \right\},
\]
we also call Spl\((r, J_n)\) the polynomial spline sieve of degree \(m \equiv r - 1\).

### 2.2 Finite-dimensional linear sieves with unbounded support

In semi-nonparametric econometric applications, sometimes the parameters of interest are functions with unbounded supports. Here we present three finite-dimensional linear sieves that can approximate functions with unbounded supports well. In the following we let \(L^2(\chi, \omega)\) denote the space of real-valued functions \(h\) such that

\[
\int_\chi |h(x)|^2 \omega(x) \, dx < \infty
\]

for a smooth weight function \(\omega : \chi \mapsto (0, \infty)\).

**Orthogonal wavelets.** Let \(m \geq 0\) be an integer. A real-valued function \(\phi\) is called a ‘father wavelet’ of degree \(m\) if it satisfies the following: (i) \(\int_\chi \phi(x) \, dx = 1\); (ii) \(\phi\) and all its derivatives up to order \(m\) decrease rapidly as \(|x| \to \infty\); (iii) \(\{\phi(x - k) : k \in \mathbb{Z}\}\) forms a Riesz basis for a closed subspace of \(L^2(\mathbb{R}, \omega)\). A real-valued function \(\psi\) is called a ‘mother wavelet’ of degree \(m\) if it satisfies the following: (i) \(\int_\chi \psi(x) \, dx = 0\) for \(0 \leq k \leq m\); (ii) \(\psi\) and all its derivatives up to order \(m\) decrease rapidly as \(|x| \to \infty\); (iii) \(\{2^{j/2} \psi(2^j x - k) : j, k \in \mathbb{Z}\}\) forms a Riesz basis of \(L^2(\mathbb{R}, \omega)\).

Given an integer \(m \geq 0\), there exist a father wavelet \(\phi\) of degree \(m\) and a mother wavelet \(\psi\) of degree \(m\), both compactly supported, such that for any integer \(j_0 \geq 0\), any function \(g\) in \(L^2(\mathbb{R}, \omega)\) has the following wavelet \(m\)-regular multiresolution expansion:

\[
g(x) = \sum_{k=0}^{\infty} a_{j_0 k} \phi_{j_0 k}(x) + \sum_{j=j_0}^{\infty} \sum_{k=-\infty}^{\infty} b_{j k} \psi_{j k}(x), \quad x \in \mathbb{R},
\]

where

\[
a_{j k} = \int_\mathbb{R} g(x) \phi_{j k}(x) \, dx, \quad \phi_{j k}(x) = 2^{j/2} \phi(2^j x - k), \quad x \in \mathbb{R},
\]

\[
b_{j k} = \int_\mathbb{R} g(x) \psi_{j k}(x) \, dx, \quad \psi_{j k}(x) = 2^{j/2} \psi(2^j x - k), \quad x \in \mathbb{R},
\]

and \(\{\phi_{j_0 k} : k \in \mathbb{Z}; \psi_{j_0 k} : j, k \geq j_0, k \in \mathbb{Z}\}\) is an orthonormal basis of \(L^2(\mathbb{R}, \omega)\); see Meyer (1992, theorem 3.3). We consider the finite-dimensional linear space spanned by this wavelet basis. For an integer \(J_n > j_0\), set

\[
\text{Wave}(m, 2^{J_n}) = \left\{ \sum_{k=0}^{2^{j_0}} a_{j_0 k} \phi_{j_0 k}(x) + \sum_{j=j_0}^{j_n} \sum_{k=0}^{2^{j-1}} b_{j k} \psi_{j k}(x), \quad x \in \mathbb{R} : a_{j_0 k}, b_{j k} \in \mathbb{R} \right\}
\]

or, equivalently,
Hermite polynomials. Hermite polynomial series \( \{ H_k; k=1,2,\ldots \} \) is an orthonormal basis of \( L_2(\mathbb{R}, \omega) \) with \( \omega(x) = \exp\left\{ -x^2 \right\} \). It can be obtained by applying the Gram–Schmidt procedure to the polynomial series \( \{ x^k; k=1,2,\ldots \} \) under the inner product \( (f, g)_\omega = \int_{\mathbb{R}} f(x) g(x) \exp\left\{ -x^2 \right\} dx \). Let \( \text{HPol}(J_n) \) denote the space of Hermite polynomials on \( \mathbb{R} \) of degree \( J_n \) or less:

\[
\text{HPol}(J_n) = \left\{ \sum_{k=1}^{J_n+1} a_k H_k(x) \exp\left\{ -\frac{x^2}{2} \right\}, x \in \mathbb{R}; a_k \in \mathbb{R} \right\}.
\]

Then any function in \( L_2(\mathbb{R}, \omega) \) can be approximated by the \( \text{Pol}(J_n) \) sieve as \( J_n \to \infty \).

Laguerre polynomials. The Laguerre polynomial series \( \{ L_k; k=1,2,\ldots \} \) is an orthonormal basis of \( L_2([0, \infty), \omega) \) with \( \omega(x) = \exp\{-x\} \). It can be obtained by applying the Gram-Schmidt procedure to the polynomial series \( \{ x^k; k=1,2,\ldots \} \) under the inner product \( (f, g)_{\omega} = \int_0^\infty f(x) g(x) \exp\{-x\} dx \). Let \( \text{LPol}(J_n) \) denote the space of Laguerre polynomials on \([0, \infty)\) of degree \( J_n \) or less:

\[
\text{LPol}(J_n) = \left\{ \sum_{k=1}^{J_n+1} a_k L_k(x) \exp\left\{ -\frac{x}{2} \right\}, x \in [0, \infty); a_k \in \mathbb{R} \right\}.
\]

Then any function in \( L_2([0, \infty), \text{leb}) \) can be approximated by the \( \text{LPol}(J_n) \) sieve as \( J_n \to \infty \).

### 2.3 Finite-dimensional nonlinear sieves

A popular class of nonlinear sieves in econometrics is single hidden layer feedforward artificial neural networks (ANN) (see for example, Barron, 1993; Hornik et al., 1994; Chen and White, 1999). A typical ANN sieve is the one with a sigmoid activation function:

\[
\text{sANN}(k_n) = \left\{ \sum_{j=1}^{k_n} \alpha_j \sigma(y_j^T x + y_{0,j}); y_j \in \mathbb{R}^d, \alpha_j, y_{0,j} \in \mathbb{R} \right\}.
\]
where $S: \mathbb{R} \rightarrow \mathbb{R}$ is a sigmoid activation function, that is, a bounded non-decreasing function such that $\lim_{u \to -\infty} S(u) = 0$ and $\lim_{u \to \infty} S(u) = 1$. Some popular sigmoid activation functions include

- **heaviside** $S(u) = 1 \{u \geq 0\}$
- **logistic** $S(u) = 1/(1+\exp(-u))$
- **hyperbolic tangent** $S(u) = (\exp(u) - \exp(-u))/\exp(u) + \exp(-u))$
- **Gaussian sigmoid** $S(u) = (2\pi)^{-1/2} \int_{-\infty}^{u} \exp(-(y^2/2)) \, dy$

Additional examples of nonlinear sieves include spline sieves with data-driven choices of knot locations (or free-knot splines), and wavelet sieves with thresholding (Donoho et al., 1995). Nonlinear sieves are more flexible and may enjoy better approximation properties than linear sieves; see for example, Chen and Shen (1998) for the comparison of linear vs. nonlinear sieves.

### 2.4 Shape-preserving sieves

There are many sieves that can preserve the shape, such as non-negativity, monotonicity and convexity, of the unknown function to be approximated. Here we mention one of such shape-preserving sieves.

**Cardinal B-spline wavelets.** The cardinal B-spline of order $r \geq 1$ is given by

$$ B_r(x) = \frac{1}{(r-1)!} \sum_{j=0}^{r} (-1)^j \binom{r}{j} \max(0, x - j) \, r^{-1}, $$

for all $x \in \mathbb{R}$, which is crucial to preserve the shape of the unknown function to be approximated. See Chui (1992, ch. 4) for a recursive construction of cardinal B-splines and their properties. Denote

$$ \text{SplWav}(r-1, 2^j n) = \left\{ \sum_{k=-\infty}^{\infty} \alpha_k 2^j n \left[ \frac{B_r(x - k)}{2^j} \right], x \in \mathbb{R} : \alpha_k \in \mathbb{R} \right\}. $$

Any non-decreasing continuous function on $\mathbb{R}$ can be approximated well by the $\text{SplWav}(r-1, 2^j n)$ sieve with non-decreasing sequence $\{\alpha_k\}$ (that is, $\alpha_k \leq \alpha_{k+1}$). See Anastassiou and Yu (1992) on shape-preserving wavelet sieves.

### 2.5 Infinite-dimensional (nonlinear) sieves

Most commonly used sieve spaces are finite-dimensional truncated series such as those listed above. However, the general theory on sieve extremum estimation can also allow for infinite-dimensional sieve spaces. For example, any function $\theta$ that belongs to a Hölder space $\Theta = \Lambda^p([0,1])$ with smoothness $p > 1/2$ can be expressed as an infinite Fourier series

$$ \theta(x) = \sum_{k=1}^{\infty} \left[ a_k \cos(kx) + b_k \sin(kx) \right], $$

and its derivative with fractional power $\gamma \in (0, p]$ can also be defined.
in terms of Fourier series:

\[ \theta(Y)(x) = \sum_{k=1}^{\infty} k^\gamma \left( (a_k \cos \frac{\pi k}{2} + b_k \sin \frac{\pi k}{2}) \cos(kx) + (b_k \cos \frac{\pi k}{2} - a_k \sin \frac{\pi k}{2}) \sin(kx) \right), \]

More generally, if the parameter space \( \Theta \) is a typical function space such as a Hölder, Sobolev or Besov space, then any function \( \hat{\theta} \in \Theta \) and its fractional derivatives can be expressed as infinite series of some known Riesz basis \( \{B_k(\cdot)\}_{k=1}^{\infty} \) such as splines and wavelets (see for example, Meyer, 1992). An infinite-dimensional sieve space could then take the form:

\[
\Theta_n = \{ \theta \in \Theta : \theta(\cdot) = \sum_{k=1}^{\infty} a_k B_k(\cdot), \quad \text{pen}(\theta) \leq b_n \text{ with } b_n \to \infty \text{ slowly,} \}
\]

(2.3)

where \( \text{pen}(\theta) \) is a smoothness (or roughness) penalty term, such as \( \text{pen}(\theta) = (\int |\theta^{(p)}(x)|^q dx)^{1/q} \) with \( p > 1/2 \) the smoothness of the function \( \theta \), and some \( q \geq 1 \). For example, Wahba (1990) considered smoothing spline sieve with \( q=2 \) to approximate conditional mean function; Koenker, Ng and Portnoy (1994) considered smoothing spline sieve with \( q=1 \) to approximate conditional quantile function. See Shen (1997) and van de Geer (2000) for more expressions of \( \text{pen}(\theta) \).

3 Sieve extremum estimation

Let \( \Theta \) be an infinite dimensional parameter space endowed with a (pseudo-) metric \( d \). A typical semi-nonparametric econometric model specifies that there is a population criterion function \( Q : \Theta \to \mathbb{R} \), which is uniquely maximized at a (pseudo-) true parameter \( \theta_o \in \Theta \). The choice of \( Q(\cdot) \) and the existence of \( \theta_o \) are suggested by the identification of an econometric model. The (pseudo-) true parameter \( \theta_o \in \Theta \) is unknown but is related to a joint probability measure \( P_o(z_1, \ldots, z_n) \), from which a sample of size \( n \) observations \( \{Z_t\}_{t=1}^n \), \( Z_t \in \mathbb{R}^d_z, 1 \leq d_z < \infty \), is available. Let \( \hat{Q}_n : \Theta \to \mathbb{R} \) be an empirical criterion, which is a measurable function of the data \( \{Z_t\}_{t=1}^n \) for all \( \theta \in \Theta \), and converges to \( Q \) in some sense as the sample size \( n \to \infty \).

When \( \Theta \) is infinite dimensional and possibly not compact with respect to the (pseudo-) metric \( d \), maximizing \( \hat{Q}_n \) over \( \Theta \) may not be well-defined; or even if a maximizer \( \arg\sup_{\theta \in \Theta} \hat{Q}_n(\theta) \) exists, it is generally difficult to compute, and may have undesirable large sample properties such as inconsistency and/or a very slow rate of convergence.

The method of sieves provides one general approach to resolve the difficulties associated with maximizing \( \hat{Q}_n \) over an infinite dimensional space \( \Theta \) by maximizing \( \hat{Q}_n \) over a sequence of approximating spaces \( \Theta_n \), called sieves by Grenander (1981), which are less complex but are dense in \( \Theta \). Popular sieves are typically compact, non-decreasing \( \{\Theta_n \subseteq \Theta_{n+1} \subseteq \ldots \subseteq \Theta\} \) and are such that for any \( \theta \in \Theta \) there exists an element \( \pi_n \theta \) in \( \Theta_n \) satisfying \( d(\theta, \pi_n \theta) \to 0 \) as \( n \to \infty \), where the notation \( \pi_n \) can be regarded as a projection mapping from \( \Theta \) to \( \Theta_n \).
An approximate sieve extremum estimate, denoted by $\hat{\theta}_n$, is defined as an approximate maximizer of $\hat{Q}_n(\theta)$ over the sieve space $\Theta_n$, that is,

$$\hat{Q}_n(\hat{\theta}_n) \geq \sup_{\theta \in \Theta_n} \hat{Q}_n(\theta) - O_P(\eta_n), \text{ with } \eta_n \to 0 \text{ as } n \to \infty .$$

(3.1)

When $\eta_n=0$, we call $\hat{\theta}_n$ in (3.1) the exact sieve extremum estimate. The sieve extremum estimation method clearly includes the standard extremum estimation method by setting $\Theta_n=\Theta$ for all $n$. Following White and Wooldridge (1991, theorem 2.2), one can show that $\hat{\theta}_n$ in (3.1) is well defined and measurable under mild sufficient conditions: (i) $\hat{Q}_n(\theta)$ is a measurable function of the data $\{Z_t\}_{t=1}^n$ for all $\theta \in \Theta_n$; (ii) for any data $\{Z_t\}_{t=1}^n$, $\hat{Q}_n(\theta)$ is upper semicontinuous on $\Theta_n$ under the metric $d(\cdot,\cdot)$; and (iii) the sieve space $\Theta_n$ is compact under the metric $d(\cdot,\cdot)$.

For a semi-nonparametric model, $\theta_o \in \Theta$ can be decomposed into two parts $\theta_o = (\beta_o, h_o) \in \mathbb{B} \times \mathcal{H}$, where $\mathbb{B}$ denotes a finite dimensional compact parameter space, and $\mathcal{H}$ an infinite dimensional parameter space. In this case, a natural sieve space will be $\Theta_n = \mathbb{B} \times \mathcal{H}_n$ with $\mathcal{H}_n$ being a sieve for $\mathcal{H}$, and the resulting estimate $\hat{\theta}_n = (\hat{\beta}_n, \hat{h}_n)$ in (3.1) will sometimes be called a simultaneous (or joint) sieve extremum estimate. For a semi-nonparametric model, we can also estimate the parameters of interest $(\beta_o, h_o)$ by the approximate profile sieve extremum estimation that consists of two steps:

- **Step 1**: for an arbitrarily fixed value $\beta \in \mathbb{B}$, compute $\hat{Q}_n(\beta, \hat{h}(\beta)) \geq \sup_{h \in \mathcal{H}_n} \hat{Q}_n(\beta, h) - O_P(\eta_n)$ with $\eta_n=0$ (1);
- **Step 2**: estimate $\beta_o$ by $\hat{\beta}_n$ solving $\hat{Q}_n(\hat{\beta}, \hat{h}(\beta)) \geq \max_{\beta \in \mathbb{B}} \hat{Q}_n(\beta, \hat{h}(\beta)) - O_P(\eta_n)$, and then estimate $h_o$ by $\hat{h}_n = \hat{h}(\hat{\beta}_n)$.

### 3.1 Sieve M-estimation

When $\hat{Q}_n(\theta)$ can be expressed as a sample average form $\hat{Q}_n(\theta) = \frac{1}{n} \sum_{t=1}^n l(\theta, Z_t)$, with $l: \Theta \times \mathbb{R}^d \rightarrow \mathbb{R}$ being the criterion based on a single observation, we also call the $\hat{\theta}_n$ solving (3.1) as an approximate sieve maximum-likelihood-like (M-) estimate. This includes sieve maximum likelihood (ML), sieve least squares (LS), sieve generalized least squares (GLS) and sieve quantile regression as special cases.

**Example 3.1:** (single spell duration models with unobserved heterogeneity): Let $C(\eta \beta, u, x)$ be a parametric structural distribution function of duration $T$ conditional on a scalar of unobserved heterogeneity $U=u$ and a vector of observed heterogeneity $X=x$.

The distribution of observed duration given $X=x$ is

$$F(\eta \beta, h, x) = \int C(\eta \beta, u, x) \, d\mathbb{H}(u),$$

where $\mathbb{H}$ is the distribution of unobserved heterogeneity.
where the unobserved heterogeneity $U$ is modelled as a random factor with unknown distribution function $h(\cdot)$. Let \( \{T_i, X_i\}_{i=1}^n \) be an i.i.d. sample of observations. Heckman and Singer (1984) propose sieve ML estimation of this semi-nonparametric single spell duration model with unobserved heterogeneity. Denote $\theta_\circ = (\beta_\circ, \eta_\circ) \in \Theta \times \mathcal{H}$ as the unknown true parameters, where $B$ is a compact subset in $\mathbb{R}^d \beta$ and $\mathcal{H}$ is the space of distribution functions. Let $\mathcal{H}_n$ denote a sieve for $\mathcal{H}$ such as the first-order spline sieve basis used in Heckman and Singer (1984). Then the sieve ML estimate is given by

$$
\hat{\theta}_n = \arg \max_{(\beta, h) \in \Theta \times \mathcal{H}_n} \frac{1}{n} \sum_{i=1}^n \log \left\{ \int g(T_i \beta, u, X_i) \, dh(u) \right\}.
$$

(3.2)

Series estimation is a special case of sieve M-estimation with concave criterion functions $\hat{Q}_n(\theta) = \frac{1}{n} \sum_{t=1}^n l(\theta, Z_t)$ and finite-dimensional linear sieve spaces $\Theta_n$ (that is, the sieves $\Theta_n$ are linear spans of finitely many known basis functions).

**Example 3.2:** (multivariate LS regression): We consider the series estimation of an unknown multivariate conditional mean function $\theta_\circ(\cdot) = h(\cdot) = E(Y|X = \cdot)$. Here $Z = (Y, X)$, $Y$ is a scalar, $X$ has support $X$ that is a bounded subset of $\mathbb{R}^d$, $d \geq 1$. Suppose $h_0 \in \Theta$, where $\Theta$ is a linear subspace of the space of functions $h$ with $E[h(X)^2] < \infty$. Let $l(h, Z) = -[Y - h(X)]^2$ and $Q(\theta) = -E\{[Y - h(X)]^2\}$; then both are concave in $h$ and $Q$ is strictly concave in $h \in \Theta$.

Let $\{p_{j}(X), j=1,2,\ldots\}$ denote a sequence of known basis functions that can approximate any real-valued square integrable functions of $X$ well; see the previous section for specific examples of such basis functions. Then

$$
\Theta_n = \mathcal{H}_n = \left\{ h: \mathcal{X} \rightarrow \mathcal{R}, h(x) = \sum_{j=1}^{k_n} a_j p_j(x): a_1, ..., a_{k_n} \in \mathcal{R} \right\},
$$

(3.3)

with $\dim(\Theta_n) = k_n \rightarrow \infty$ slowly as $n \rightarrow \infty$, is a finite-dimensional linear sieve for $\Theta_n$ and

$$
\hat{h} = \arg \max_{h \in \mathcal{H}_n} \frac{1}{n} \sum_{t=1}^n [Y_t - h(X_t)]^2
$$

is a series estimator of the conditional mean $h_0(\cdot) = E(Y|X = \cdot)$.

Moreover, this series estimator $\hat{h}$ has a simple closed-form expression:

$$
\hat{h}(x) = p^{k_n}(X)' (P' P)^{-} \sum_{j=1}^n p^{k_n}(X_i) Y_i, \ x \in \mathcal{X},
$$

(3.4)

with $p^{k_n}(X) = (p_1(X), ..., p_{k_n}(X))'$, $P = (p^{k_n}(X_1), ..., p^{k_n}(X_n))'$ and $(P' P)^{-}$ the Moore–Penrose generalized inverse. The estimator $\hat{h}$ given in (3.4) is called a series LS estimator.

Many popular semi-nonparametric regression models, such as the partially linear regression of Engle et al. (1986) and...
Robinson (1988), the additive regression model of Stone (1985) and Andrews and Whang (1990), can be easily estimated via the series LS estimation.

3.2 Sieve MD estimation of semi-nonparametric conditional moment models

Many economic models imply semi-nonparametric conditional moment restrictions of the form

\[ E[\rho(Z_t, \theta|X_t)] = 0, \quad \theta \equiv (\beta_0, h_0)' \]  

(3.5)

where \( \rho(\cdot;\cdot) \) is a column vector of residual functions whose functional forms are known up to unknown parameters, \( \theta \equiv (\beta_0', h_0')' \), and \( \{Z_t = (Y_t', X_t')\}_{t=1}^n \) is the data where \( Y_t \) is a vector of endogenous variables and \( X_t \) is a vector of conditioning variables. Here \( E[\rho(Z_t, \theta|X_t)] \) denotes the conditional expectation of \( \rho(Z_t, \theta) \) given \( X_t \), and the true conditional distribution of \( Y_t \) given \( X_t \) is unspecified (and is treated as a nuisance function). The parameters of interest \( \theta_0 \equiv (\beta_0, h_0)' \) contain a vector of finite dimensional unknown parameters \( \beta_0 \) and a vector of infinite dimensional unknown functions \( h_0(\cdot) = (h_{01}(\cdot), ..., h_{0q}(\cdot))' \), where the arguments of \( h_{0j}(\cdot) \) could depend on \( Y, X \), known index function \( \delta_j(Z, \beta_0) \) up to unknown \( \beta_0 \), other unknown function \( h_{0k}(\cdot) \) for \( k \neq j \), or could also depend on unobserved random variables. This class of models (3.5) includes many semi-nonparametric models with endogeneity and/or latent heterogeneity as special cases. A leading, yet difficult example is the purely nonparametric instrumental variables (IV) regression \( E[Y_{1i} - h_0(Y_{2i})|X_i] = 0 \) studied by Newey and Powell (2003), Darolles, Florens and Renault (2006), Blundell, Chen and Kristensen (2007), and Hall and Horowitz (2005). A more difficult example is the nonparametric IV quantile regression \( E[I\{Y_{1i} \leq h_0(Y_{2i})\} - \gamma|X_i] = 0 \) for some known \( \gamma \in (0,1) \) considered by Chernozhukov, Imbens and Newey (2007), Horowitz and Lee (2007) and Chen and Pouzo (2007). Both examples belong to the so-called ‘ill-posed inverse’ problems. See for example, Blundell and Powell (2003), Florens (2003) and Carrasco, Florens and Renault (2006) for additional examples of ill-posed inverse semi-nonparametric models.

Newey and Powell (2003) and Ai and Chen (2003) propose to estimate the model (3.5) by the sieve minimum distance (MD) procedure:

\[ \sup_{\theta \in \Theta_n} \hat{Q}_n(\theta) = \sup_{\theta \in \Theta_n} -\frac{1}{n} \sum_{t=1}^n \hat{m}(X_t, \theta)' \left( \hat{\Sigma}(X_t) \right)^{-1} \hat{m}(X_t, \theta), \]  

(3.6)

where \( \Theta_n \) is compact sieves, \( \hat{m}(X_t, \theta) \) is any nonparametrically consistent estimate of the conditional mean function \( m(X_t, \theta) = E[\rho(Z_t, \theta)|X = X_t] \), and \( \hat{\Sigma}(X_t) \) is a possibly nonparametrically consistent estimate of a positive definite weighting matrix \( \Sigma(X_t) \).

Example 3.3: (nonparametric external habit-based consumption asset pricing models): A consumption-based asset pricing model assumes that at time zero a representative agent maximizes the expected present value of the total utility
function \( E \left\{ \sum_{t=0}^{\infty} \delta^t u(C_t) \right\} \), where \( \delta \) is the time discount factor and \( u(C_t) \) is period \( t \)'s utility. The consumption-based asset pricing models imply that for any traded asset indexed by \( \star \), with a gross return at time \( t+1 \) of \( R_{\ell,t+1} \), the following Euler equation holds:

\[
E \left\{ M_{t+1} R_{\ell,t+1} | W_t \right\} = 1, \; \ell = 1, \ldots, N,
\]

(3.7)

where \( M_{t+1} \) is the intertemporal marginal rate of substitution in consumption, and \( E(\cdot|W_t) \) denotes the conditional expectation given the information set at time \( t \) (which is the sigma-field generated by \( W_t \)). Hansen and Singleton (1982) have assumed that the period \( t \) utility takes the power specification \( u(C_t) = [(C_t)^{1-\gamma} - 1] / [1 - \gamma] \), where \( \gamma \) is the curvature parameter of the utility function at each period, which implies the Euler equation:

\[
E \left\{ \delta^t \left( \frac{C_{t+1}}{C_t} \right)^{-\gamma} R_{\ell,t+1} - 1 | W_t \right\} = 0, \; \ell = 1, \ldots, N,
\]

(3.8)

where the unknown scalar parameters \( \delta, \gamma \) can be estimated by Hansen's (1982) GMM. However, this classical power utility-based asset pricing model (3.8) has been rejected empirically. Chen and Ludvigson (2003) combine the power utility specification with a nonparametric internal habit formation:

\[
H_t = H(C_t, C_{t-1}, \ldots, C_{t-L})
\]

(3.9)

for \( \ell = 1, \ldots, N \), where \( \gamma, \delta > 0 \) are unknown scalar preference parameters, \( h_o(\cdot) \in [0,1) \) is an unknown function and

\[
H_{t+1} = C_{t+1} h_o \left( \frac{C_t}{C_{t+1}}, \ldots, \frac{C_{t+1-L}}{C_{t+1}} \right)
\]

is the habit level at time \( t+1 \). Chen and Ludvigson (2003) have applied the
sieve method to estimate this model and its generalization which allows for internal habit formation of unknown form. Their empirical findings, using quarterly data, are in favor of flexible nonlinear internal habit formation.

3.3 Large sample properties

For an infinite-dimensional, compact parameter space $\Theta$, Gallant and Nychka (1987) derived the consistency of sieve M-estimates; Newey and Powell (2003) established the consistency of sieve MD estimates. For an infinite-dimensional, possibly non-compact parameter space $\Theta$, Geman and Hwang (1982) obtained the consistency of sieve MLE with i.i.d. data; White and Wooldridge (1991) obtained the consistency of sieve M-estimates with dependent and heterogeneous data; Chen (2006) and Chen and Pouzo (2007) established the consistency of sieve MD estimates that is applicable to general ill-posed semi-nonparametric problems.

Unfortunately, so far there is no general theory on limiting pointwise distribution of sieve extremum estimators yet. Nevertheless, such results are established for series estimators (that is, sieve M-estimators with finite-dimensional linear sieves) (see Andrews, 1991b; Newey, 1997; Huang, 2003).

There is also no general theory on data-driven choice of smoothing parameters (‘complexity of sieves’) at the time of writing. There are some results for sieve M-estimation (see, for example, Barron, Birgé and Massart, 1999; Shen and Ye, 2002). There are well developed results for series LS regression and series density estimation (see for example, Li, 1987; Hurvich, Simonoff and Tsai, 1998; Andrews, 1991a; Coppejans and Gallant, 2002; Donald and Newey, 2001). Also see Chen (2006) for a detailed survey of theories on large sample properties of sieve estimation.

signalling and screening

Johannes Hörner

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Signalling refers to any activity by a party designed to influence the perception and thereby the actions of other parties. This presupposes that one market participant holds private information that for some reason cannot be verifiably disclosed, and which affects the other participants’ incentives. The classic example of market signalling is due to Spence. Consider a labour market in which firms know less than workers about their innate productivity. Under certain conditions, some workers may wish to signal their ability to potential employers, and do so by choosing a level of education that distinguishes them from workers with lower productivity.

asymmetric information; introductory pricing; limit pricing; multiple equilibria; political competition; pooling equilibrium; screening; separating equilibrium; signalling; single-crossing conditions; signalling and screening; uniqueness; warranties

Article

Mathematical formulation

We consider here the simplest game-theoretic version of Spence’s (1973; 1974) model. A worker’s productivity, or type, is either \( \theta_H \) or \( \theta_L \), with \( \theta_H > \theta_L > 0 \). Productivity is private information. Firms share a common prior \( p = \Pr(\theta = \theta_H) \in (0, 1) \). Before entering the job market, the worker chooses a costly education level \( e \geq 0 \). Workers maximize \( U(w, e, \theta) = w - c(e, \theta) \), where \( w \) is their wage and \( c(e, \theta) \) is the cost of education. Assume that \( c(0, \theta) = 0 \), \( c(e, \theta) > 0 \), \( c\theta(e, \theta) > 0 \), \( c\theta\theta(e, \theta) < 0 \) for all \( e > 0 \), where \( c\theta(e, \cdot; \theta) \) and \( c\theta\theta(e, \cdot; \theta) \) denote the derivatives of the cost with respect to education and types, respectively, and \( c\theta\theta(e, \cdot; \theta) \) is the second derivative of cost with respect to education. The key assumption made in the literature is that on the cross-derivative: \( c\theta\theta(e, \theta) < 0 \). That is, the marginal cost is lower for a high-productivity worker. This single-crossing condition ensures that the indifference curves of a high and a low-productivity worker cross at most once, with the indifference curve of the high-productivity worker having a smaller slope where they do. See Figure 1.

Figure 1

\[
\begin{array}{c}
W \\
\end{array}
\]
\[ U(w^c e; \psi_L) = \bar{U}_L \]

\[ U(w^c e; \psi_H) = \bar{U}_H \]
To focus on signalling, assume that education does not affect productivity. If a firm assigns probability \( p(e) \) to the high-productivity worker conditional on education \( e \), the worker's expected productivity is \((1 - p(e))\theta_L + p(e)\theta_H\). If the worker accepts wage \( w \), the firm's profit is then \((1 - p(e))\theta_L + p(e)\theta_H - w\).

The basic signalling game

There is one worker and two firms. In the first stage, the worker chooses education. Education is observable. In the second stage, firms compete through wages in Bertrand-competition fashion. Following usual arguments, the wage \( W(e) \) offered and accepted equals the expected productivity of the worker, given the observed education. A (perfect Bayesian) equilibrium specifies an education function \( e^*: (\theta_L, \theta_H) \rightarrow \mathbb{R}^+ \), and a belief function \( p^*: \mathbb{R}^+ \rightarrow [0, 1] \), giving respectively the education chosen by each type and the probability assigned to a high-productivity worker conditional on each possible education level, so that the worker's choice is optimal given the wage determined by \( p^* \), and the belief function is derived from this choice using Bayes's rule whenever possible.

Either the worker chooses distinct education levels depending on his productivity or he does not. An equilibrium is separating if \( e^*(\theta_L) \neq e^*(\theta_H) \), and pooling otherwise. In the first case, education perfectly reveals productivity, so that the worker's wage equals his productivity: \( W(e^*(\theta_i)) = \theta_i \) for \( i = L, H \). In the second case, education reveals no information, and the wage is equal to his expected productivity given the prior \( p \): \( W(e^*(\theta)) = (1 - p)\theta_L + p\theta_H = E(\theta) \) for \( i = L, H \).

Observe that, in any separating equilibrium, the low-productivity worker gets the lowest possible wage. Since education is costly, this implies that he chooses no education: \( e^*(\theta_L) = 0 \). The high-productivity worker, on the other hand, gets the highest possible wage. Therefore, the corresponding education level \( e^*(\theta_H) \) must be high enough to deter the low-productivity worker from pretending he has high productivity. That is, it must be that \( e^*(\theta_H) \geq e' \), where \( e' \) solves \( \theta_L - c(0; \theta_L) = \theta_H - c(e'; \theta_L) \). At the same time, the education level \( e^*(\theta_H) \) cannot be too high, since the high-productivity worker must choose it. That it, it must be that \( e^*(\theta_H) \leq e'' \), where \( e'' \) solves \( \theta_L - c(0; \theta_L) = \theta_H - c(e''; \theta_H) \).

Single-crossing implies that the interval \( [e', e''] \) is non-empty. Indeed, since the indifference curves \( \{(e, w) : U(w, e; \theta_L) = U(w, e; \theta_H) \} \) and \( \{(e, w) : U(w, e; \theta_L) = U(w, 0; \theta_L) \} \) cross at \( (0, \theta_L) \), the point \( (e', \theta_H) \) which lies along the first one must be to the right of the point \( (e'', \theta_H) \) which lies along the second. See Figure 2. Because a high-productivity worker is more willing to trade off an increase in education to induce an increase in wage, it is possible to find a suitable education level that is worth acquiring if and only if the worker's productivity is high.

Figure 2
Each education level \( e^* \in \left[ e', e'' \right] \) can be supported in equilibrium, for suitable beliefs. For instance, by setting \( p^*(\varepsilon) = 0 \) if \( e < e^* \), and \( p^*(\varepsilon) = 1 \) otherwise, a high-productivity worker optimally chooses \( e^*_{\psi_H} = e^* \). Observe that these equilibria are Pareto-ranked. The best equilibrium outcome, involving \( e^* = e' \), is known as the Riley outcome (Riley, 1979).

The low-productivity worker is worse off than in the case in which signalling is not available. Without signalling, the worker would not acquire any education, independently of his type, and he would receive the wage \( E(\theta) \). Here, instead, the low-productivity worker earns only \( \theta_L \). Surprisingly, the high-productivity worker may also be worse off. As no
education is interpreted as evidence of low productivity, the outcome without signalling is no longer available to him in a separating equilibrium, his utility is at most \( \theta_H - c \left( e'; \theta_H \right) \).

Without signalling opportunities, his utility is \( E(\theta) - c(0; \theta_H) \). While \( E(\theta) \) tends to \( \theta_H \) as \( p \) tends to one, \( e' \) is independent of \( p \). Therefore, if \( p \) is large enough, the high-productivity is worse off. See Figure 3.

**Figure 3**

\[
U(w, e; \theta_L) = U(\theta_L, 0; \theta_L)
\]

\[
U(w, e; \theta_H) = U(\theta_H, e'; \theta_H)
\]
There is also a continuum of pooling outcomes. Let \( \hat{\theta} \) solve \( U(\theta_L, \hat{\theta}; \theta_L) = U(E(\theta), \hat{\theta}; \theta_L) \). Every level of education \( e^* \in [0, \hat{\theta}] \) can be supported by the beliefs \( \rho^*(e) = 0 \) if \( e < e^* \), \( \rho^*(e) = \rho \) otherwise. Since education is costly, we need only check that the worker prefers \( e(\hat{\theta}) = e^* (l = L, H) \) to no education at all. This is true for the low-productivity worker by definition of \( \hat{\theta} \), and follows from single-crossing for the high-productivity worker. Here as well, the outcomes are Pareto-ranked, with the best equilibrium outcome, sometimes referred to as the *Hellwig outcome*, specifying \( e^* = 0 \) (Hellwig, 1987). In addition to these separating and pooling outcomes, there also exists a continuum of equilibria in mixed strategies.

The basic screening game

While it is standard in the literature to call signalling models those in which the informed party moves first, they are closely related to screening models, in which the uninformed parties take the lead. Classic references include Rothschild and Stiglitz (1976) and Wilson (1977) in the context of insurance markets. In these models, the two firms simultaneously announce a menu of pairs \( (e, w) \). Given these contracts, the worker chooses which contract to accept, if any. We sketch here the main results of this model. An equilibrium is *separating* if the worker accepts distinct contracts depending on his type, and *pooling* otherwise.

Observe that, in equilibrium, firms must just break even. Otherwise, if the worker of type \( l = L, H \) accepts contract \( (e, w) \), a contract \( (e, w + \epsilon) \) for small \( \epsilon > 0 \) would attract both types of worker, and the firm earning less than half the aggregate profits would gain by offering it.

Also, there can be no pooling equilibrium. Because a pooling contract \( (e^*, w^*) \) would have to break even, a firm whose rival offered this contract would gain by offering a contract \( (e, w) \) specifying a higher wage and education level, accepted only by the high-productivity worker. See Figure 4.
Finally, in any separating equilibrium, wages paid must equal the worker's productivity. In particular, the contract accepted by the low-productivity worker specifies education \( e_L = 0 \) and wage \( W_L = \theta_L \). Indeed, if \( (e_L, W_L) \neq (0, \theta_L) \), then the firm whose rival offered \( (e_L, W_L) \) would gain by offering a contract with either a slightly lower wage, or a slightly lower education, independently of the worker's type accepting it. Similarly, if the wage accepted by the high-productivity worker fell short of \( \theta_H \), a firm whose rival offered the contract accepted by the low-productivity worker would gain by offering a contract specifying a slightly higher wage and education than those specified by the contract accepted by the high-productivity worker. Since \( W_i = \theta_i \), \( i = L, H \), and \( e_L = 0 \), it follows that \( e_H \) solves \( \theta_H - c(e_H, \theta_L) = \theta_L - c(0, \theta_L) \), that is, \( e_H = e^* \); if instead the low-productivity worker preferred his contract to \( (e_H, W_H) \), at least one firm would gain by offering a contract specifying a wage and education just below \( W_H \) and \( e_H \).

However, such an equilibrium need not exist for large \( p \). If \( E(\theta) - c(0; \theta_H) > \theta_H - c(e^*; \theta_H) \), the contract \( (0, E(\theta) - \epsilon) \) for small \( \epsilon > 0 \) attracts both types of workers and makes profits. Thus, if the cost of sorting outweighs the gain, no equilibrium exists. As emphasized by Riley (2001), existence requires a strengthening of single-crossing, as marginal cost must be sufficiently lower for a high-productivity worker, given \( p \). This is the same condition as earlier, under which the high-productivity worker prefers signalling to be unavailable.

