There has been little research on the welfare implications of moral hazard. An exception is Stiglitz (see for example Arnott and Stiglitz, 1985), who noted that the existence of moral hazard creates second best contracts. In an economy characterized by such contracts, changes in contracts between any two parties have significant first order effects on social welfare, in contrast to the Arrow–Debreu economy, where first order effects of individual actions are zero at an optimum. As we have seen, moral hazard may lead to rationing and queues, suboptimal expenditure of hidden actions and imperfections in capital markets. This is not surprising because moral hazard is basically a form of externality. It is well known that uninternalized externalities lead to non-concavities, possible non-existence of equilibria and inefficiencies. The existence of such inefficiencies signals a possible role for government. However, government intervention may well cause more problems than it solves. For example, attempts to supplement deficient insurance markets in the form of universal income (social security, income taxation) insurance have run into serious moral hazard problems of work incentives, tax avoidance and evasion, and so on. It is at least partly because of these moral hazard problems that such markets failed to develop. It is therefore unclear whether government supply of these services enhances welfare. In contrast, government policies which enhance complete contracts and improve their enforcement, can be welfare enhancing. Examples are contract law, liability rules and trade regulations.

Morgenstern, Oskar (1902–1977)

Martin Shubik
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

game theory; Morgenstern, O.; perfect foresight; prediction; rational behaviour; von Neumann, J.

Article

Morgenstern was born in Goerlitz, Silesia, on 24 January 1902. He died on 26 July 1977 at his home in Princeton, New Jersey. The two main intellectual centres of his life were Vienna and Princeton. In each case the source of his intellectual stimulation was not primarily the university but institutions such as the Wienerkreis of Moritz Schlick in Vienna, where he counted among his friends Karl Popper, Kurt Gödel and Karl Schlesinger, and the Institute for Advanced Study at Princeton. He obtained his doctorate in 1925 from the University of Vienna, where he was greatly influenced by Karl Menger and the writings of Eugen Böhm-Bawerk.

Morgenstern's first major work, Wirtschaftsprognose (1928), which was published in Vienna, served as his Habilitation thesis leading to his appointment as a privatdozent at the University of Vienna in 1929. In this book he began to consider the difficulties and paradoxes inherent in economic prediction, being particularly concerned with prediction where the action of a few powerful individuals could influence the outcome. He illustrated some of these difficulties with the example of Sherlock Holmes's pursuit of Professor Moriarty (an example repeated in the Theory of Games, 1944).

He became a professor at the University of Vienna in 1935, and in the same year published in the Zeitschrift für Nationalökonomie (of which he was managing editor) an article on fundamental difficulties with the assumption of perfect foresight in the study of economic equilibrium. It was then that the mathematician Edward •ech noted that the problems raised by Morgenstern were related to those treated by von Neumann in his article ‘Zur Theorie der Gesellschaftsspiele’, published in 1928. Morgenstern did not have the opportunity to meet von Neumann until somewhat later. They both recalled meeting at the Nassau Inn in Princeton on 1 February 1939, although each believed that they had met once before. They became close friends and remained so until von Neumann's death on 8 February 1957.

In Vienna, Morgenstern was also director of the Austrian Institute for Business Cycle Research (1931–8).
where he employed Abraham Wald, whom he later helped go to the United States. In 1938, due to his opposition to the Nazis, Morgenstern was dismissed from the University of Vienna as ‘politically unbearable’ and he accepted an offer from Princeton, to some extent because of the presence of von Neumann at the Institute for Advanced Study. Their close collaboration resulted in the publication in 1944 of their book, *The Theory of Games and Economic Behavior*. This major work contained a radical reconceptualization of the basic problems of competition and collaboration as a game of strategy among several agents, as well as an important novel approach to utility theory (presented in detail in the second edition, 1947).

Both Morgenstern and von Neumann were well aware of the limitations of their great work. They stressed that they were beginning by offering a sound basis for a static theory of conscious individually rational economic behaviour and that the history of science indicated that a dynamic theory might be considerably different. They warned against premature generalization.