While equilibria in mixed strategies exist (Dasgupta and Maskin, 1986), they have not been characterized.
To a large extent, the theoretical literature on signalling has focused on selecting among the equilibria, while the literature on screening has addressed the non-existence issue. The early literature takes the view that the screening model ignores the dynamic adjustments between firms. To account for these, Wilson (1977) and Riley (1979) define equilibria differently. A set of contracts is a Wilson equilibrium if no firm has a profitable deviation that remains profitable once existing contracts that lose money after the deviation are withdrawn, while it is a Riley, or reactive equilibrium, if no firm has a profitable deviation that remains profitable once new contracts that make money after the deviation are added. Under either definition, equilibria exist. Wilson equilibria involve some pooling, while the unique Riley equilibrium is separating. Hellwig (1987) offers a game-theoretic treatment of Wilson by modelling a second stage in which firms may withdraw any contract offered previously. In the two-type case, the Hellwig outcome can be supported as an equilibrium. Formal game-theoretic treatments of signalling appear in the 1980s. Many refinements have been applied to and inspired by the basic signalling game, shedding new light on the somewhat ad hoc selection procedures used previously. While sequential equilibrium (Kreps and Wilson, 1982) does not reduce the multiplicity of equilibria, the intuitive criterion (Cho and Kreps, 1987) selects the Riley outcome in the basic signalling model. This result, as striking as it is, has several limitations. First, uniqueness does not obtain with more types. Second, the Riley outcome is not necessarily persuasive when the probability of the high-productivity worker is nearly one. As long as this probability is less than 1, the high-productivity worker acquires education $\rho' > \rho$, independently of $p$. But if he is known to be of high productivity, we should expect him not to acquire education, as it serves no signalling purpose. Third, the motivation behind the intuitive criterion also underlies the more stringent perfect sequential equilibrium (Grossman and Perry, 1986). Yet such an equilibrium fails to exist in the situation described earlier, in which the basic screening game has no equilibrium. An alternative is offered by the concept of undefeated equilibrium (Mailath, Okuno-Fujiwara and Postlewaite, 1993), which selects the Riley outcome when it is also a perfect sequential equilibrium outcome, and the Hellwig outcome otherwise. In settings with more types, stronger refinements are needed to select the Riley outcome. These include Banks and Sobel's (1987) divinity and universal divinity, Cho and Kreps's (1987) criterion $D_1$, and Kohlberg and Mertens's (1986) stability concepts. See also Cho and Sobel (1990). It is worth pointing out that, with a continuum of types and under weak assumptions, the separating outcome is unique in the signalling model (Mailath, 1987), while no equilibrium exists in the screening model (Riley, 2001).

The single-crossing condition has been generalized to multidimensional signals by Engers (1987) for the case of screening and by Cho and Sobel (1990) and Ramey (1996) for the case of signalling. Quinzii and Rochet (1985) consider multidimensional types. Little is known about equilibria when single-crossing fails, as may occur in applications. Maskin and Tirole (1992) enlarge the set of contracts. In the screening version, firms offer contracts that let the worker choose ex post among a set of pairs $(E, W)$. In the signalling version, the worker offers such a contract to the firm. Under weak assumptions, the set of equilibrium outcomes coincides. In particular, only the Riley outcome obtains when the basic screening model has an equilibrium.

Acquiring education takes time, and there is no reason to expect firms to wait until graduation before drawing inferences. In Nöldeke and van Damme (1990) and Swinkels (1999), firms make offers before workers complete their education. Offers are public in Nöldeke and van Damme, and private in Swinkels. As the time between offers diminishes, only the Riley outcome satisfies Kohlberg and Mertens' never weak best response criterion when offers are public, while only the Hellwig outcome is a sequential equilibrium outcome when offers are private.

Following Spence's early suggestion, Nöldeke and Samuelson (1997) extend the basic signalling model by considering a dynamic model in which agents adjust their beliefs and actions to past market outcomes, and introduce perturbations into the process. The dynamic process admits at most two recurrent sets, closely related to the Riley and Hellwig outcomes. Several known refinements reappear in their characterization.

**Application**

Signalling has found many applications besides education, insurance and labour. Whenever possible, the reader is referred to surveys.

**Industrial organization**

**Finance**

http://www.dictionaryofeconomics.com.proxy.library.csi.cuny.edu/article?id=pde2008_S000129&goto=B&result_number=1555(第 8/11 页)2009-1-3 1:01:45
Myers and Majluf (1984) show that stock issues may signal the firm's value, so that the choice of financing (equity or debt) affects a firm's investment policy when the firm is better informed about returns than investors. In Bhattacharya (1979), dividends signal cash flows, as managers are better informed about those than investors. In Leland and Pyle (1977), the owner's stake signals the firm's underlying quality in an initial public offering, provided the owner is risk averse. These early applications have been extended in several directions, and their predictions empirically tested. See Allen and Morris (2001).

**Political science**

Signalling has been applied to electoral competition. Banks (1990a) shows how campaign platforms signal the candidates’ future actions if elected, while Banks (1990b) argues that agenda-setting signals the bureaucrat's private information about the ‘reversion level’ if the proposal is turned down. See Banks (1991) for a survey. Lohmann (1993) shows how individuals engage in costly political actions to signal their private information, if politicians are responsive to turnout. Prat (2002) considers a signalling game in which an interest group has private information about candidates, based on which they can offer contributions that are used as campaign advertising.

**Social norms**

Bernheim (1994) develops a theory of social conformity based on signalling. Agents are motivated both by private tastes and status. When society censures extreme preferences, consumers with centrist preferences may choose to pool, while extremists refuse to conform. Fang (2001) provides a model of social culture rich enough to endogenously generate the single-crossing condition supporting the separating equilibrium. Austen-Smith and Fryer (2005) study signalling when workers have both a social and an economic type, and education affects both the wage and their perception by their peers. Peer pressure may induce educational underinvestment by accepted types.

**Biology**

Following Zahavi's (1975) ‘handicap principle’, asserting that animal signals are reliable because they are costly, a large literature on signalling has emerged in biology. Grafen (1990) provides a game-theoretic treatment. See Maynard Smith and Harper (2003) for a survey.

silver standard

Lawrence H. Officer
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Silver was the dominant monetary standard for many centuries. It was supplanted by gold, in England in the early 18th century, in the United States in 1834, and in almost all of western Europe and in most of the British Empire in the 1870s and 1880s. With France no longer bimetallic, the exchange rate between gold-standard and silver-standard currencies fluctuated. The consequence was more countries leaving the silver standard for gold. By the First World War, China was the sole major country still on silver. US silver-purchase policy in the 1930s caused the virtual demonetization of silver worldwide.

Keywords

bimetallism; bullion; central banking; gold standard; gold-exchange standard; monometallism; seigniorage; silver standard

Article

The silver standard, the dominant monetary system for many centuries, lost much importance with the advent of the classical gold standard; and, due to US policy, residual monetary use of silver was virtually eliminated in the 1930s.

Definition of silver standard

A silver standard involves (a) a fixed silver content of the monetary unit, (b) ‘free coinage’ of silver, that is, privately owned silver in form other than domestic coin convertible into domestic silver coin at, or approximately at, the mint price (the inverse of the silver content of the monetary unit), (c) no restrictions on private parties (i) melting domestic coin into bullion, or (ii) importing or exporting silver in any form, and (d) full legal-tender status for domestic silver coin. Other forms of money may exist, but silver is the primary money. Foreign silver coin may be given
equal legal-tender status with domestic coin. Gold coin may be in circulation, but its value is in terms of the silver monetary unit and may fluctuate by weight, varying with the market gold–silver price ratio. Paper currency and deposits may exist, but, as liabilities of the issuer or bank, are payable in legal tender, that is, silver coin (or silver-convertible government or central-bank currency).

If silver (whether domestic or foreign coin, or both) constitutes the only money, then, even absent free coinage, the economy is clearly on a silver standard. This conclusion holds with gold coin circulating as well, providing it is circulating by weight or is a minor part of the money supply. A silver standard might be effective even though the monetary system is legally bimetallic. If the coinage gold–silver price ratio is sufficiently below the market ratio, then gold, undervalued at the mint, will be sold on the world market (even in the form of melted domestic coin), while silver, overvalued, will be imported and coined. Ultimately, an effective silver standard may result. Depreciation of the silver coinage involves an increased ratio of the legal (face) value of coins relative to silver content, usually by debasement (reducing the silver content, whether weight or fineness, of given-denomination coins) rather than by increasing the denomination of existing (given-weight-and-fineness) coins. In England, the penny (of sterling, 11/12th fineness) was steadily reduced in size from 24 grains in the eighth century to less than 1/3 that weight in 1601.

A silver standard, just as the gold standard, provides a constraint on the money stock. Depreciation of silver coinage was a way of escaping that constraint, even though the authority's objective typically was to increase government revenue (in the form of seigniorage) and/or to change the coinage ratio (under legal bimetallism).

Countries on silver standard to 1870

A silver standard first occurred in ancient Greece. Notwithstanding generally legal bimetallism, silver was everywhere the effective metallic standard – or at least the far-more-important coined metal in the money stock – well into the 18th century. Because of its relative scarcity and high density, gold was always much more valuable than silver on a per-ounce basis: coinage and market ratios were far above unity. So, with most transactions of low value compared with the unit of account, silver was better suited than gold to serve as a medium of exchange. In US history, ‘one dollar’ was both the smallest gold piece and the largest silver piece ever coined.

In England, from the Anglo-Saxon period until the late 13th century, the only coin in existence (with rare exceptions) was the silver penny, with 240 pence coined ideally from one pound of silver and later constituting one pound sterling (where ‘sterling,’ of course, denotes silver). This was a silver standard by default. With coinage of gold, in 1257, there was legal bimetallism; but the practice of denominating gold coins in (silver) shillings and pence was implicit recognition of an effective silver standard. Even the popular, consistently coined, (gold) guinea, first issued in 1663, was left to find its own market value in shillings and pence. However, by the turn of the 18th century, foreign gold–silver price ratios had been falling and, having been increased greatly in 1696, the British coinage ratio was not subsequently reduced enough to compensate. England went briefly on a bimetallistic standard, and then on an effective gold standard, legalized in 1774 and 1816.

In the United States, since colonial times a silver standard was in effect, based on the Spanish dollar, the primary circulating silver coin, which varied much in weight and fineness. Yet the dollar was accepted everywhere at face value in terms of local (individual-state) pound–shilling–pence units of account.
Gold coins were rated in dollars according to fine-metal content. The Coinage Act of 1792 placed the United States on a legal bimetallic standard; but the coinage ratio soon fell below the (increasing) world-market ratio. An effective silver standard resulted, until the coinage ratio was corrected in 1834. In 1870, just before Germany united and established the gold standard (using as financing the French indemnity, emanating from the Franco–Prussian War), Netherlands, Denmark, Norway, Sweden, India, China, Straits Settlements, Hong Kong, Dutch East Indies, Mexico and some German states were on a silver standard. In the 1870s these European countries (and Dutch East Indies) abandoned silver in favour of gold. By 1885 almost all of western Europe – along with the United States, Britain, its dominions and various colonies – was on gold.

Asian abandonment of the silver standard prior to the First World War

Traditionally, Asian countries preferred silver to gold for both monetary and non-monetary use, and the low market ratios in the Far East reflected that fact. The silver standard continued after 1885 in the Asian countries listed above. Further, in the 1880s the Philippines and Japan went on de facto silver. Until 1873, bimetallic France kept the world market gold–silver price ratio around a narrow band centred on the French coinage ratio of $15 \frac{1}{2}$. When France ended bimetallism in 1873, the market ratio lost its anchor and escalated tremendously. The exchange rates between silver-standard and gold-standard currencies also lost their anchor. Following the market gold–silver price ratio, silver currencies depreciated greatly with respect to gold currencies. Exports were enhanced, imports were more expensive, debt and other obligations stated in terms of gold or gold currencies increased greatly in domestic currency, domestic inflation increased, and foreign investment was discouraged due to exchange-rate instability.

The problem of a depreciating currency was especially acute for India, which had the obligation of substantial recurring sterling-denominated ‘home charges’ to Britain (for debt service, pensions, military and other equipment, and so forth). In 1893 India abandoned the silver standard, and in 1898 went on the gold-exchange standard, pegging the (silver) rupee against the pound sterling.

In 1897 Japan switched from a de facto silver standard under legal bimetallism to a monometallic gold-coin standard, using as financing the indemnity received from defeated China in the Sino–Japanese War. In 1903 the Philippines adopted a gold-exchange standard, with the (silver) peso pegged to the US (gold) dollar. The impetus was transfer of the country from Spain to the United States, thanks to US victory in the Spanish–American War.

Mexico, a large silver producer, with both commodity exporters and silver producers in favour of a continued silver standard, finally adopted a gold-coin standard in 1905. At the beginning of the First World War, the silver standard encompassed only China, Hong Kong and a few minor countries.

Termination of the silver standard

The final blow to the silver standard was delivered by the United States, ironically after it left the gold standard. In December 1933, when the (fluctuating) market price of silver was 44 cents per ounce, President Roosevelt proclaimed that US mints should purchase all new domestically produced silver at a net price (to the depositor, or seller) of 64.65 cents per ounce (half the official, but inoperative, mint
price of silver). In 1934 this policy was reinforced by the Silver Purchase Act, which directed the Treasury to purchase silver at home and abroad as long as (a) the Treasury stock of gold constituted less than one-quarter its total monetary stock, and (b) the market price did not exceed the US official mint price. Subsequently, the president ordered that all silver (with minor exceptions) then situated in the continental United States was to be delivered to US mints, at a net price of 50.01 cents per ounce. In 1935, in response to a higher foreign market price of silver (largely due to the US silver-purchase policy itself!), the president increased the net price for newly produced domestic silver to 71.11 cents.

The reason for the US silver-purchase policy was to provide a subsidy to the (politically powerful) domestic silver producers. Inadvertently, the policy effectively destroyed what remained of the silver standard. The last major country on the silver standard was China. As the gold-standard world suffered monetary and real deflation in 1929–30, the price of silver fell. The Chinese, silver-based, currency (yuan) therefore depreciated against the, gold-based, currencies of important trading partners (Britain, India, Japan). The enhanced competitiveness of export and import-competing industries, and resulting balance-of-payments surplus, prevented deflation. China lost some ‘silver protection’ in 1931, after Britain, India and Japan left the gold standard, as the yuan appreciated against the pound, rupee and yen; but the United States was still on the gold standard, and the yuan continued to fall, slightly, against the dollar. After the United States abandoned the gold standard, in 1933, the yuan appreciated against all four currencies.

While China had lost its ‘silver protection’ from the world depression, it nevertheless retained the silver standard and probably suffered less economically than its main trading partners. Disaster struck with the US silver policy of 1933–4. The huge increase in the US and market price of silver involved a corresponding appreciation of the yuan. Loss of competitiveness, balance-of-payments deficit, export of silver (and gold) to finance the deficit, and deflation followed. China had no choice but to leave the silver standard, effectively in 1934, and legally in 1935.

Other silver-standard, as well as silver-using, countries were also adversely affected by the US policy. Hong Kong followed China, and left the gold standard in 1935. Though not on the silver standard, various Latin American countries had a large silver coinage. These were token coins (face value higher than metallic-content value). Nevertheless, the high US price for silver encouraged the melting and export of these coins. The affected countries resorted to debasement and re-coining in order to retain their silver coinage.

Mexico was a special case. Silver coins constituted a high proportion of its money supply; but, as the world's largest producer of silver, Mexico benefited from a higher price for a major export. However, as other countries left the silver standard, the price of silver began to fall, and this advantage was reduced. Mexico prohibited melting or export of silver coins in 1935, and replaced the coins with paper money. Later, re-coinage occurred, and melting and export were again permitted. Yet the damage had been done, and Mexico was now on a ‘managed paper standard’, having lost the discipline provided by metallic money. In sum, in the 1930s, a US domestic-oriented policy reduced considerably such monetary use of silver as remained.

The New Palgrave Dictionary of Economics Online

Simon, Herbert A. (1916–2001)

Mie Augier
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article discusses how Simon's vision for behavioural economics (and social science generally) was found in the context of his early work in public administration and political science. It was strengthened as Simon proceeded to make contributions to economics, and found an intellectual home with the establishment of behavioural science in the 1950s.

Keywords

administrative theory; artificial intelligence; behavioural economics; bounded rationality; Carnap, R.; choice; computational capability; computer science; Cowles Commission; decision theory; econometrics; employment contracts; operations research; Organization theory; payoff function; perfect information; satisficing; Simon, H.

Article

Herbert A. Simon was born on 15 June 1916 in Milwaukee, Wisconsin, USA. He received his Ph.D. in political science from the University of Chicago in 1943, and taught at the Illinois Institute of Technology from 1942 to 1949 before going to Carnegie Mellon University in 1949, where he stayed until he died on 9 February 2001. Simon received major awards from many scientific communities, including the A.M. Turing Award (in 1975), the National Medal of Science (in 1986), and the Nobel Prize in Economics (in 1978). During his career, Simon also served on the Committee on Science and Public Policy and as a member of the President's Science Advisory Committee.

Simon made important contributions to economics, psychology, political science, sociology, administrative theory, public administration, organization theory, cognitive science, computer science and philosophy. His best known books include Administrative Behavior (1947), Organizations (1958, with James G. March), The Sciences of the Artificial (1969), Human Problem Solving (1972, with Allen Newell), and his autobiography, Models of My Life (1991). Although contributing to so many seemingly
different domains and traditions, Simon's main research interest remained the same: understanding human decision making.

**Early life**

Simon spent his early years with his parents and his older brother on the West Side of Milwaukee in a middle-class neighbourhood. Attending public schools, Simon at first intended to study biology. However, after he went on a strawberry hunting trip, and discovered that he was colour-blind (he was unable to distinguish the strawberries from the plants), he changed his mind, thinking that colour blindness would be too big a handicap in biology. He then thought briefly about studying physics, but he gave up that idea after discovering that there weren't really any major advances left to be made in physics. ‘They have all these great laws’, he said in conversation. ‘Newton had done it, no use messing around with it.’ As a result, upon finishing high school in 1933 Simon enrolled instead at the University of Chicago, with an interest in making social science more mathematical, and an intention to major in economics. In keeping with his strong wish to be independent, Simon preferred reading alone to taking classes; and as he particularly refused to take the class in accounting, which was required for graduation in economics, he majored instead in political science.

Political science wasn't physics, of course, with all its ‘great laws’. However, as a science it could encompass both theory and practice; and, being an empirical science, it had to take the data seriously. Furthermore, Simon found he was attracted to interdisciplinary thinking (in particularly psychology) in understanding political behaviour. The details of Simon's mature work differ, but the underlying ideas, interdisciplinary thinking and the necessity of bringing together theory and reality remain. Also present from the start was the essential idea of limited rationality, which would stay with Simon as he proceeded to translate his insights in political science and public administration into his work in economics, organization theory, psychology and artificial intelligence.

Early on Simon was invited by Clarence Ridley to participate as a research assistant in a project for the International City Managers’ Association (Simon, 1991, p. 64). Together with Ridley, Simon published the results of this project in several articles as well as a book, *Measuring Municipal Activities* (1938). This brought an invitation to join the University of California's Bureau of Public Administration in order to study local government. While working in Berkeley on directing a study of the administration of state relief programmes, intended to demonstrate how quantitative empirical research could contribute to understanding and improving municipal government problems (1991, p. 82), Simon was also working on an early manuscript of his thesis, which became *Administrative Behavior* (1947), intended to reforming administrative theory. The first working title of *Administrative Behavior* was ‘The Logical Structure of an Administrative Science’. Simon had intended the book to have a heavy philosophical component, in particular reflecting the influence of Rudolph Carnap. Furthermore, Simon introduced the importance of organizations to individual decision making; a theme later elaborated especially in *Organizations* (1958). ‘Human rationality’, he wrote, ‘gets its higher goals and integrations from the institutional settings in which it operates and by which it is molded. … [Therefore] … [t]he rational individual is, and must be, an organized and institutionalized individual’ (1947, pp. 101–2). Simon argued that organizations make it possible to make decisions by constraining the set of alternatives to be taken into account and the considerations that are to be treated as relevant. Organizations can be improved by improving the ways in which those limits are defined and imposed. Finally, *Administrative
Behavior criticized existing administrative theory for being based on ‘proverbs’ (often contradictory common-sense principles), a perspective he wanted to replace with a more empirically oriented outlook investigating the nature of the decision processes in administrative organizations.

It was in Administrative Behavior that Simon first systematically examined the importance of limits to human rationality. ‘The dissertation contains both the foundation and much of the superstructure of the theory of bounded rationality that has been my lodestar for nearly fifty years’ (1991, p. 86). The core chapters of this book were intended to develop a theory of human decision making which was broad and realistic enough to accommodate both ‘those rational aspects of choice that have been the principal concern of the economist, and those properties and limitations of the human decision making mechanisms that have attracted the attention of psychologists and practical decision makers’ (1947, p. xi). Bringing together insights from economics and psychology, Simon laid the foundation for the later establishment of behavioural economics and for organization theory. In Simon's view, the significance of his early work was in replacing ‘economic man’ with ‘administrative man’ by bringing insights from psychology to bear on studying decision-making processes (1947, p. xxv).

While finishing his dissertation Simon moved to Illinois Institute of Technology, in an environment in Chicago in the early 1940s where most of his fellow researchers were believers in rational decision making, Simon remained a strong advocate of the idea of limited rationality. He began to discuss his ideas with prominent economists, in particularly those connected to the Cowles Commission, a group of mathematical economists doing pioneering research in econometrics, linear and dynamic programming, and decision theory, among other things. The economists connected to the Cowles Commission included such well-known names as Kenneth Arrow, Jacob Marshak, Tjalling Koopmans, Roy Radner and Gerard Debreu, and they held regular seminars to discuss their research. During the last years of Simon's stay in Chicago he began attending the Cowles Commission seminars; this became very important to Simon both because, as he noted in his autobiography, his interaction with Cowles almost made him ‘a full time economist’ (1991, p. 140) and because several members of the Cowles Commission would become good friends. Furthermore, Simon seems to have realized that among economists the possibilities for exploring the limits of rationality were themselves limited, for only later did he proceed to construct the broad behavioural programme upon which the foundation of the psychology of decision making in behavioural science could rest. ‘In none of [the] early papers’, wrote Simon, ‘did I challenge the foundations of economic theory strongly’ (1991, p. 270).

In 1949 Simon moved to Pittsburgh to join the newly established School of Industrial Administration at Carnegie Mellon University, an early engineering school trying to become a business school. Business education at that time wasn’t oriented mostly towards research, but Simon and colleagues wanted to be different: they wanted to do research. They wanted their research to be relevant for business leaders, while at the same time emphasizing the tools of good science (Cooper, 2002). Early core courses in the programme included ‘quantitative control and business’ (consisting of basically accounting and statistics) taught by Bill Cooper, a sequence of micro and macroeconomics taught by Lee Bach, and organization theory taught by Simon. As a result of their early efforts to build up a research programme at Carnegie Mellon GSIA was picked by the Ford Foundation as one of the foremost places where the new science of behavioural economics could be developed. It became a pioneer in the establishment of business education in the United States, and must be seen as part of the Simon legacy, perhaps as important as his direct intellectual contributions.
Decision making was also the core of Simon's later work, and it became the basis of his other contributions to organization theory, economics, psychology, and computer science. Decision making, as Simon saw it, is purposeful yet not rational, because rational decision making would involve a complete specification of all possible outcomes conditional on possible actions in order to choose the single option that is best. In challenging neoclassical economics, Simon found that such complex calculation is not possible. As a result, Simon wanted to replace the assumption of global rationality in economics with an assumption that was more in correspondence with how humans make decisions, their computational limitations, and how they accessed information in their current environment (1955), thereby introducing the ideas of bounded rationality and satisficing. Satisficing is the idea that decision makers interpret outcomes as either satisfactory or unsatisfactory, with an aspiration level constituting the boundary between the two. Whereas decision makers in neoclassical rational choice theory would list all possible outcomes evaluated in terms of their expected utilities, and then chose the one that is rational and maximizes utility, decision makers in Simon's model face only two possible outcomes, and look for a satisfying solution, continuing to search only until they have found a solution which is good enough. The ideas of bounded rationality and satisficing became important for the subsequent development of economics.

The emphasis on bounded rationality introduced a more psychological and realistic assumption into the analysis. As Simon noted early on:

> [T]he first principle of bounded rationality is that the intended rationality of an actor requires him to construct a simplified model of the real situation in order to deal with it. He behaves rationally with respect to this model, and such behavior is not even approximately optimal with respect to the real world. To predict his behavior, we must understand the way in which this simplified model is constructed, and its construction will certainly be related to his psychological properties as a perceiving, thinking, and learning animal. (1957, p. 199)

Both satisficing and bounded rationality were introduced in 1955, when Herbert Simon published a paper that provided the foundation for a behavioural perspective on human decision making and introduced the ideas of satisficing and bounded rationality. The paper provided a critique of the assumption in economics of perfect information and unlimited computational capability, and replaced the assumption of global rationality with one that was more in correspondence with how humans (and other choosing organisms) made decisions, their computational limitations and how they accessed information in their current environments (1955, p. 99). In Simon's illustration of the problem, the influence of his early ideas outlined in *Administrative Behavior* is clear, echoing the view that decisions are reasoned and intendedly rational yet limited (1947). He first suggested a simple and very general model of behavioural choice which analyses choosing organisms (such as humans) in terms of basic properties to understand what is meant by rational behaviour. He introduced the simplifying assumptions (such as the choice alternatives, the payoff function, possible future states and the subset of choice alternatives which is considered, as well as the information about the probability that a particular outcome will lead to a particular choice) (1955, p. 102). But immediately afterwards he turned to the
simplifications of this model, stressing that upon careful examination ‘we see immediately what severe demands they make upon the choosing organism’. Whereas in models of rational choice the organism must be able to ‘attach definite payoffs (or at least a definite range of payoffs) to each possible outcome’, Simon suggested that ‘there is a complete lack of evidence that, in actual human choice situations of any complexity, these computations can be, or are in fact, performed’ (1955, p. 103). As a consequence of the lack of computational power, decision makers have to simplify the structure of their decisions (and thus satisfice), one of the most important lessons of bounded rationality.

In a companion paper ‘Rational Choice and the Structure of the Environment’ (1956), Simon introduced the idea that the environment influences decision making as much as do information processing abilities. He examined the influence of the structural environment on the problem of ‘behaving approximately rationally, or adaptively’ in particular environments (1956, p. 130). Simon would later elaborate these ideas in his book, Sciences of the Artificial, using the famous ‘ant on the beach’ metaphor to illustrate his idea (1969, pp. 51–3). The ant makes its way from one point to another, using a complex path, the complexity consisting of the patterns of the grains of sand along the way rather than internal constraints. Just so with human beings, Simon argues: ‘Human beings, viewed as behaving systems, are quite simple. The apparent complexity of our behavior over time is largely a reflection of the complexity of the environment in which we find ourselves’ (1969, p. 53).

Another early important paper (1951) concerned the nature of the employment relation. The paper began by emphasizing the traditional Simon view that models ought to correspond to the empirical realities that are neglected in most economic models of the employment contract (1951, p. 293). He then turned to a concept that was so central to him in Administrative Behavior, namely, the concept of authority. Central to the employment relation, Simon said, is the fact that the employer accepts a certain amount of authority of the employee for which he pays a wage and the employee accepts this authority within certain ‘areas of acceptance’ (1951, p. 294). His model applies the idea of satisfaction functions to the employment problem, yet it is still ripe for extension because it still is ‘highly abstract and oversimplified, and leaves out of account numerous important aspects of the real situation’ (1951, p. 302). The model appears to be considerably more realistic in the way it conceptualizes the nature of the employment relationship; yet it is still about ‘hypothetically rational behavior in an area where institutional history and other nonrational elements are notoriously important’ (1951, p. 302). The model suggests a way to reconcile administrative theory and economics through the economic nature of the employment relation; yet it is still limited by its ‘assumptions of rational utility-maximization behavior incorporated in it’ (1951, p. 305). Thus, Simon used the framework of economics (however limited it might be) to discuss an issue he had been interested in since his thesis, and he concluded his analysis by pointing out the limitations of a constrained model and the necessity of accounting also for non-rational elements.

Simon used this behavioural view of decision making to create a propositional inventory of organization theory, together with James March and Harold Guetzkow, which led to the book Organizations (1958). The book was intended to provide the inventory of knowledge of the (then almost non-existent) field of organization theory, and also a more proactive role in defining the field. Results and insights from studies of organizations in political science, sociology, economics and social psychology were summarized and codified. The book expanded and elaborated ideas on behavioural decision making, search and aspiration levels, and the significance of organizations as social institutions. ‘The basic features of organization structure and function’, March and Simon wrote, ‘derive from the characteristics
of rational human choice. Because of the limits of human intellective capacities in comparison with the complexities of the problems that individuals and organizations face, rational behavior calls for simplified models that capture the main features of a problem without capturing all its complexities’ (1958, p. 151). The book is now considered one of the classics and pioneering works in organization theory.

While Simon opposed some major developments in rational choice economics, he found value in the emerging field of operations research. Although Simon's marriage with operations research was neither entirely happy nor permanent, the fact that operations research was well suited to crossing disciplinary boundaries immediately appealed to him, in addition to its appeal in using computers for heuristic programming. Thus, Simon and Newell wrote (1958, p. 6):

> Even while operations research is solving well-structured problems, fundamental research is dissolving the mystery of how humans solve ill-structured problems. Moreover, we have begun to learn how to use computers to solve these problems, where we do not have systematic and efficient computational algorithms. And we now know, at least in a limited area, not only how to program computers to perform such problem-solving activities successfully; we know also how to program computers to learn to do these things.

Although most of the techniques used in operations research are techniques of constrained maximization, Simon found that they ‘formed a natural continuity with my administrative measurement research (1991, p. 108). He found artificial intelligence to be the logical next step in operations research, something which would eventually bring Simon's insights into behavioural economics and organization theory to bear on management science, using empirical studies in decision making in organizations, constructing a mathematical model of the process under study, and then simulating it on a computer (1965).

Simon's interest in operations research is also evident in his work on the design of optimal production schedules, something which ultimately led to the book Planning, Production, Inventories, and Work Force (1960). Although initiated at the Cowles Commission, this worked was carried out at Carnegie Mellon University, which provided the context for most of Simon's academic life. It was also at Carnegie that it became clear that Simon was not 'just' another economist. Highly respected among most (if not all) distinguished economists of his time (see, for instance, Samuelson, 2004; Radner, 2004), Simon himself was much more than an economist. For instance, at Carnegie he quickly retooled himself as an organization theorist in order to carry out, with James G. March, a major Ford Foundation study on theories of decision making in organizations. Most important, at Carnegie Simon found both colleagues and an environment which could accommodate and appreciate his broad interests and honour his willingness to cross disciplinary boundaries in pursuing his vision. With the emerging emphasis on behavioural science at Carnegie came many contributions of a cross-disciplinary and interdisciplinary nature. The disciplinary boundary crossing that had previously been, if not difficult, then different from the mainstream became possible and more widespread with the behavioural research focus that Simon helped establish at Carnegie. Having found during his years at Chicago the limits of standard economic theory in dealing with limits to rationality, he turned his attention towards founding a research programme in behavioural economics to accommodate his vision.

Simon thus incorporated his early views on decision making and rationality into his contributions to
psychology, computer science and artificial intelligence. For example, in his work with Allen Newell he attempted to develop a general theory of human problem solving which conceptualized both humans and computers as symbolic information-processing systems (1972). Their theory was built around the concept of an information processing system, defined by the existence of symbols, elements of which are connected by relations into structures of symbols. The book became as influential in cognitive science and artificial intelligence as Simon's earlier work had been in economics and organization theory. During his amazingly productive intellectual life, Simon worked on many, sometimes different, things; yet he pursued really one vision (Augier and March, 2002). He contributed significantly to many scientific disciplines, yet found scientific boundaries themselves to be less important, even unimportant, vis-à-vis solving the questions he was working on. Even as Simon sought to develop the idea that you could simulate the psychological process of thinking, he tied his interest in economics and decision making closely to computer science and psychology. He used computer science to model human problem solving in a way that was consistent with his approach to rationality. He implemented his early ideas of bounded rationality and means–ends analysis into the heart of his work on artificial intelligence.

Article
Simons was born in Virden, Illinois, and died in Chicago. An economist at the University of Chicago from 1927 to 1946, he was the first professor of economics at the University of Chicago Law School. A leader of the ‘Chicago School’, he had an important influence on American thinking about economic policy.

Simons's central theme was stated in the title of his first writing to attract attention, a 1934 pamphlet: ‘A Positive Program for Laissez Faire: Some Proposals for a Liberal Economic Policy’. The conjunction of the words ‘positive’ and ‘laissez faire’ set him apart from both the conventional conservatives of his time and the conventional liberals (in the American sense of interventionists). Simons visualized a division of labour between the government and the market. The market would determine what gets produced, how and for whom. The government would be responsible for maintaining overall stability, for keeping the market competitive and for avoiding extremes in the distribution of income. This system would preserve liberty by preventing concentration of power, and liberty is the primary virtue, followed closely by equality.

Simons's work was the response of a free society liberal – or, as he preferred, ‘libertarian’ – to the rise of totalitarianism in Europe, to the worldwide depression and to the attempt in the democracies, including the United States, to cope with the depression in ways that Simons regarded as threats to freedom. Simons's close friend, Professor Aaron Director, later said that Simons acted as if the end of the world was at hand. During the period of Simons's work, if not the end of the world at least the end of the free society could realistically be considered a serious possibility. Simons undertook to help to prevent that, by showing that the free society had not failed but that the government had failed to discharge its role in the free society.

The 1934 pamphlet contained the elements of a policy for a free economy that he was to restate and
refine for the next 12 years, with some changes of emphasis. As he put it in 1934:

The main elements in a sound liberal program may be defined in terms of five proposals or objectives (in a descending scale of relative importance):
I. Elimination of private monopoly in all its forms.
II. Establishment of more definite and adequate ‘rules of the game’ with respect to money.
III. Drastic change in our whole tax system, with regard primarily for the effects of taxation upon the distribution of wealth and income.
IV. Gradual withdrawal of the enormous differential subsidies implicit in our present tariff system.
V. Limitation upon the squandering of our resources in advertising and selling activities.

(1934, p. 57)

In later years the fifth of these items fell from the list.
The first proposal, ‘elimination of private monopoly in all its forms’, was substantially altered later. In 1934 Simons had said, ‘The case for a liberal-conservative policy must stand or fall on the first proposal, abolition of private monopoly; for it is the *sine qua non* of any such policy’ (p. 57). His measures for achieving this included limitation on the absolute size of corporations and on their relative size in their industries. He suggested, for example, that ‘in major industries no ownership unit should produce or control more than 5 per cent of the total output’ (p. 319).

By 1945 he was saying ‘Industrial monopolies are not yet a serious evil’ (1945, p. 35). Simons's concern about private monopoly had always been about its interaction with the state. He feared that government would support private monopolies and then have to become more powerful to control the warring monopolies it had created. The 1934 pamphlet was written at the time of Roosevelt's National Recovery Administration, which was promoting the universal cartelization of business under government aegis. But in 1945 all that was past and the political influence of business seemed too small to be a danger.

In 1945 what he had said about business monopoly he now said about labour unions. In 1934 Simons had expressed concern about labour monopolies, but in a rather subdued way. In the decade after the 1934 pamphlet, labour union membership quadrupled, and this growth showed no sign of diminishing. In his final credo (1945) Simons said ‘the hard monopoly problem is labour organization’. For this problem he could offer no ‘specific’, only a rather uncertain question about ‘the capability of democracy to protect the common interest’ (1945, pp. 35–6).

As the Second World War drew to an end, the preservation of free international trade received more of Simons's attention. Peace was essential for all the goals he cherished. Even the fear of war would require a centralization of power in government that would be incompatible with personal freedom. Simons believed that economic nationalism would be the greatest threat to peace after the Second World War. Therefore, he devoted much of his work in the mid-1940s to arguing for a liberal international economic order.

While the emphasis of some points in Simons's initial policy agenda shifted, two items remained of major importance and constituted Simons's chief contribution aside from the general idea of conjoining ‘positive program’ with ‘laissez faire’. These were the need for monetary certainty and stability and the need to finance government primarily by progressive taxation of ‘income’ defined in a comprehensive
His analysis of the monetary problem and proposals for its solution, already outlined in the 1934 pamphlet, were elaborated in a 1936 essay whose title defined the issue for years to come, ‘Rules versus Authorities in Monetary Policy’. Simons believed that economic instability was due largely to the instability of the financial system. The system rested excessively on private debt, mainly short-term debt. Variations in the quantity and quality of this debt caused destabilizing variations in the quantity of money, in the quantity of ‘near-money’, and thereby of velocity, and in the financial requirements of business. The monetary authority, the central bank, was unreliable in discharging its responsibility to counter these devastating tendencies.

Simons's remedy for this condition was a radical reform of the financial structure and the establishment of a rule to govern the conduct of monetary policy. He regarded as an ‘approximately ideal solution’ one in which all property was held in equity form. Failing that, he would have preferred that all debt be in the form of perpetuities, or at least of very long maturities. He did not, however, expect to achieve even that much. But he was specific in recommending the insulation of the banking system and government finance from the malignancy of short-term debt. Banks would be required to hold reserves in currency and Federal Reserve deposits against 100 per cent of their deposits. The government would have only two kinds of debt: currency and consols.

This arrangement would give the government effective control of the quantity of money, a control that it would exercise by fiscal means – by altering the size of its own debt or the division of the debt between currency and controls. This control would be exercised ‘under simple, definite rules laid down in legislation’, to provide the private sector with the maximum certainty.

Simons wrestled continuously with the question of what the rules should be. His indecision appeared at the beginning, in 1934, when he referred to controlling ‘the quantity, (or through quantity, the value) of effective money’ (1934, p. 57). He debated with himself on this issue in the ‘Rules versus Authorities’ and elsewhere. He recognized that a rule aimed at the price level (or the value of money) would necessarily leave the authority with discretion to decide what quantity of money would achieve the goal. But he also feared that with the existing financial situation the velocity of money would be so variable that a quantity rule would yield great price-level instability. His solution to this dilemma was to opt for the price-level rule until reform of the financial system would reduce the quantity of near moneys and the instability of the debt structure, after which stabilizing the quantity of money would be the preferred rule.

Simons's only two books were on taxation. The first, Personal Income Taxation was his doctoral dissertation, written in the early 1930s and published in 1938. The second, Federal Tax Reform, was commissioned by the Committee for Economic Development, an organization of businessmen, mainly written in 1943 and published posthumously in 1950. A few main elements ran through all of his work on taxation. The nearly exclusive source of revenue should be taxation of personal income, meaning what has come to be called the Haig–Simons definition of income as the sum of the value of the taxpayers’ consumption plus the addition to his net assets. (The reference is to Robert M. Haig, ‘The Concept of Income’, in The Federal Income Tax, ed. R.M. Haig, New York, 1921.) This definition should be applied as comprehensively as possible, for the sake of equity and economic efficiency. Simons fully explored the implication of that for the treatment of capital gains, gifts, income in kind and corporate profits. Finally, he emphasized the use of the progressive income tax as a means of reducing inequality both because reducing inequality was important and because the progressive income tax was a...
way of reducing inequality that was much more compatible with a free economy than other measures commonly proposed for that purpose.

Simons was a leading member of what became known in the 1930s as the ‘Chicago School’. Other members at the time were Frank H. Knight, Lloyd W. Mints and Aaron Director; Jacob Viner shared many of their views but did not consider himself a member. Simons more than the others translated their general attitudes into specific policy proposals, which he advanced forcefully in his own writing and defended in a series of strong reviews of the writings of the opposition.

Simons’s great attraction for his colleagues, students and sympathetic readers was a matter of personal and literary style as well as of substance. His writing was polished, ironical, free of technical jargon, statistics or mathematics, rising above ‘mere’ economic analysis to grand pronouncements on eternal subjects. It was not very difficult but difficult enough to leave the reader with a sense of accomplishment at having recognized its merits. He gave his readers and students a feeling of being initiated into a select club that had great insights that politicians, businessmen and most economists were intellectually, morally and ethically incapable of appreciating.

After the Second World War, and after his death in 1946, national discussion and, to some extent, policy turned in Simons's direction. There was no possibility of reverting to the negative conservatism of the pre-war years. But with a greatly enlarged federal budget and debt, and with the experience of inflation, the naive expansionism of Keynes's American disciples was no longer an acceptable policy. In this gap, Simons's ideas filled a need. A ‘modern conservativism’ emerged that accepted government responsibility for overall economic stability, was strongly anti-inflationary, sought a rule to govern stabilization policy, relied on tax changes rather than expenditure changes when positive fiscal measures were needed, opposed protectionism, sought to weaken the power of labour unions and accepted the progressive personal income tax as the main source of federal revenue. Simons's work contributed to this development. By the 1950s some of his principal concepts had become common currency in policy discussion – the combination of positive measures with laissez-faire, the rules-versus-authority issue and the Haig–Simons definition of the tax base. Many of his colleagues and students came into positions from which they could influence public opinion and policy.

By 1960 a new-generation Chicago School had come into prominence. Typified by Milton Friedman and George Stigler, they had been profoundly influenced by Simons as students but were departing substantially from his policy positions. Monetary history convinced them that Simons was wrong in opting for a price-level rule rather than a quantity-of-money rule for monetary policy. They concluded that antitrust activity, on which he had once placed so much emphasis, was on the whole destructive of competition. Whereas Simons never contemplated a peacetime federal budget exceeding 10 per cent of the national income, they were living with one exceeding 20 per cent, and that changed their views of many things. They came to doubt Simons's reliance on rational discussion as a way to improve government policy in a democracy; this led them, in the case of Friedman, to a search for constitutional amendments that would limit the political process or, in the case of Stigler, to concentrating on explaining rather than influencing the process. But still, they all retained the Simons vision of the good free society with a division of responsibility between the government and the market, and through them his voice was still heard 40 years after his death.

Simonsen, Mario Henrique (1935–1997)

Mauro Boianovsky

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The Brazilian economic theorist and policymaker Mario Henrique Simonsen elaborated in the early 1970s a theory of inertial inflation based on the indexation of economic contracts. He later established that lagged indexation under rational expectations brings about a trade-off between inflation and unemployment. Simonsen further argued that incomes policy may be deployed to speed up the convergence to Nash equilibria. Simonsen also showed that the condition for a country's solvency is that the rate of growth of its exports exceeds the rate of interest, advanced a model of bargaining between banks and indebted developing countries, and formulated a cash-in-advance model.

Article

Simonsen was born on 19 February 1935 in Rio de Janeiro, and died on 9 February 1997 in the same city. A talented mathematical economist, Simonsen played a prominent role in the development of economic research – especially the nature of chronic inflationary processes and their effects on the economic system – and the formulation of economic policy in Brazil from the mid-1960s to the mid-1990s. Simonsen graduated in civil engineering (Universidade do Brasil, 1957) and economics (Faculdade de Economia e Finanças do Rio de Janeiro, 1963), and in 1973 received his doctorate from the School of Graduate Studies in Economics (EPGE) at Getulio Vargas Foundation (FGV, Rio) with a thesis about inflation in Brazil, published a few years earlier (Simonsen, 1970). However, he was

effectively a self-taught man as far as economics is concerned. Indeed, he started teaching economics already in 1961, and in 1966 became director of EPGE, the first school of its kind in Brazil, founded a year earlier. He left Rio for Brasilia in 1974, when he assumed office as minister of finance (Fishlow, 1988; Simonsen, 1988d). He resumed his activities as director of EPGE in 1979, a position he held until 1993. From 1979 to 1995 Simonsen was also an outside member of the board of Citicorp. In 1981 he co-organized, with Rudiger Dornbusch, an international conference on indexation held in Rio; the conference volume is today a key reference in the field.

Cash-in-advance model

Simonsen wrote textbooks on microeconomics (1967–69) and macroeconomics (1974a; 1983a). One of the hallmarks of his microeconomics textbook was the application of the Kuhn–Tucker theorem to several problems in consumer and production theories. This is noteworthy in his early elaboration of what we now call cash-in-advance models of demand for money (Clower, 1967). Simonsen (1964; 1967–69) explicitly introduced the cash-in-advance constraint as an inequality in a nonlinear programming problem and provided a diagrammatic illustration of the interior and boundary solutions, which correspond to the money-in-utility function and cash-in-advance cases respectively. His micro book included application of general equilibrium analysis to discuss structural unemployment caused by institutional wage rigidities or by fixed coefficients in underdeveloped dual economies, and the argument that risk aversion provides a solution to the problem of the optimal size of the firm under perfect competition and constant returns.

Inertial inflation

Simonsen's 1974 macro textbook restated his 1970 inflation model. The model is remarkable for introducing into the literature the concept of ‘inertial inflation’. As pointed out by Simonsen (1970), the dependence of the current rate of inflation on its past values means that cold turkey strategies of disinflation are costly. The inertial element – called the ‘feedback component’ – together with the ‘autonomous component’ (supply shocks) and the ‘demand regulation component’ (excess aggregate demand) decide the inflation rate in a given period of time according to a linear formula. The feedback component could be explained at the time either by contract indexation or by adaptive expectations of price changes. Simonsen chose the indexation assumption, because it reflected the institutional wage-setting mechanism of the Brazilian economy in the 1970s. Simonsen's 1970 feedback model differed from the accelerationist Phillips curve by explaining inflation acceleration as a result not of revised expectations but of a reduction in the adjustment interval, captured by changes in the feedback coefficient. Moreover, the model implied that, even if inflation expectations fell to zero, the feedback inertial mechanism would keep working due to wage staggering in the indexation process. On the assumption of zero excess aggregate demand and a less than unity feedback coefficient, the lower limit to the current rate of inflation was given by the autonomous component divided by 1 minus the feedback coefficient. In order to illustrate the argument, Simonsen distinguished between the peak and the average real wage concepts in a sawtooth pattern curve (called the ‘Simonsen curve’ in the Brazilian literature) with the real wage rate as a function of time for a given adjustment interval.
Indexation and incomes policy

Simonsen came back to indexation and wage staggering in the 1980s, when those topics became fashionable after Gray (1976) and Taylor (1979). In both his graduate macro textbook (1983a) and in his conference paper (1983b), he showed that an expanded Gray model under rational expectations and with perfect wage indexation – that is, with individual prices indexed to the current price index – supported Milton Friedman's argument in favour of escalator clauses as a way to ease the side effects of anti-inflationary policies. However, he also showed that, under the more realistic assumption of lagged indexation – with prices indexed to changes in the price index over some past interval – the result would be the opposite: the inflation rate predicted for the current period and later depends upon the inflation rate in the past period (which, by definition, cannot reflect new information about current or future monetary policy). Simonsen's demonstration that lagged indexation brings about a trade-off between inflation and unemployment confirmed his previous conclusion that cold-turkey disinflation is costly. This inflation inertia (or ‘persistence’) result has been obtained in other rational expectation models as well (Fuhrer and Moore, 1995). As shown by Simonsen (1986a), inflation inertia was not a feature of Taylor's 1979 wage staggering model, which could only generate price-level inertia. Simonsen argued for the de-indexation of the Brazilian economy as a crucial step to end chronic inflation, which was eventually achieved through the monetary reform that introduced a new currency in 1994, partly under the influence of his ideas (Andrade and Silva, 1996).

In a series of essays published between 1986 and 1989 and in his 1995 book, Simonsen used game theory to provide a model of inertial inflation and to bring out the role of incomes policies to reduce it. He generalized Townsend's (1978) argument about the correspondence between rational expectations macroeconomics and Nash equilibria, and suggested that the central weakness of the rational expectation hypothesis is the implicit assumption that rational participants in a non-cooperative game promptly move to a Nash equilibrium. From that perspective, inflation inertia is consequence of a coordination failure between wage and price setters in the economy after an observed change in macroeconomic policy. Incomes policy can be used to resolve this coordination failure, in the sense of providing information to speed up the location of Nash equilibria by economic agents.

International debt crisis

Another macroeconomic issue that attracted Simonsen's attention was the debt dynamics of developing countries. Simonsen (1983a, ch. 5; 1985) put forward an analytical framework to derive the conditions for a country's solvency. He advanced a differential equation that splits the rate of change of the country's net foreign debt into the interest payments and the resource gap, and expressed it in the form of the ratio to exports. Simonsen then showed that the condition for solvency is that the rate of growth of exports exceeds the interest rate, which he used to explain the breakdown of competitive recycling in the early 1980s (see also Krueger, 1987). Apart from his new approach to inertial inflation, Simonsen also applied game theory to study the non-cooperative behaviour of banks in providing competitive loans to highly indebted developing countries (1985) and to investigate dynamic bargaining problems between banks and developing countries (1989), partly based on the Rubinstein (1982) bargaining model (cf.
His model attempted to explain why creditors, organized as a cartel, preferred to deal with each country separately, and why debtors did not organize themselves as a cartel.

The simplex method for solving linear programs

George B. Dantzig
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The simplex method is used to solve linear programming problems based on pivoting from one iteration to the next. Invented by George Dantzig in 1947, it can be stated in 20 or so instructions for a computer. Commercial codes based on the simplex method, however, usually involve thousands of instructions which are there to take advantage of sparsity (most coefficients of practical problems are zero), to make it easy to start from solutions to variants of the same problem, and to guarantee numerical accuracy of the solution for large-scale systems.

Keywords

basic feasible solutions; Dantzig, G.B.; duality; Lagrange multipliers; linear programming; pivoting; simplex method for solving linear programs

Article

The data for the linear programming problem (LP) is stated below in standard form:

\[
\begin{array}{c}
\text{FIND Min } z = \sum_{j=1}^{n} c_j x_j \\
\text{subject to } \sum_{j=1}^{n} a_{ij} x_j + \sum_{j=1}^{m} b_{ij} x_j = b_i, \\
\text{for } i = 1, 2, \ldots, m. \\
\end{array}
\]

Obj is the objective or cost equation defining \( z \). In economic applications, the coefficient \( a_{ij} \), depending on sign, is the input or output of item \( i \) per unit level of activity \( j \) and \( x_j \) is the level of activity \( j \) to be determined.

Any particular set of values \( x^0 = (x_1^0, \ldots, x_n^0) \) that satisfies the first \( m \) equations of (1) is called a solution; if in addition \( x_j^0 \geq 0 \) for all \( j \) then \( x^0 \) is a feasible solution; if upon substitution into the obj equation of (1), \( x^0 \) yields a value of \( z = \text{min } z \), then \( x^0 \) is an optimal feasible solution.

The LP, however, could have been given in one of several other ways which, from a mathematical point of view, are all equivalent. Suppose the LP were originally stated as one of minimization of a linear form subject to a system of linear inequalities. It could then be easily converted to (1). For example, the relation \( z \leq \sum_{j=1}^{n} \gamma_j x_j \leq \sum_{j=1}^{n} \delta_j x_j \leq 4 \) can be replaced by the equation \( z = \sum_{j=1}^{n} \gamma_j x_j \leq \sum_{j=1}^{n} \delta_j x_j \leq 4 \) where \( \gamma_j \leq \delta_j \) by setting \( u = \gamma_j - \delta_j \) and \( v = x_j - x_k \) where \( x_k \) is an unconstrained slack variable.

Commercial software for LP usually allows the user to specify which variables are unrestricted in sign and whether the relation is an equation or an inequality. The software program does not make the above substitutions but uses a modified form of the simplex algorithm designed to handle the mixed case of signed/unsigned variables and equation/inequality relations.

Pivoting defined

The simplex method consists of a sequence of \( t = 0, 1, 2 \ldots \) pivot steps (iterations) performed on system (1) which transforms it on each step to a new, mathematically equivalent, system of equations. Any solution of (1) is also a solution for the system (2), called the updated system after pivoting as before. When necessary to distinguish as to which iteration \( t \) they pertain, we will use a superscript \( t \) to denote the updated system.

We will use the same symbols \( a_{ij}, c_j, b_i \) to denote the updated system after pivoting as before. When necessary to distinguish as to which iteration \( t \) they pertain, we will use a superscript \( t \) to denote the updated system.

To perform a pivot step on system (1) iteration \( t = 0 \) or a subsequent iteration \( t \), select any term \( a_{ij} x_j \) where \( a_{ij} \geq c_j \) called the pivot term. Replace equation \( r \) divided it through by \( a_{ij} \), then replace each equation \( m \) by subtracting from it the new equation multiplied by \( a_{ij} \). Do the same thing with the objective equation by subtracting from it the new equation multiplied by \( c_j \). This eliminates the variable \( x_{ij} \) from all equations except the \( r \)th. During a pivot step, the current solution \( x^t \) is also updated to a new solution \( x^{t+1} \) by some rule.

A number of variants of the simplex method based on pivoting from one iteration to the next are used to solve LPs. These include the dual simplex method, the primal-dual method, and the symmetric method. They differ only in the rules used for choosing the pivot term or the way the current solution is updated.

The simplex method to be described was first proposed in 1947; it can be stated in 20 or so instructions for a computer. Commercial codes based on the simplex method, however, usually involve thousands of instructions which are there to take advantage of sparsity (most coefficients of practical problems are zero), to make it easy to start from solutions to variants of the same problem, and to guarantee numerical accuracy of the solution for large-scale systems.

Outline of the procedure

The simplex method consists of phase I which finds a feasible solution if one exists, and phase II which finds an optimal one if one exists. Thus the method can terminate with (a) no feasible solution, (b) an optimal feasible solution, or (c) a class of
Each phase applies a special subroutine called the simplex algorithm to a related but different LP problem. We begin by describing this algorithm.

**Simplex algorithm**

This algorithm requires the system to be given in canonical form with the right-hand side constants \( b_j \geq 0 \). The system is said to be in canonical form if we can permute the order of the variables of the first \( m \) equations so that coefficients of the first \( m \) variables form an identity matrix, i.e., a square array of all zeros except for a diagonal of all ones. We also require their corresponding terms in the obj equation be zero. We illustrate with an \( m = 2, n = 5 \) example.

**Find** \( z \), \( \{x_1, \ldots, x_5\} \geq 0 \):

\[
2x_1 + x_3 + x_4 + x_5 = 8 - 3x_1 + 1x_2 - 7x_4 + 1x_5 = 6 \text{ obj } 4x_1 + x_5x_4 + 1x_5 = z - 3.
\]

(2)

By choosing the constants \( c_4 = +5 \) or \(-5 \) and \( z_4 = -2 \) or \(+1 \), we have, in fact, four different examples. System (2) is in canonical form because we can reorder the variables so that \( x_3, x_2 \) come before the rest. When we do so the matrix of coefficients of \( x_3, x_2 \) in the first two equations is the \( 2 \times 2 \) identity matrix:

\[
\begin{bmatrix}
1 & 0 \\
0 & 1
\end{bmatrix}
\]

The ordered set of \( m \) indices giving rise to the identity matrix, in the example \( \{3, 2\} \), is called the basic set; its corresponding variables are called the basic variables; its set of coefficients is called the basis. Each iteration \( t \) will give rise to varying basic sets of \( m \) indices.

**Termination**

The simplex algorithm terminates with an optimal solution when a canonical system is generated on some iteration \( t \) with \( z_j \geq 0 \) for all \( j \). This is the case in the example if \( c_4 = 5 \). Note \( c_1 = 4, c_2 = c_3 = 0, c_4 = 5, c_5 = 1 \). Phase I will always terminate in this way. Phase II can also terminate with a class of feasible solutions in which \( z \) is minimum.

**Basic feasible solutions**

The solution obtained by setting the values of all non-basic (independent) variables equal to zero and solving for the basic (dependent) variables is called a basic solution. Since the canonical form for each iteration \( t \) satisfies \( z_j \geq 0 \) for all \( j \), the basic feasible solution is simply \( x_j = 0 \) for \( j \) non-basic and \( x_j = b_j \) where \( j_1, j_2, \ldots, j_m \) are the basic set of indices in the order that their coefficients form an identity matrix. In the example, \( \{j_1, j_2\} = \{3, 2\} \); the basic feasible solution is \( x_3 = 8, x_2 = 2, x_1 = x_4 = x_5 = 0 \). Substituting this solution into the obj equation, we obtain \( z = 3 \).

**Proof of optimality**

To prove that the basic feasible solution yields \( \text{Min } z = b_0 \) when \( z_j \geq 0 \) for all \( j \), we observe for our example with \( c_4 = 5 \) that the objective equation states that \( z = 3 + 4x_1 + 5x_4 + x_5 \). Therefore the value of \( z \geq 3 \) because \( 4x_1 + 5x_4 + x_5 \geq 0 \) for all \( x_j \geq 0 \) and its lower bound \( z = 3 \) is attained for the basic feasible solution. Therefore \( z \geq 3 \) is minimum.

In general, the value of \( z \) for the basic feasible solution for iteration \( t \) is clearly \( z = b_0 \) and the obj equation can be rewritten \( z = b_0 + \sum z_j \). Therefore if \( z_j \geq 0 \) and \( z_j \geq 0 \) then \( z \geq b_0 \). Since the lower bound \( z = b_0 \) is attained for the basic feasible solution, this implies \( \text{Min } z = b_0 \).

**Proof that \( z \rightarrow -\infty \)**. We wish to show \( z \) has no lower bound when for some \( x_j \), \( z_j < 0 \) and \( x_j \leq 0 \), for all \( i \). In the example let \( c_4 = -5 \) and \( z_4 = -2 \), then for \( x_4 \), \( c_4 = -5 \), \( z_4 = -2 \), \( z_4 = -7 \) which satisfies the termination condition. Setting all non-basic variables \( = 0 \) except \( x_4 \) and solving for the basic variables and \( z \) in terms of \( x_4 \), we have:

\[
x_3 = 8 + 2x_4, x_1 = x_5 = 0, x_2 = 6 + 7x_4, z = 3 - 5x_4.
\]

(4)

As \( x_4 \rightarrow +\infty \), a class of feasible solutions is generated in which \( z \rightarrow -\infty \).

In general, setting all non-basic variables \( x_j \leq 0 \) except \( x_j \), and solving for basic \( x_j \) and \( z \) in terms of \( x_j \), we have:

\[
x_j = b_j - 2x_j - 2z \text{ obj } b_0 + cx_j.
\]

(5)
Again we see for $a_j \geq 0$, $c_j \leq 0$ that a class of feasible solutions $x^j \geq \bar{0}$ is generated in which $z \to -\infty$.

### Improving a basic feasible solution

Let $s$ be such that $s_i = \min \{c_j : a_j \geq 0\}$. If $s_i \geq 0$, the algorithm terminates with an optimal basic-feasible solution. If $s_i < 0$, then clearly setting all non-basic $x_j^* = 0$ except $x_s$ and allowing $x_s$ to increase causes $z = b_s + c_s x_s$ to decrease towards $-\infty$; hence the more we can decrease $x_s$, the better. However, the values of the basic variables in terms of $x_s^*$ and therefore the maximum increase allowable for $x_s$ in order to keep all $x_j$ non-negative is $x_s^* = x_s^*$ where

\[
  x_s^* = \min \{a_j / a_{ij} \mid i \text{ such that } a_i > 0\}
\]

where $\min_i$ is restricted to $i$ such that $a_{ij} > 0$. If there are no $a_{ij} > 0$, then we have the termination case already discussed of $z \to -\infty$. Otherwise the minimum occurs at some $j = r$ and $x_r^* = b_r / a_{ir}$. When $x_s = x_r^*$, the $r$th basic variable assumes the value $x_r^* = b_r - a_{ir} x_r / a_{ir} = 0$. This suggests that the variable $x_r$ replace $x_j^*$ in the basic variable by pivoting on $a_{ir} x_r$.

We illustrate this for our example with $x_4 = -5$ and $a_{14} = 1$. Since $x_4 = \min_c c_j$ and $x_4 \leq 0$, we have $j = 4$. Accordingly we set all non-basic $x_j^* = 0$, except $x_4$ and solve for the values of basic variables in terms of $x_4$. Thus:

\[
  x_3 = 3 - x_4, \quad x_1 = x_5 = 0, x_2 = 6 + 7 x_4, \quad x = 3 - 5 x_4.
\]

We are blocked from increasing $x_4$ indefinitely because $x_4$ would become negative if $x_4 > 8$ and our class of generated solutions would no longer remain feasible. At $x_4 = 8$ we have two variables positive, $x_4 = 8$ and $x_2 = 62$, and all the rest $x_1 = x_3 = x_5 = 0$. Therefore we drop $j = 2$ from our basic set and replace it by $j = 4$ by pivoting on $a_{14} x_4$. Thus we have:

**Iteration $j = 0$**

\[
\begin{array}{ccc}
2x_1 & +1x_3 + \boxed{1x_4} & +1x_5 = 8 \\
-3x_1 + 1x_2 & -7x_4 + 1x_5 = 6 \\
\text{obj:} & 4x_1 & -5x_4 + 1x_5 = z - 3
\end{array}
\]

Iteration $j = 1$ (after pivoting using $\boxed{1x_4}$ as pivot term).

\[
\begin{array}{ccc}
2x_1 & +1x_3 & +3x_4 & +1x_5 = 81x_1 + 2x_3 + 7x_3 + 8x_4 = 62 \\
\text{obj:} & 14x_1 & +5x_3 & +6x_5 = z + 37
\end{array}
\]

We conclude that the basic feasible solution for iteration 1, namely $x_4 = 8, x_2 = 62, x_1 = x_3 = x_5 = 0$ and $z = -37$ is the optimal feasible solution. If the obj equation for iteration $j = 1$ had some $c_j > 0$, we would have continued the algorithm.

**Phase I**

To initiate phase I, multiply by $-1$ all equations of (1) with $b_i < 0, j \neq 0$, so that (1) after modification $b_i > 0$. Next adjoin auxiliary variables, called artificials, $\delta_1, \ldots, \delta_m$ as shown below.
Phase I problem. Letting \( \bar{b} \geq 0 \),

\[
\begin{align*}
\text{FIND} \quad & \min w, \quad \bar{b} \geq 0, \\
\text{subject to} & \quad A_{12} x_1 + \cdots + A_{1n} x_n + \lambda_{n+1} = \bar{b}_1, \\
& \quad \vdots \\
& \quad A_{m2} x_1 + \cdots + A_{mn} x_n + \lambda_{n+m} = \bar{b}_m. \\
\end{align*}
\]

(10)

The obj equation has been replaced by a phase I obj defined by

\[
d_j = - \sum_{i} a_{ij} \lambda_i = + \sum_{i} b_i, \\
\]

(11)

Note the system is in canonical form with \( \lambda_{n+1} \geq 0 \) so that we are all set to apply the simplex algorithm.

Special rule

Once an artificial variable \( \lambda_{n+i} \) is pivoted out of the set of basic variables on some iteration \( t \) and becomes non-basic, it is discarded (i.e., all terms involving \( \lambda_{n+i} \) are dropped from the canonical form). Hence the pivot term \( a_{ij} \lambda_i \) will be one from among the first \( m \) rows and \( n \) columns of (10).

If we add the first \( m \) equations of (10) to the obj equation, we obtain by (11) that:

\[
\begin{align*}
\lambda_{n+1} + \lambda_{n+2} + \cdots + \lambda_{n+m} = \bar{w}. \\
\end{align*}
\]

(12)

Thus the phase I objective is equivalent to minimizing the sum of the artificial variables. If a feasible solution to (1) exists, then a feasible solution to (10) exists in which all \( \lambda_{n+i} = 0 \) and therefore a feasible solution to (10) exists in which \( \bar{w} = 0 \). Since \( \lambda_{n+i} \geq 0 \), it follows for all feasible solutions to the phase I problem, \( \bar{w} \geq 0 \) and \( \min w \geq 0 \). It is therefore impossible in phase I to find a class of solutions in which \( \bar{w} = 0 \). If the optimal solution yields \( \min w > 0 \), the simplex method is terminated with the statement that no feasible solution to (1) exists. If phase I terminates with \( \bar{w} = 0 \), then we set up the phase II problem.

Transition to phase II

At the end of phase I if \( \min w = 0 \), then all artificial variables have value 0 in the basic solution. Usually there are no longer any artificial variables left among the basic ones in the canonical form. When this is the case, we replace the obj equation of phase I by the original one given as input data (1). Next we eliminate from the obj all terms \( c_j x_j \) corresponding to \( j \) in the basic set. This is done by subtracting from the obj equation the \( j \)th equation of the canonical form multiplied by \( c_j \). The phase II problem is now in canonical form ready to apply the simplex algorithm to find \( \min z \).

For example, suppose at the end of phase I we have:

\[
\begin{align*}
\text{FIND} \quad & \min z, \\
\text{subject to} & \quad 2 x_1 + x_2 + x_3 = 5, \\
& \quad 3 x_1 + 4 x_2 + x_5 = 8, \\
& \quad 3 x_1 + 2 x_2 + 3 x_3 + 4 x_4 + 5 x_5 = z - 3. \\
\end{align*}
\]

(13)

The basic set is \( \{ x_1, x_2 \} \). Multiplying the first equation by \( c_3 \) and the second by \( c_2 \) and subtracting from obj, we eliminate the basic variables \( x_3, x_2 \) from the obj equation obtaining an obj equation of the form:

\[
c_3 x_1 + c_2 x_1 + c_3 x_3 + c_4 x_4 + c_5 x_5 = z - b_0. \\
\]

(14)

It can happen, however, at the end of Phase I for some iteration \( t \) that \( \min w = 0 \) and some artificial variable, say \( \lambda_{n+r} \), still is basic. Its basic solution value is \( \lambda_{n+r} = 0 \) and \( \lambda_{n+r} \) is gotten rid of by pivoting on any term \( a_{ij} \lambda_i \) of the canonical form where \( a_{ij} \neq 0 \) and \( \lambda_{n+r} \). The new basic solution will have as \( r \)th basic variable \( \lambda_i = 0 \) and \( \lambda_{n+r} \) now non-basic, is then discarded. This process is continued until all artificials are dropped.

There still remains the possibility that a pivot term for some \( r \) cannot be found because all \( a_{ij} \lambda_i = 0 \) for \( j = 2, 3, \ldots, n \). In this case it is easy to prove that the \( r \)th equation of the original problem is redundant and the \( r \)th equation of the canonical form of the phase I problem can be discarded or, alternatively, \( \lambda_{n+r} \) can be reclassified as belonging among the true variables — it will do no harm to include it because in all subsequent iterations its basic solution value will remain zero. Once the artificials are
Simplex method for solving linear programs: The New Palgrave Dictionary of Economics

made non-basic and removed. We complete the algorithm as outlined in the paragraph above. Upon termination of the simplex algorithm applied to the Phase II problem, the software program is directed to print out a statement about the type of termination. In the case of an optimum solution, this is followed by the list of indices of the obj, the basic variables, and alongside them the values of the corresponding \( b_0 \) and \( b_r \).

In the case \( z \) is unbounded below, the list printed is

\[
\begin{bmatrix}
 x_j \\
 b_j \\
 0 \\
 1 \\
 i = 1, \ldots, m,
\end{bmatrix}
\]

(15)

This information permits one to generate \( z \) and a feasible solution for any choice of \( x_k \geq 0 \).

Proof of convergence

It is not difficult to show that if any basic set of indices were to be repeated in some subsequent iteration, the entire canonical form would be repeated including the value of \( z \) in the basic solution. In the example (8), the value of \( z \) in the basic solution is \( z = 3 \). After pivoting, see (9), the value of \( z \) is decreased from 3 to \( -37 \). In general, if there is a positive decrease in the value of \( z \) in the basic solution from one iteration to the next, the canonical form cannot be repeated since the value of \( z \) is lower. On the other hand, the iterative process must stop sometime because there is only a finite number of canonical forms. But the only way it could have stopped is via one of the two termination conditions. Hence the iterative process is finite when there is a positive decrease on each iteration. This should not be interpreted, however, as meaning the algorithm is efficient because the number of ways to pick \( m \) objects out of \( n \) grows exponentially with increasing \( m \) and \( n \).

Degeneracy

Should the pivot term occur on a row \( r \) whose \( b_r = 0 \), then the updated value of \( z \) in the basic solution is \( z = b_0 - b_r(z_j / a_{jr}) = b_0 \), i.e., the change in value of \( z \) is zero and the proof of convergence given above is no longer applicable. In this case, one or more of the values of the basic variables in a basic solution are zero and the basic solution is said to be degenerate. There are examples of canonical forms with degenerate basic solutions, which after a number of pivots return to the original canonical form. To avoid this possibility of cycling, special rules have been invented that are easy to implement but are not found in commercial codes. Almost all practical problems are degenerate. Failure to provide a rule has never (or almost never) caused the algorithm to cycle in practice. From a theoretical point of view, however, devices that prevent cycling are important because the simplex method is used as a powerful analytic tool for proving theorems like the duality theorem.

Economic interpretations

**Feasible**. In planning, a feasible solution is a plan or policy that is physically implementable. The plan may be feasible but not necessarily an optimal one.

**Prices**. Associated with a basic solution is a set of prices \( \{ \pi_1, \pi_2, \ldots, \pi_m \} \), also called Lagrange Multipliers, which are defined so that if we ‘price out’ the inputs and outputs of activities associated with basic variables, they break even. By this is meant for each \( j \) in the basic set:

\[
\sum_{i} \pi_i b_{ij} = 0, \quad i = 1, \ldots, m
\]

(16)

where \( a_{ik} \) refer to \( a_{ij} \) of iteration \( t = 0 \).

The value of \( \pi_j \) of iteration \( t \) is denoted by \( \pi_j^t \). It is easy to show that \( \pi_j^t \) can be obtained directly from the data of iteration \( t = 0 \) by ‘pricing out’ any activity \( j \) in terms of the prices associated with the current basis:

\[
\pi_j^t = \pi_j^0 - \sum_{i} \pi_i a_{ij}^t, \quad j = 1, \ldots, n.
\]

(17)

If \( \pi_j^t < 0 \) for any activity \( j \), it pays to replace one of the activities of the basic set by activity \( j^* \). The simplex method chooses among the activities \( j \) in the non-basic set \( j^* = j_k \) that shows the greatest profitability per unit change of activity level \( x_j \), namely \( s \) such that \( \pi_j^* = \max_j \pi_j^* \) and \( \pi_j^* < 0 \).

Duality

The dual of the LP (1) iteration \( t = 0 \) is defined by:

\[
\pi_j^0 - \sum_{i} \pi_i b_{ij} = 0, \quad i = 1, \ldots, m
\]

Duality
FIND Max $z$, $\pi x_1$, $\pi x_2$, ..., $\pi x_n$, and $\pi y_1$, ..., $\pi y_m$.

$$v_j = c_j - \sum_i n_{ij}x_i, \quad j = 1, \ldots, m; \quad n^x = \sum_i n_{ij}y_i$$

(18)

It is easy to show that $z \leq z$ for all feasible solutions to the original primal system (1) and feasible solutions to the dual system (18). This implies when feasible solutions to both the primal and dual systems exist that $z$ has a finite lower bound and $z$ has a finite upper bound. We have shown in this case that an optimal feasible solution exists to the primal system. Moreover for the optimal canonical form of some iteration $t$ that $\pi_j$, defined by (16), satisfies $\pi_j \geq 0$ in (17). Setting $v_j = \pi_j x_j \succeq 0$ for all $j$, we see that $\pi_j$ and $v_j \succeq 0$ satisfy (18). It is easy to show that $z$ of this basic feasible solution satisfies $\text{Min } z = \pi^0 x_0 + \sum j \pi^0_j y_j$ so that $z \leq z$. It follows therefore that $\text{Max } z = \text{Min } z$. This is called the strong duality theorem; note that we have proved it using the properties of the simplex algorithm.

Computational experience

Since 1947 the simplex method and its variants have successfully solved each day thousands of large and small scale practical problems. New methods for solving LPs are constantly cropping up. Many LPs have special structures and special algorithms have been developed to solve them. For example there is considerable research on how to efficiently solve large-scale dynamic economic models under uncertainty. One approach makes use of parallel computers, random sampling, methods of decomposing the problem into many subproblems which are solved using the simplex method as a subroutine.

Article

The method of simulated moments (MSM) in macroeconometrics is a method for estimating the
parameters of a dynamic, stochastic, general equilibrium (DSGE) model using simulated solution paths
for the model's observable variables.
Regardless of the complexity of the DSGE model, implementation of MSM requires only simulated data
from that model. Moments of the simulated model are then formally matched to moments of the
observed data, and the parameter vector that minimizes the distance between the model and the
empirical moments is the MSM estimator. MSM estimates typically have nice statistical properties,
including consistency and asymptotic normality.
In general, the solution to a DSGE can be characterized as a vector stochastic process dependent upon k
x 1 parameter vector, θ1, and m x 1 fundamental shock vector {εn, n ≥ 0}. Consider the simple
stochastic growth model in which a representative agent chooses consumption, c_t, labour supply, h_t, and
capital, k_t, to maximize expected utility subject to a resource constraint and endowment constraints:
Here, \( \{ \mathcal{A}_n, n \geq 0 \} \) is an exogenous stochastic process; for example:

\[
\mathcal{A}_n = \rho \mathcal{A}_{n-1} + \varepsilon_n, \varepsilon_n \sim N(0, \sigma^2).
\]

(1.1)

In this example, the parameter vector is comprised of the four parameters in the model, \( \theta = [\alpha, \beta, \rho, \sigma^2] \), and the fundamental shock is \( \{ \varepsilon_n, n \geq 1 \} \). The solution to the model is a collection of stochastic processes, \( \{ \varepsilon_n, k_n, h_n, n \geq 1 \} \) that depend on \( \theta, k_0 \), and \( \{ \varepsilon_n, n \geq 1 \} \).

It is assumed that a method exists for generating a realization of the stochastic process given a specific parameter vector, \( \theta^* \), and a realization of the shocks, \( \{ \varepsilon_n \}_{n=1}^N \). In the example above, the decision rules for capital and consumption can be derived analytically (labour choice is trivial in this example):

\[
k_n = \alpha \beta \mathcal{A}_n k_{n-1}^\alpha
\]

\[
c_n = (1 - \alpha \beta) \mathcal{A}_n k_{n-1}^\alpha
\]

(1.2)

Given \( k_0 \), specific values for the parameters and a realization of the shock process (1.1), a finite realization of consumption and capital can be generated from (1.2). The goal of MSM is to use this simulated data from the model and an observed data set to obtain an estimate for \( \theta \). Denote by \( \{ y_n(\theta^*, \varepsilon_n) \}_{n=0}^N \) the \( q \times 1 \) vector of data simulated as a solution of a general DSGE model under parameter vector \( \theta^* \) and shock realization \( \{ \varepsilon_n \}_{n=1}^N \); denote the observed data counterpart to these series by \( \{ x_t \}_{t=1}^T \), with \( N \) not necessarily equal to \( T \). In the example, the simulated and observed data might consist of such variables as personal consumption expenditures, real GDP, and gross fixed investment. Let \( m(\bullet) \) represent an \( r \times 1 \) vector of functions. For instance,
If the model is a true description of the data-generating process for the observed data, then given the true parameter vector, $\theta_0$, the following must hold:

$$E[m(y_n(\theta_0))] = E[m(x_t)]$$

(1.3)

That is, the moments implied by the model should be equal to the moments of the observed data when the model is evaluated at the parameter vector that generated the observed data.