In his years at Princeton from 1938 until his retirement in 1970, Morgenstern encouraged the work of a distinguished roster of younger scholars in game theory and combinatoric methods. This was feasible primarily through the strength of the Mathematics Department and its connections with the Institute. There was little interest in the subject in the Department of Economics at the time. The ideas of the *Theory of Games* were so radical that they have taken many years to permeate the social sciences. Even at the time of his death many in the economics profession were sceptical of or indifferent to its contributions.

Although his work on the theory of games was undoubtedly Morgenstern's greatest contribution and collaboration, his interests were wide-ranging. His two books, *On the Accuracy of Economic Observations* (1950), and *Predictability of Stock Market Prices* (1970), written jointly with Clive W. Granger, indicate these interests. He was also concerned with matters of national defence and in 1959 published *The Question of National Defense*.

In 1959 he was one of the founders of Mathematica, a highly successful and sophisticated consulting firm, and served as Chairman of the Board. After retiring from Princeton he was Distinguished Professor at New York University until his death.

Morishima, Michio (1923–2004)

Meghnad Desai
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Morishima's contribution to economic theory was in tackling questions of equilibrium and dynamics with and without money, with heterogenous capital and in a multisectoral framework. He tried to synthesize and answer questions raised by Ricardo, Marx, Walras, Wicksell, Keynes and Schumpeter. His work was influenced by von Neumann's model and Hicks's style of theorizing.

Article

Michio Morishima was one of the most distinguished economic theorists of his generation. He taught in Japan at Kyoto and Osaka Universities, and in the UK he was the Keynes Visiting Professor at the University of Essex 1969–70 and Professor of Economics, later the John Hicks Professor of Economics, at the London School of Economics 1970–84 and Emeritus Professor for the rest of his life. He was awarded the Order of Culture [Bunka Kunsho] of Japan by the Emperor in 1976, a Fellowship of the British Academy in 1981 and an Honorary Fellowship of the LSE upon his retirement. Morishima became the first Japanese to be the President of the Econometric Society in 1965. He died aged 80 on 13 July 2004, leaving behind his wife Yoko and two sons and a daughter.
Morishima's work encompasses general equilibrium theory with heterogeneous capital, growth and money, as part of a coherent attempt to tackle one of the most intractable problems in economic theory, namely, the construction of an adequate theory of a dynamic growing economy with heterogeneous capital and money as well as credit or, to put it another way, a theory of how the capitalist system works. Morishima's Ph.D. thesis at Kyoto University (published in Japanese in 1950 and in English in 1996 under the title *Dynamic Economic Theory*) dealt with stability of equilibrium. The standard (Hicksian) theory says that if the market starts out at a price away from the equilibrium given by the intersection of the demand and supply curves, then the price must change until the equilibrium point is reached. But how? Walrasians posit an auctioneer who would call out prices and register demands and supplies at each price. No trades are made until the auctioneer is satisfied that demands and supplies balance, that is, no false trading. The corollary of a no false trading equilibrium is that there can be never be involuntary unemployment, raising the issue of the consistency of micro and macro theories with each other.

Morishima prefers the case in which trading takes place at each price, but the price changes if, at that price, after transactions are closed, there is excess supply or demand. This would be a non-tâtonnement process, where some traders may buy (sell) at a price higher (lower) than the equilibrium price. He does not, however, develop this any further in the thesis but asks: are we exploring the path of convergence of the ‘groping’ prices, that is, virtual prices at which no trades are carried out and hence within ‘the market day’, or are we talking of the path of equilibrium prices arrived at, at the end of the tâtonnement in each market day from one day to the next?

Within the Hicksian week, the groping process traces out a path of virtual prices which converge to equilibrium under certain well-known conditions. But what of the sequence over several weeks of the equilibrium price? What are the dynamics of the path itself? It is this question that Morishima poses in *Dynamic Economic Theory* and pursues over his entire career. It is obviously connected to the stability of a growth path, since the path of income is analogous to the path of equilibrium prices. Morishima's discussion of growth paths was therefore always concerned not only with the quantity variables such as income and the stock of capital but also prices and interest rates.