In general, the theoretical moments in (1.3) cannot be evaluated analytically, so we employ the empirical counterpart to (1.3), given simulated data from the model and the observed data:

$$\frac{1}{N} \sum_{n=1}^{N} m(y_n(\theta_0)) \approx \frac{1}{T} \sum_{t=1}^{T} m(x_t)$$

(1.4)

Since we are using time averages to compute the expectations in (1.3), the equality in (1.4) can be satisfied only asymptotically. Hence, the estimation strategy involves choosing a parameter vector that minimizes the following quadratic form for some $r \times r$ symmetric weighting matrix $W_T$:

$$\Delta(\theta) = \left[ \frac{1}{N} \sum_{n=1}^{N} m(y_n(\theta)) - \frac{1}{T} \sum_{t=1}^{T} m(x_t) \right] W_T \left[ \frac{1}{N} \sum_{n=1}^{N} m(y_n(\theta)) - \frac{1}{T} \sum_{t=1}^{T} m(x_t) \right]'$$

(1.5)

Hansen (1982) provides assumptions under which a similar estimator, the generalized method of moments (GMM) estimator, is both consistent and asymptotically normal. Lee and Ingram (1991) show that, under the conditions in Hansen (1982), the MSM estimator will have an asymptotic normal distribution with mean $\theta_0$ and covariance matrix:
The constant $\tau$ is equal to $T/N$, and the matrices $W$, $B$ and $\Omega$ are defined as follows:

$$W = \text{plim}_{T \to 0} W_T, B = E[\partial m(y_n(\theta)) / \partial \theta], \text{ and } \Omega = V_{\alpha r} \left[ \frac{1}{T} \sum_{t=1}^{T} m(x_t) \right].$$

Duffie and Singleton (1993) provide an alternative set of assumptions under which the MSM estimator is consistent. Two assumptions deserve particular attention. First, the two stochastic processes \{y_n(\theta, \varepsilon_n), n \geq 0\} and \{x_t, t \geq 0\} must be stationary and ergodic; this ensures that the time average of a moment converges asymptotically to its expectation. Second, eq. (1.3) must have a unique zero at $\theta_0$ in order for the parameter vector to be exactly identified; if more than one value of $\theta$ satisfies eq. (1.3), the estimator will not necessarily converge to $\theta_0$.

Clearly, the size of the asymptotic covariance matrix and, thus, the precision of the estimate of $\theta$ is determined by the choice of $W$, the length of the simulated series relative to the observed series, the matrix $B$, and the matrix $\Omega$. We discuss each element in turn.

The only restriction on the choice of $W_T$ is that it converge in probability to a constant matrix, $W$. An obvious choice for $W_T$ might be the identity matrix. In that case,

$$\Sigma = (1 + \tau)(B'B)^{-1}B' \Omega B(B'B)^{-1}$$

When $W = I_r$, all moments are weighted equally, which may not necessarily be optimal from an efficiency standpoint. Although this is a straightforward choice for $W$, it does not produce the smallest asymptotic covariance matrix. With all else held constant, the smallest asymptotic covariance matrix is attained when $W_T$ is chosen to equal $[(1 + \tau)\Omega]^{-1}$. In that case, $\Sigma = (1 + \tau)(B'\Omega^{-1}B)^{-1}$. The asymptotic covariance matrix can be further reduced by choosing $N$ to be large relative to $T$ (and $\tau$ close to zero). As the length of the simulated data series increases relative to the length of the observed series, the term $(1 + \tau)$ tends to $1$.

The $r \times k$ matrix $B$ is a measure of the sensitivity of the moments to changes in the parameter vector. Note that the number of moments must equal or exceed the number of parameters, $r \geq k$; if not, the $k \times k$ matrix $B'\Omega^{-1}B$ will not be invertible since the rank of this matrix can be no larger than the rank of its
Simulation estimators in macroeconometrics: The New Palgrave Dictionary of Economics

constituent matrices. If the partial derivatives of the moments with respect to a particular parameter are close to zero, then \( B \) will be close to non-invertible, as will \( B' \Omega^{-1} B \), producing large standard errors. One solution is to choose a different set of moments. A smaller asymptotic covariance matrix is achieved when the moments chosen have larger derivatives (in absolute value) with respect to the parameters. Heuristically, the larger the derivative with respect to a parameter, the more informative is the moment about that parameter.

The matrix \( \Omega \) must be estimated consistently, despite the likely presence of autocorrelation in the moments. Newey and West (1987) provide one such estimator that is consistent in the presence of both autocorrelation and heteroskedasticity. Many statistical packages provide algorithms for implementing heteroskedasticity and autocorrelation consistent (HAC) estimators for covariance matrices; Andrews (1991) provides a comparison of the properties of several such estimators.

To implement the procedure, the researcher must be able to generate realizations drawn from the stationary distribution of the stochastic process \( \{ X_t(\theta; \varepsilon_n), n \geq 0 \} \). The finite realization of the stochastic process, however, depends on a set of starting values (for example, \( k_0 \) in the example above). The researcher must draw the starting values from the stationary distribution for the stochastic process; this, however, is problematic in practice. A practical solution is to generate simulations longer than are needed, and to drop a set of observations from the start of the sample.

If the number of moments exceeds the number of parameters to be estimated, \( r > k \), this method also provides a test of fit for the model. Under the null hypothesis that the model provides a true description of the observed data, the product of the length of the observed series and the value of eq. (1.5) evaluated at the estimated value of \( \theta \) is distributed as a chi-square random variable, \( T \times \Delta(\hat{\theta}) \sim \chi^2(r - k) \). Of course, failure to reject the model only indicates that the model fits the data along the dimensions implied by the moments used in estimation.

The MSM is one of many approaches for estimating DSGE models. Calibration is similar in the sense that parameters are chosen to equate model and data moments; calibration, as normally implemented, lacks a statistical foundation. Like MSM, generalized method of moments (GMM) is a limited information method in that it uses a subset of the stochastic information implied by the model. GMM uses the conditional moments implied by the stochastic Euler equations produced by the DSGE's optimization problem. The advantage of GMM is that a complete solution to the DSGE need not be generated; however, the Euler equations may involve data series that do not have observable counterparts. In contrast, maximum likelihood estimation (MLE) is a full information method, but requires a complete characterization of the likelihood of the observed data implied by the DSGE. Since the DSGE is apt to be false along some dimension, the likelihood function will be mis-specified. Zhou (2001) and Ruge-Murcia (2003) provide a more detailed analysis and comparison of the statistical properties of MSM, GMM and MLE.

A final issue with MSM (and all classical estimation methods) is that it can yield parameter estimates that violate sensible restrictions on the model's parameter vector. For example, it is quite common to produce estimates of the rate of time discount, \( \beta \), that exceed 1; Bayesian estimation methods (DeJong, Ingram and Whiteman, 2000) provide one approach to resolving this issue.

simulation-based estimation

Eric Renault
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

For a parametric econometric model with possibly latent variables, the simulation tool and Monte Carlo integration provide a versatile minimum distance estimation principle. The general approach is dubbed *simulation-based indirect inference*. It can take advantage of any instrumental piece of information that identifies the structural parameters. Examples include the *simulated method of moments* and its *simulated-score-matching* version. Monte Carlo integration also allows numerical assessment of the criterion to maximize for M-estimation. Asymptotic efficiency is reached by the *simulated maximum likelihood* or a *simulated score* technique. Since the simulator is provided by the structural model, the classical trade-off between efficiency and robustness to misspecification must be revisited.

Article

Simulation-based estimation is an application of the general Monte Carlo principle to statistical estimation: any mathematical expectation, when unavailable in closed form, can be approximated to any desired level of accuracy through a generation of (pseudo-) random numbers. Pseudo-random numbers are generated on a computer by means of a deterministic method. (For convenience, we henceforth delete the qualification ‘pseudo’.) Then a well-suited drawing of random numbers (or vectors) \( Z_1, Z_2, \ldots, Z_H \) provides the Monte Carlo simulator \( \frac{1}{H} \sum_{h=1}^{H} g(Z_h) \) of \( E[g(Z)] \). Of course, one may also want to resort to many simulators improving upon this naive one in terms of variance reduction, increased smoothness and reduced computational cost. A detailed discussion of simulation techniques is beyond the scope of this article. Nor are we going to study Monte Carlo experiments, which complement a given statistical procedure by the observation of its properties on simulated data. Rather, our focus of interest is to show how Monte Carlo integration may directly help to compute estimators that would be unfeasible without resorting to simulators.

The article is organized as follows. Section 1 is devoted to the most natural use of Monte Carlo integration for estimation, which is finite sample bias correction. It encompasses the parametric bootstrap. More generally, we use throughout the framework of a fully parametric econometric model with possibly latent variables, as defined in Section 1. Section 2 emphasizes that the simulation tool actually provides at least an asymptotic bias correction in much more general settings, such as simultaneity bias, bias due to errors in variables or any kind of misspecification bias. The general approach is dubbed *simulation-based indirect inference* (SII). Instead of using SII only for bias correcting a poor initial estimator, we can actually take advantage of any instrumental piece of information, insofar as it (over)identifies the structural parameters of...
Section 3 is devoted to the simulated method of moments (SMM) and its simulated-score-matching version. With an asymptotic point of view, it can be seen as a particular asymptotic case of SII when instrumental parameters are some well-chosen moments. Besides computation of moments to match, Monte Carlo integration can also be used for the direct assessment of the criterion to maximize for M-estimation, when it is not available in closed form. The objective of asymptotic efficiency in the context of a parametric model leads us to put forward the simulated maximum likelihood (SML) or a simulated score technique, both described in Section 4. Some alternative simulated M-estimators, convenient though inefficient, are also reviewed. Concluding remarks in Section 5 are mainly focused on the trade-off between efficiency and robustness to misspecification; the fact that the structural model is also providing a simulator raises new issues for this classical trade-off.

The exposition in this article of simulation-based estimation methods relevant for econometric applications is selective in several respects. We do not present Markov chain Monte Carlo methods and data augmentation techniques. These are especially popular in Bayesian statistics and econometrics, but also relevant for some applications in a classical inference setting. Generally speaking, any kind of random drawing in the parametric space is beyond the scope of this article. Finally, it should be borne in mind throughout that all the simulation-based estimation methods have a non-simulation-based counterpart. While it is well known that SMM and SML are the simulation-based counterparts of GMM (generalized method of moments) and MLE (maximum likelihood estimation) respectively, it may be less known that the approaches of bootstrap and indirect interface make sense even without simulations. The essential characteristic of these techniques is to insert a consistent estimator of the data generating process in a functional of the true data distribution. Simulations are only a tool to evaluate the resulting estimated functional which, more often than not, is not available in closed form. There are, however, interesting exceptions like linear indirect least squares. Moreover, even though we always refer to the general concept of Monte Carlo integration, it does not necessarily involve a large number of simulated paths. Asymptotic theory of simulation-based estimation techniques will be considered when the length of the observed sample path goes to infinity. Depending on the techniques, the number of simulated paths may or may not be constrained to tend to infinity to get consistent estimators.

1. General framework and simulation-based bias correction

Let us denote by $\theta$ a vector of $p$ unknown parameters. We want to build an accurate estimator $\hat{\theta}_T$ of $\theta$ from an observed sample path of length $T$. Let us assume that we have at our disposal some initial estimator, denoted by $\hat{\beta}_T$. Note that we purposely use a letter $\beta$ different from $\theta$ to stress that the estimator $\hat{\beta}_T$ may give a very inaccurate assessment of the true unknown $\theta^0$ we want to estimate. In particular this estimator is potentially severely biased: its expectation $E_T(\theta^0)$ does not coincide with $\theta^0$. The notation $b_T(\theta^0)$ refers to the so-called binding function (Gourieroux and Monfort, 1995) and depends on at least two things: not only on the true unknown value of the parameters of interest but also on the sample size. The bootstrap is a method for estimating the distribution of an estimator, and in particular its expectation, by re-sampling the data. We refer the reader to Hall (1992) and Horowitz (1997) for surveys from which we borrow here. Since the bootstrap estimate is built upon an estimator of the data distribution, it is always recommended to use a parametric estimator of it when available. This is why, since this article is about estimation in parametric models, we focus on the parametric bootstrap, which was first considered in econometrics for the linear regression model with Gaussian errors:

$$y_i = x_i^T \beta + \sigma \varepsilon_i, \quad \varepsilon_i \sim \text{IN}(0, 1).$$

Of course, bootstrapping is not very useful in such a simple context but it may become relevant if for instance the dependent variable is replaced by its Box–Cox transformation with some unknown parameters (Horowitz, 1997). More generally we allow for any kind of non-linear transformation and also for dynamic models in reduced form, possibly including lagged endogenous variables among the explanatory variables (see Monfort and van Dijk, 1995 for a thorough exposition of the general framework presented below):

$$y_t = r[z(1, t), y_0(0, t - 1), \varepsilon_{i_t}, \theta], \quad t = 1, \ldots, T$$
where \((\varepsilon_t)\) is a white-noise process whose marginal distribution \(P_{\varepsilon}\) is known, \((z_t)\) is a process which is independent of \((\varepsilon_t)\), \(z(1,t) = (z_t)_{1 \leq t \leq T}\) and \(r(\cdot)\) is a known function. Model (0) defines the conditional pdf \(f[\gamma|\gamma; \theta]\) where \(\gamma\) includes the realization of all the predetermined variables \(z(1,t)\) and \(y(0,t-1)\). Then, by drawing independently from \(P_{\varepsilon}\), it is possible to simulate values of \(t = 1, \ldots, T\) and \(h = 1, \ldots, H\) and to compute:

\[
\gamma_t^h(\theta) = r(z(1, t), y(0, t - 1), \varepsilon_t^h, \theta), \quad t = 1, \ldots, T, \quad h = 1, \ldots, H.
\]

The pdf of \(\gamma_t^h(\theta)\) is precisely \(f[\gamma|\gamma; \theta]\). In other words, it is possible to perform conditional simulations, that is, to draw, for each \(t\), from the conditional distribution whose pdf is \(f[\gamma|\gamma; \theta]\) for any given value \(\theta\) of the unknown parameters and for the observed value of \(x_t\). Note that, in all simulation-based estimation methods considered below, the basic drawings \(\varepsilon_t^h\) will be kept fixed when \(\theta\) changes.

For the purpose of SMM, it will actually be worthwhile making a distinction between such conditional simulations and (unconditional) path simulations, which may be the only ones feasible in the more general case of a non-linear state-space model defined as:

\[
\begin{align*}
\gamma_t &= r_1(z(1, t), y(0, t - 1), y^*(0, t), \varepsilon_{1t}; \theta), \quad t = 1, \ldots, T \\
y_t^* &= r_2(z(1, t), y(0, t - 1), y^*(0, t - 1), \varepsilon_{2t}; \theta), \quad t = 1, \ldots, T
\end{align*}
\]

where \(\varepsilon_t = (\varepsilon_{1t}, \varepsilon_{2t})\) is a white-noise process whose marginal distribution \(P_{\varepsilon}\) is known, \((z_t)\) is independent of \((\varepsilon_t)\), \((y_t^*)\) is a process of latent variables and \(r_1\) and \(r_2\) are two known functions. The big difference between models (1) and (2) is that the latter only recursively defines the observed endogenous variables through a path of latent ones, making conditional simulation impossible. More precisely, from independent random draws \(\varepsilon_t^h, t = 1, \ldots, T\) and \(h = 1, \ldots, H\) in \(P_{\varepsilon}\) we can now compute recursively:

\[
\begin{align*}
\gamma_t^h(\theta) &= r_2(z(1, t), y^h(0, t - 1)(\theta), y^*(0, t - 1)(\theta), \varepsilon_{2t}^h; \theta), t = 1, \ldots, T, \quad h = 1, \ldots, H \\
y_t^h(\theta) &= r_1(z(1, t), y^h(0, t - 1)(\theta), y^*(0, t)(\theta), \varepsilon_{1t}^h; \theta), t = 1, \ldots, T, \quad h = 1, \ldots, H
\end{align*}
\]

In other words, while each simulated path \(y_t^h(0, T)(\theta), h = 1, \ldots, H\) has been correctly drawn from its distribution given the observed path \(z(1,T)\) of exogenous variables for each possible value of \(\theta\), the draw of \(y_t^h(\theta)\) at each given \(t\) is conditional to past simulated \(y_t^h(0, t - 1)(\theta)\) and not to past observed \(y(0,t-1)\); hence the terminology path simulations. Note, however, that the model does not specify the probability distribution of exogenous variables and thus, all simulations are conditional to the observed path \(z(1,T)\) of exogenous variables.

In both cases, model (1) or (2), since the spirit of bootstrap is re-sampling from a preliminary estimator, \(\hat{\theta}_T\) gives rise to \(H\) bootstrap samples \(y_t^h(0, T)(\hat{\theta}_T), h = 1, \ldots, H\).
each bootstrap sample, the same estimation procedure can be applied to get $H$ estimators denoted as $b^h_T(\hat{\theta}_T)$, $h=1, \ldots, H$. These $H$ estimations characterize the bootstrap distribution of $\hat{\theta}_T$ and allow us for instance to approximate the expectation $b_T(\theta_D)$ by $b_T(\hat{\theta}_T)$. Of course, $b_T(\hat{\theta}_T)$ is not known in general but may be approximated at any desired level of accuracy, from the Monte Carlo average \[ \left( \frac{1}{H} \sum_{h=1}^{H} b^h_T(\hat{\theta}_T) \right), \] for $H$ sufficiently large. As already mentioned, one may imagine non-simulation based versions of bootstrap when the binding function is available in closed form. In any case, the bias-corrected bootstrap estimator is then defined as:

$$\hat{\theta}_T = \hat{\theta}_T - [b_T(\hat{\theta}_T) - \hat{\theta}_T] \quad (3)$$

It is worth mentioning however that this parametric bootstrap procedure requires that we sufficiently trust the initial estimator $\hat{\theta}_T$ to consider that the estimated bias $[b_T(\hat{\theta}_T) - \hat{\theta}_T]$ gives a correct assessment of the true bias $[b_T(\theta_D) - \theta_D]$. This is the reason why Gourieroux, Renault and Touzi (2000) have rather proposed an iterative procedure which, at step $j$, improves upon an estimator $\hat{\theta}^j_T$ by computing $\hat{\theta}^{j+1}_T$ as:

$$\hat{\theta}^{j+1}_T = \hat{\theta}^j_T + \lambda [\hat{\theta}_T - b_T(\hat{\theta}^j_T)] \quad (4)$$

for some given updating parameter $\lambda$ between 0 and 1. In other words, at each step, a new set of simulated paths $\tilde{\theta}^{0, H}_T(\hat{\theta}^j_T)$, $h=1, \ldots, H$ is built and it provides a Monte Carlo assessment $b_T(\hat{\theta}^j_T)$ of the expectation of interest. It is worth noting that this does not involve new random draws of the noise $\varepsilon$. Note that (3) corresponds to the first iteration of (4) in the particular case $\lambda = 1$ with a starting value $\hat{\theta}^1_T = \hat{\theta}_T$. While this preliminary estimator is indeed a natural starting value, the rationale for considering $\lambda$ smaller than 1 is to increase the probability of convergence of the algorithm, possibly at the cost of slower convergence (if faster update would also work). If the algorithm converges, its limit will define an estimator $\hat{\theta}_T$ solution of:

$$b_T(\hat{\theta}_T) = \hat{\theta}_T \quad (5)$$

Gourieroux, Renault and Touzi (2000) study more generally the properties of the estimator (5), which is actually a particular case of SII estimators developed in the next section. The intuition is quite clear. Let us call $\hat{\theta}_T$ the naive estimator. Our preferred estimator $\hat{\theta}_T$ is the value of unknown parameters $\theta$, which, if it had been the true one, would have generated a naive estimator which, in average, would have coincided with our actual naive estimation. In particular, if the bias function $[b_T(\theta) - \theta]$ is linear with respect to $\theta$, we deduce $b_T[E(\hat{\theta}_T)] = E(\hat{\theta}_T) = b_T(\theta_D)$ and thus our estimator is unbiased. Otherwise, unbiasedness is only approximately true to the extent a linear approximation of the bias is reasonable. Since, in the context of stationary first order autoregressive processes, the negative bias of the OLS estimator of the correlation...
coefficient becomes more severely non-linear in the near unit root case, Andrews (1993) has put forward a median-unbiased estimator based on the principle (5) with median replacing expectation. The advantage of median is to be immune to nonlinear monotonic transformations. However, its generalization to multivariate parameters is problematic.

Another well-documented advantage of bootstrap is to provide asymptotic refinements when the initial procedure is not too bad. Gourieroux, Renault and Touzi (2000) have shown that SII does as well as bootstrap in this respect.

2 Simulation-based indirect inference

Let us start from the simple textbook example of a just-identified supply–demand system in equilibrium:

\[ Q_t^s = \theta_1 p_t + \theta_2 z_{1t} + \nu_{1t} Q_t^d = \theta_3 p_t + \theta_4 z_{2t} + \nu_{2t} Q_t^s = Q_t = Q_t. \]

Then the reduced form can obviously be written as a bivariate regression of \((Q_t, p_t)\) on \((z_{1t}, z_{2t})\) and the reduced form regression coefficients \(\hat{\beta}\) are given as a function \(\beta = b(\theta)\) of the structural parameters:

\[ \theta = (\theta_1, \theta_2, \theta_3, \theta_4) b(\theta) = (\theta_1 - \theta_2)^{-1}(-\theta_2 \theta_3, \theta_1 \theta_4, - \theta_2, \theta_4). \]

Under standard assumptions, the vector \(\hat{\beta}\) of reduced form parameters can be consistently estimated by its OLS counterpart \(\hat{\beta}_T\). Moreover, the binding function \(\hat{\beta} = b(\theta)\) relating the vector \(\hat{\beta}\) of reduced form parameters to the vector \(\theta\) of structural parameters is clearly one-to-one. Inverting the binding function is a straightforward exercise and suggests computing a consistent estimator \(\hat{\theta}_T\) of the structural parameters as \(\hat{\theta}_T = b^{-1}(\hat{\beta}_T)\). This estimator has been known since the early days of the simultaneous equations literature as the *indirect least squares* estimator. We conclude from this example that defining an indirect estimator \(\hat{\theta}_T\) of the parameters of interest from an initial estimator \(\hat{\beta}_T\) and a binding function \(b_T(\cdot)\) by solving the equation:

\[ b_T(\hat{\theta}_T) = \hat{\beta}_T \]

may be worthwhile in many situations other than the bias-correction setting of Section 1. The vector \(\hat{\beta}\) of the so-called *instrumental parameters* must identify the *structural parameters* \(\theta\) but does not need to bear the same interpretation. However, the example of *indirect least squares* is too simple to display all the features of indirect inference as more generally devised by Smith (1993) and Gourieroux, Monfort and Renault (1993). Two complications may arise.

First, the binding function is not in general available in closed form and can be characterized only thanks to Monte Carlo integration. Moreover, by contrast with the simple linear example, the binding function does depend in general on the sample size \(T\).

Second, most interesting examples allow for over-identification of the structural parameters, for instance through a bunch of instrumental variables in the simultaneous equation case. This is the reason why we refer henceforth to the auxiliary parameters \(\hat{\beta}\) as instrumental parameters.
The key idea is that, as already explained in Section 1, our preliminary estimation procedure for instrumental parameters not only gives us an estimation \( \hat{\beta}_T \) computed from the observed sample path but can also be applied to each simulated path \( \mathcal{Y}^h(0, T)(\theta), h=1, \ldots, H \), always associated to the observed path \( z(1,T) \) of exogenous variables. Thus, we end up, for any fixed value of \( \Theta \), with a set of \( H \) ‘estimations’ \( \hat{\beta}^{(h)}_T (\theta) \). Averaging them, we get a Monte Carlo binding function:

\[
\beta_{T,H}(\theta) = \frac{1}{H} \sum_{h=1}^H \hat{\beta}^{(h)}_T (\theta).
\]

The exact generalization of what we did in Section 1 amounts to defining the binding function \( b_T(\theta) \) as the probability limit (w.r.t. the random draw of the process \( \varepsilon \)) of the sequence \( \beta_{T,H}(\theta) \) when \( H \) goes to infinity. However, for most non-linear models, the instrumental estimators \( \hat{\beta}^{(h)}_T (\theta) \) are not reliable for finite \( T \) but only for a sample size \( T \) going to infinity. It is then worth realizing that when \( T \) goes to infinity, for any given \( h=1, \ldots, H \), \( \hat{\beta}^{(h)}_T (\theta) \) should tend towards the so-called asymptotic binding function \( b(\theta) \) which is also the limit of the finite sample binding function \( b_T(\theta) \). Therefore, as far as consistency of estimators when \( T \) goes to infinity is concerned, a large number \( H \) of simulations is not necessary and we will define more generally an indirect estimator \( \hat{\theta}_T \) as solution of a minimum distance problem:

\[
\text{Min}_{\theta} \left\{ \left[ \hat{\beta}_T - \beta_{T,H}(\theta) \right] \right\}^\top \Omega_T \left[ \hat{\beta}_T - \beta_{T,H}(\theta) \right] \tag{7}
\]

where \( \Omega_T \) is a positive definite matrix converging towards a deterministic positive definite matrix \( \Omega \). In case of a completed Monte Carlo integration (\( H \) large) we end up with an approximation of the exact binding function-based estimation:

\[
\text{Min}_{\theta} \left\{ \left[ \hat{\beta}_T - b_T(\theta) \right] \right\}^\top \Omega_T \left[ \hat{\beta}_T - b_T(\theta) \right] \tag{8}
\]

which generalizes the bias-correction procedure of Section 1. As in Section 1, we may expect good finite sample properties of such an indirect estimator since, intuitively, the finite sample bias is similar in the two quantities, which are matched against each other and thus should cancel out in the matching process.

In terms of asymptotic theory, the main results under standard regularity conditions (see Gourieroux, Monfort and Renault, 1993) are:

1. (i) the indirect inference estimator \( \hat{\theta}_T \) converges towards the true unknown value \( \theta^0 \) insofar as the asymptotic binding function identifies it:

\[
b(\theta) = b(\theta^0) = \theta = \theta^0;\]
2. (ii) the indirect inference estimator $\hat{\theta}_T$ is asymptotically normal insofar as the asymptotic binding function first order identifies the true value:

$$\frac{\partial L}{\partial \theta}(\theta^0) \text{ is of full-column rank;}$$

3. (iii) we get an indirect inference estimator with a minimum asymptotic variance if and only if the limit-weighting matrix is proportional to the inverse of the asymptotic variance $\Sigma_H$ of $\sqrt{T}(\hat{\theta}_T - \theta_T, H(\theta^0))$.

4. (iv) the asymptotic variance of the efficient indirect inference estimator is the inverse of

$$\frac{\partial L}{\partial \theta}(\theta^0)(\Sigma_H)^{-1} \frac{\partial L}{\partial \theta}(\theta^0)$$

with

$$\Sigma_H = \left[1 + \frac{1}{H}\right]\Sigma_\infty.$$ 

An implication of these results is that, as far as asymptotic variance of the indirect inference estimator is concerned, the only role of a finite number $H$ of simulations is to multiply the optimal variance (obtained with $H=\infty$) by a factor $(1+1/H)$. Actually, when computing the indirect inference estimator (7), one may be reluctant to use a very large $H$ since it involves, for each value of $\Theta$ along a minimization algorithm, computing $H$ instrumental estimators $\hat{\theta}_T(h)$, $h = 1, \ldots, H$. We will see in Section 3 several ways to replace these $H$ computations by only one. However, this will come at a price, which is the probable loss of the nice finite sample properties of (7) and (8).

As a conclusion, let us stress that indirect inference is able, beyond finite sample biases, to correct for any kind of misspecification bias. The philosophy of this method is basically to estimate a simple model, possibly wrong, to get easily an instrumental estimator $\hat{\theta}_T$ while a direct estimation of structural parameters $\Theta$ would have been a daunting task. Therefore what really matters is to use an instrumental parameter that captures the key features of the parameters of interest, while being much simpler to estimate. For instance, Pastorello, Renault and Touzi (2000) and Engle and Lee (1996) have proposed to first estimate a GARCH model as an instrumental model to indirectly recover an estimator of the structural model of interest, a stochastic volatility model much more difficult to estimate directly. Other natural examples are models with latent variables such that an observed variable provides a convenient proxy. An estimator based on this proxy suffers from a misspecification bias, but we end up with a consistent estimator by applying the indirect inference matching. Examples of this approach are:

- (i) Pastorello, Renault and Touzi (2000), who use Black and Scholes implied volatilities as a proxy of realizations of the latent spot volatility process.
- (ii) Li (2006), who, following a suggestion of Renault (1997), uses observed bids in an auction market as a proxy of latent private values.
3 Simulated method of moments

SMM, as introduced by Ingram and Lee (1991) and Duffie and Singleton (1993), is the simulation-based counterpart of GMM to take advantage of the informational content of some conditional moment restrictions:

$$E\left\{ K[\nu_t, z(1, t)] | z(1, t) \right\} = k[z(1, t); \theta^0].$$

The role of simulations in this context is to provide a Monte Carlo assessment of the population conditional moment function $K[z(1, t); \theta]$ when it is not easily available in closed form. Typically, with $\nu_t^h(\theta)$ drawn as above for $h=1, \ldots, H$ (model (1) or (2)), a convenient Monte Carlo counterpart is:

$$(1/H) \sum_{h=1}^H K[\nu_t^h(\theta), z(1, t)].$$

Even though we will mainly present SMM in this simple setting, two possible extensions are worth mentioning.

1. First, in dynamic settings, one may want to consider conditional moment restrictions given not only past and current exogenous variables but also past endogenous variables:

$$E\left\{ K[\nu_t, z(1, t), \nu(0, t - 1)] | z(1, t) \right\} = k[z(1, t), \nu(0, t - 1); \theta^0].$$

SMM can still be applied to this kind of dynamic moment insofar as one is able to draw simulated values $\nu_t^h(\theta)$ in the conditional probability distribution (corresponding to the value $\theta$ of parameters) of $\nu_t$ given $\nu_t = \{z(1, t), \nu(0, t - 1)\}$. In other words, we need conditional simulations and not only path simulations. As explained above, such conditional simulations are not feasible when the structural model is only defined through a recursive form (2). By contrast, either path simulations or conditional simulations work for static moment conditions (9).

2. Second, the introduction of latent variables paves the way for many other Monte Carlo assessments of the population expectation $E\{K[\nu_t, z(1, t)] | z(1, t)\}$. Let us assume to simplify that $\nu_t = r_1(\nu_t^*)$ with i.i.d. latent variables $\nu_t^*$ endowed with a probability distribution with fixed support (independent of the unknown parameters $\theta$). Of course, the density function $f[\nu_t^* | z(1, t); \theta]$ does depend on $\theta$ but one may also pick, as a sampling tool called importance function, another distribution with a given density function $\phi(u_t)$ on the same support. Then, instead of assessing the population expectation with its naive Monte Carlo counterpart

$$(1/H) \sum_{h=1}^H K[r_1(\nu_t^* h(\theta)), z(1, t)].$$

one may prefer to resort to
where the \( u_t^h, h=1, \ldots, H \), are independently drawn from the distribution with density function \( \varphi(u_t) \). This kind of \textit{importance sampling} may be helpful, for instance, for removing some nasty lack of smoothness with respect to the unknown parameters.

As far as static conditional moment restrictions like (9) are concerned, the natural way to extend GMM with a Monte Carlo assessment of the population moment is to minimize with respect to the unknown parameters \( \theta \) a norm of the sample mean of:

\[
\frac{1}{(1/H) \sum_{h=1}^{H}} K[y_t(\theta), z(1, t)] \frac{f[u_t^h z(1, t), \theta]}{\varphi(u_t^h)}
\]

where \( Z_t \) is a matrix of chosen instruments, that is a fixed matrix function of \( z(1,t) \). It is then clear that the minimization programme which is considered is a particular case of (7) above with:

\[
\hat{\theta}_T = \frac{(1/T) \sum_{t=1}^{T} Z_t K[y_t, z(1, t)]}{1 + 1/H}
\]

and \( \hat{\theta}_T, H(\theta) \) defined accordingly. In other words, we reinterpret SMM as a particular case of \textit{indirect inference}, when the instrumental parameters to match are simple moments rather than themselves defined through some structural interpretations. Note, however, that the moment conditions for SMM could be slightly more general since the function \( K[y_t, z(1,t)] \) itself could depend on the unknown parameters \( \theta \). In any case, the general asymptotic theory sketched above for SII is still valid. It may be a little more involved when using importance sampling, since then the variance of the simulator no longer coincides with the variance of the initial moments, and then computing the asymptotic variance of the SMM estimator is no longer simply akin to multiplying standard formulas by a factor \( 1+1/H \). However, we still note that the number \( H \) of simulated paths does not need to be large for getting consistent and rather accurate estimators.

In contrast with general SII as presented above, an advantage of SMM is that the instrumental parameters to match, as simple moments, are in general easier to compute than estimated auxiliary parameters \( \hat{\theta}_T(\theta), h=1, \ldots, H \), derived from some computationally demanding \textit{extremum} estimation procedure. Gallant and Tauchen (1996) have taken advantage of this remark to propose a practical computational strategy for implementing indirect inference when the estimator \( \hat{\theta}_T \) of the instrumental parameters is obtained as an M-estimator solution of:

\[
\text{Max}_{\theta} (1/T) \sum_{t=1}^{T} Q_t[y(0, t), z(1, t); \theta]
\]
The key idea is then to define the moments to match through the (pseudo)-score vector of this M-estimator. Let us denote

\[ K[\gamma(0, t), z(1, t); \beta] = \frac{\partial q_T}{\partial \beta} [\gamma(0, t), z(1, t); \beta] \]

and consider an SMM estimator of \( \theta \) obtained as a minimizer of the norm of a sample mean of:

\[ K[\gamma(0, t), z(1, t); \hat{\theta}_T] - (1 / H) \sum_{h=1}^{H} K[\gamma^h(0, t)(\theta), z(1, t); \hat{\theta}_T]. \]

For a suitable GMM metric, such a minimization defines a so-called simulated-score matching estimator \( \hat{\theta}_T \) of \( \theta \). In the spirit of Gallant and Tauchen (1996), the objective function that defines the initial estimator \( \hat{\theta}_T \) is typically the log-likelihood of some auxiliary model. However, this feature is not needed for the validity of the asymptotic theory sketched below. Several remarks are in order:

1. By contrast with a general SMM criterion, the minimization above does not involve the choice of any instrumental variable. Typically, over-identification will be achieved by choosing an auxiliary model with a large number of instrumental parameters \( \beta \) rather than by choosing instruments.
2. By definition of \( \hat{\theta}_T \), the sample mean of \( K[\gamma(0,t),z(1,t);\hat{\theta}_T] \) takes the value zero for \( \hat{\theta} = \hat{\theta}_T \). In other words, the minimization programme above amounts to:

\[
\text{Min}_{\theta} \left\| \frac{1}{TH} \sum_{t=1}^{T} \sum_{h=1}^{H} \frac{\partial q_T}{\partial \beta} \left[ \gamma^h(0, t)(\theta), z(1, t); \hat{\theta}_T \right] \right\| \Omega_T
\]

for a suitable GMM metric \( \Omega_T \).
3. It can be shown (see Gourieroux, Monfort and Renault, 1993) that under the same assumptions as for the asymptotic theory of SII, the score-matching estimator is consistent asymptotically normal. We get a score-matching estimator with a minimum asymptotic variance if and only if the limit-weighting matrix \( \Omega \) is proportional to the inverse of the asymptotic conditional variance of

\[
\sqrt{T} \sum_{t=1}^{T} \frac{\partial q_T}{\partial \beta} [\gamma(0, t), z(1, t); \theta(0)]
\]
given the exogenous variables $z$. Then the resulting efficient score-matching estimator is asymptotically equivalent to the efficient indirect inference estimator.

4. Owing to this asymptotic equivalence, the score-matching estimator can be seen as an alternative to the efficient SII estimator characterized in Section 2. This alternative is often referred to as efficient method of moments (EMM) since, when $q_t[y(0,t),z(1,t);\beta]$ is the log-likelihood $\int q_t[y(1,t),y(0,t-1);\beta]$ of some auxiliary model, the estimator is as efficient as maximum likelihood under correct specification of the auxiliary model. More generally, the auxiliary model is designed to approximate the true data generating process as closely as possible and Gallant and Tauchen (1996) propose the semi-nonparametric (SNP) modelling to this end. These considerations and the terminology EMM should not lead us to believe that score-matching is more efficient than indirect inference. The two estimators are asymptotically equivalent even though the score-matching approach makes more transparent the required spanning property of the auxiliary model to reach the Cramer Rao efficiency bound of the structural model.

5. Another alleged advantage of the score-matching with respect to parameter-matching in SII is its low computational cost. The fact is that with a large number of instrumental parameters $\beta$, as will typically be the case with a SNP auxiliary model, it may be costly to maximize $H$ times the log-likelihood of the auxiliary model (for each value of $\Theta$ along an optimization algorithm) with respect to $\beta$ to compute $\hat{\beta}_T^{(H)}(\theta), h=1, \ldots, H$. By contrast, the programme (10) minimizes only once the norm of a vector of derivatives with respect to $\hat{\beta}$. One must realize, however, that not only is this cheaper computation likely to lose the expected nice finite sample properties of SII put forward in the previous section, but also that the point is not really about a choice between matching (instrumental) parameters $\beta$ or matching the (instrumental) score $\sum_{t=1}^T \frac{\partial q_t}{\partial \beta}$. The key issue is rather the way to use $H$ simulated paths of size $T$ each as explained below.

6. It is worth realizing that the sum of $TH$ terms considered in the definition (10) of the score-matching estimator is akin to consider only one simulated path $y^*(0, TH)(\theta)$ of size $TH$ built from random draws as above (conditional simulations or path simulations) from a fictitious path $z^*(1,TH)$ of exogenous variables defined in the following way:

$$z_1^* = z_1, \ldots, z_T^* = z_T, z_{T+1}^* = z_1, \ldots, z_{2T}^* = z_T, z_{2T+1}^* = z_1, \ldots, z_{TH}^* = z_T.$$ 

If for instance $(z_t)$ is Markov of order 1, such a fictitious path is a correct draw except possibly for $H$ values, which is immaterial when $T$ goes to infinity. From such a simulated path, estimation of instrumental parameters would have produced a vector $\hat{\beta}_{TH}^{(1)}(\theta)$ that could have been used for indirect inference, that is to define an estimator $\hat{\beta}_T$ solution of:

$$\min_{\beta} [\hat{\beta}_T - \hat{\beta}_{TH}^{(1)}(\theta)]' \Omega_T [\hat{\beta}_T - \hat{\beta}_{TH}^{(1)}(\theta)].$$

This parameter-matching estimator is not more computationally demanding than the corresponding score-matching estimator computed from the same simulated path as solution of:

$$\min_{\beta} \left\| \left( 1 / TH \right) \sum_{t=1}^{TH} \frac{\partial q_t}{\partial \beta} [y^*(0,t)(\theta), z^*(1,t); \hat{\beta}_T] \right\| \Omega_T.$$
Actually, (11) and (12) are numerically identical in the case of just-identification \((\dim \theta = \dim \beta)\). Then the choice of a GMM metric is immaterial and both estimators are basically the solution \(\hat{\theta}_T\) of:

\[
\frac{1}{TH} \sum_{t=1}^{TH} \frac{\partial q_t}{\partial \beta} \left[ \gamma^1(0, t)(\hat{\theta}_T), z^*(1, t); \hat{\theta}_T \right] = 0.
\]

More generally, the four estimators (7), (10), (11) and (12) are asymptotically equivalent when \(T\) goes to infinity and the GMM weighting matrix is efficiently chosen accordingly. However, it is quite obvious that only (7) performs the right finite sample bias correction by matching instrumental parameters values estimated on both observed and simulated paths of lengths \(T\). The trade-off is thus between giving up finite sample bias correction or paying the price for computing \(H\) estimated instrumental parameters.

4 Simulated M-estimators

Even though well-chosen moments to match may allow one to get accurate estimators, it is somewhat contradictory to resort to a fully parametric model to perform simulations needed for SMM while Hansen’s (1982) GMM was semi-parametric in spirit. Simulated maximum likelihood (SML) methods aim at exploiting the whole parametric structure for efficient estimation. The key role of simulations would then be to provide an unbiased simulator of each conditional p.d.f. \(f[\gamma|x_\theta, \theta]\) (also denoted \(f[y|x_\theta, \theta]\)) because it is not available in closed form. This is typically the case in a model with latent variables, and then conditioning may provide a convenient simulator. The simplest example comes from model (2) when latent variables are exogenous. Let us write it without observed exogenous variables for sake of expositional simplicity:

\[
\begin{align*}
\gamma_t &= r_1[\gamma(0, t - 1), \gamma^*(0, t), \epsilon_1, \theta], & t = 1, \ldots, T \nonumber \\
\gamma^*_t &= r_2[\gamma^*(0, t - 1), \epsilon_2, \theta], & t = 1, \ldots, T.
\end{align*}
\]

Then \(f[y|x_\theta, \theta]\) is nothing but the expectation with respect to the probability distribution of \(y^*(0, t)\) of \(f[y|x_\theta, \gamma^*(0, t), \theta]\). While the latter is easily deduced from the pdf of \(\epsilon_1\) through the measurement equation (the first equation above), the former is in general easy to compute from the evolution equation (the second equation above). Then Monte Carlo integration provides an unbiased estimate of \(f[y|x_\theta, \theta]\) with \((1/H) \sum_{h=1}^{H} f[y|x_\theta, \gamma^h(0, t) \theta; \theta]\) where \(\gamma^h(0, t) \theta; h=1, \ldots, H\) are independent draws obtained from independent draws in the known distribution of \(\epsilon_2\). Of course, importance sampling must also be relevant in this context. Moreover, for a general model (2), when \(y\) does cause \(y^*\), this naive approach may be very inefficient (in terms of speed of convergence of the variance towards zero) and one may want to refer to either accelerated versions of importance sampling (Danielsson and Richard, 1993), simulated expectation maximization algorithm (SEM, see for example Shephard, 1993) and other more sophisticated simulators, which are beyond the scope of this article.
Irrespective of the choice of the simulator, the main difficulty with SML is that the logarithm of an unbiased simulator of the likelihood is not an unbiased simulator of the log-likelihood. Therefore, in contrast with SMM, SML is consistent only when both $H$ and $T$ go to infinity. Note, however, that asymptotic bias corrections are possible (see Gourieroux and Monfort, 1996). Under standard regularity conditions, SML is asymptotically efficient insofar as $T$ goes to infinity slower than $H^2$. Another version of the SML method is the simulated score method (see Hajivassiliou, 1993). This is basically a version of SMM where the latent score is used as a simulator for the score of the model on observables, while the later is not tractable analytically. This method should not be confused with simulated score matching of the former section, where the score to match was not something to simulate to get it in closed form.

Finally, it is worth mentioning that simulation-based estimation methods are not always to be recommended, even in some fully parametric modelling situations with latent variables making standard maximum likelihood unfeasible. Such situations typically occur with structural econometric models where equilibrium of a market or of a game implies a deterministic relationship between latent variables and observed ones. Then, not only is the above SML theory no longer valid but any other simulation based method will in general be highly inefficient because the dependence between the two blocks of unknown ‘parameters’, namely, structural parameters and latent variables, is sharp. In such contexts, some authors have, however, considered some simulated non-linear least squares methods (Laffont, Ossard and Vuong, 1995 for auction markets) or more generally simulated pseudo-likelihood methods (Laroque and Salanie, 1993). While the focus of interest of Laroque and Salanie (1993) on a disequilibrium model raised more involved issues due to non-differentiability, it is rather clear that some implied state GMM methods (Pan, 2002; Pastorello, Patilea and Renault, 2003) are more efficient than SMM in the contexts of smooth equilibrium relationships like those produced by option pricing theory. The key issue is to take advantage of the deterministic relationship between $y_t$ and $\frac{1}{T}$ (for a given value of the parameters $\theta$) to track what would have been an efficient estimation if latent variables had been observed.

5 Concluding remarks

The econometrician’s search for a well-specified parametric model (‘quest for the Holy Grail’ as stated by Monfort, 1996) and associated efficient estimators even remain popular when MLE becomes intractable due to highly non-linear dynamic structure including latent variables. The efficiency properties of SML, EMM and more generally of SMM and SII when the set of instrumental parameters to match is sufficiently large to span the likelihood scores are often advocated as if the likelihood score is well specified. However, the likely misspecification of the structural model requires a generalization of the theory of SII as recently proposed by Dridi, Guay and Renault (2007).

As for MLE with misspecification (see White, 1982; Gourieroux, Monfort and Trognon, 1984) such a generalization entails two elements. First, asymptotic variance formulas are complicated by the introduction of sandwich formulas. Ignoring this kind of correction is even more detrimental than for QMLE since two types of sandwich formulas must be taken into account, one for the data generating process (DGP) and one for the simulator (based either on model (1) or model (2)) which turns out to be different from the DGP in case of misspecification.

Secondly, and even more importantly, misspecification may imply that we consistently estimate a pseudo-true value, which is poorly related to the true unknown value of the parameters of interest. Dridi, Guay and Renault (2007) put forward the necessary (partial) encompassing property of the instrumental model (through instrumental parameters $\beta$) by the structural model (with parameters $\theta$) needed to ensure consistency towards true values of (part of) the components of $\theta$ in spite of misspecification. The key issue is that, since structural parameters are recovered from instrumental ones by inverting a binding function $\beta = b(\theta)$, all components are interdependent. The requirement of encompassing typically means that, if one does not want to proceed under the maintained assumption that the structural model (1) or (2) is true, one must be parsimonious with respect to the number of moments to match or more generally to the scope of empirical evidence that is captured by the instrumental parameters $\beta$. In other words, robustness to misspecification requires an instrumental model choice strategy opposite to that commonly used for a structural model: the larger the instrumental model, the larger the risk of contamination of the estimated structural parameters of interest by what is wrong in the structural model. Of course, there is no such thing as a free lunch: robustness to misspecification through a parsimonious and well-focused instrumental model comes at the price of efficiency loss. Efficiency loss means not only lack of accuracy of estimators of structural parameters but also lack of power of specification tests.

**Bibliography**

**How to cite this article**

Models that attempt to explain the workings of the economy typically are written as interdependent systems of equations describing some hypothesized technological and behavioural relationships among economic variables. Supply and demand models, Walrasian general equilibrium models, and Keynesian macromodels are common examples. A large part of econometrics is concerned with specifying, testing and estimating the parameters of such systems. Despite their common use, simultaneous equations models still generate controversy. In practice there is often considerable disagreement over their proper use and interpretation.

In building models economists distinguish between endogenous variables which are determined by the system being postulated and exogenous variables which are determined outside the system. Movements in the exogenous variables are viewed as autonomous, unexplained causes of movements in the endogenous variables. In the simplest systems, each of the endogenous variables is expressed as a function of the exogenous variables. These so-called ‘reduced-form’ equations are often interpreted as causal, stimulus–response relations. A hypothetical experimental is envisaged where conditions are set and an outcome occurs. As the conditions are varied, the outcome also varies. If the outcome is described by the scalar endogenous variable $y$ and the conditions by the vector of exogenous variables $x$, then the rule describing the causal mechanism can be written as $y = f(x)$. If there are many outcomes of the experiment, $y$ and $f$ are interpreted as vectors; the rule describing how the $i$th outcome is determined can be written as $y_i = f_i(x)$.

Most equations arising in competitive equilibrium theory are motivated by hypothetical stimulus–response experiments. Demand curves, for example, represent the quantity people will purchase when put in a price-taking market situation. The conditions of the experiment are, in addition to price, all the other determinants of demand. In any given application, most of these determinants are viewed as fixed...
Simultaneous equations models: The New Palgrave Dictionary of Economics

as the experiment is repeated; attention is directed at the handful of exogenous variables whose effects are being analysed. In an $n$ good world, there are $n$ such equations, each determining the demand for one of the goods as a function of the exogenous variables.

Reduced-form models where each equation contains only one endogenous variable are rather special. Typically, economists propose interdependent systems where at least some of the equations contain two or more endogenous variables. Such models have a more complex causal interpretation since each endogenous variable is determined not by a single equation but simultaneously by the entire system. Moreover, in the presence of simultaneity, the usual least-squares techniques for estimating parameters often turn out to have poor statistical properties.

Why simultaneity?

Given the obvious asymmetry between cause and effect, it would at first thought appear unnatural to specify a behavioural economic model as an interdependent, simultaneous system. Although equations with more than one endogenous variable can always be produced artificially by algebraic manipulation of a reduced-form system, such equations have no independent interpretation and are unlikely to be interesting. It turns out, however, that there are many situations where equations containing more than one endogenous variable arise quite naturally in the process of modelling economic behaviour. These so-called ‘structural’ equations have interesting causal interpretations and form the basis for policy analysis. Four general classes of examples can be distinguished.

1. Suppose two experiments are performed, the outcome of the first being one of the conditions of the second. This might be represented by the two equations $y_1=f_1(x)$ and $y_2=f_2(x, y_1)$. In this two-step causal chain, both equations have simple stimulus–response interpretations. Implicit, of course, is the assumption that the experiment described by the first equation takes place before the experiment described by the second equation. Sequential models where, for example, people choose levels of schooling and later the market responds by offering a wage are of this type. Such recursive models are only trivially simultaneous and raise no conceptual problems although they may lead to estimation difficulties.

2. Nontrivial simultaneous equations systems commonly arise in multi-agent models where each individual equation represents a separate hypothetical stimulus–response relation for some group of agents, but the outcomes are constrained by equilibrium conditions. The simple competitive supply–demand model illustrates this case. Each consumer and producer behaves as though it has no influence over price or over the behaviour of other agents. Market demand is the sum of each consumer's demand and market supply is the sum of each producer's supply, with all agents facing the same price. Although the market supply and demand functions taken separately represent hypothetical stimulus–response situations where quantity is endogenous and price is exogenous, in the combined equilibrium model both price and quantity are endogenous and determined so that supply equals demand.

Most competitive equilibrium models can be viewed as (possibly very complicated) variants of this supply–demand example. The individual equations, when considered in isolation, have straightforward causal interpretations. Groups of agents respond to changes in their environment. Simultaneity results from market clearing equilibrium conditions that make the environments endogenous. Keynesian macromodels have a similar structure. The consumption function, for example, represents consumers’ response to their (seemingly) exogenous wage income – income that in fact is determined by the
3. Models describing optimizing behaviour constitute a third class of examples. Suppose an economic agent is faced with the problem of choosing some vector $y$ in order to maximize the function $F(y, x)$, where $x$ is a vector of exogenous variables outside the agent's control. The optimum value, denoted by $y^*$, will depend on $x$. If there are $G$ choice variables, the solution can be written as a system of $G$ equations, $y^* = g(x)$. If $F$ is differentiable and globally concave in $y$, the solution can be obtained from the first-order conditions $f(y^*, x) = 0$, where $f$ is the $G$-dimensional vector of partial derivatives of $F$ with respect to $y$. The two sets of equations are equivalent representations of the causal mechanism. The first is a reduced-form system with each endogenous variable expressed as a function of exogenous variables alone. The second representation consists of a system of simultaneous equations in the endogenous variables. These latter equations often have simple economic interpretations such as, for example, setting marginal product equal to real input price.

4. Models obtained by simplifying a larger reduced-form system are a fourth source of simultaneous equations. The Marshallian long-run supply curve, for example, is often thought of as the locus of price–quantity pairs that are consistent with the marginal firm having zero excess profit. Both price and quantity are outcomes of a complex dynamic process involving the entry and exit of firms in response to profitable opportunities. If, for the data at hand, entry and exit are in approximate balance, the reduced-form dynamic model may well be replaced by a static interdependent equilibrium model. This last example suggests a possible reinterpretation of the equilibrium systems given earlier. It can be argued (see, for example, Wold, 1954) that multi-agent models are necessarily recursive rather than simultaneous because it takes time for agents to respond to their environments. From this point of view, the usual supply–demand model is a simplification of a considerably more complex dynamic process. Demand and supply in fact depend on lagged prices; hence current price need not actually clear markets. However, the existence of excess supply or demand will result in price movement which in turn results in a change in consumer and producer behaviour next period. When time is explicitly introduced into the model, simultaneity disappears and the equations have simple causal interpretations. But, if response time is short and the available data are averages over a long period, excess demand may be close to zero for the available data. The static model with its simultaneity may be viewed as a limiting case, approximating a considerably more complex dynamic world. This interpretation of simultaneity as a limiting approximation is implicit in much of the applied literature and is developed formally in Strotz (1960).

The need for structural analysis

These examples suggest that systems of simultaneous equations appear quite naturally when constructing economic models. Before discussing further their logic and interpretation, it will be useful to develop some notation. Let $y$ be a vector of $G$ endogenous variables describing the outcome of some economic process; let $x$ be a vector of $K$ ‘predetermined’ variables describing the conditions that determine those outcomes. (In dynamic models, lagged endogenous variables as well as the exogenous variables will be considered as conditions and included in $x$.) By a simultaneous equations model we mean a system of $m$ equations relating $y$ and $x$: 
In the important special case where the functions are linear, the system can be written as the vector equation

$$B y + \Gamma x = 0,$$

(1)

where $B$ is an $m \times G$ matrix of coefficients, $\Gamma$ is an $m \times K$ matrix of coefficients, and 0 is an $m$-dimensional vector of zeros. (The intercepts can be captured in the matrix $\Gamma$ if we follow the convention that the first component of $x$ is a ‘variable’ that always takes the value one.) A complete system occurs when $m=G$ and $B$ is non-singular. Then the vector of outcome variables can be expressed as a linear function of the condition variables.

$$y = -B^{-1}\Gamma x = \Pi x.$$  

(2)

Although the logic of the analysis applies for arbitrary models, the main issues can most easily be illustrated in this case of a complete linear system.

If both sides of the vector equation (1) are premultiplied by any $G \times G$ nonsingular matrix $F$, a new representation of the model is obtained, say

$$B^* y + \Gamma^* x = 0$$

(3)

where $B^* = FB$ and $\Gamma^* = F\Gamma$. If $F$ is not the identity matrix, the systems (1) and (3) are not identical. Yet if one representation is ‘true’ (that is, the real world observations satisfy the equation system) then the other is also ‘true’. Which of the infinity of possible representations should we select? The obvious answer is that it does not matter. Any linear combination of equations is another valid equation. Any nonsingular transformation is as good as any other. For simplicity, one might as well choose the solved reduced form given by eq. (2).
In practice, however, we are not indifferent between the various equivalent representations. There are a number of reasons for that. First, it may be that some representations are easier to interpret or easier to estimate. The first-order conditions for a profit maximizing firm facing fixed prices may, depending on the production function, be much simpler than the reduced form. Secondly, if we contemplate using the model to help analyse a changed regime, it is useful to have a representation in which the postulated changes are easily described. This latter concern leads to the concept of the degree of autonomy of an equation.

In the supply–demand model, it is easy to contemplate changes in the behaviour of consumers that leave the supply curve unchanged. For example, a shift in tastes may modify demand elasticities but have no effect on the cost conditions of firms. In that case, the supply curve is said to be autonomous with respect to this intervention in the causal mechanism. Equations that combine supply and demand factors (like the reduced form relating quantity traded to the exogenous variables) are not autonomous. The analysis of policy change is greatly simplified in models where the equations possess considerable autonomy. If policy changes one equation and leaves the other equations unchanged, its effects on the endogenous variables are easily worked out. Comparative static analysis as elucidated, for example, by Samuelson (1947) is based on this idea. Indeed, the power of the general equilibrium approach to economic analysis lies largely in its separation of the behaviour of numerous economic agents into autonomous equations.

As emphasized by the pioneers in the development of econometrics, it is not enough to construct models that fit a given body of facts. The task of the economist is to find models that successfully predict how the facts will change under specified new conditions. This requires knowing which relationships will remain stable after the intervention and which will not. It requires the model builder to express for every equation postulated the class of situations under which it will remain valid. The concept of autonomy and its importance in econometric model construction is emphasized in the classic paper by Haavelmo (1944) and in the expository paper by Marschak (1953). Sadly, it seems often to be ignored in applied work.

The autonomy of the equations appearing in commonly proposed models is often questionable. Lucas (1976) raises some important issues in his critique of traditional Keynesian macromodels. These simultaneous equations systems typically contain distributed lag relations which are interpreted as proxies for expectations. Suppose, for example, consumption really depends on expected future income. If people forecast the future based on the past, the unobserved expectation variable can be replaced by some function of past incomes. However, since income is endogenous, the actual time path of income depends on all the equations of the model. Under rational expectations, any change in the behaviour of other agents or in technology that affects the time path of income will also change the way people forecast and hence the distributed lag. Thus it can be argued that the traditional consumption function is not an autonomous relation with respect to most interesting policy interventions. Sims (1980) pursues this type of argument further, finding other reasons for doubting the autonomy of the equations in traditional macroeconomic models and concluding that policy analysis based on such models is highly suspect. Although one may perhaps disagree with Sims's conclusion, the methodological questions he raises cannot be ignored.

Even if one accepts the view that structural equations actually proposed in practice often possess limited autonomy and are not likely to be invariant to many interesting interventions, it may still be the case that...
these equations are useful. A typical reduced-form equation contains all the predetermined variables in the system. Given the existence of feedback, it is hard to argue a priori about the numerical values of the various elements of $\Pi$. It may be much easier to think about orders of magnitude for the structural coefficients. Our intuition about the behaviour of individual sectors of the economy is likely to be considerably better than our intuition about the general equilibrium solution. As long as there are no substantial structural changes, specification in terms of structural equations may be appropriate even if some of the equations lack autonomy.

Some econometric issues

The discussion up to now has been in terms of exact relationships among economic variables. Of course, actual data do not lie on smooth monotonic curves of the type used in our theories. This is partially due to the fact that the experiments we have in the back of our mind when we postulate an economic model do not correspond exactly to any experiment actually performed in the world. Changing price, but holding everything else constant, is hypothetical and never observed in practice. Other factors, which we choose not to model, do in fact vary across our sample observations. Furthermore, we rarely pretend to know the true equations that relate the variables and instead postulate some approximate parametric family. In practice we work with models of the form

$$g_i(x, y, \Theta, u_i) = 0 \quad (i = 1, \ldots, m)$$

where the $g$'s are known functions, $\Theta$ is a vector of unknown parameters, and the $u$'s are unobserved error terms reflecting the omitted variables and the misspecification of functional form. In the special case where the functions are linear in $x$ and $y$ with an additive error, the system can be written as

$$By + \Gamma x = u,$$

(4)

where $u$ is a $m$-dimensional vector of errors. If $B$ is non-singular, the reduced form is also linear and can be written as

$$y = -B^{-1}\Gamma x + B^{-1}u = \Pi x + \nu.$$

(5)
Equation system (4) as it stands is empty of content since, for any value of \( x \) and \( y \), there always exists a value of \( u \) producing equality. Some restrictions on the error term are needed to make the system interesting. One common approach is to treat the errors as though they were draws from a probability distribution centred at the origin and unrelated to the predetermined variables. Suppose we have \( T \) observations on each of the \( G+K \) variables, say, from \( T \) time periods or from \( T \) firms. We postulate that, for each observation, the data satisfy eq. (4) where the parameters \( B \) and \( \Gamma \) are constant but the \( n \) error vectors \( u_1, \ldots, u_T \) are independent random variables with zero means. Furthermore, we assume that the conditional distribution of \( u_t \) given the predetermined variables \( x_t \) for observation \( t \) is independent of \( x_t \).

A least-squares regression of each endogenous variable on the set of predetermined variables should then give good estimates of \( \Pi \); if the sample size is large and there is sufficient variability in the regressors. However, unless the inverse of \( B \) contains blocks of zeros, eq. (5) implies that each of the endogenous variables is a function of all the components of \( u \). In general, every element of \( y \) will be correlated with all the endogenous variables, if the correlation is small compared with the sample variation in those variables.

The conclusion that structural parameters in interdependent systems cannot be well estimated using least squares is widely believed by econometric theorists and widely ignored by empirical workers. There are probably two reasons for this discrepancy. First, although the logic of interdependent systems suggests that structural errors are likely to be correlated with all the endogenous variation, if the correlation is small compared with the sample variation in those variables, least squares bias will also be small. Given all the other problems facing the applied econometrician, this bias may be of little concern. Secondly, alternative estimation methods that have been developed often produce terrible estimates. Sometimes the only practical alternative to least squares is no estimate at all—a solution that is rarely chosen.

In some applications, the reduced form parameters \( \Pi \) are of primary concern. The structural parameters \( B \) and \( \Gamma \) are of interest only to the extent they help us learn about \( \Pi \). For example, in a supply–demand model, we may wish to know the effect on price of changes in the weather. Price elasticities of supply and demand are not needed to answer that question. On the other hand, if we wish to know the effect of a sales tax on quantity produced, knowledge of the price elasticities might be essential. Although least squares is generally available for reduced-form estimation (at least if the sample is large), it is not obvious that, without further assumptions, good structural estimates are ever attainable. The key assumption of the model is that the \( G \) structural errors are uncorrelated with the \( K \) predetermined variables. These \( GK \) orthogonality assumptions are just enough to determine (say by equating sample moments to population moments) the \( GK \) parameters in \( \Pi \). But the structural coefficient matrices \( B \) and \( \Gamma \) contain \( G^2+GK \) elements. Even with \( G \) normalization rules that set the units in which the parameters of each equation will be measured, there are more coefficients than orthogonality conditions. It turns out that structural estimation is possible only if additional assumptions (for example, that some elements of \( B \) and \( \Gamma \) are known a priori) are made. These considerations lead to three general classes of questions that have been addressed by theoretical econometricians: (1) When, in principle, can good structural estimates be found? (2) What are the best ways of actually estimating the structural parameters, given that it is possible? (3) Are there better ways of estimating the reduced-form parameters than by least squares?

These questions are studied in depth in standard econometrics textbooks and will not be examined here. The answers, however, do have a common thread. If each structural equation has more than \( K \) unknown
parameters, structural estimation is generally impossible and least squares applied to the reduced form is optimal in large samples. If, on the other hand, each structural equation has fewer than $K$ unknown coefficients, structural estimation generally is possible and least squares applied to the reduced form is no longer optimal. In this latter situation, various estimation procedures are available, some requiring little computational effort. However, the sample size may need to be quite large before these procedures are likely to give good estimates. The assumption that the errors are independent from trial to trial is obviously very strong and quite implausible in time-series analysis. If the nature of the error dependence can be modelled and if the lag structure of the dynamic behavioural equations is correctly specified, most of the estimation results that follow under independence carry over. Unfortunately, with small samples, it is usually necessary to make crude (and rather arbitrary) specifications that may result in very poor estimates. Despite the fact that simultaneous equations analysis in practice is mostly applied to time-series data, it can be argued that the statistical basis is much more convincing for cross-section analysis where samples are large and dependency across observations minimal. Even there, the assumption that the errors are unrelated to the predetermined variables must be justified before simultaneous equations estimation techniques can be applied.

The role of simultaneous equations

Many applied economists seem to view the simultaneous equations model as having limited applicability, appropriate only for a very small subset of the problems actually met in practice. This is probably unwise. Estimated regression coefficients are commonly used to explain how an intervention which changes one explanatory variable will affect the dependent variable. Except for very special cases, this interpretation requires us to believe that the proposed intervention will not affect any of the other explanatory variables and that, in the sample, the errors were unrelated to the variation in the regressors. That is, the mechanism that determines the explanatory variables must be unrelated to the causal mechanism described by the equation under consideration. Unless the explanatory variables were in fact set in a carefully designed controlled experiment, viewing the explanatory variables as endogenous and possibly determined simultaneously with the dependent variable is a natural way to start thinking about the plausibility of the required assumptions. In a sense, the simultaneous equations model is an attempt by economists to come to grips with the old truism that correlation is not the same as causation. In complex processes involving many decision-makers and many decision variables, we wish to discover stable relations that will persist over time and in response to changes in economic policy. We need to distinguish those equations that are autonomous with respect to the interventions we have in mind and those that are not. The methodology of the simultaneous equations model forces us to think about the experimental conditions that are envisaged when we write down an equation. It will not necessarily lead us to good parameter estimates, but it may help us to avoid errors.

Single Tax is a generic label for the programme of Henry George and others to socialize land rent by substituting one heavy tax on land value for most other taxes. It is not an adequate descriptor but a slogan that caught on. ‘Land value taxation’ is more used today, especially for a limited tax by a local authority. In Scotland and England ‘taxation of ground values’ and ‘site-value rating’ are used. Specifically, the ‘Single Tax’ slogan marked a shift in the movement after 1887 as George swung towards the Centre after purging the Marxists from his United Labour Party, losing Powderley and Gompers, and demurring to the quixotic demands of Fr. Edward McGlynn. He was losing Irish-American support from the hostility of Parnell and the Catholic hierarchy. Thomas Shearman, a corporate lawyer, coined ‘Single Tax’ to differentiate George's free-market, pro-capitalist programme from those of others who had coalesced around him in the radical and protest awakening of 1879–87. Soon it also served to differentiate Georgism from Bellamy nationalism and Bryan inflationism. In Britain it distinguished Georgists from Wallace's land nationalizers, Hyndman's Marxists, Webb's Fabians, and Parnell's and Chamberlain's movements for peasant proprietorship. A change of emphasis followed. George had originally striven for rent socialization, redistribution and augmented social spending. Critics on the Right saw too much taxation and levelling. The Single Tax slogan emphasized the counterpart benefits of relief from other taxes. Single Taxers would remove state and local property taxes from buildings and movable capital, and lower most transit and utility rates, often to zero, meeting deficits from the rent fund (anticipating the marginal-cost pricing policies elaborated by Hotelling and Vickrey). Critics on the Left now saw too limited a revenue; so did machine Democrats, militarists, public contractors, and of course landholders seeking developmental public works at the general expense. The heavy national taxes in America were tariffs. With Protection or Free Trade? (1886) George...
attacked them, invoking Quesnay, Ricardo, Cobden and Bright. Two million copies were printed, equalling his earlier Progress and Poverty. He supported Grover Cleveland in 1888 and 1892, hoping that free trade would force Congress to turn to land for revenues. Single Taxers in Congress succeeded in having the Income Tax Act of 1894 include land rent and unearned increments in the base, even though that was likely to be the grounds for its being held unconstitutional, and was. Single Tax began to connote tax limitation.

In Protection or Free Trade? George had restated the Physiocratic doctrine of tax incidence, while broadening it to include urban land, which most Physiocrats (except Turgot) had oddly excluded. There is only so much taxable surplus to tap under any system, and most of it lodges in land rent. Single Tax was simply the way to tax this surplus without what is now called the excess burden of indirect taxation. This might refute the charge of inadequacy, but the point has not been widely understood, and some still question revenue adequacy.

Shearman invited more such questions when he went another step from the Left with his ‘Single Tax Limited’, the upper limit being two-thirds of economic rent. To some adherents Single Tax is a tax limitation device. George remained a ‘Single Taxer, Unlimited’. He held that taxation is only a means to justice; justice means every infant has an equal right to the Earth, its use and its rents. He remained a populist who supported Bryan in 1896, even though cold to the free silver panacea.

In Scotland and England George was active and well received by the radical wing of the Liberal Party. But Single Tax continued to mean an extreme position which moderates shunned, even when the Liberal Party put a land tax plank in its platform after Gladstone retired in 1895. Liberals under Asquith and Lloyd George introduced a token land tax in their 1909 budget. The Single Tax bogey frightened the Conservative members of the House of Lords into an intransigent obstructionism that alienated the voters and was used to consolidate the power of the Commons, the Liberals and Lloyd George, who then temporized away the land tax. Labour reintroduced a land tax in 1931 under MacDonald and Snowden, but Neville Chamberlain scuttled it finally in 1934. Post-war Labour governments abandoned Single Tax as being too market-oriented.

Henry George died in 1897. Single Tax remained a power for another generation. Leaders like Shearman and Louis Post sought to professionalize the movement and reconcile it with middle-class values, a timely adaptation to the ethos of progress under scientific management. Somers, Pollock and Zangerle professionalized land assessment. Lawson Purdy helped found the National Tax Association. The Progressive and New Freedom movements absorbed many Single Taxers and reflected some of their ideals.

A century earlier at the court of Louis XV, François Quesnay and his Physiocrats had advanced the ‘impôt unique’, an even more limited single tax restricted to farm land, and one-third the rent. Like Shearman, Quesnay argued efficiency and laissez-faire, not redistribution: it was the age of enlightened despotism, not of populism. They (and later their disciple Walras) called it ‘co-proprietorship of land by the state’.

But there is a touch of class-levelling inherent in any proposal to tax land directly, however sugar-coated with the doctrine that landholders gain from removing other taxes, however limited by the safeguard of ‘co-proprietorship’. Physiocracy could beguile a despot dreaming of energizing a decadent gentry, and liberating his people from tax farmers and a jumble of enervating excises that weakened France's economy. It was the fate of Quesnay, and of France, that the privileged gentry proved more sensitive to Physiocracy's threat than others were to its benefits.
Quesnay was closer than he knew to an age of populism; he might better have addressed the new constituency. Indirectly, he did through his influence on Jefferson, transmitted through his disciples Pierre Samuel Du Pont and Destutt de Tracy; and through his influence on Smith, Ricardo and Mill, whose special treatment of land rent set the stage for George's Single Tax.

A number of concepts and theories that later became important in the history of economics first appeared in the writings of the Swiss economist J.C.L. Simonde de Sismondi. Whether or not these can be considered as his ‘contributions’ to economics is a question not unlike that as to whether a tree that falls in a deserted forest makes a sound. Sismondi developed the first aggregate equilibrium income theory and the first algebraic growth model. Yet both concepts had to be rediscovered and redeveloped by others before they entered the mainstream of economics, long after Sismondi's time. The fact that Sismondi wrote in French may have been part of the reason why his work made so little impact at a time when the development of classical economics was largely the work of British economists. However, the fame achieved by his French contemporary, Jean-Baptiste Say, suggests that language differences alone cannot explain the neglect of Sismondi. His economic writings were neglected in France and Switzerland as well.

When he was born in Geneva in 1773, his name was Jean Charles Leonard Simonde. After an exile in Italy, during which he determined that he was descended from a noble Italian family named Sismondi, he returned to Geneva in 1800 with his new surname, Simonde de Sismondi. However, he was sufficiently tentative about it to use his original name on his first book in economics, De la richesse commerciale, in 1803. Sismondi also wrote extensively on history, including a 16-volume history of Italy. All his writings were pervaded by considerations of public policy in general, and the interests of the less fortunate in particular.

Sismondi was born into a prosperous bourgeois family, which was despoiled of much of its wealth during Swiss political upheavals reflecting the contemporary revolution in France. Shifting political fortunes led not only to Sismondi's exile but to two imprisonments as well. After the turmoil subsided,
Sismondi worked at a variety of occupations, including gentleman farmer and professor of philosophy. Sismondi's first venture into economics, the two-volume *De la richesse commerciale*, was intended as a systematic exposition of the ideas of Adam Smith. Yet in it Sismondi also pointed out that he was presenting an 'absolutely new' way of looking at aggregate output changes. Crude arithmetic examples depicted output during a given year as a function of investment during a previous year, and showed how a closed economy differed from an economy with international trade, and how the latter differed when there was an export surplus and an import surplus. Algebraic formulas in his footnotes repeated the same arguments presented arithmetically in the text. But the book was little noticed, and so Sismondi's original efforts produced no contribution to the development of economics.

In the wake of the post-Napoleonic War depression, Sismondi turned his attention once more to economics and to issues of aggregate income equilibrium. In 1814, he produced a long article entitled 'Political Economy', written in English for the *Edinburgh Encyclopaedia*. In the midst of a summary presentation of classical economics appeared an early version of Sismondi's own theory of aggregate equilibrium income. This theory was elaborated in Sismondi's main economic work, the two-volume *Nouveaux principes d’économie politique* (1819). With this work he entered the controversy over Say's Law and general gluts.

According to Sismondi, the utility of output was balanced against the disutility of work, whether by Robinson Crusoe on an island or by a complex society. But, with different people doing partial balancing in isolation from one another in a complex economy, the aggregate balance was not always continuously assured. Whenever the disutility of labour exceeded the utility of output in a given time period, subsequent time periods would see a decline in aggregate output until the balance was restored. Conversely, when the utility of output exceeded that of labour, output would tend to rise.

The germ of this reasoning had already appeared in *L’Ordre naturel* by the Physiocrat Mercier de la Rivière in 1767. Sismondi elaborated it into a theory of equilibrium income, with which he challenged the reigning view, expressed in Say's Law, that there were no limits to production. Say's Law, then as later, had many meanings. But one of the contemporary meanings was that there was no such thing as an equilibrium level of aggregate output. Whatever level of output was supplied could always find a demand, and where this did not happen, it was because the assortment of goods did not match consumer preferences, not because the total output was at an unsustainable level. Sismondi rejected this reasoning, arguing that the demand for leisure would at some point outweigh the demand for other goods, and that when production went beyond the point at which this happened, it would be unsaleable at cost-covering prices and so fail to be reproduced in subsequent time periods.

Sismondi understood the full implications of what he was saying and how it contradicted prevailing views. The balance of aggregate supply and demand he considered the most important question in economics, and especially so during the depression following the Napoleonic wars. J.B. Say and the Ricardians maintained that the unsaleability of some goods showed only that insufficient other goods had been produced to exchange with them – that output had the wrong internal proportions, not an excess in the aggregate, and that the proper proportions could be restored at a still higher level of aggregate production. In this view, there could be a partial glut of particular commodities but not a general glut of commodities.

Sismondi argued that there could be a general glut of commodities because one of the goods desired was leisure – that is, exemption from the production of commodities. He did not believe that this occurred in the normal course of free market competition but because government policy sometimes artificially

fostered production at an unsustainable level. Like the orthodox economists of his time, Sismondi regarded money as an unessential factor, a ‘veil’ obscuring but not fundamentally changing the behaviour of economic aggregates. His disagreements with the classical economists had nothing to do with monetary controversies such as those in 20th-century macroeconomics.

When Sismondi's *Nouveaux principes* appeared in 1819, it was immediately attacked in the *Edinburgh Review* in October of that year, in the midst of a discussion of Robert Owen. Its reasoning was declared a ‘fallacy’ and once more ‘proportions’ – not aggregates – were declared to be the only prerequisites for markets to be cleared and increased output sustained. A glut was there defined as ‘an increase in the supply of a particular class of commodities, unaccompanied by a corresponding increase in the supply of those other commodities which should serve as their equivalents’. In short, there were partial gluts but no general gluts and a still higher level of output was sustainable if properly proportioned internally. The basis of this reasoning was explicitly attributed to ‘the celebrated M. Say’, with a ‘most clear and conclusive’ treatment of the subject added by James Mill.

The appearance of T.R. Malthus's *Principles of Political Economy* the following year added fuel to the debate, for he too challenged Say's Law in the same way. Marx later characterized Malthus's book as simply the ‘English translation’ of Sismondi, but in fact it represented views which Malthus had long expressed in correspondence with Ricardo. Replies to both authors began to appear in both French and English publications during the 1820s, provoking rejoinders in books and articles. Their controversy over general gluts persisted for more than a decade, involving not only the leading economists of the time – Say, Ricardo, Malthus, Sismondi, Torrens, McCulloch and both Mills – but also Samuel Bailey, William Blake, Thomas Chalmers, and others either forgotten or little remembered in the history of economics. These published controversies were supplemented by correspondence between Sismondi and Say, Sismondi and Ricardo, Malthus and Say, and Malthus and Ricardo. Only Say seems to have acknowledged that the theory of aggregate equilibrium income had relevance to one version of Say's Law that was current at the time. In the fifth edition of his *Traité d'économie politique* in 1826 he added three paragraphs to his chapter on the law of markets, discussing ‘the limit to a growing production’ and repeating (without citation) Sismondi's argument that when output’s ‘utility is not worth what it cost’, such output is unsustainable. A year later he admitted in a letter to Malthus that his law of markets was ‘subject to some restrictions’ which he had included in the most recent edition of his book. (Unfortunately, the English translation of Say's *Traité* is from the previous edition.) Finally, in a textbook published in 1828–9, Say followed the chapter on his law of markets with a chapter entitled, ‘Limits to Production’ – a phrase from Sismondi.