Morishima's first book in English, *Equilibrium, Stability and Growth* (1964), tried to integrate Walras into the growth story, which had not hitherto been attempted, and also gave prominence to Marx's work on accumulation at the same time. Morishima constructed Walras–Leontieff and Marx–von Neumann models, which are pioneer efforts. *Equilibrium, Stability and Growth* is growth-oriented with an emphasis on linear technology and balanced maximal growth paths with fixed coefficients. But there is also a chapter on a spectrum of techniques. This is Morishima's response to the then ongoing capital controversy between Cambridge England and Cambridge Massachusetts.

Very soon after *Equilibrium, Stability and Growth* was published, Morishima came out with his most ambitious work to date, *Theory of Economic Growth* (1969). Here Morishima sets out a rigorous multisectoral framework – the von Neumann model – and integrates Walras as well as Hicks into this framework. Prices are solved out along with quantities throughout. Turnpikes are discussed under various assumptions. But Morishima also deals with the issue of the optimality of the maximal growth paths.

Morishima was not happy with *Theory of Economic Growth*. Thus started his long detour via Marx, Walras and Ricardo, until he could come back to his major concern. Morishima's book *Marx's Economics* (1973) deals with the statics and dynamics of Marx's growth and exploitation theory and
tackled joint production with innovative insights. It shows that labour values can be used to tackle the aggregation problem for heterogeneous capital.

The crucial next step is provided by Walras. Most economists think that Walras provided consistent microfoundations for a full employment–all markets clearing theory of the macroeconomy. Morishima had a different Walras in his 1977 book with the intriguing title *Walras’ Economics: A Pure Theory of Capital and Money*. Morishima's purpose in the book is to see whether he can exploit Walras's work to provide the microfoundations of Keynesian macroeconomics. He focuses on the contrast between nominal demands (neoclassical) and effective demands (Keynesian) as well as the alternative hypotheses that investments adjust to savings (neoclassical) and that investments are prior and saving adjust (Keynesian). Walras's entrepreneurs have no income; they work on altruistic principles. Morishima adjusts Walras's investment function as well as giving entrepreneurs an income (profits) which makes the model closer to real capitalism. But he also shows why one needs a theory of accumulation and growth, that is, a story with time and future in it, in order to have a rationale for holding money in a Walrasian world. In a static general equilibrium, money can, and does, play no role.

The heart of Morishima's book *Ricardo's Economics* (1989) is in the final section entitled ‘Three Paradigms Compared’. Say's Law is at issue. Ricardo established Say's Law as a dominant mode of theorizing. Usual departures from Say's Law involve a non-trivial role for money and/or a growth process via an active investment function. Ricardo had neither and so could subscribe to Say's Law. Marx had both but his investment function was very restrictive and made no use of money or credit. Walras had money towards the end of *Elements* but his growth theory lacked an investment function which led the way for savings to adjust to investment. Keynes of course had money and investment functions, but he did not spell out the microfoundations. Growth is not sufficient to justify a violation of Say's Laws; money or an investment function which has a role for entrepreneurs to respond to uncertainty is required.

In *Ricardo's Economics* a model is set up in which excess demand and supply for labour and capital are modelled in a simple diagram (1989, fig. 6, p. 218). Here, around an equilibrium point, zones of excess supply and demand for the two factors are mapped out. Morishima's axes are the real wage and the output capital ratio. Within the same general model all the three paradigms are embedded. Again, the investment function turns out to be the crucial relationship for the Anti-Say's Law result that Keynes established.