No such impact or even acknowledgement occurred in British economic writings. There Sismondi and Malthus were answered as if they were arguing for secular stagnation instead of temporary aggregate disequilibrium. John Stuart Mill enshrined this misunderstanding of Sismondi and Malthus in his classic *Principles of Political Economy* in 1848. Thus things stood for nearly a century, until John Maynard Keynes resurrected Malthus, but not Sismondi, as his predecessor in aggregate equilibrium theory. Sismondi’s anticipations of later economic theory were not limited to aggregate income theory. In the course of dealing with that large topic he also proposed a theory of destabilizing responses to overproduction, which would initially take the economy further from equilibrium, though it would ultimately return to equilibrium ‘after a frightful suffering’. He also dealt with the issue of the short-run shut down point of a firm, which he argued would produce even below cost-covering prices if much of its cost was fixed rather than variable. Sismondi also argued against the reigning Malthusian population
theory, pointing out fatal ambiguities in the word ‘tendency’ as Malthus used it and using empirical
evidence to show that the historical tendency was for food supply to grow faster than population.
In many ways Sismondi also anticipated Marx. Sismondi's emphasis on ‘the proletarians’, on an
increasing concentration of capital, recurring business cycles, technological unemployment and
economic dynamics in general all reappeared (without credit) in Marx's writings.
None of these pioneering efforts by Sismondi received either contemporary acknowledgement or later
recognition by the profession. His loose and sometimes inconsistent writings and his emotional
assertions made it easy to dismiss him and throw away his insights along with his errors. He left no
disciples and his eclecticism provided no dogma around which a school could crystallize.

size of nations, economics approach to the

Enrico Spolaore
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The economics approach to the size of nations proceeds from the trade-off between benefits and costs of larger size. Benefits of scale come from sharing public goods among more taxpayers. Larger countries can also better internalize cross-regional externalities and insure against regional shocks. But a larger size brings about higher heterogeneity of preferences over public policies. The trade-off depends on the domestic political regime and on the international environment. In a world of free trade and low international conflict small countries can prosper, while a large size matters more when trade barriers and conflict are high.

Article

The number and size of sovereign states has been at the centre of human history for thousands of years, from the times of Sumerian city states to the post-cold war era. Plato in The Laws (360 bc, Book V) calculated the optimal size of a state as 5,040 heads of family. According to Aristotle in The Politics (350 bc, Book VII, ch. 4), experience had shown that a very populous state could rarely, if ever, be well governed (a view probably not shared by Aristotle's famous pupil, Alexander the Great). Montesquieu in The Spirit of Laws (1748, Book VIII, ch.16) wrote that ‘in a small [republic], the interest of the public is more obvious, better understood, and more within the reach of every citizen’. A theory of optimal size was sketched by Beccaria (1764, p. 91), the Italian philosopher who inspired Bentham's utilitarian approach:
The more society grows, the smaller part of the whole does each member become, and the republican sentiment diminishes proportionately if the laws neglect to reinforce it. Societies have, like human bodies, their circumscribed limits, increasing beyond which the economy is necessarily disturbed. It would seem that the size of a state ought to vary inversely with the sensitivity ['sensibilità'] of its constituency … A republic grown too vast can escape despotism only by subdividing and then reuniting itself as a number of federated little republics.

These are selective quotations from an enormous philosophical, political and historical literature (see for example Dahl and Tufte, 1973). By contrast, for a long while economists have taken political borders as given. Only in recent years has a small but expanding economic literature started to address questions of country formation and break-up with the tools of economic analysis (for discussions, see Bolton, Roland and Spolaore, 1996; Alesina and Spolaore, 2003; Spolaore, 2006). This research is motivated by the fact that political borders are not a fixed part of the geographical landscape but human-made institutions, affected by the decisions and interactions of individuals and groups who pursue their objectives under constraints. The economics approach to the size of nations can be viewed as a natural extension of the research programme of modern political economics, whose aim is to ‘endogenize’ collective decisions and institutions.

This economic literature has addressed the determination and change of political borders in different political and economic environments and using various solution concepts. Friedman (1977) studies the formation of borders as set by rent-maximizing Leviathans. Findlay (1996) analyses the expansion of empires. Alesina and Spolaore (1997; 2003) derive and compare the number and size of countries under different solution concepts: efficient (that is, welfare-maximizing) borders, voting equilibria, equilibria under unilateral secessions, and equilibria in a world of rent-maximizing Leviathans. Bolton and Roland (1997) study the break-up of nations by direct majority vote, when income distributions differ across regions, and regional median voters have different preferences over redistribution. The relationship between economic integration and the size of countries has been analysed by Alesina and Spolaore (1997) and Alesina, Spolaore and Wacziarg (2000; 2005). Wittman (1991; 2000) focuses on welfare-maximizing solutions. Optimal secession rules have been studied by Bordignon and Brusco (2001). Le Breton and Weber (2003) analyse equilibria when groups of individuals can secede unilaterally, and compensation mechanisms are possible within countries. Contributions to the literature also include Casella and Feinstein (2002), Goyal and Staal (2003), and many others.

When one considers the size of nations from an economic perspective, a natural starting point is the trade-off between benefits and costs from a larger size. Important benefits of scale are associated with the provision of public goods, which are cheaper in per capita terms when more taxpayers pay for them (empirically, smaller countries do have larger governments). Larger countries can also better internalize cross-regional externalities, a point extensively studied in the literature on decentralization and fiscal federalism. Additional benefits from size come from insurance against natural and economic shocks through inter-regional transfers. But size also comes with costs. As countries become larger, congestion may overcome some of the above benefits. More importantly, an expansion of a country's borders is likely to bring about higher heterogeneity of preferences across different individuals. Being part of the
same country implies sharing jointly supplied public goods and policies in ways that cannot satisfy everybody’s preferences. Decentralization of some public goods and policies may offer a partial response to heterogeneity. However, many policies that characterize a sovereign state (basic characteristics of the legal system, foreign policy, defence policy) are indivisible and must be shared among the whole population. This induces a trade-off between economies of scale in the provision of public goods and heterogeneity of preferences. This trade-off has played a central role in the economic literature on the size of nations (see Alesina and Spolaore, 1997; 2003). The trade-off depends not only on the degree of heterogeneity of preferences but also on the political regime through which preferences are turned into policies. For example, rent-seeking Leviathans that are less concerned with the preferences of their subjects may pursue expansionary policies that lead to the formation of inefficiently large countries and empires. By contrast, democratization leads to secessions, and, in the absence of effective mechanisms to integrate populations with diverse preferences, self-determination can be associated with excessive fragmentation and costly break-up. Historically, successful societies are those that have managed to minimize the costs of heterogeneity while maximizing the benefits stemming from a diverse pool of preferences, skills and endowments.

Economic analyses of the size of nations have pointed out that the trade-off between benefits and costs of size is also a function of the degree of international economic integration (Alesina and Spolaore, 1997; Alesina, Spolaore and Wacziarg, 2000; 2005; Spolaore and Wacziarg, 2005). The size of the market may or may not coincide with the political size of a country as defined by its borders. Larger nations mean larger domestic markets when political borders imply barriers to international exchange. By contrast, market size and political size would be uncorrelated in a world of perfect free trade in which political borders imposed no costs on international transactions. Therefore, market size depends both on country size and on the trade regime. If market size matters, small countries can prosper in a world of free trade and high economic integration, while a large size is more important for economic success in a world of trade barriers and protectionism. In fact, empirically the effect of size on economic performance (income per capita, growth) tends to be higher for countries that are less open, and the effect of openness is much larger for smaller countries (Alesina, Spolaore and Wacziarg, 2000; 2005; Spolaore and Wacziarg, 2005). As economic integration increases, the benefits of a large political size are reduced, and political disintegration becomes less costly. Conversely, smaller countries tend to benefit from more openness. Hence, economic integration and political disintegration tend to go hand in hand.

The economic literature on the size of nations is connected to other established bodies of research, such as the literature on local public goods and clubs, pioneered by Tiebout (1956) and Buchanan (1965). But while local jurisdictions are not completely autonomous and people are free to move across them, the analysis of nations explicitly focuses on sovereign states that can impose direct barriers to economic exchange and mobility, and can use force in settling disputes with their neighbours. The study of nations is also connected to the literature on customs unions and trade blocs. In so far as modern nations tend to promote free trade within their own borders, countries can be seen as ‘trade blocs’ of regions. In general, free trade areas, customs unions, supranational organizations, confederations and sovereign states can be viewed as points on a continuum of increasing coordination and integration of political functions. A third body of connected research is the economic analysis of conflict, pioneered by Boulding (1962), Tullock (1974), Hirshleifer (1991; 1995), Grossman (1991) and others. Alesina and Spolaore (2005;

skill-biased technical change

Giovanni L. Violante
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Skill-biased technical change is a shift in the production technology that favours skilled over unskilled labour by increasing its relative productivity and, therefore, its relative demand. Traditionally, technical change is viewed as factor-neutral. However, recent technological change has been skill-biased. Theories and data suggest that new information technologies are complementary with skilled labour, at least in their adoption phase. Whether new capital complements skilled or unskilled labour may be determined endogenously by innovators’ economic incentives shaped by relative prices, the size of the market, and institutions. The ‘factor bias’ attribute puts technological change at the center of the income-distribution debate.

Article

Skill-biased technical change (SBTC) is a shift in the production technology that favours skilled (for example, more educated, more able, more experienced) labour over unskilled labour by increasing its relative productivity and, therefore, its relative demand. Ceteris paribus, SBTC induces a rise in the skill premium – the ratio of skilled to unskilled wages.

From factor-neutral to factor-biased technical change

Economic theory views production technology as a function describing how a collection of factor inputs
can be transformed into output, and it defines technical change as a shift in the production function, that is, a change in output for given inputs. The traditional measure of economy-wide technological change, introduced by Solow (1957), is aggregate total factor productivity (TFP). Solow defines a TFP advancement as an increase in output that leaves marginal rates of transformations untouched for given inputs; thus, a change in TFP is a form of *factor-neutral* technical change.

For illustrative purposes, suppose that the aggregate production function is constant returns to scale and Cobb–Douglas in aggregate capital \((K)\) and aggregate labor \((L)\) services, that is, \(Y = ZK^\alpha L^{1-\alpha}\), where \(Y\) is aggregate output, \(\alpha\) is the elasticity of output to capital, and \(Z\) denotes precisely TFP. If output and input markets are competitive, then the share of income going to capital equals \(\alpha\). Solow’s (1957) fundamental insight is that, armed with this estimate of \(\alpha\) and measures of \((Y, K, L)\) from national accounts, neutral technical change can be quantified ‘residually’. This clever and parsimonious approach to growth accounting has dominated the literature for decades, creating an overwhelming consensus that neutral technological improvements are the primary source of growth in income per capita.

However, a key fact that recently emerged from the data highlights the limits of this conceptualization of technical change. Since the mid-1970s, the rental price of skilled labour has soared dramatically relatively to that of unskilled labour despite a major increase in the relative supply of skills: for example, the college wage premium – defined as the ratio between the wage of college graduates and the wage of high-school graduates – jumped from 1.45 in 1965 to 1.7 in 1995, while the relative supply of college skills tripled over the same period. Given the observed movements in the relative quantities, these price changes could not be generated by movements ‘along the production function’. Neutral technical change is, by definition, silent on changes in relative prices. Therefore, to make sense of these recent developments one must introduce the concept of *factor-biased* technical change.

For this purpose, I now generalize the aggregate production function above by letting labour input, \(L\), be a constant elasticity of substitution (CES) function of skilled and unskilled labour, \(L_s\) and \(L_u\), with factor-specific productivities \(A_s\) and \(A_u\):

\[
L = [(A_sL_s)^\sigma + (A_uL_u)^\sigma]^{1/\sigma}, \sigma < 1.
\]

At this point, it is not necessary to specify what makes a worker more skilled than another: it could be education, innate ability or experience. The (log of the) marginal rate of transformation (MRT) between the two labour inputs is

\[
\ln(MRT_{s,u}) = \sigma \ln\left(\frac{A_s}{A_u}\right) + (1 - \sigma) \ln\left(\frac{L_u}{L_s}\right).
\]
Note that the TFP term $Z$ does not enter the above equation. A change in the ratio $A_s/A_u$ is a form of factor-biased technical change since it modifies the marginal rates of transformation, at a given input ratio. In particular, under the empirically plausible parametric assumption $\sigma > 0$, technical change is \textit{skill-biased} if $A_s/A_u$ increases. With competitive input markets, the (log of the) skill premium can be read off the right-hand side of (2) as well. Therefore, skill-biased technical change induces an increase in the relative productivity of skilled labour that raises its relative demand and, ceteris paribus, the skill premium.

To take this logic one step further, given an estimate of the elasticity of substitution between types of labour $1 / (1 - \sigma)$, and time-series on relative wages and relative factor supplies, one can measure skill-biased technical change residually from (2). For example, with an elasticity of substitution of 1.4 (or $\sigma = 0.29$) between college graduates and the rest of the labour force, the dynamics of the US college premium and of the relative supply of college skills imply a growth of skill-biased technical change (that is, of the ratio $A_s/A_u$) in excess of ten per cent per year from 1963 to 1987 (Katz and Murphy, 1992).

\textbf{The skill bias of information technologies}

Recent shifts in technology have been skill-biased. But SBTC appears all but an unexplained residual very much like Solow TFP, a ‘black box’ that needs to be filled with economic content. What really accounts for this shift in the production process since the mid-1970s? The timing of the rise in the skill premium has coincided with the rapid diffusion of information and communication technologies in the workplace. Thus, a natural candidate for this wave of SBTC is the ‘information technology revolution’.

Expenditures in information processing equipment and software, as a share of US private non-residential fixed investment, rose from six per cent in 1960 to 40 per cent in 2000. At the heart of these dynamics there is a staggering improvement in the quality and productivity of all those equipment goods relying heavily on semiconductors, like computers, software, and switching equipment underlying much of communication technology.

Ample microeconometric research and several case studies document a statistical correlation between the use of new technologies, like computers, and either the employment share of skilled workers (Bartel and Lichtenberg, 1987) or their wage share (Autor, Katz and Krueger, 1998) across industries. These studies firmly establish that the new technologies are deployed with better-qualified and better-paid labour, but they fail to explain why. This deeper question requires a quantitative theory built around an explicit economic mechanism.

\textbf{Technology-skill complementarity}

A large number of economic models in the literature provides a foundation for SBTC (for surveys, see Acemoglu, 2002; Aghion, 2002; Hornstein, Krusell and Violante, 2005). The central tenet of all these theories is technology–skill complementarity and takes three alternative formulations. The first formulation is built on a defining feature of the post-war US economy: the sharp decline of the constant-quality relative price of equipment investment (Gordon, 1990; Greenwood, Hercowitz and
Skill-biased technical change: The New Palgrave Dictionary of Economics

Krusell, 1997), especially evident for information technologies whose prices fell at ten per cent per year.

Krusell et al. (2000) argue that the substantial cheapening of equipment capital is the force behind
SBTC. This decline in price led to an increased use of equipment capital in production. At least since
Griliches (1969), various empirical papers support the idea that skilled labour is relatively more
complementary to equipment capital than is unskilled labour. As a result of capital–skill
complementarity in production, the faster growth of the equipment stock pushed up the relative demand
for skilled labour and, in turn, the skill premium.

More explicitly, these authors generalize the aggregate production function to:

\[ Y = K_s^\alpha \left[ \gamma \left( \mu (K_e)^\rho + (1 - \mu) (L_s)^\rho \right)^{\sigma / \rho} + (1 - \lambda) (L_u)^\sigma \right]^{1 - \alpha / \sigma}, \]  

(3)

where \( K_s \) denotes structures capital and \( K_e \) equipment capital. Profit-maximizing behaviour of price-
taking firms implies that the skill premium (and the MRT between labor inputs) can be approximated as

\[ \ln \left( \frac{W_s}{W_u} \right) \approx \frac{\lambda - \sigma}{\rho} \ln \left( \frac{K_e}{L_s} \right)^\rho + (1 - \sigma) \ln \left( \frac{L_u}{L_s} \right). \]  

(4)

If \( \sigma > \rho \), as estimated by Krusell et al., the relative demand for skills increases with the stock of
equipment capital. Note the difference between eqs. (2) and (4): capital–skill complementarity gives
economic content to the notion of SBTC by replacing an unobserved residual trend \((A_s / A_u)\) with the
actual upward trend in equipment–skilled labour ratio. This model replicates well the dynamics of the
US skill premium since the mid-1960s. Moreover, historical evidence suggests that complementarity
between skilled labour and capital characterized technological developments throughout the entire 20th

The second formulation is inspired by the Nelson–Phelps view of human capital. In the words on Nelson
and Phelps (1966, p. 70), ‘educated people make good innovators, so that education speeds the process
of technological diffusion’. In particular, they contend that more educated, able or experienced labour
deals better with technological change. Skilled workers are less adversely affected by the turmoil created
by major technological transformations since it is less costly for them to learn the additional knowledge
needed to adopt a new technology. Therefore, rapid technological transitions, such as that witnessed
since the mid-1970s, are skill-biased, as more able workers adapt better to change (Greenwood and
Yorukoglu, 1997; Caselli, 1999; Galor and Moav, 2000).
Incidentally, this version of the technology–skill complementarity hypothesis, by emphasizing the importance of learning during episodes of drastic technical change, is consistent with the TFP slowdown experienced by most developed economies in the 1980s: upon the arrival of the new information technologies, aggregate productivity can fall temporarily as workers and firms learn how to deploy the new production methods at their best (Hornstein and Krusell, 1996; Aghion, 2002). The Nelson–Phelps conjecture implies that the rise in the skill premium is transitory: it is only in the early adoption phase of a new technology that those who adapt more quickly can reap some benefits. As time goes by, there will be enough workers learning how to work with the new technology to offset the wage differential. Note the difference from the hypothesis set forth by Krusell et al. (2000), where the effect of capital deepening on the skill premium is permanent.

The third formalization of this hypothesis is based on Milgrom and Roberts (1990). These authors argue that information technologies reduce costs of data storage, communication, monitoring and supervision activities within the firm, which triggers a shift towards a new organizational design. In particular, the layers of the hierarchical structure can be reduced, so that the organization of the firm becomes ‘flatter’. Workers no longer perform routinized, specialized tasks, but they are now responsible for a wide range of tasks within teams. Therefore, adaptable workers who have general skills and who are more versed at multi-tasking activities benefit from this transformation. In other words, the change in technology induces an organizational shift which is skill-biased. An elegant formalization of this hypothesis is contained in Garicano and Rossi-Hansberg (2004).

Microeconomic evidence consistent with all these formulations of the technology–skill complementarity hypothesis is offered by Autor, Levy and Murnane (2003). Based on data on the skill content and tasks of various occupations, they split job requirements into ‘routine’ and ‘non-routine’ tasks and document that, starting from the 1970s, the labour input of non-routine analytic and interactive tasks increased sharply relative to routine cognitive and manual tasks. This shift was concentrated in rapidly computerizing industries and it was pervasive at all educational levels. The authors interpret these findings as evidence that information technologies substituted for unskilled labour employed on simple and more repetitive tasks – more amenable to computerization – and complemented workers endowed with generalized problem-solving, complex communication, and analytical skills.

**Endogenous direction of technical change**

In the same vein as the endogenous growth literature developed in the 1990s, one could contend that not only the speed – as traditionally argued – but also the **direction** of technical change is endogenous. Profit incentives of innovators determine the amount of R&D activity directed towards different factors of production (Acemoglu, 1998). The main determinants of profit incentives are market size, relative prices and institutions. These forces can shed light on numerous episodes in the history of technology. Under the assumption that the R&D is fixed, the market size of the innovation determines its revenues. The expansion of educated labour during the postwar period made it profitable to develop machines complementary to skilled workers. The vast rural–urban migration wave towards English cities during the late 18th century opened the way to the development of the factory system and, later, to the Tayloristic assembly line which quickly replaced skilled artisans’ craft shops. Incidentally, this is a notable example of **unskill bias** which proves that, historically, the direction of technical progress has
Profit maximization dictates that, ceteris paribus, innovation be directed towards those factors that are more intensely used in the production of highly priced goods. The recent burst of North–South trade increased the relative price of skill-intensive goods in the North, representing yet another force which pushed towards skill-biased innovations in the post-war period.

Labour institutions that keep wages high despite reductions in productivity induce firms to direct efforts towards labour-saving technologies. Such a fall in labour demand may explain the rise in European unemployment, after the upward wage push secured by the ‘labour movement’ in the 1970s. The hump-shaped dynamics of the European labour share between 1970 and 1990 validate this conjecture. The theory of endogenous factor bias in technology is, potentially, far reaching. The main limit, at this early stage of development, is the lack of quantitative analysis of the proposed mechanisms. For example, is the acceleration in the growth of college skills of the 1970s large enough to generate the observed rise in the productivity of skilled labour and in the skill premium, under a plausible model calibration? Such questions remain unanswered to date.

To conclude: traditionally, in the growth literature technological progress is associated with productivity improvements that benefit all workers, and it is viewed as the chief long-run determinant of average income levels. The notion of ‘skill bias’ – and the literature that has recently blossomed around it – has introduced the theoretical possibility that technological progress benefits only a sub-group of workers, placing technical change also at the center of the income distribution debate.

Slavery entails the ownership of one person by another. As a form of labour organization it has existed throughout history, in a large number of different societies. Indeed, while today we regard slavery as ‘the peculiar institution’, by historical standards it is wage-labour markets that are ‘unusual’. Given slavery's long and varied history a precise definition is not always agreed upon, but there are certain general characteristics found in most societies. The status of slave is generally applied to outsiders – individuals not belonging to the dominant nation, religion or race – although the definition of exactly who is an outsider has varied; Orlando Patterson (1982) considers the basic characteristic of slavery to be ‘social death’, with a loss of honour as well as legal rights by the enslaved. So widespread and acceptable was slavery that in Europe and the Americas no movement developed to attack slavery as a system until the late 18th century. In Western thought slavery had long been regarded as a necessity or as a ‘necessary evil’. The pre-19th-century discussions of slavery often pointed to the desirability (on grounds of religion and morality) of ameliorating the conditions of the enslaved or of facilitating the liberation of individual slaves, but it was only in the late 18th century that widespread thought was given to abolishing the institution itself (see Davis, 1966; 1975; 1984).

The economic basis of slavery

In some societies, particularly at low levels of income, slavery was entered into voluntarily as a means of obtaining a minimum level of living. Slavery generally played a quite different role in such cases than in the major slave societies of Greece, Rome, Brazil, the United States South and the West Indies (see Finley, 1980), where slave labour was used on large-scale agricultural units and in mines to produce...
goods to be sold in foreign or urban markets. These major slave societies were marked by an extensive external trade in slaves – war captives, kidnapped or otherwise acquired.

The economic basis of slavery seems quite straightforward (see, however, Pryor, 1977). While slavery existed in some parts of the world to provide prestige to owners or for purposes of lineage needs, slavery as an economic institution generally persisted because it provided slaveowners with an ability to capture a surplus of the value of production above the costs of the slave's subsistence. In 1900 the Dutch ethnographer H.J. Nieboer presented a detailed comparative study of slavery throughout the world. He argued that at relatively primitive stages of production, among hunters and fishers and in pastoral societies, slavery was generally non-existent. It was only with the development of settled agriculture in areas with productive land still available that slavery became widespread. The role of 'open resources' – free land – has been more formally presented by Evsey Domar (1970), who argues that only two of the following three conditions can hold simultaneously: free land, free peasants and non-working landowners. The basic argument is that if it were possible for workers to produce more than their subsistence, with unrestricted mobility they would move to freely available land; it is only with a form of labour coercion (serfdom or slavery) that landowners can obtain an income. The benefit of coerced labour to the slaveowner involves a redistribution of that part of the income above subsistence that would go to a free worker. Thus if everything (for example, crops grown, slave and free productivity) were equal, slavery would provide a means of redistributing the excess above subsistence from the labourer to the landed slaveowner.

While this model of forced redistribution points to the need for slave output to exceed subsistence to make the system desirable to slaveowners, it is incomplete as an explanation for most large-scale slave economies. The critical point has been that free labourers have avoided certain types of labour – producing certain crops, or working in certain locations, as well as limiting their labour force participation. Thus slavery expanded the available labour supply, and was particularly important to the production of certain outputs – from mines and in large-scale agricultural units – for which labour would have been available only at very high prices needed to offset non-pecuniary aspects of the labour process (Barzel, 1977). It is the existence of crops such as sugar, for which free labour cannot easily be attracted, that explains the development of New World slavery and accounts for the fact that where slavery has been economically important the slaves have performed functions quite different from those of free labourers.

The Domar–Nieboer argument, by itself, explains neither the existence of slavery as a form of coerced labour nor even the actual existence of coerced labour. The theoretical point is consistent with any form of coerced labour– slavery as well as serfdom – with the general pattern being that slavery dominated where it was necessary to move more labour into an area. The availability of free land by itself can have a quite opposite impact, as Adam Smith (1776) and others argued was the case for the northern states of the United States. There, free land (and labour mobility) meant a wider distribution of property and a more egalitarian society. The conditions for a successful cartel of slaveowners require methods of restricting the movement of the labour force, measures precluding direct bargaining between labourers and potential owners, and means of identifying and returning those slaves who attempt to leave the system. Why such restrictions would not be enforced against Europeans was no doubt the outcome of various cultural, religious and racial forces, so that the availability of free land provided quite different outcomes in the northern and in the southern states. Importantly, different technologies of crop
slavery: The New Palgrave Dictionary of Economics

production – the larger optimum scale for cotton, sugar, rice and tobacco, in comparison with the family farm for grains – meant that some form of coerced labour was needed to attract workers onto the southern plantations, while the prices of slaves became too high to permit large numbers of slave imports into the north.

Between the ending of Roman slavery and the origins of large-scale slavery in the New World settlements of the European powers, slavery persisted throughout Europe, but the relative absence of a large trading sector and the limited need to attract a larger population to new areas of settlement meant that slavery was generally economically unimportant and serfdom was a more frequent form of labour organization.

The transatlantic slave trade

The slave trade westward from Africa began with the movement of African slaves to the offshore islands by Portuguese traders in the middle of the 15th century. From that year until the last slave was landed in Cuba in the late 1860s, more than ten million Africans landed in the New World. Allowing for death in the ‘Middle Passage’ about 12 million slaves left Africa (Curtin, 1969; Lovejoy, 1983). Higher numbers for the impact of the slave trade on Africa have been presented, allowing for deaths between enslavement and shipment, as well as for estimates of the deaths due to military actions which led to enslavement. While the transatlantic slave trade was most intense in terms of numbers carried per year, it has been estimated that the trans-Saharan slave trade to Arabia and the Middle East may have carried a comparable number over a longer time span. It appears, however, that except for some small areas, the slave trade did not lead to depopulation within Africa. And, although slavery had long existed in Africa, many believe that it was the European contact that transformed African slavery into a harsher institution. Most countries of western Europe were involved in the Atlantic slave trade, and slaves were sent to all parts of the Americas. Although the high-risk nature meant that some voyages could be very profitable, recent work has cast doubt on the argument that the slave trade provided abnormal profits to European traders, given the African control of the inland traffic and competition among shippers. The first attacks upon slavery were aimed at restricting the transatlantic shipments of Africans. The British, after initial regulatory legislation beginning in 1788, and the United States, as a result of a constitutional compromise permitting its outlawing, ended the slave trade in 1808. Denmark, a minor carrier, had ended the slave trade in 1802. Due to British pressures other countries ended their slave trades, although the ‘illegal’ slave trade to Cuba and Brazil did not end until after mid-century (Eltis, 1987).

The slave trade was linked to European overseas expansion and played an important part in the settlement of the Caribbean colonies. Because of its early start and late ending Brazil was the largest of the New World recipients of slaves. Large numbers were sent to the British and the French West Indian colonies, whose populations soon became 80 to 90 per cent enslaved blacks. The United States, which was to become the largest slaveholding nation in the 19th century, received only a small part of the African slave trade, its large population being due to the unusually rapid rate of natural increase of the slave population. Cuba rose to dominance as a sugar producer in the 19th century but, unlike the other major sugar-producing Caribbean islands, its population was only about one-third slave, a ratio similar to that in Brazil and in the United States at that time.

The major use of slave labour during the period of the slave trade was in the production of sugar (see Deerr, 1949–50; Klein, 1986). In the case of mainland North America, although slavery existed in every
colony, the major uses of slave labour in the 18th century were for tobacco production in the
Chesapeake area and rice and indigo production in South Carolina. Cotton was grown in the West Indies
and Brazil and, after the invention of the cotton gin in 1793, it became the most important crop produced
by slave labour in the United States. These and other slave-grown crops in the Americas, such as coffee
and cocoa, were grown on units larger than the family farm.

Slavery in the Americas

In the Americas, after some initial attempts at the enslavement of the native Americans, the condition of
slave became limited to Africans and their descendants. The black–white ratio was generally highest in
the Caribbean, declining as one moved north and south. There were pronounced differences in the
demographic performance of slave populations in the Americas, as reflected in differences between the
total number of slaves imported and the number of blacks in various areas. The most dramatic and
widely noted differences were seen between the United States and the West Indies. In the West Indies,
with few exceptions, the slave population was unable to maintain its numbers, and there was a continued
need for new slaves brought from Africa. In the British Caribbean, for example, it is estimated that the
approximately two million Africans received before 1808 left a population of only about 780,000 blacks
at the time of emancipation (1834). The United States provided a quite different case – unique for a
slave population and unusual for any population. There an estimated 600,000 slaves imported resulted in
a black population of over 2.3 million in 1830, rising to about 4.4 million in 1860. The relatively high
death rates during the period euphemistically known as ‘seasoning’ (the initial period of exposure to the
new disease environment) accounts for some of the correlation between imports and mortality. Despite
claims at the time there seems little evidence that planters systematically either worked slaves to death
or deliberately engaged in the breeding of slaves.
There was both a considerably higher birth rate for slaves in the United States than in the West Indies (a
rate about equal to that of United States whites, about 50 per cent above that in Europe and the West
Indies), as well as a lower death rate. The higher birth rate was due in part to an earlier onset of
menarche in the United States (due to better nutrition), a shorter child-spacing interval (reflecting
differences in lactation practices) and a higher frequency of childbearers among adult women (due
perhaps to differences in working conditions as well as in nutrition and health care) (see Steckel, 1985).
The lower death rate reflected, in part, the differences between the location and work routines of tropical
sugar plantations and the major uses of slave labour in the United States – tobacco and cotton (see
Higman, 1984).

Recent studies of the New World slave economies indicate that, despite arguments of contemporaries
and subsequent scholars, slavery was expanding throughout its period of existence and that there were
no signs that slavery was becoming unprofitable and non-viable on economic grounds. Slave prices in
Brazil, Cuba and the United States peaked around 1860 (Moreno Fraginals, Klein and Engerman, 1983).
The United States Civil War ended slavery there, and while prices in Brazil and Cuba declined
somewhat from peak levels, they remained higher than they had been before mid-century, until there
were clear signals that the system was soon to be ended legislatively. The basic importance of labour
coercion in sugar production can also be seen in the drive to import contract labour from India, China
and Africa, in the West Indies after the ending of slavery – in some cases (most importantly Cuba) even
while slavery still existed.
Whatever alternatives may be argued to have been ultimately in their self-interest, throughout the 19th century (and earlier) slavery was profitable to planters. Rather than facing economic difficulties, planters were benefiting from the increased European demands for sugar, cotton, coffee and other plantation commodities. Despite the theoretical logic of the arguments by Cairnes (1862) and others about the ultimate limits to slavery's profitability, for the major slave powers of the New World emancipation required political or military action to overcome a profitable slave economy in which few planters anticipated an immediate collapse in the productive value of their principal assets.

Emancipation and its economic effects

Several states of the northern United States ended slavery by judicial or legislative measures between the Revolutionary War and the early 19th century, as did several of the formerly Spanish colonies after their independence was achieved in the first part of the 19th century, but these were areas where slavery was relatively unimportant. The major sugar-producing area of Saint-Domingue (now Haiti) ended slavery, as the result of a major slave revolt, by the start of the 19th century, and after violently opposing attempts by its new leaders to reintroduce a plantation economy to produce sugar, it became an area devoted to small-scale peasant production.
The first major area to end slavery after the Haitian Revolution was the British West Indies in 1834. The legislation passed in 1833 in response to a decade of pressure by the antislavery movement, provided for (1) a cash payment to owners and slaves of £20 million based on (but less than one-half of) the 1823–30 market values; and (2) an ‘apprenticeship’ of from four to six years, depending upon the slave's occupation. It is estimated that the value of the monetary compensation, plus the labour dictated by apprenticeship, would be nearly equal to the average 1823–30 value of slaves although, as the slaveowners pointed out, the loss in the value of land due to emancipation was not compensated (Fogel and Engerman, 1974b). The period of apprenticeship was terminated in 1838. Metropolitan legislations ended slavery, with compensation, in the French West Indies and in the Danish West Indies in 1848, and in the Dutch colonies in 1863. The American Civil War provided an uncompensated end to United States slavery with the passage of the Thirteenth Amendment. The Moret Law of 1870 provided that all those born to slave mothers in Cuba and Puerto Rico (which then ended slavery, with compensation to masters, in 1873) were considered free, subject to a period of compelled labour. The Rio Branco Law of 1871 in Brazil included a similar provision – a ‘law of the free womb’ – with a period of controlled labour. In Cuba slavery was ended in 1880, subject to a proposed eight-year period of patronato, which was terminated in 1886. In Brazil slavery was ended without compensation in 1888.
The causes of this century-long process of emancipation have become a major historical controversy, with particular attention given to the movements in England and the United States. For England, the view that emancipation was the outcome of disinterested humanitarianism came under attack with the economic interpretation of Eric Williams (1944), which related the timing of the ending of the slave trade and of slave emancipation to the British Industrial Revolution. While the specific groups and mechanisms remain debated, the linkage now stresses the rise of individualism, the ‘free labour ideology’ and ‘modernization’, all of which meant that slavery was considered an unacceptable
arrangement. Similarly for the United States the link between the ‘free labour ideology’ and anti-slavery has become central to the interpretation of various political issues of the 1850s which culminated in the Civil War.

The economic effects of slavery upon production can be seen clearly in the general patterns of output that developed after the emancipation of the slaves in most areas. With few exceptions, emancipation led to initial declines in the level of output, with particularly sharp declines in the production of the staple export commodities (Engerman, 1982). There was a movement of ex-slaves away from the plantation sector into small-scale agriculture. The ending of slavery thus demonstrated anew why most New World slavery had developed – people, given free choice, preferred not to work on plantations producing staple crops for exports, since landowners would (or could) not provide sufficient wages to provide an adequate voluntary plantation force from the local population.

There were, however, several notable exceptions. In Barbados the end of slavery did not end the plantation system nor did it lead to declines in sugar production. Rather the labour-to-land ratio was already so high that land for the ex-slaves to move to was unavailable. Barbados thus maintained its plantation sector, while serving as an area for labour outflow to other parts of the Caribbean through the 19th and 20th centuries. Another important exception was Cuba. By the time of emancipation the rise of the large central mill utilizing cane from smaller farms permitted an alternative there which offset the impact of declines in the plantation labour force, and so the output of sugar did not decline after slavery ended.

The two largest slave economies, the United States and Brazil, were nations where slave labour did not reach the proportionate dominance that it did in most of the Caribbean and they had rather different problems. United States sugar, rice, cotton and tobacco production declined with emancipation, with output recovering pre-Civil War levels subsequently, at speeds that were in inverse relation to the optimum scale of plantation production – tobacco and cotton recovering fastest, and sugar and rice least rapidly. Dramatic regional shifts occurred, with prolonged declines in the older tobacco areas of Virginia and the ultimate transfer of rice production from its antebellum base in South Carolina and Georgia to Louisiana. Cotton production expanded quickly after the post-emancipation decline, recovering antebellum peaks within a decade and the United States regained its dominance in world markets by 1880. Yet plantation production declined, and there emerged a system of small-scale farms, often sharecropped, which were less productive than were antebellum plantations; and while most blacks remained within the cotton sector, increased numbers of whites became involved in the cotton economy. Unlike most other ex-slave societies, with this expansion of cotton production the South was exporting a higher proportion of its agricultural output than before emancipation.

In Brazil, the emancipation of slaves had a sharp initial impact upon the expanding coffee industry. Recovery occurred with a decline in the importance of plantations and a shift in the nature of the labour force, with the attraction of immigrants from southern Europe (mainly Italy) to produce on small units. A move to smaller farms producing sugar for central mills also permitted recovery in the production of sugar, with limited numbers of ex-slaves remaining in sugar production.

This general pattern of ex-slave withdrawal from plantation work was a characteristic of the post-emancipation period throughout the Americas. Important in some parts of the Caribbean after slave emancipation was the attraction of a new labour force from overseas, through indentured labour transported under contract to work on plantations for specified periods of time. The areas of the British Caribbean expanding in the late slave period – Trinidad and British Guiana – regained pre-emancipation
levels of sugar output within a plantation-based economy. The labour force on the plantations was not primarily ex-slave, but rather indentured labour brought in from Africa, Madeira, China and India, the latter being the predominant group. This system of contract labour had been employed initially in the British Indian Ocean colony of Mauritius. Called ‘a new system of slavery’, contract labour was a widely discussed and regulated form of labour movement by metropolitan powers as well as in areas of outflow and inflow until its abolition in 1917. The importance of the problem of maintaining a labour force on a continuous basis on sugar plantations is seen also in the expansion of contract labour from foreign areas to the newly emerging sugar-producing regions, such as Fiji, Hawaii, Natal and Australia, in the late 19th century. As late as 1880, the production of most cane sugar that entered export markets took place in areas where the predominant plantation labour force was based either on slavery or indentured labour (Engerman, 1983).

Slavery in economic thought

The consideration of slavery in the literature of economics has helped shape subsequent interpretations of the slave economy. Adam Smith (1776) has been the most frequently quoted economist against slavery, his arguments featuring in contemporary debates as well as historical writings. To Smith slavery was an inefficient system: the slave lacked incentives to work as well as to innovate in technological change. Smith explained the existence of slavery in the production of such crops as sugar and tobacco as indicative that these were so profitable that they could afford to utilize slave labour, something not possible with less profitable crops such as corn. Smith drew upon existing arguments, his proposition on relative incentives having a long history going back to the classical world; but Smith's reputation as a political economist served to make his arguments a central component in the emerging anti-slavery argument. Recent views on Smith stress less that he was presenting an empirical proposition than that his remarks on slavery should be regarded as a basic ideological statement.

Several of the classical economists, for example McCulloch (1825) and Mill (1848), agreed with Smith's contention as to the relative effectiveness of slave and free labour when both were undertaking the same type of work, but they stressed that slavery seemed essential for production in areas and in conditions where free labour could not be obtained, particularly in tropical areas for the production of plantation crops. These, however, they regarded either as special cases (where a different economics applied) or else a transient stage (of undefined duration) along the road to free labour.

The most systematic writer on the economics of slavery was John Elliot Cairnes, whose The Slave Power (1862) focused on the United States and combined a theoretical analysis of slave labour with a propagandistic attempt to influence British opinion during the Civil War. He argued that slave labour was inefficient – it is given reluctantly; it is unskilful; it is wanting in versatility – and that it precluded southern economic development because of its negative effects upon technology and upon the attitudes of the free white population towards labour. Cairnes did allow that slavery could survive under certain unusual or temporary conditions – the availability of new lands which would offset the retarding effects of the land exhausted by slave labour. This statement, one of theoretical tendencies, was consistent with arguments that expansion was economically necessary for the southern economy. The role of the increasing ratio of labour-to-land in ending slavery's profitability in the long run was also a theme of various American writers of the early 19th century, and the same point re-emerged in the historiography.
of United States slavery in the 1920s, with arguments about the natural limits of slavery's expansion, the
imminent unprofitability of slavery and the 'needless' Civil War.

Discussions of the economic role of slavery and the causes of its ending were often presented in the 19th
and 20th centuries. Yet because of the ideological views of many writers and the emotive implications of
slavery it was often difficult to secure entirely accurate descriptions. To the Marxist, slavery is an
inefficient economic system, incapable of high levels of productivity and of technical innovation – a
system which, however necessary in its time, is incapable of generating sustained economic
development. The decline of Roman slavery was thus attributed to its inability to innovate and adapt,
and the re-emerged slavery of the modern world was similarly doomed to defeat in economic
competition with the capitalistic order. (The relation of slavery and capitalism has itself become a
debated subject, even among Marxists.) So, in the examination of the slave economies of the Americas,
a perhaps surprising consistency of opinion between those coming from the classical, laissez-faire
tradition and those coming from a Marxist perspective meant that a view of slavery as a backward,
inefficient economic system had come to dominate the economic and historical literature on slavery.

Economic history and the economics of slavery

In the mid-20th century, work of a detailed empirical nature on slavery in the British Caribbean and in
the United States was expanded. This has provided more detailed information as well as having led to
new questions and issues being studied. Perhaps the dominant figure in the historiography of the British
West Indies has been Eric Williams, the late Prime Minister of Trinidad and Tobago, whose most
famous work *Capitalism and Slavery* (1944) dealt with three topics of importance: (1) the link of slavery
and racism; (2) the role of slavery and the slave trade in the British Industrial Revolution; and (3) the
impact of a declining West Indian economy upon the British abolition of the slave trade and the
emancipation of slaves. Williams argued that it was the need for a cheap labour force that led to slavery,
and that the justification for enslavement of Africans led to the development of racist beliefs about
blacks – a view which remains the subject of a major historical controversy. Using arguments provided
by contemporaries justifying the slave trade, Williams traced an important role in financing and in
providing markets for British industrial development to the slave economies of the West Indies and the
slave trade with Africa. Williams's last two propositions have formed the basis of much of the recent
work on slavery in West Indian economic history. Recent writings point to a more limited role for
slavery and the slave trade in British industrialization than that advanced by Williams. Even more
attention has been devoted to the question of the conditions for the abolition of slavery and its link to a
possible decline of the economies of the British West Indies. The thesis of decline has come under
strong attack, particularly by Seymour Drescher (1977), who argues that the politically mandated end of
the slave trade led to declining West Indian economic fortunes, and not vice versa. The issue of the
specifies of the movement to end the slave trade, and the relative contributions of ideological, class and
economic forces has become a central historical issue (see Drescher, 1986; Solow and Engerman, 1987).
In the United States there has been a more specific concern by economists and economic historians with
issues related to the economics of slavery. A key breakthrough in the new approach to the economics of
slavery was an article by Conrad and Meyer (1958) which dealt with the profitability of antebellum
slavery. This article was concerned with a major historical issue – was slavery economically
unprofitable in the late antebellum period? – and was also intended more generally to demonstrate the value of an economic approach to historical problems. By framing the issue as one of the rate of return on investment, and using available data on interest rates, slave prices, life expectation, costs of consumption by slaves and of their supervision, and crop production and prices, they argued that a planter purchasing a slave at the market price in the late antebellum period would have earned a return equal to that upon alternative assets. The response to this article – both positive and negative, in regard to substance as well as method – has been enormous, and the economics of slavery became one of the most heated and widely discussed topics in American history. It was seen, however, that profitability, as measured by “normal” profits on an existing asset, did not really adequately answer the question of the possible economic ending of slavery in the absence of the Civil War, since the comparison had been based on market price, and not on the cost of ‘producing’ a slave.

An analysis by Yasukichi Yasuba (1961) pointed out that, given the illegality of slave imports and the constraints on the demographic expansion of the slave population, the market price of slaves could exceed the costs of rearing slaves, yielding a rent to the slaveowning class (see also Evans, 1962). Yasuba showed that the surplus above rearing costs for slaves was rising in the late antebellum period, peaking just before the onset of the Civil War. Thus, far from being on the verge of economic collapse, slavery was becoming more profitable to the slaveowning class, who did not foresee an economic end to their system in the immediate future. The linking of Easterlin's regional income estimates with Gallman's GNP estimates for 1840 to 1860 indicated that the South was growing about as rapidly in terms of per capita income as was the North, and in 1860 had reached a level of per capita income above that of the agrarian Midwest and most of the rest of the world (Fogel and Engerman, 1971; 1974a).

While these estimates cover only a limited time span, they did help to provide a different view of the dynamics of the southern slave economy.

Questions of profitability, viability, and rates of growth of income were not seen, however, as of central historical interest by historians such as Eugene Genovese (1965), who argued that the important questions concerned rather the development and potential for industrialization in the slave economy, reflected particularly in the differences in economic structure in comparison with that of the northern states, as well as the political issues posed by the differing class structures of the two societies. It is argued that the antebellum expansion of the South was due to the demand for one major crop, cotton, leading to a less diversified and industrialized economy than in the North – a growth that could not be sustained. At debate remain the causes and consequences of the southern specialization in agriculture rather than the development of a larger manufacturing sector, and the implications of the limited industrialization, urbanization, and expansion of education (in comparison with the North).

An extensive debate on the efficiency of slavery in United States agriculture was generated by the application of total factor productivity estimates by Fogel and Engerman (1974a). The question was an old one – frequent comparisons of slave versus free labour had been made by contemporaries as part of the anti-slavery argument. In their analysis Fogel and Engerman used a sample of over 5,000 farms in cotton-producing counties, drawn by William Parker and Robert Gallman from the census manuscript schedules. The specific contention that in 1860 southern agriculture was more efficient than northern, in the sense of getting more output per unit of input, became widely discussed and criticized (see David et al., 1976; Wright, 1978). The extensive debate included discussion of alternative measures of factor inputs and adjustments for variations in crop-mix, as well as arguments about the emotive content of the
term ‘efficiency’. Nevertheless, this debate did lead to changes in depictions of the slave economy. More attention was paid to the flexibility of the economy, in terms of shifting patterns of production and location in response to economic stimuli as well as in the use of various mechanisms, in addition to the whip, to elicit work effort from the slaves. More attention was also given to the standard of living provided for the slaves and to their actual work experiences.

Much of the writing on United States slavery in the 1970s, coming from a variety of backgrounds and using different sources, also led to reinterpretations of the nature of slavery and the slave experience. Attention was given to the slave culture, affected, but not destroyed, by the controls of the master. While there remain disagreements about the frequency of the sales of slaves and the extent to which they separated spouses as well as young children, much work has established the strength of the slave family. Descriptions of slave religion, slave culture and the slave family all pointed to the capacity of the slaves to resist being reduced to Sambos – a point with obvious implications for the behaviour of masters as well. Slavery has come to be seen as a system which, with its initial imbalance of power, permitted a range of give-and-take between master and slave (see Genovese, 1974), with the power of the former not as complete, and the impact on the latter not as destructive, as earlier argued.

Slichter, Sumner Huber (1892–1959)

John T. Dunlop
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
Slichter, S. H.; forecasting

Article

Slichter was both a wide-ranging general economist and a scholar in industrial relations, regarding the two disciplines as parts of a seamless whole. He wrote an introductory economics textbook (1931) and was probably the most widely read economist by the general public of his day. He was a highly respected economic forecaster, Paul Samuelson calling him ‘our best economic forecaster for the period 1935–55’, and served as president of the American Economic Association, 1940–1. In industrial relations his two large classics (1941 and 1960) grew out of extended field work. Slichter took his undergraduate degree in 1913 at the University of Wisconsin (where his father was professor of mathematics), did graduate work there with John R. Commons and completed his doctorate (1918) at the University of Chicago with H.A. Millis. He taught at Cornell for a decade, moved to Harvard Graduate School of Business Administration in 1930 and joined the Department of Economics in 1935. In 1940 he was appointed the first university professor at Harvard.

Among the themes that Slichter stressed were that the American economy was not in danger of stagnation; that the Second World War would not be followed by a depression but rather a boom; that America was becoming a ‘laboristic’ economy in which value judgements of the community reflect those of employees; that the challenges that unions have presented to managements have created superior and better-balanced managements; and that a vigorous and healthy economy is associated with an upward creep in prices that results from strong demand for goods and services and a slow climb in labour costs.

sliding scales (wages)

Christopher Hanes
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

labour market contracts; sliding scales

Article

Theories of long-term employment contracts imply strong private incentives for employers and employees to link wages to product prices, quite apart from the external benefits emphasized by Weitzman (1984), whether or not wages are also indexed to other variables such as consumption goods’ prices. Such arrangements have been extremely rare since the Second World War, but many schemes linking wage rates to product prices, referred to generally as ‘sliding scales’, were observed in Britain and the United States from the 1860s to the 1930s (Howard, 1920; Munro, 1885–6; Palgrave, 1896; Poole, 1938; US Industrial Commission, 1901, pp. 89–98, 135–6). Recent studies of historical sliding scales include Greenfield (1960), Treble (1987), South (1990), and Hanes (2007).

Most sliding scales were a result of negotiation or arbitration between unions and employers’ associations in coal or iron-ore mining, or in the metals industries – iron, steel and tinplating. In the United States, sliding scales were also used in zinc, silver and copper mines, in glass manufacture, and in the textile mills of Fall River, Massachusetts, between 1905 and 1910. They were written agreements but not legally enforceable contracts, and were meant to hold for at most one year or for no fixed duration – either side could withdraw after some weeks’ notice. Terms specified time- or piece-rate wages, but not employment levels. Nearly all sliding scales set minimum levels below which wages could not fall, no matter what happened to prices; some included maximums as well. Within these limits, wage adjustments took place at predetermined points in time, with intervals ranging from one week to six months, as a continuous or stepped-schedule function of prices observed in the previous interval. A number of scales based wages on the ‘margin’ between prices of products and material inputs. Agreements were frequently renegotiated in response to changes in external labour-market conditions or costs of non-labour inputs left unaccounted for in the scale’s formula. For some sliding scales, prices were taken from press reports of open-market transactions. More frequently, prices were taken from employers’ account books, examined by professional accountants approved by both parties or the
arbitrator. Because firms did not want to reveal sales information to competitors, examiners typically reported only a summary statistic used in the wage formula.

In the United States, unions and their sliding scales were expelled from most iron and steel plants after the 1900s. Where unions survived they continued to negotiate sliding scales up to the 1920s (Daugherty, de Chazeau and Stratton, 1937, pp. 143–4). By the early 1940s, however, sliding scales had nearly disappeared, even in mining (US Bureau of Labor Statistics, 1940, p. 13). In Britain, sliding scales or similar ‘proceeds-sharing’ plans remained widespread within mining and the metals industries throughout the 1930s. These schemes were suspended at the beginning of the Second World War in response to the advent of price controls, and never revived (Burn, 1961, p. 27; Haynes, 1953, p. 26).

Hanes (2007) argues that pre-1940s sliding scales were not examples of indexation as described by theoretical employment-contract models, but rather devices to reduce the frequency of costly strikes in the absence of contracts; that their scope was severely limited by the inability of rank-and-file union members to observe product prices, even in industries where price information was relatively plentiful; and that they disappeared after the 1930s because US unions gained the ability to enter long-term contracts, while British mining and metals industries remained under forms of government control that broke the link between product prices and labour demand.

Slutsky, Eugen (1880–1948)

Giancarlo Gandolfo

Edited by Steven N. Durlauf and Lawrence E. Blume

Article

Born in the Yaroslav province of Russia, Slutsky had troubled years as a student: he enrolled in the department of physics and mathematics at Kiev University, was expelled for taking part in student revolts, went abroad to the Munich Institute of Technology to study engineering and finally graduated in the department of law in 1911 back at Kiev University. He became a member of the faculty at Kiev Institute of Commerce in 1913 and full professor there in 1920. In 1926 he moved to Moscow as a staff member of the Conjuncture Institute; in 1934 he became a staff member of the Mathematical Institute of the University of Moscow and in 1936 a member of the Mathematical Institute of the Academy of Sciences, Moscow, a post which he held until his death.

Slutsky was a mathematician, statistician and economist. His fame as an economist rests mainly on one single contribution (1915), which went unnoticed until the 1930s, when it was discovered independently by Dominedò (1933, p. 790), Schultz (1935, pp. 439ff), and Allen (1936), and subsequently influenced the further development of consumer theory. Hicks – who, together with Allen (Hicks and Allen, 1934), had independently arrived at Slutsky's results – writes: ‘The theory to be set out in this chapter and the two following is essentially Slutsky’s•••The present volume is the first systematic exploration of the territory which Slutsky opened up’ (Hicks, 1939, p. 19). Building on earlier work by Pareto (who had already derived the formulae which express the change in the consumer's demand when any one of its arguments changes, but without seeing their implications), Slutsky showed that the effect of a price change on the quantity demanded can be divided into two effects. One is the effect of a compensated variation of price; if a price increases and the consumer is given an income increase so as to make possible the purchase of the same quantities of all the goods previously purchased, the individual – though being in the position to purchase the preceding bundle of goods – will no longer consider it preferable to any other, and there will take place some kind of residual variation of demand. This is called the residual variability by Slutsky (the substitution effect in Hicks's terminology). It should be noted that the compensated variation of price can also be defined in terms of the income change which leaves the consumer's real income unchanged, that is which causes the consumer to remain on the same indifference curve (this is the concept used by Hicks, 1939, in the text, while in the mathematical appendix he gives the same definition as Slutsky). Although the two definitions are equivalent for
infinitesimal changes (as was first shown by Mosak, 1942), Slutsky’s is preferable from the operational point of view since it does not require knowledge of the consumer’s indifference map. The other effect is the *income effect*, which gives the change in the consumer’s purchases when his money income changes at unchanged prices. The two effects turn out to be independent and additive and their algebraic sum gives the *price effect*: this is, in Hicks’ terminology, the ‘Fundamental Equation of Value Theory’, also called the Slutsky Equation.

Slutsky proved the complete properties of the various effects and of the demand curves. The income effect may be either normal (demand increases as income increases: ‘relatively indispensable goods’ in Slutsky’s terminology) or abnormal (‘relatively dispensable’ goods). The ‘own’ substitution effect is always negative (‘The residual variability of a good in the case of a compensated variation of its price, is always negative’, [1915] 1953, p. 42) and the cross substitution effect is symmetric (‘The residual variability of the j-th good in the case of a compensated variation of the price $p_i$ is equal to the residual variability of the i-th good in the case of a compensated variation of the price $p_j$’, [1915] 1953, p. 43). The ‘own’ price effect, therefore, is necessarily normal in the case of relatively indispensible goods. Slutsky also proved the relation which implies that the individual demand functions are homogeneous of degree zero. He gave a definition of complementary and competing goods, and made an important methodological point which is usually overlooked in his contribution: he stressed the need for *experiment* in order to obtain all the values of the relevant magnitudes (which cannot be obtained by observation of existing budgets) which enter into the definition. This emphasis on the need for experimental verification of economic laws, which concludes his contribution, is worthy of note and obviously arises from his statistical background.

Slutsky did no other noticeable work in economics but made important contributions to mathematical statistics and probability theory.

In (1914) he suggested the use of a $\chi^2$ variate to test the goodness of fit of a regression line (‘line’ is taken in the broad sense, i.e. including both straight lines and curves); as a logical consequence, he introduced the concept of *minimum chi-square estimator* (‘the most probable values of the coefficients will be those which bring our $\chi^2$ to a minimum’, 1914, p. 83) as a general method of fitting regressions. This paper was written several years before R.A. Fisher's work on the subject.

Slutsky was one of the originators of the theory of stochastic processes and time-series analysis. In his renowned (1927) paper he proved several important theorems. One is that the summation of random causes may be the source of cyclic or undulatory processes, and that these waves will show an approximate regularity in the sense that they can be approximated quite well by a relatively small number of terms (sine curves) of the Fourier series. Another is the sinusoidal limit theorem, which states that under certain conditions the summation of random causes will tend to give rise to a specific sine wave. For example, if one takes a moving average (of two terms) of a random series $n$ times and then takes the $m$th difference of the result, and lets $n \to \infty$ so that $mn$ tends to a constant $c$ between zero and one, it follows that the series will tend to a sine wave with wavelength $\arccos \left( \frac{1-c}{1+c} \right)$. A corollary of these theorems is the famous Slutsky-Yule Effect (so named because it was also independently discovered by Yule): if a moving average of a random series is taken (for example to determine trend), this may *generate* an oscillatory movement in the series where none existed in the original data. Slutsky also worked in the theory of probability, where he studied the concept of asymptotic convergence in probability (e.g. 1925, 1928, 1929). He spent the last years of his life in preparing tables...

small-world networks

Duncan J. Watts
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The ‘small-world hypothesis’ expresses the idea, long an article of popular belief, that every individual in a given population can reach every other via some ‘short’ chain of intermediaries. Exactly what is ‘short’, how individuals ‘reach’ one other, and how the hypothesis, if true, relates to the structure of social networks are all qsts on which recent progress has been made. Here I describe the genesis of the hypothesis, discuss supporting experimental evidence, and explore some recent mathematical models of small-world networks.

Keywords

small-world hypothesis; small-world networks

Article

Small-world networks – so named on account of their resemblance to the ‘small-world hypothesis’ – exhibit short global path lengths in spite of considerable local structure. The small-world hypothesis, long an article of popular belief (Guare, 1990), was first investigated by Pool and Kochen (1978), who posed the following qst: ‘How many pairs of persons in the population can be joined by a single acquaintance, how many by a chain of two persons, how many by a chain of three, etc?’ Pool and Kochen showed that when all individuals choose their acquaintances uniformly at random from the entire population, the number of pairs connected by a path of length $d$ increases exponentially fast in $d$. Thus under quite reasonable assumptions regarding the average number $k$ of acquaintances per person, most pairs of individuals in even a very large population should be connected by paths only a few steps long. For example, for the population of the United States at the time – roughly 200 million – and assuming that individuals possessed an average of roughly 1,000 acquaintances, Pool and Kochen estimated that a randomly selected pair could be connected in only three or four steps.

This result, it turns out, is equivalent to a standard result from the theory of random graphs (Bollobas, 1985; Erdos and Renyi, 1959; Solomonoff and Rapoport, 1951), namely, that the average shortest path length separating two randomly chosen individuals should be proportional to $\log N$ (for $N \gg k \gg 1$), where $N$ is the size of the population. (Strictly speaking, this result holds only when the network is connected, which is not guaranteed for small $k$; hence the second condition $k \gg 1$.) From this result, we can infer our first definition of what it means for the world to be ‘small’:

Definition 1: A network can be said to exhibit the small-world property when the average shortest path length of the network $L \propto \log N$.

Pool and Kochen noted, however, that social networks, far from being random, exhibit considerable structure; that is, individuals are more likely to know each other when they share certain traits, such as geographical proximity, socio-economic status or common interests. The interesting (but far less tractable) version of the small-world hypothesis is therefore not that path lengths can be short but that path lengths should remain short even when the network in question is far from random. Pool and Kochen also speculated that the increase in $L$ resulting from the introduction of social structure to a random network would be a good measure of that structure. As we shall see, however, the validity of the small-world hypothesis actually implies the converse of this claim.

Six degrees of separation
Stimulated by Pool and Kochen’s paper, the social psychologist Stanley Milgram, along with his graduate student Jeffrey Travers, decided to test the small-world hypothesis experimentally, using what they called the ‘small-world method’ (Milgram, 1967; Travers and Milgram, 1969):

1. 1. Recruit one or more volunteers to be ‘targets’ of the experiment.
2. 2. For each target, recruit some large number of initial ‘senders’.
3. 3. Give each sender a description of the target sufficient to identify him or her uniquely (for example, name, address, occupation and employer, wife's maiden name, and so on).
4. 4. Instruct each sender to forward a message to the target in one of two ways:
   1. (a) If target is an acquaintance (that is, is known to sender on a first-name basis), forward directly to target.
   2. (b) If not, forward message, target information, and instructions to an acquaintance who is ‘closer’ to target than sender.
5. 5. Repeat steps 3 and 4 with additional senders until chain either completes (reaches target) or terminates (is not forwarded for any other reason). In Milgram’s version, subsequent senders also received a list of previous senders, in order to avoid cycles; however, in practice these cycles are extremely unlikely, and this requirement has subsequently been dropped (Dodds, Muhamad and Watts, 2003).

Travers and Milgram implemented this protocol using a single target (a Boston stockbroker who was an acquaintance of Milgram's) and 296 senders: 100 from Boston, 100 blue-chip stockholders from Omaha, Nebraska, and 96 Omaha residents who were randomly selected from a list of people who had agreed to receive marketing literature. Famously, they found that the chains which reached the target were surprisingly short – approximately six steps on average, where, unsurprisingly, chains initiated by stockholders in Nebraska were shorter than those from randomly selected Nebraskans, and chains that began in Boston were shorter still. However, most chains (roughly 80 per cent) terminated before completion. Travers and Milgram also noted that a disproportionate fraction of completed chains were delivered at the last step by a small number of individuals (one man delivered 16 letters) whom Travers and Milgram dubbed ‘sociometric stars’. Subsequently, small-world experiments have been conducted a number of times for different-sized populations (for reviews, see Garfield, 1979; Kleinfeld, 2002; Kochen, 1989). In most of these studies completion rates are low, but the chains that do complete are short (Dodds, Muhamad and Watts, 2003; Korte and Milgram, 1970).

If one assumes that chains terminate out of insufficient interest or motivation on the part of senders, and not because the underlying network is disconnected or non-navigable (this assumption has been disputed recently by Kleinfeld, 2002, but no internally self-consistent alternative has yet been proposed), then it is possible to compute the hypothetical distribution of chain lengths corresponding to zero attrition (Dodds, Muhamad and Watts, 2003; White, 1970). Because longer chains have more opportunities to terminate, this ‘ideal’ distribution necessarily yields higher estimates of chain length than estimates based solely on completed chains. Nevertheless, the revised estimates – typically between seven and nine steps – are still consistent with the small-world hypothesis, even for reasonably high attrition rates. Small-world experiments therefore suggest two surprising features of large social networks: (a) in spite of their considerable structure, any pair of randomly selected individuals is likely to be connected via some short path; and (b) these individuals can actually find such a path, given only local information about the network.

Small-world networks

Addressing the first property – that randomly selected individuals in a large network can be connected via a short chain of intermediaries – Watts and Strogatz (1998) analysed a network model that incorporated elements of both social structure and randomness. In the model ‘social structure’ was represented by a uniform one-dimensional lattice, where each node was connected to its $k$ nearest neighbours on the lattice, and ‘randomness’ was characterized by a tunable parameter $p$, which specified the probability that a link in the lattice would be randomly rewired (see Figure 1). Defining the clustering coefficient $C$ of a network as the average probability that two neighbours of a given node would themselves be neighbours, they showed that when $p = 0$ (completely ordered) the network is ‘large’ ($L(0) \sim N / 2k$) and ‘highly clustered’ ($C(0) \approx 3 / 4$), and when $p = 1$ (completely random) it is ‘small’ ($L(1) \sim \log N / \log k$) and ‘poorly clustered’ ($C(1) \sim k / N$), thus suggesting that path lengths are short only when clustering is low. In contrast with Pool and Kochen’s prediction, however, they showed that the model exhibits a broad region of $p$ values in which $C(p)$ is high relative to its random limit $C(1)$, yet $L(p)$ is roughly speaking as ‘small’ as possible (see Figure 2).

Figure 1
Schematic of the Watts–Strogatz model of partly ordered, partly random networks. Note: $p$=the probability of random edge rewiring.
Figure 2
Normalized average path length $L(p) / L(0)$ and clustering coefficient $C(p) / C(0)$ versus $p$ (note log scale)
Watts and Strogatz coined the term ‘small-world networks’ to refer to networks in this class. Because the conditions required for any network to exhibit small-world properties (just a small fraction of long-range, random ‘short cuts’) were relatively weak, Watts and Strogatz predicted that many real-world networks – whether social networks or otherwise – would be small-world networks. They then checked this prediction by considering three network data-sets – the affiliation network of movie actors, the power transmission grid of the
small-world networks: The New Palgrave Dictionary of Economics

western United States, and the neural network of the nematode *C. elegans* — and found that all three examples satisfied the small-world criteria (Watts and Strogatz, 1998). Numerous authors have since investigated the properties of this model, and many large empirical networks have been found to exhibit small-world-like properties (see Newman, 2000; 2003, and Watts, 2004, for reviews of this literature, as well as Newman, Barabasi and Watts, 2006, for a collection of early papers).

### Searchable small-world networks

The small-world network models of the kind proposed by Watts and Strogatz, however, do not satisfy the second striking feature of Travers and Milgram's results, namely, that individuals can locate short paths using only local information about the network structure. This point, first raised by Kleinberg (2000a; 2000b), led him to propose a more general class of partly ordered, partly random networks in which the spatial distribution of random links is permitted to vary according to the probability distribution $P(u) \propto r_{ij}^{-y}$, where $r_{ij}$ is the distance between nodes $i$ and $j$ measured on some underlying lattice of dimension $D$, and $y$ is a tunable parameter. Kleinberg then proved that only when $y = D$ will the network be searchable in the sense that short paths not only exist but are also discoverable: when $y < D$ short paths exist, but cannot be found using only local information; and when $y > D$ the shortest paths, although discoverable, are not short. Subsequently, more realistic models of searchable small-world networks have been proposed, incorporating for example 'social' (Adamic and Adar, 2005; Watts, Dodds and Newman, 2002) as well as geographical (Liben-Nowell et al., 2005) distance, and also heterogeneity of degree (Simsek and Jensen, 2005).

### What is a ‘short’ path anyway?

Although the observed path lengths in small-world experiments do indeed seem to be ‘short’, it is not clear that they are short in the sense of Definition 1 above; that is, proportional to $\log N$. Indeed, short of conducting controlled experiments in which $N$ is varied systematically over several orders of magnitude, strict logarithmic scaling of chain lengths would be difficult to establish empirically. Furthermore, Chung and Lu (2002) have demonstrated that so-called ‘scale-free’ random networks, whose degree distributions exhibit ‘power law’ tails (that is, $P[K > k] \propto k^{-\alpha}$ for $k \gg 1$, where $1 < \alpha < 2$), exhibit even shorter average path lengths than in Definition 1 (formally, $L \propto \log \log N$); whereas in contrast Kleinberg (2000b) has suggested that the small-world hypothesis is consistent with longer path lengths (formally, $L \propto (\log N)^{\frac{\alpha}{2}}$, where $\alpha > 1$). Ultimately, however, it may not matter, as for realistic network sizes all these definitions yield similar answers, and thus are unlikely to be empirically distinguishable. Also, in the presence of chain attrition, the absolute length of chains is more relevant than its scaling behaviour: from a practical perspective, if a chain doesn't complete, it doesn't matter whether or not it is as short as it could be; it is still too long. For these reasons, Watts, Dodds and Newman (2002) have proposed an alternative definition of ‘short’:

**Definition 2**: Given a message failure probability $p$ and minimal required chain completion rate $r$, the small-world hypothesis requires (approximately) that average path length $L \leq \log r / \log (1 - p)$.

### Sociometric stars

The final result of Travers and Milgram above – that chains tend to be completed by highly connected individuals, called variously ‘stars’, ‘hubs’, ‘connectors’ or ‘funnels’ – appears to be supported by recent theoretical models (Adamic et al., 2001; Adamic, Lukose and Huberman, 2003), which suggest that when otherwise random networks are characterized by extremely skewed degree distributions, the most connected individuals do indeed serve a critical role in directing decentralized searches. The hubs in these models, however, are analogous to airline network hubs, which tend to be connected directly to a large fraction of total airports in a given region, and, in particular, are connected to most other hubs. In social networks, by contrast, even the most gregarious individuals are estimated to know only on the order of 1,000 others (Bernard et al., 1991; Killworth et al., 1990), and thus are adjacent to a negligible fraction of the entire network. Hubs in social networks, therefore, cannot play the role that they do in so-called ‘scale-free’ networks. Furthermore, they do not need to: empirical work shows no evidence that ‘special individuals’ are required to resolve social search problems (Dodds, Muhamad and Watts, 2003), and recent theoretical models suggest that networks can be searchable even when all individuals have exactly the same acquaintance volume (Kleinberg, 2000a; 2000b; Watts, Dodds and Newman, 2002).

William Smart was an entrepreneur turned academic economist. Born at Barrhead in Renfrewshire on 10 April 1853, he was educated at the University of Glasgow, where he was later to occupy the (newly created) Adam Smith Chair of Political Economy from 1896 until his death on 19 March 1915. However, his transition from student to professor was interrupted by a successful career in industry which began in the early 1870s and terminated in 1884 when the firm in which he was a partner was sold to the considerable financial advantage of its principals.

Smart's main contribution to economics probably remains his translations into English of the work of Böhm-Bawerk (1890; 1891a), and his edition of von Wieser (1893). In certain circles, Smart is felt to have been primarily responsible for introducing the work of the Austrian School to English readers. As well as making available the originals, Smart published in 1891 his own account of Austrian economics under the title *Introduction to the Theory of Value* – a book which went through three editions during Smart's lifetime. Smart's other work includes a book (1895) dealing principally with wages, consumption and currency. It seems that Smart's advocacy of a bimetallic standard had made his election to the Adam Smith Chair at Glasgow in 1896 more problematic than it might have been. He also wrote on the distribution of income (1899), the single tax (1900), and tariff reform (1904), the last two being essentially contributions to popular debates of the day.

As a young man, and while still a practising businessman, Smart was a Ruskinite. He was a member of the Guild of St George and his first publication was his inaugural address as president of the Ruskin Society of Glasgow (1880). Smart's own account of these intellectual influences on his early development can be found in his *Second Thoughts of an Economist* (1916).

Separate mention should be made of Smart's *Economic Annals of the Nineteenth Century* (1910–17), which he began as a result of the difficulties he had experienced in gathering information in his role as member of the Poor Law Commission in 1905. The simple rationale was to render more accessible
official material related to actual economic conditions and debates of the period. Although Smart only saw through to completion two volumes of the *Annals* before he died (which cover less than one third of the 19th century), a glance at the material assembled in the extant volumes is sufficient to confirm their value.

Smith's conception of 'economic man' was primarily a product of his moral philosophy. While defending the motive of self-interest against Hutcheson's claim that it could never be virtuous, he emphasized that self-interested actions take place within a social setting and that humanity is generally motivated by a desire for approbation. Far from an advocate of laissez-faire, Smith envisaged a broad, open-ended agenda of government to rectify market failure, including education to offset the atomizing effects of urbanization. His prowess arguably rests on his sophisticated grasp of the economic process as opposed to any outstanding analytical or conceptual competence.

Adam Smith was born in Kirkcaldy, on the east coast of Scotland, and baptized on 5 June 1723. He was the son of Adam Smith, Clerk to the Court Martial and Comptroller of Customs in the town (who died before his son was born) and of Margaret Douglas of Strathendry.

Smith attended the High School of Kirkcaldy, and then proceeded to Glasgow University. He first matriculated in 1737, at the not uncommon age of 14. At this time the university, or more strictly the college, was small. It housed only 12 professors who had in effect replaced the less specialized system of regents by 1727. Of the professoriate, Smith was most influenced by the ‘never-to-be-forgotten’ Francis Hutcheson (Corr., letter 274, dated 16 November 1787). Hutcheson had succeeded Gerschom Carmichael, the distinguished editor of Pufendorf's *De Officio Hominis et Civis* as Professor of Moral Philosophy.

Smith left Glasgow in 1740 as a Snell Exhibitioner at Balliol College to begin a stay of six years. The atmosphere of the college at this time was Jacobite and ‘anti-Scotch’. Smith was also to complain: ‘In the university of Oxford, the greater part of the publick professors have, for these many years, given up altogether even the pretence of teaching’ (WN,V.i.f.8). But there were benefits, most notably ease of access to excellent libraries, which in turn enabled Smith to acquire an extensive knowledge of English and French literature, which was to prove invaluable, not least in terms of his knowledge of the sciences.

Smith left Oxford in 1746 and returned to Kirkcaldy without a fixed plan. But in 1748 he was invited to give a series of public lectures in Edinburgh, with the support of three men – the Lord Advocate, Henry Home; Lord Kames; and a childhood friend, James Oswald of Dunnikier.

The lectures, which are thought to have been primarily (not exclusively) concerned with rhetoric and belles letters, brought Smith £100 a year (Corr. letter 25, dated 8 June 1758). They also seem to have been wide-ranging.

Smith's reputation as a lecturer brought its reward. In 1751 he was elected to the Chair of Logic in Glasgow University, again with the support of Lord Kames. According to John Millar, Smith's most distinguished pupil, he devoted the bulk of his time to the delivery of a system of rhetoric and belles lettres, which was based on the conviction that the best way of:

> explaining and illustrating the various powers of the human mind, the most useful part of metaphysics, arises from an examination of the several ways of communicating our thoughts by speech, and from an attention to the principles of those literary compositions which contribute to persuasion or entertainment. (Stewart, I. 16)

Smith continued to teach the main part of his lecture course on logic after he had been translated to the Chair of Moral Philosophy in 1752. A set of lecture notes, discovered by J.M. Lothian in 1958, relate to the session 1762/3. The notes correspond closely to Millar's description of the course given more than a decade earlier, in that they are concerned with such problems as the development of language, style and the organization of forms of discourse which include the oratorical, narrative and didactical (scientific).

Smith was primarily concerned with the study of human nature and with the analysis of the means and forms of communication. He no doubt continued to lecture on these subjects to students of moral philosophy because he rightly believed them to be important (see J.M. Lothian, 1963: W.S. Howell, 1975).

Smith's lectures on language were published in expanded form as *Considerations Concerning the First*
Smith, Adam (1723–1790) : The New Palgrave Dictionary of Economics

Formation of Language, in the Philological Miscellany for 1761. They were reprinted in the third edition of the Theory of Moral Sentiments in 1767.

Smith's teaching from the Chair of Moral Philosophy fell into four parts and in effect set the scene for the major published works which were to follow. Again on the authority of John Millar, it is known that Smith lectured on natural theology, ethics, jurisprudence and ‘expediency’ or economics, in that order. The lectures on natural theology (a sensitive subject at the time) have not yet been found. But Millar made it clear that the lectures on ethics form the basis for the Theory of Moral Sentiments and that the subjects covered in the last part of the course were to be further developed in the Wealth of Nations (Stewart, I. 20). As to the third part, on jurisprudence, Millar noted that:

Upon this subject he followed the plan that seems to be suggested by Montesquieu; endeavouring to trace the gradual progress of jurisprudence, both public and private, from the rudest to the most refined ages, and to point out the effects of those arts which contribute to subsistence, and to the accumulation of property, in producing correspondent improvements or alterations in law and government. (Stewart, I. 19)

Illustration and confirmation of this claim proved impossible until 1896 when Edwin Cannan published an edition of the Lectures on Jurisprudence. The notes edited by Cannan are dated 1766, although they were taken in the session 1763/4. This was Smith's last session in Glasgow, so that these lectures, where ‘public’ (broadly constitutional law) precedes ‘private’ jurisprudence (concerning man's rights as a citizen), may reflect a preferred order. A second set of notes, this time relating to the previous session, were also found by J.M. Lothian as recently as 1958 and are here styled LJA.

Academically, the major event for Smith was the publication of the Theory of Moral Sentiments in 1759. The book was well received by both the public and Smith's friends. In a delightful letter Hume reminded Smith of the futility of fame and public approbation, and having encouraged him to be a philosopher in practice as well as profession, continued:

Supposing therefore, that you have duly prepared yourself for the worst by these Reflections; I proceed to tell you the Melancholy News, that your Book has been most unfortunate: For the Public seem disposed to applaud It extremely. (Corr, letter 31, dated 12 April 1759)

The book was to establish Smith's reputation. There was a second revised edition in 1761 and further editions in 1767, 1774, 1781 and 1790.

Charles Townshend was among those to whom Hume had sent a copy of Smith's treatise. Townshend had married the widowed Countess of Dalkeith in 1755 and was sufficiently impressed by Smith's work as to arrange for his appointment as tutor to her son, the young Duke of Buccleuch. The position brought financial security (£300 sterling p.a. for the rest of his life), and Smith duly accepted, formally resigning his chair early in 1764.