*Capital and Credit: A New Formulation of General Equilibrium Theory* (1992) brings together all the major themes of money, heterogeneous capital, underemployment equilibria and growth. The major innovation in *Capital and Credit* is that banks play a crucial role in financing production. This is Schumpeter rather than Keynes. While in Keynes's scheme entrepreneurs may underinvest because of expectations or a low marginal efficiency of capital relative to the rate of interest, Schumpeter allows for overshooting of credit creation by bankers. Thus, inflation as well as underemployment is possible. *Capital and Credit* is therefore concerned with innovations and their financing and monetary disequilibrium. The economy is split into Say's Law and Anti-Say's Law activities. There is a scope for Anti-Say's Law if production is financed by credit, and this of course requires that it is not instantaneous but has an input–output lag. With instantaneous production and investment adjusting to savings, Say's Law is confirmed. But in any realistic capitalist economy it breaks down due to the presence of credit. The amount of credit determines activity in the Anti-Say's Law sector (manufacturing industry, in other words), and this, via the multiplier, determines the overall levels of activity and employment. This need
not be full employment.
The separation of the economy as between relative prices determined by demand/supply and absolute
prices as determined by money – ‘the classical dichotomy’ is no longer valid. It is only by omitting banks
and the financial requirements for production that the dichotomy is sustained.
In the last chapter, on ‘Monetary Disequilibrium’, Wicksell's cumulative process is examined from the
point of view of von Neumann. The real system establishes the rate of profits (= rate of growth), but it
leaves the price level indeterminate. Credit creation by bankers determines the nominal level of interest
with the natural rate given by the real system. Then the monetary side determines the price level by the
intersection of the money demand function and the real growth rate. But it is not a stable equilibrium. It
is a kind of IS–LM model, but with its axes as interest rate and price level rather than income.
So we now enter a new development in monetary and growth theory. If the economy is growing and/or
if the natural rate is a variable, then we need to extend Wicksell's analysis, which assumed a constant
natural interest rate. But the natural rate may be above or below the von Neumann rate, and if the natural
rate is also variable then the gap between the natural and the money rate is variable over the cycle. Thus,
if the natural rate is above the money rate and the von Neumann rate, then inflation follows, but that may
reduce the natural rate. If it then crosses over to being below the money rate, deflation follows and the
natural rate may approach the von Neumann rate from above. Prices keep falling, and the economy may
converge to the von Neumann rate.
In the converse case, the economy starts off with the natural rate below the money rate and below the
von Neumann rate, and then deflation comes first as the natural rate approaches the von Neumann rate
from below. Once it crosses over the constant money rate, then inflation follows and the economy
approaches the von Neumann rate in an explosive inflationary situation.
This is the most sophisticated discussion of money and growth in the classical Wicksell framework. A
variable natural rate is seldom modelled, and the deflation–inflation cycles enrich the Wicksell model
greatly. But we are still in the world of Say's Law. What happens if we break away from it? The
shortage of credit will restrict the economy below full employment, as Keynes envisaged, and
abundance of credit will start off an inflationary growth process, as Schumpeter said. This then is the
climax of the entire edifice of Morishima's work. He can now combine Anti-Say's Law with credit and
disequilibrium. Credit creation determines the natural rate via the Anti-Say's Law sector, which is often
the most innovative and dynamic. Morishima can then tackle the classical dichotomy.
This is the homogeneity postulate whereby nominal variables cannot have real effects and so money
must be a veil. But the homogeneity postulate requires that a monetary shock be evenly spread across all
agents. It also requires that the elasticity of demand with respect to money balances be identical across
all agents. Morishima shows in the final pages of Capital and Credit that neither of these assumptions is
likely to be fulfilled in a monetary economy. Agents including households and firms and the Anti-Say's
Law firms are much more credit-sensitive than other firms, for one thing. And if the homogeneity
postulate falls, so does the quantity theory.
The challenge of integrating money and growth with general equilibrium but without Say's Law has
been accomplished. There is much more to be gained from a careful study of these writings and one can
only hope that future scholars will mine the rich source of theoretical insights in the decades to come.

Article
Mortality is one of the three demographic components that shape the size, structure, and dynamics of populations; the other two are fertility and migration. Death rates have declined remarkably in modern times. The populations of the more developed countries have been aging for more than 100 years and the process of rising life expectancy also has begun in most of the less developed countries. Survival is increasing as a result of progress in economic development, social improvements, and advances in medicine. Mortality has been falling steadily especially in wealthier, economically advanced countries and has continued to do so during the second half of the 20th century and after, particularly at higher ages. We are getting older and the number of the elderly is increasing in most countries.