Smith and his party left almost immediately for France to begin a sojourn of some two years. At the outset, the visit was unsuccessful, causing Smith to write to Hume, with some humour, that ‘I have begun to write a book in order to pass away the time. You may believe I have very little to do’ (Corr., letter 82, date 5 July 1764, Toulouse).
But matters improved with Smith's increasing familiarity with the language and the success of a series of short tours. In 1765 Smith, the Duke, and the Duke's younger brother Hew Scott, reached Geneva, giving Smith an opportunity to meet Voltaire, whom he greatly admired as 'the most universal genius perhaps which France has ever produced' (Letter, 17). The party arrived in Paris in mid-February 1766, where Smith's fame, together with the efforts of David Hume, secured him a ready entrée to the leading salons and, in turn, introductions to philosophes such as d'Alembert, Holbach and Helvetius.

During this period Smith met François Quesnay, the founder, with the Marquis de Mirabeau, of the Physiocratic School of economics (Meek, 1962). By the time Smith met Quesnay, the latter's model of the economic system as embodied in the Tableau économique (1757, trans. in Meek, 1962) had already been through a number of editions. Quesnay was then working on the Analyse (trans. in Meek, 1962), while it is also known that A.R.J. Turgot was currently engaged on his Reflections on the Formation and Distribution of Riches (trans. in Meek, 1973).

Smith, who had already developed an interest in political economy, had arrived in Paris at the very point in time that the French School had reached the zenith of its influence and output. The contents of Smith's library amply confirm his interest in this work (Mizuta, 2000).

Smith's stay in Paris had been enjoyable both socially and in academic terms. But it was marred by the developing quarrel between Hume and Rousseau and sadly terminated by the death of Hew Scott. Smith returned to London on 1 November 1766.

Smith spent the winter in London, where he was consulted by Townshend and engaged in corrections for the third edition of the Theory of Moral Sentiments. By the spring of 1767 (the year in which Sir James Steuart published his Principles of Political Economy) Smith was back in Kirkcaldy to begin a study of some six years. It was during this period that he struggled with the Wealth of Nations. Correspondence of the time amply confirms the mental strain involved. But by 1773 Smith was ready to return to London, leaving his friends, notably David Hume, under the impression that completion was imminent. As matters turned out, it took Smith almost three more years to finish his book; a delay which may have been due to part to his increasing concern with the American War of Independence and with the wider issue of the relationship between the colonies and the 'mother country' (WN, IV. vii). An Inquiry into the Nature and Causes of the Wealth of Nations was published by Strahan and Cadell on 9 March 1776, and elicited once more a warm response from Hume:

Dear Mr. Smith: I am much pleas'd with your Performance, and the Perusal of it has taken me from a State of great Anxiety. It was a Work of so much Expectation, by yourself, by your Friends, and by the Public, that I trembled for its Appearance; but am now much relieved. Not but the Reading of it necessarily requires so much Attention, and the Public is disposed to give so little, that I shall still doubt for some time of its being at first very popular. (Corr., letter 150, dated 1 April 1776)

In fact, the book sold well, with subsequent editions in 1778, 1784, 1786 and 1789. The year 1776 was marred for Smith by the death of David Hume, after a long illness, and by his concern over the future of the latter's Dialogues Concerning Natural Religion. This work, together with Hume's account of 'My Own Life' had been left in the care of William Strahan, to whom Smith wrote expressing the hope that the Dialogue should remain unpublished, although Hume himself had
But Smith proposed to ‘add to his life a very well authenticated account’ of Hume's formidable courage during his last illness (Corr., letter 172, dated 5 September 1776). The letter was published in 1777, and as Smith wrote later to Andreas Holt, ‘brought upon me ten times abuse than the very violent attack I had made upon the whole commercial system of Great Britain’ (Corr., letter 208, dated October 1780). In 1778 Smith was appointed Commissioner of Customs, due in part to the efforts of the Duke of Buccleuch. The office brought an income of £600, in addition to the pension of £300 which the Duke refused to discontinue (Corr., letter 208). Smith settled in Edinburgh, where he was joined by his mother and a cousin, Janet Douglas.

During 1778 Alexander Wedderburn sought Smith's advice on the future conduct of affairs in America. Smith's ‘Thoughts on the State of the Contest with America’ were written in the aftermath of the battle of Saratoga. The Memorandum was first published by G.H. Guttridge in the *American Historical Review* (vol. 38, 1932/3).

In this document, Smith rehearsed a number of arguments which he had already stated in WN (IV.vii.c). He advocated the extension of British taxes to Ireland and to America, provided that representatives from both countries were admitted to Parliament at Westminster in conformity with accepted constitutional practice. Smith noted that ‘Without a union with Great Britain, the inhabitants of Ireland are not likely for many ages to consider themselves as one people’ (WN,V.iii.89). With respect to America, he observed that her progress had been so rapid that ‘in the course of little more than a century, perhaps, the produce of American might exceed that of British taxation. The seat of the empire would then naturally remove itself to that part of the empire which contributed most to the general defence and support of the whole’ (WN, IV.vii.c.79).

But Smith also repeated a point already made in WN; namely, that the opportunity for union had been lost, and proceeded to review the bleak options, now all too familiar, which were actually open to the British government. Military victory was increasingly unlikely (WN, V.i.s.27) and military government, even in the event of victory, unworkable (Corr., letter 383). Voluntary withdrawal from the conflict was a rational but politically impracticable course, given the probable impact on domestic and world opinion (Corr., letter 383). The most likely outcome, in Smith's view, was the loss of the thirteen united colonies and the successful retention of Canada – the worst possible solution since it was also the most expensive in terms of defence (Corr., letter 385).

Smith worked hard as a Commissioner, and to an extent which, as he admitted, affected his literary pursuits (Corr., letter 208). But in this period he completed the third edition of WN (1784), incorporating major developments which were separately published as ‘Additions and Corrections’. The third edition also features an index and a long concluding chapter to Book IV entitled ‘Conclusion of the Mercantile System’.

After 1784 Smith must have devoted most of his attention to the revision of TMS. The sixth edition of 1790 features an entirely new Part VI which includes a further elaboration of the role of conscience, and the most complete statement which Smith offered as to the complex social psychology which lies behind man's broadly economic aspirations.

In addition to the essay on the ‘Imitative Arts’, which is mentioned in his letter to Andreas Holt (Corr., letter 208), Smith observed that ‘I have likewise two other great works upon the anvil; the one is a sort of Philosophical History of all the different branches of Literature, of Philosophy, Poetry and Eloquence; the other is a sort of theory and History of Law and Government’ (Corr., letter 248, dated 1 November
Smith, Adam (1723–1790) : The New Palgrave Dictionary of Economics

1785, addressed to the duc de la Rochefoucauld).

Smith's literary ambitions also feature in the Advertisement to the 1790 editions of TMS, where he drew attention to the concluding sentences of the first edition of 1759. In these passages Smith makes it clear that TMS and WN are parts of a single plan which he hoped to complete with a published account of ‘the general principles of law and government, and of the different revolutions which they had undergone in the different ages and periods of society’. Smith's ‘present occupations’ and ‘very advanced age’ prevented him from completing this great work, although the approach is illustrated by LJA and LJB, and by those passages in WN which can now be recognized as being derived from them (most notably WN, III and V.i.a.b).

Smith died on 17 July 1790, having first instructed his executors, Joseph Hutton and James Block, to burn his papers, excepting those which were published in Essays on Philosophical Subjects (1795).

In what follows, Smith's system will be expounded in terms of the order of argument which he is known to have employed as a lecturer; namely, ethics, jurisprudence and economics. But it will be convenient to begin with his treatment and knowledge of the literature of science.

The literature of science

It should be recalled that each separate component of Smith's system represents scientific work in the style of Newton, contributing to a greater whole which was conceived in the same image. Smith's scientific aspirations were real, as was his consciousness of the methodological tensions which may arise in the course of such work.

Smith's interest in mathematics dates from his time as a student in Glasgow (Stewart, I. 7). He also appears to have maintained a general interest in the natural and biological sciences, facts which are attested by his purchases for the University Library (Scott, 1937, p. 182) and for his own collection (Mizuta, 2000). Smith's ‘Letter to the Authors of the Edinburgh Review’ (1756), where he warned against any undue preoccupation with Scottish literature, affords evidence of wide reading in the physical sciences, and also contains references to contemporary work in the French Encyclopédie as well as to the productions of Buffon, Daubenton and Reaumur. D.D. Raphael has argued that the Letter owes much to Hume (TMS, pp. 10, 11).

The essay on astronomy, which dates from the same period (it is known to have been written before 1758 and may well date from the Oxford period) indicates that Smith was familiar with classical as well as with more modern sources, such as Galileo, Kepler and Tycho Brahe, a salutary reminder that an 18th-century philosopher could work close to the frontiers of knowledge in a number of fields.

But Smith was also interested in science as a form of communication, arguing in the LRBL that the way in which this type of discourse is organized should reflect its purpose as well as a judgement as to the psychological characteristics of the audience to be addressed.

In a lecture delivered on 24 January 1763 Smith noted that didactic or scientific writing could have one of two aims: either to ‘lay down a proposition and prove this, by the different arguments that lead to that conclusion’ or to deliver a system in any science. In the latter case Smith advocated what he called the Newtonian method, whereby we ‘lay down certain principles known or proved in the beginning, from whence we account for the several phenomena, connecting all together by the same Chain’ (LRBL, ii. 133). Two points are to be noted. First, Smith makes it clear that Descartes rather than Newton was the first to use this method of exposition, even although the former was now perceived to be the author of...
‘one of the most entertaining Romances that have ever been wrote’ (LRBL, ii. 134; see Letter 5).

Secondly, his reference to the pleasure to be derived from the ‘Newtonian method’ (LRBL, ii. 134) draws attention to the problem of scientific motivation, a theme which was to be developed in the ‘Astronomy’, where Smith considered those principles ‘which lead and direct philosophical enquiry’. The ‘Astronomy’ takes as given certain results which had already been established in the lectures on language and in the Considerations; namely, that men have a capacity for acts of ‘arrangement or classing, or comparison, and of abstraction’ (LRBL, ii. 207; cf. Corr., letter 69, dated 7 February 1763). But the essay on astronomy approaches the matter in hand in a different way by arguing that a mind thus equipped derives a certain pleasure from the contemplation of relation, similarity or order – or as Hume would have put it, from a certain association of ideas. Smith struck a more original note in arguing that when the mind confronts a new phenomenon which does not fit into an already established classification, or where we confront an unexpected association of ideas, we feel the sentiment of surprise, and then that of wonder (Astronomy, II. 9). This is typically followed by an attempt at explanation with a view to returning the ‘imagination’ to a state of tranquillity (Astronomy, II. 6). Looked at in this way, the task of explanation is related to a perceived need, which can only be met if the account offered is coherent and conducted in terms which are capable of account for observed appearances in terms of ‘familiar’ principles. It was Smith's contention that the philosopher or scientist would react in the same way as the casual observer, and that nature as a whole ‘seems to abound with events which appear solitary and incoherent’, thus disturbing ‘the easy movement of the imagination (Astronomy, II. 12). But he also observed that philosophers pursue scientific study ‘for its own sake, as an original pleasure or good in itself’ (Astronomy, III. 3).

The bulk of the essay is concerned to illustrate the extent to which the four great systems of thought which he identified were actually able to ‘soothe the imagination’, these being the systems of Concentric and Eccentric Spheres, together with the theories of Copernicus and Newton. But Smith added a further dimension to the argument by seeking to expose the dynamics of the process, arguing that each thought-system was subject to a process of modification as new observations were made. Smith suggested that each system was subjected to a process of development which eventually resulted in unacceptable degrees of complexity, thus paving the way for the generation of an alternative explanation of the same phenomena, but one which was better suited to meet the needs of the imagination by offering a simpler account (Astronomy, IV. 18, 28). In Smith's eyes, the work of Sir Isaac Newton thus marked the apparent culmination of a long historical process (Astronomy, IV. 76).

The argument as a whole also contains some radical conclusions. There is nothing in the analysis which suggests that the Newtonian (or Smithian) system embodies some final truth. At the same time, Smith seems to have given emphasis to what is now known as the problem of ‘subjectivity’ in science in arguing that scientific thought often represents a reaction to a perceived psychological need. He also likened the pleasure to be derived from great productions of the scientific intellect to that acquired when listening to a ‘well composed concerto of instrumental music’ (Imitative Arts, II. 30). Elsewhere he referred to a propensity, natural to all men, ‘to account for all appearances from as few principles as possible’ (TMS, VII.i.2.14) and commented further on the ease with which the ‘learned given up the evidence of their senses to preserve the coherence of the ideas of their imagination’ (Astronomy, IV. 35). Smith also emphasized the role of the prejudices of sense and education in discussing the reception of new ideas (Astronomy, IV. 35).

He drew attention to the importance of analogy in suggesting that philosophers often attempt to explain
the unusual by reference to knowledge gained in unrelated fields, noting that in some cases the analogy chosen could become not just a source of 'ingenious similitude' but the great hinge upon which everything turned' (Astronomy, II. 12).

Smith made extensive use of mechanistic analogies, sometimes derived from Newton, seeing in the universe 'a great machine' wherein we may observe 'means adjusted with the nicest artifice to the ends which they are intended to produce' (TMS, II.ii.3.5). In the same way he noted that 'Human society, when we contemplate it in a certain abstract and philosophical light, appears like a great, an immense machine' (TMS, VII.ii.1.2), a position which leads quite naturally to a distinction between efficient and final causes (TMS, II.ii.3.5), which is not inconsistent with the form of Deism associated with Newton himself. It is also striking that so sympathetic a thinker as Smith should have extended the mechanistic analogy to systems of thought.

Systems in many respects resemble machines. A machine is a little system created to perform, as well as to connect together, in reality, those different movements and effects which the artist has occasion for. A system is an imaginary machine invented to connect together in the fancy those different movements and effects which are already in reality performed. (Astronomy, IV. 19)

Each part of Smith's contribution is in effect an 'imaginary' machine which conforms closely to his own stated rules for the organization of scientific discourse. All disclose Smith's perception of the 'beauty of a systematical arrangement of different observations connected by a few common principles' (WN, V.i. f.25). The whole reveals much as to Smith's drives as a thinker, and throws an important light on his own marked (subjective) preference for system, coherence and order.

The Theory of Moral Sentiments

The *Theory of Moral Sentiments* shows clear evidence of a model, and of a form of argument which is in part designed to explain how so self-regarding a creature as man succeeds in erecting barriers against his own passions.

In Part VII of TMS, Smith reviewed different approaches to the questions confronting the philosopher in this field, basically as a means of differentiating his own contribution from them. In Smith's view there were two main questions to be answered: 'First, wherein does virtue consist’, and secondly, ‘by what means does it come to pass, that the mind prefers one tenour of conduct to another’? (TMS, VII.i.2). In dealing with the first question, Smith described all classical and modern theories in terms of the emphasis given to the qualities of propriety, prudence and benevolence. In each case, he argued that the identification of a particular quality was appropriate, but rejected what he took to be undue emphasis on any one. He criticized those who found virtue in propriety, on the ground that this approach emphasized the importance of self-command at the expense of ‘softer’ virtues, such as sensibility. He rejected others who found virtue in prudence because of the emphasis given to qualities which are useful, thus echoing his criticism of David Hume in TMS, Part IV. In a similar way, while he admired benevolence, Smith argued that proponents of this approach (notably Francis Hutcheson) had neglected virtues such as prudence.

Smith's criticism of Hutcheson's teaching is remarkable for the emphasis which he gave to self-interest
Smith, Adam (1723–1790) : The New Palgrave Dictionary of Economics

and his denial of Hutcheson's proposition that self-love 'was a principle which could never be virtuous in any degree or in any direction' (TMS, VII.ii.3.12). Smith also rejected the argument of Mandeville, whose fallacy it was 'to represent every passion as wholly vicious, which is so in any degree' (TMS, VII.ii.4.12). Smith contended that 'The conditions of human nature were peculiarly hard, if these affections, which, by the very nature of our being, ought frequently to influence our conduct, could upon no occasion appear virtuous, or deserve esteem and commendation from anybody' (TMS, VII.ii.3.18).

A further distinctive element in Smith's approach emerges in his treatment of the second question. He accepted Hutcheson's argument that the perception of right and wrong rests not upon reason but 'immediate sense and feeling' (TMS, VII.iii.2.9). But Smith rejected Hutcheson's emphasis on a special sense, the moral sense, which was treated as being analogous to 'external' senses, such as sight or touch. But in so doing Smith in effect elaborated on the argument of his teacher, who had already presented moral judgements as being disinterested and as based upon sympathy or fellow-feeling. Smith also enlarged on the role of the spectator, which had been a feature of the work done by Hutcheson and Hume.

Smith argued that the spectator may form a judgement with respect to the activities of another person by visualizing how he would have behaved or felt in similar circumstances. It is this capacity for acts of imaginative sympathy which permits the spectator to form a judgement as to the propriety or impropriety of the conduct observed, and as to the 'suitableness or unsuitableness, the proportion or disproportion which the affection seems to bear to the cause or object which excites it' (TMS, I.i.3.6). Since we can 'enter into' the feelings of another person only to a limited degree, Smith was able to identify the 'amiable' virtue of sensibility with the quality of imagination, and that of self-command with a capacity to control expressions or feeling to such an extent as to permit the spectator to comprehend, and thus to 'sympathize', with them.

The argument was extended to take account of those actions which have consequences for other people, in suggesting that in such cases the spectator may seek to form a judgement as to the propriety of the action taken and of the reaction to it. The sense of merit is a compounded sentiment, made up of two distinct emotions; a direct sympathy with the sentiments of the agent, and an indirect sympathy with the gratitude of those who receive the benefit of his actions' (TMS, II.i.5.2). Conversely, a sense of demerit is compounded of 'antipathy to the affections and motives of the agent' and 'an indirect sympathy with the resentment of the sufferer' (TMS, II.i.5.4).

Smith further contended that 'Nature, when she formed man for society, endowed him with an original desire to please, and an original aversion to offend his brethren' (TMS, III.2.6).

But this general disposition is not of itself sufficient to ensure an adequate degree of control. The first problem which Smith confronted is that of information, a problem which arises from the fact that the actual spectator of the conduct of another person is unlikely to be familiar with his motives.

Smith solved this problem by arguing that we tend to judge our own conduct by trying to visualize the reaction of an imagined or 'ideal spectator' to it, that is, by seeking to visualize the reaction of a spectator, who is necessarily fully informed, with regard to our own motives. Smith gave more and more attention to the role of the ideal spectator in successive editions as an important source of control; that is, to the voice of 'reason, principle, conscience… the great judge and arbiter of our conduct' (TMS, III.3.4). Looked at in this way, the argument depends on man's desire not merely for praise, but praiseworthiness (TMS, III.2.32).

The second problem arises from the fact that Smith, following Hume, presents man as an active, self-
regarding being, whose legitimate pursuit of the objects of ambition, notably wealth, can on some occasions have hurtful consequences for others. The difficulty here is that of partiality of view, even where we have the information which is needed to arrive at accurate judgements. When we are about to act, ‘the eagerness of passion will seldom allow us to consider what we are doing with the candour of an indifferent person’, while after we have acted, we often ‘turn away our view from those circumstances which might render … judgement unfavourable’ (TMS, III.4.3–4). The solution to this particular problem is found in man's capacity for generalization on the basis of particular experience:

It is thus that the general rules of morality are formed. They are ultimately founded upon experience of what, in particular instances, our moral faculties, our natural sense of merit and propriety, approve, or disapprove of. … The general rule … is formed, by finding from experience, that all actions of a certain kind, or circumstanced in a certain manner, are approved or disapproved of. (TMS, III.4.8)

It is these rules that provide the yardstick against which man can judge his actions in all circumstances; rules which command respect by virtue of the desire to be praiseworthy and which are further supported by the fear of God (TMS, III.5.12).

Smith thus offered an explanation of the way in which men were fitted for society, arguing in effect that they typically erect a series of barriers to the exercise of their own (self-regarding) passions, which culminate in the emergence of generally accepted rules of behaviour.

The rules themselves vary in character. Those which relate to justice ‘may be compared to the rules of grammar, the rules of the other virtues, to the rules which critics lay down for the attainment of what is sublime and elegant in composition. The one, are precise, accurate and indispensable. The other, are loose, vague, and indeterminate’ (TMS, III.6.11).

But Smith was in no doubt that the rules of justice were indispensable. Justice ‘is the main pillar that upholds the whole edifice’ (TMS, II.i.3.4). Smith added that the final precondition of social order was a system of positive law, embodying current conceptions of the rules of justice and administered by some system of magistracy:

As the violation of justice is what men will never admit to from one another, the public magistrate is under the necessity of employing the power of the commonwealth to enforce the practice of this virtue. Without his precaution, civil society would become a scene of bloodshed and disorder, every man revenging himself at his own hand whenever he fancied he was injured. (TMS, VII.iv.36)

Smith's ethical argument forms an integral part of his treatment of jurisprudence precisely because it is concerned to show how particular rules of behaviour emerge. In LJ the focus is narrower than in TMS, but it is still the spectator that is of critical importance whether Smith is discussing accepted standards of punishment or of law. Attention has also been drawn to the role of the magistrate in this connection (Bagolini, 1975) and of the Legislator (Haakonssen, 1981).

Smith's emphasis in TMS is interesting. He chose to concentrate on the means by which the mind forms judgements as to what is fit and proper to be done or to be avoided as distinct from trying to formulate.
specific rules of behaviour. He had recognized that while the processes of judgement might claim universal validity, specific judgements must be related to experience. No one living in the age of Montesquieu could fail to be aware of variations in standards of accepted behaviour in different societies at the same point in time, and in the same societies over time. The point at issue seems to have been grasped by Edmund Burke in writing to Smith: ‘A theory like yours founded on the Nature of man, which is always the same, will last, when those that are founded upon his opinions, which are always changing, will and must be forgotten’ (Corr., letter 38, dated 10 September 1759).

But Smith did not deny that common elements could be found on the basis of experience. Although he did not complete his intended account of ‘general principles’ (TMS, VII.iv.37), Smith did provide an argument which related the discussion of private and public jurisprudence to four broad types of socio-economic environment, the stages of hunting, pasture, farming and commerce. The importance of the argument in the present context is that it was designed in part to explain the origin of government, thus solving a problem which was only noted in TMS. At the same time the historical dimension throws light on the causes of change in accepted rules of behaviour. As part of the same exercise, Smith supplied a successful account of the emergence of the state of commerce, the stage with which he, as an economist, was primarily concerned.

Emergence of the exchange economy

As we have seen in the last section, Smith's analysis of general rules of behaviour suggests that such rules are the result of man's capacity to form judgements as to what is fit and proper to be done or to be avoided. One implication of this argument is that men, at all times and places, form judgements by using the same mental processes. On the other hand it is clear that judgements formed on particular occasions will be related to experience and to the environment which happens to prevail. This in turn, means that accepted patterns of behaviour may vary between different societies at any point in time, but also that they may vary within a particular society over time. There is a comparative aspect, but also a concern with change. The point was caught by Dugald Stewart, Professor of Moral Philosophy in Edinburgh, and an acute commentator on Smith, when he noted that:

> When in such a period of society as that in which we live, we compare our intellectual acquirements, our opinions, manners and institutions with those which prevail among rude tribes, it cannot fail to occur to us as an interesting question, by what gradual steps the transition has been made from the first simple efforts of uncultivated nature, to a state of things so wonderfully artificial and complicated. (Stewart, II. 45)

Stewart appreciated that the problem of change applied to the sciences and the arts but also to the treatment of the ‘astonishing fabric of … political union’ – our main concern at this point. While Smith's interest in the history of civil society is illustrated very clearly in WN, there can be little doubt that his reputation was enhanced by the discovery of LJ. But at the same time, we should recall that interest in this area of study was widespread notably in Italy and France. The point is neatly caught by Voltaire, whom Smith greatly admired, when he observed that:

> When in such a period of society as that in which we live, we compare our intellectual acquirements, our opinions, manners and institutions with those which prevail among rude tribes, it cannot fail to occur to us as an interesting question, by what gradual steps the transition has been made from the first simple efforts of uncultivated nature, to a state of things so wonderfully artificial and complicated. (Stewart, II. 45)
My principal object is to know, as far as I can, the manners of peoples, and to study the
human mind. I shall regard the order of succession of kings and chronology as my guides,
but not as the objects of my work. (Quoted in Black, 1926, p. 4)

In Scotland, the theme was pursued by David Hume in his History of England, but also by Adam
Ferguson (History of Civil Society, 1767), John Millar, William Robertson and Lord Kames, to name but
a few (see Berry, 1997, chs 5 and 6).

At the same time there was a growing interest among both Scottish and French writers in the link
between economic organizations (modes of subsistence) and patterns of behaviour in the fields of
sociology and politics. The link that was established between the form of economic and the social and
political structure was so explicit as to permit William Robertson, Histographer Royal and Principal of
Edinburgh University, to state the main propositions with economy and accuracy. First, Robertson noted
that:

In every enquiry concerning the operations of men when united together in society, the
first object of attention should be their mode of subsistence. According as that varies, their
laws and policy must be different.

Secondly, Robertson drew attention to the relationship between property and power, noting for example
that ‘Upon discovering in what state property was at any particular period, we may determine with
precision what was the degree of power possessed by the king or the nobility at that juncture’, that is, by

Smith managed to isolate four distinct modes of subsistence to which there corresponded different types
of social and political structures, together with different patterns of ‘manners’, to use Hume's phrase.
The thesis was common among Smith's Scottish contemporaries. The different modes of subsistence are
represented by the stages of ‘hunting, pasturage, farming and commerce’ (LJB, p. 149). The most
detailed treatment of the first two stages will be found in WN, Book V, where Smith considers the
historical provision of defence and justice. The third and fourth stages are examined in WN, Book III.
Smith's historical sweep was wide ranging, starting as his discourse did from the record of early classical
Greece before proceeding to the Decline and Fall of the Roman Empire in the West, and thus to the
emergence of the modern state. It should be noted that while the perspective adopted in the third Book is
European in its emphasis, the focus gradually narrows to the consideration of British and indeed English
experience.

Early history

When the German and Scythian nations over-ran the western provinces of the Roman
empire, the confusions which followed so great a revolution lasted for several centuries.
The rapine and violence which the barbarians exercised against the antient inhabitants,
interrupted the commerce between the towns and the country. The towns were deserted,
and the country was left uncultivated, and the western provinces of Europe, which had
enjoyed a considerable degree of opulence under the Roman empire, sunk into the lowest
At the same time, however, Smith argued that the domination of the barbarian nations had generated not only a desert but also an environment from which a particular form of European civilization was ultimately to emerge. Smith's explanation of this general trend begins with the fact that the primitive tribes which overran the empire had already attained a relatively sophisticated form of the pasturage economy, with some idea of agriculture and of property in land. He argued that they would naturally use existing instructions in their new situation and that in particular their first act would be a division of the conquered territories.

The chiefs and principal leaders of those nations, acquired or usurped to themselves the greater part of the lands … A great part of them was uncultivated; but no part of them, whether cultivated or uncultivated, was left without a proprietor. All of them were engrossed, and the greater part by a few great proprietors. (WN, III.ii.1)

In this way we move in effect from a developed version of one economic stage to a primitive version of another; from the state of pasture to that of ‘agriculture’. Under the circumstances outlined, property in land became the source of power and distinction, with each estate assuming the form of a separate principality. As a result of this situation, Smith argued, a gradual change took place in the laws governing property, featuring the introduction of primogeniture and entails, designed to protect estates against division and to preserve a ‘certain lineal succession’. The basic point emphasized was the ‘The security of a landed estate … the protection which its owner could afford to those who dwelt on it, depended upon its greatness. To divide it was to ruin it, and to expose every part of it to be oppressed and swallowed up by the incursions of its neighbours’ (WN, III.ii.3).

Such institutions as these quite obviously reflect a change in the mode of subsistence and in the form of property, thus presenting some important contrasts with the previous state of pasture. On the other hand, the great proprietor has still nothing on which to expend his surpluses other than the maintenance of dependants – and at the same time has a positive incentive to do so since they contribute to his military power and security. While Smith carefully distinguished between retainers and cultivators in this context, he took pains to emphasize that the latter group were in every respect as dependent on the proprietor as the first, and added that ‘Even such of them as were not in a state of villanage, were tenants at will, who paid a rent in no respect equivalent to the subsistence which the land afforded them’ (WN, III.iv.6).

In short, the period was marked by clear relations of power and dependence – but above all by disorder and conflict, and it was from this source that the first important changes in the outlines of the system were to come. As Smith put it by way of summary:

In those disorderly times, every great landlord was a sort of petty prince. His tenants were his subjects. He was their judge, and in some respects their legislator in peace, and their leader in war. He made war according to his own discretion, frequently against his neighbours, and sometimes against his sovereign. (WN, III.ii.3)
It was this state of conflict, Smith suggests, which gave the proprietors some incentive to alter the pattern of landholding, in two quite different ways. First, Smith argued that the heavy demands which were inevitably made on their immediate tenants (as distinct from villains) for military service would inevitably change the quit-rent system in terms of which land was normally held. Smith argued in effect that the great lords would naturally begin to grant leases for a term of years, and then in a form which gave security to the tenant's family and ultimately to his posterity. In this way, land came to be held in a feudal relationship, which was being designed to give both parties a benefit: the lord, in terms of the supply of military service, and the tenant, security in the use of land. Smith also noted certain consequential developments which reflected the basic purpose of the arrangement, in describing what he called the feudal casualities.

Secondly, Smith argued that the need for protection which had altered the relationship between the great lord and his tenants would also lead to patterns of alliance between members of the former group and, therefore, to arrangements which gave some guarantee of mutual service and support. It was for these reasons, Smith argued, that the lesser landowners gradually entered into feudal arrangements with those greater lords who could ensure their survival (thus enhancing their ability to do so), just as the great lords would be led to make similar arrangements amongst themselves and with the king. These changes took place about the ninth, tenth and eleventh centuries, and by imposing some shackles on the free enterprise of the proprietors contributed thereby to the emergence of a more orderly form of government. However, while Smith did describe the feudal as a higher form of the agrarian economy than the allodial, he also took some pains to emphasize the limited possibilities for economic growth which it presented; limitations which were themselves the reflection of the political institutions now prevailing. He argued that the quit-rent system, so far as it survived, gave no incentive to industry, and that the institution of slavery ensured that it was in the interest of the ordinary individual to ‘eat as much, and to labour as little as possible’ (WN, III.ii.9). In the same way he also cited the disincentive effects of the arbitrary services and feudal taxes which were imposed. But, undoubtedly, Smith placed most emphasis on the continuing problem of political instability:

The authority of government still continued to be, as before, too weak in the head and too strong in the inferior members, and the excessive strength of the inferior members was the cause of the weakness of the head. After the institution of feudal subordination, the king was as incapable of restraining the violence of the great lords as before. They still continued to make war according to their own discretion, almost continually upon one another, and very frequently upon the king; and the open country still continued to be a scene of violence, rapine, and disorder. (WN, III.iv.9)

Once again, a state of instability was to produce some change in the outlines of the social system, and once again the motive behind this change was political rather than economic – but now with the kings rather than the great lords as the main actors in the drama.

The exchange economy

The kind of economy which Smith described as appropriate to the agrarian state in its developed form is fundamentally a simple one. It consisted of a division between town and country, that is, between those
who produce food and those who make the manufactured goods without which no large country could subsist – the critical point being, however, that such an economy was not wholly based on exchange.

The cities which Smith described were small, and composed of those merchants, tradesmen and mechanics who were not bound to a particular place and who might find it in their (economic) interest to congregate together. Smith had in fact relatively little to say about the historical origins of such groupings, but he did emphasize that the inhabitants of the towns were in the same servile condition as the inhabitants of the country, and that the wealth which they did manage under such unfavourable conditions would be subject to the arbitrary exactions of both the king and those lords in whose territories they might happen to reside (WN, III.iii.2).

But evidently some developments must have been possible, for Smith examined the role of cities from the period in time when three distinctive features of royal policy with regard to them were already in evidence. First, Smith noted that cities had often been allowed to farm the taxes to which they were subject, the inhabitants thus becoming ‘jointly and severally answerable’ for the whole sum due (WN, III.iii.3). Second, he noted that in some cases these taxes, instead of being farmed for a given number of years, had been ‘let in fee’, that is ‘forever, reserving a rent certain never afterwards to be augmented’ (WN, III.iii.4). Third, Smith observed that the cities:

were generally at the same time erected into a commonality or corporation, with the privilege of having magistrates and a town-council of their own, of making bye-laws for their own government, of building walls for their own defence, and of reducing all their inhabitants under a sort of military discipline, by obliging them to watch and ward … (WN, III.iii.6)

It was as a result of following these policies that some kings has achieved the apparently remarkable result of freezing the very revenues which were most likely to increase over time, and at the same time effectively curtailing their own power by erecting ‘a sort of independent republicks in the heart of their own dominions’ (WN, III.iii.7).

Smith advanced two main reasons to explain the apparent paradox. First, he argued that by encouraging the cities the king made it possible for a group of his subjects to defend themselves again the power of the great lords, when he personally was frequently unable to do so, and, secondly, that by imposing a limit on taxation ‘he took away from those whom he wished to have for his friends, and, if one may so do, for his allies, all ground of jealousy and suspicion that he was ever afterwards to oppress them, either by raising the farm rent of their town, or by granting it to some other’ (WN, III.iii.8).

The encouragement given to the cities represented in effect a tactical alliance which was beneficial to both parties. In speaking of the burghers, Smith remarked that ‘Mutual interest … disposed them to support the king, and the king to support them against the lords. They were the enemies of his enemies, and it was his interest to render them as secure and independent of those enemies as he could’ (WN, III. iii.8).

Smith also noted that this development was directly related to the weakness of kings, so that it was likely to be more significant in some countries than in others, and that in general the policy had been successful where employed. He also remarked that the granting of powers of self-government to the inhabitants of the cities had set in motion forces which were ultimately to weaken the authority of the kings through creating an environment within which the forces of economic development could, for the
first time, be effectively released. In Smith's own words:

Order and good government, and along with them the liberty and security of individuals, were, in this manner, established in cities at a time when the occupiers of land … were exposed to every sort of violence. But men in this defenceless state naturally content themselves with their necessary subsistence; because to acquire more might only tempt the injustice of their oppressors. On the contrary, when they are secure of enjoying the fruits of their industry, they naturally exert it to better their condition, and to acquire not only the necessaries, but the conveniences and elegancies of life. (WN, III.iii.12)

The stimulus to economic growth and to further social change was thus seen to emanate from the cities; institutions which had themselves been developed and protected in an attempt to solve a political problem. From this point, Smith's attention shifted to the analysis of the process of economic growth in the manufacturing and trading sectors, before going on to examine its impact on the agrarian sector. Smith clearly recognized that growth was limited by the size of the market and, since the agrarian sector was relatively backward, that the main stimulus to economic growth would have to come from foreign trade. He concluded that cities such as Venice, Genoa and Pisa, all of which enjoyed ready access to the sea, had provided the models for the process. In general Smith laid most emphasis on three sources of encouragement to the development of trade and manufactures. First, he argued that in many cases agrarian surpluses could be acquired by the merchants and used in exchange for foreign manufacturers, and suggested as a matter of fact that the early trade of Europe had largely consisted in the exchange ‘of their own rude, for the manufactured products of more civilized nations’. Secondly, he suggested that over time the merchants would naturally seek to introduce similar manufactures at home (with a view to saving carriage). Such manufactures, it was suggested, would require the use of foreign materials, thus inducing an important change in the general pattern of trade. Thirdly, he argued that some manufactures would develop ‘naturally’, that is through the gradual refinement of the ‘coarse and rude’ products which were normally produced at home and which were, therefore, based on domestic materials. Smith suggested that such developments were normally found in those cities which were ‘not indeed at a very great, but at a considerable distance from the sea coast, and sometimes even from all water carriage’ (WN, III.iii.20). He suggested that manufacturers might well develop in areas to which artisans had been attracted by the cheapness of subsistence, thus allowing trade to develop within the locality:

The manufacturers first supply the neighbourhood, and afterwards, as their work improves and refines, more distant markets. For though neither the rude produce, nor even the coarse manufacture, could, without the greatest difficulty, support the expence of a considerable land carriage, the refined and improved manufacture easily may. In a small bulk it frequently contains the price of a great quantity for rude produce. (WN, III.iii.20).

Smith cited the silk manufacture at Lyons and Spitalfields as examples of the first category of manufactures; those of Leeds, Halifax, Sheffield, Birmingham and Wolverhampton as examples of the second, the natural ‘offspring of agriculture’ (WN, III.iii.19, 20). He also added that manufacturers of the latter kind were generally posterior to those ‘which were the offspring of foreign commerce’ and that the process of development just outlined made it perfectly possible for the city within which economic
development took place to grow up to a great wealth and splendour, while not only the country in its neighbourhood, but all those to which it traded, were in poverty and wretchedness’ (WN, III.iii.13).

In the next stage of analysis, however, it was argued that the situation as outlined was unlikely to continue; that the development of manufacturers and trade within the cities was bound to impinge on the agrarian sector and, ultimately, to destroy the service relationships which still subsisted within it.

Essentially, this process may be seen to stem from the fact that the development of trade and manufacturers had given the proprietors a means of expending their wealth, other than in the maintenance of dependants. The development of commerce and manufacturers:

gradually furnished the great proprietors with something for which they could exchange the whole surplus produce of their lands, and which they could consume themselves without sharing it either with tenants or retainers. All for ourselves, and nothing for other people, seems, in every age of the world, to have been the vile maxim of the masters of mankind. (WN, III.iv.10)

This situation generated two results. First, since the proprietor's objective was now to increase his command over the means of exchange, it would be in his interest to reduce the number of retainers:

till they were at last dismissed altogether. The same cause gradually led them to dismiss the unnecessary part of their tenants. Farms were enlarged, and the occupiers of land, notwithstanding the complaints of depopulation, reduced to the number necessary for cultivating it, according to the imperfect state of cultivation and improvement in those times. (WN, III.iv.13)