While the reduction in human mortality can be considered one of the greatest achievements of modern civilization, rising longevity and the increasing number of elderly will pose major challenges to health
Mortality and social security systems. Declines in birth rates and increases in adult life-expectancy result in aging societies. These demographic changes will impact the life-course decisions of individuals, social interaction, economic development, and policy reforms in the countries involved. Rising life expectancy has globally been a widespread phenomenon, but mortality differentials remain. Death rates vary significantly in different parts of the world and are particularly high in sub-Saharan Africa by global standards. Mortality conditions have changed throughout history and vary among and within populations. Death rates differ according to the country of origin, place of residence, sex, socio-economic status, level of education and marital status.

Mortality and life expectancy

Various indicators exist to measure mortality. Two of the indicators most often used and cited are the central death rate and life expectancy. The former, which is age-specific and time-specific, is defined as the number of deaths occurring at a given age during a given year, divided by the mean population of that age and year. Life expectancy is an estimate of average age at death under current death rates. It is calculated by imposing the age-specific death rates of the respective year on a hypothetical cohort of newborns. In 2004, Japan reached the highest female life expectancy (85.59 years) ever obtained by a country. Lowest life expectancy is generally recorded in sub-Saharan Africa. An example is Zimbabwe, a country that in 2004 suffered the world's lowest life expectancy, 34 years for men and 37 years for women, according to WHO (2006). The United Nations estimated worldwide life expectancy for 2000–5 at 67.7 and 63.2 for women and men, respectively (United Nations, 2005).

Remaining life expectancy at age \( x \) is usually denoted as \( e_x \) and \( e^0_x \). A value of \( x = 0 \) leads to the most often published indicator, ‘life expectancy at birth’. Note that ‘life expectancy’ for a given year is based on a hypothetical cohort. Only if death rates are not changing can the average newborn be expected to live the number of years indicated by life expectancy. If age-specific mortality continues to decrease – as was the case in many developed countries during recent decades – then the actual average age at death of a birth cohort would be higher than the one estimated for the hypothetical cohort.

Age trajectories of human mortality and the Gompertz law of mortality

As individuals age, they tend to suffer an increasing loss of physical function and greater susceptibility to disease and injury. Benjamin Gompertz, a British actuary, described in 1825 the gradual increase in mortality rates with age, using an exponential curve, today known as the ‘Gompertz law of mortality’. The model implies that there is a constant rate of increase in the age-specific mortality of adult populations; for many populations this rate of increase is about ten per cent per year. The Gompertz model fits human mortality rates well for adults aged 30 to 85 in most modern populations with high life expectancies.

The overall age trajectory of human mortality is roughly U-shaped. Mortality is high immediately after birth. During infancy it decreases rapidly with age to reach a minimum between the ages of 10 and 15. Thereafter, the risk of dying rises more or less exponentially according to the Gompertz law of mortality, with some excess mortality among young adults. A rise in mortality during early adulthood is
often referred to as ‘accident hump’, as it is mainly caused by accidents in many modern populations (Heligman and Pollard, 1980). Especially in industrialized countries, this hump is more pronounced for men than for women. The hazards associated with being a woman of childbearing age have been greatly reduced in developed countries, but those connected with the transition to manhood are still substantial. Maternal mortality, in contrast, is confined almost exclusively to developing countries. Among women worldwide, those in sub-Saharan Africa are at highest risk of dying during pregnancy and at childbirth: The lifetime risk was estimated by WHO at 1 in 16 in 2002; this compares to a risk of 1 in 2,500 in the United States (WHO, 2004).

Most deaths in developed countries today are concentrated at older ages. Death rates at older ages have, however, declined markedly during the second half of the 20th century. Furthermore, after age 80 death rates rise more slowly than predicted by the Gompertz exponential formula, and may roughly level off around age 110, albeit at the high level of about 50 per cent mortality per year (Thatcher, Kannisto and Vaupel, 1998; Robine and Vaupel, 2002).

**Rising life expectancy in industrialized countries**

The rise in life expectancy is one of the great achievements of modern times. In the countries with the highest levels, female life expectancy has been rising for 160 years at a steady pace of almost three months per year (Oeppen and Vaupel, 2002). The four-decade increase in best-practice life expectancy is so extraordinarily linear that it may be the most remarkable regularity of mass endeavour observed. On average, women live longer than men, but record life expectancy has also risen linearly for men since 1840, albeit a little more slowly than for women. The improvements in survival leading to the linear climb in record life expectancy result from the intricate interplay of advances in income, salubrity, nutrition, education, sanitation and, in recent decades, medicine (Riley, 2001).

When we look at individual countries, gains in life expectancy have not progressed as linearly. The gap between the record level and the national level can be regarded as a measure of how much better a country might do. Neither the trend in record life expectancy nor the life expectancy trajectories in different countries suggest that a limit to life expectancy is in sight. Although rapid progress in catch-up periods is typically followed by slower increases, none of the curves appear to be approaching a maximum value (Oeppen and Vaupel, 2002).

The rising numbers of centenarians in developed countries is another striking piece of evidence for the continuing increase in longevity. Lifespans exceeding 100 years, which seemed almost impossible to achieve in the past, despite spectacular reports, are increasingly becoming part of our reality today. It is unlikely that any person living in Sweden before 1800 attained the age of 100 (Jeune, 1995) and throughout the world centenarians must have been very rare (Wilmoth, 1995). Data on the pre-18th century period have to be interpreted with caution. Few reliable statistics are available on mortality levels among the very old living under conditions of low life expectancy. The lower life expectancy is, the greater is the tendency to exaggerate age at older ages (Kannisto, 1994). Today, the number of centenarians in developed countries is increasing at an exceptionally rapid rate of six to nine per cent per year in many countries. While 265 centenarians were counted in England and Wales in 1950, there were 5,895 of them 50 years later, that is, more than 20 times the 1950 figure (Kannisto–Thatcher Database). In developed countries, the number of people celebrating their 100th birthday doubled each decade.
between 1950 and 1980; by the end of the 20th century it was multiplying by a factor of 2.4 per decade.

The history of mortality decline

How can the transition from high to low mortality be explained? Over most of the course of human existence, life expectancy hovered between 20 and 30 years. Infant mortality was high, people fell victim to infectious and parasitic diseases or simply to the harshness of everyday living conditions. Even in western Europe life expectancy did not reach age 40 until after 1800, and it stayed below age 50 until after 1900 (Vaupel and Jeune, 1995). Over the course of the 20th century, life expectancy rose dramatically by more than 30 years in many industrialized countries. Rising life expectancy in industrialized countries since the 19th century is related to a fundamental epidemiological transition. There was a shift from the predominance of high mortality from infectious disease to conditions in which non-communicable and degenerative diseases among the elderly became more important. By the beginning of the 19th century in European areas of the world epidemics had been reduced, food supply became more stable, and fluctuations in mortality decreased. Over the course of the 19th century, the standard of living and hygiene improved and some public health services were established in a number of countries (Bongaarts and Bulatao, 2000). Infectious disease was the greatest scourge of mankind until the first half of the 20th century, that is, until vaccination, antibiotics, and other medical advances finally began to combat successfully many of the life-threatening diseases in industrialized countries. By the same token, they lowered the rates of infant and child mortality and limited the devastating effects of the largest epidemics, although some outbreaks of influenza and the HIV/AIDS epidemic are exceptions. Parallel to these changes, there was a shift from high to low fertility. Mortality associated with pregnancy and birth decreased considerably.

The second half of the 20th century saw a dramatic reduction in death rates at advanced ages (Vaupel and Jeune, 1995; Kannisto, 1994; Kannisto et al., 1994; Vaupel, 1997). The time around 1950 marks a distinct change in mortality conditions among the ‘oldest old’ (85 or more years of age) in developed countries: While improvements in survival were slow in the years preceding 1950, progress made after 1950 and especially after 1970 has been impressive. Data from England, Wales, France, Iceland, Japan, and the United States show clearly that old-age survival has been increasing since 1950 (Vaupel, 1997; Vaupel et al., 1998). The population of centenarians and even super-centenarians (persons older than 110 years) is growing rapidly. The increase in the number of births about a century ago coupled with a sharp decline in mortality from childhood to age 80 contributed to the rising numbers. Demographic analyses, however, demonstrate that the most important factor behind the explosion of the centenarian population has been the decline in the mortality rate after age 80, a factor that has been two to three times more important than the other factors combined (Vaupel and Jeune, 1995). The ongoing increase in life expectancy is largely attributable to continuous improvements in survival at advanced ages (Vaupel and Jeune, 1995; Vaupel, 1997).

In developed countries, the decline in mortality caused by infectious diseases and the postponement of degenerative diseases has delayed deaths to increasingly older ages. Today, cardiovascular disease and cancer are the major causes of death in industrialized countries. In 2002, heart disease and stroke accounted for more than half of all deaths, and cancers were responsible for around 20 per cent of all deaths in Europe (WHO, 2004).
The human survival curve, which depicts the proportion of an initial (hypothetical) cohort still alive, has changed its shape as a consequence. The survival curve is becoming more rectangular due to the concentration of deaths at higher ages. To provide an example, the 2002 life table for Japanese women shows that more than 95 per cent of the initial hypothetical cohort would be still alive under current mortality rates at age 60. Mortality decline is neither a regular process in industrialized countries nor is it a process confined to these nations. Life expectancy has risen in most developing countries, too, especially in many Asian states and in Latin America. The mortality transition is driven by the same factors as in the developed countries – combating infectious disease plays a major role here. However, the transition proceeds much faster than it did in industrialized nations and there are considerable differences in the degree of progress (Bongaarts and Bulatao, 2000).

**The plateau in late-life mortality**

Human death rates increase slowly after age 80. Data analyses of very large cohorts reveal that death rates reach a plateau at advanced ages and may level off around age 110 (Thatcher, Kannisto and Vaupel, 1998; Robine and Vaupel, 2002). This observation is not unique to humans, however. Late-life mortality deceleration has been noticed in and confirmed for a number of model organisms as diverse as yeast, nematodes, or fruit flies. For all species for which large cohorts have been followed to extinction, age-specific mortality decelerates and, for the largest populations studied, even declines at older ages (Vaupel et al., 1998).

Some concepts contributing to an understanding of the astonishing improvement in survival at late ages come from biodemography, a subject that has emerged at the confluence of demography and biology. One biodemographic explanation builds on heterogeneity in frailty. All populations are heterogeneous, and even genetically identical populations display phenotypic differences. Frailer individuals have a lower probability of survival to late ages; robust individuals have a higher one. The frail tend to suffer high mortality, leaving a select subset of robust survivors. This results in compositional change in the surviving, aging population and in slower increases in age-specific death rates (Vaupel, Manton and Stallard, 1979; Curtsinger et al., 1992; Vaupel and Carey, 1993; Yashin, Vaupel and Iachine, 1994). Another biodemographic explanation refers to changes in survival capacities at the individual level. Generally, the longevity of individual organisms is influenced by the living conditions to which they are exposed. Studies with different species have shown that several environmental factors of non-lethal stress, for example dietary restriction or heat shock, can induce increases in both resistance and longevity (Lithgow et al., 1995; Murakami and Johnson, 1996; Masoro, 2000). Hormesis, a biologically favourable response to low exposure to stress or toxins, is a well-known physiological phenomenon. Caloric restriction has proven to be an effective way to extend life span in a wide range of species, from yeast to mammals (Masoro, 2000). It is not clear, however, whether fasting is a way of prolonging life in humans.

**The influence of current conditions on age-specific death rates**

Studies involving model organisms have provided valuable insights into the biological processes of aging. An example can be drawn from a study on the Drosophila fruit fly. When flies fed a restricted diet...
were switched to a full diet, mortality soared to the level suffered by flies that had been fully fed all their lives. Conversely, when the diet of fully fed Drosophila was restricted, mortality plunged within 48 hours to the level enjoyed by flies that had experienced a lifelong restricted diet (Mair et al., 2003). The results support the repeated finding that age-specific death rates for humans (and other species) are strongly influenced by current conditions and behaviour (Kannisto, 1994; Vaupel et al., 1998).

Placed in a broader context, the conclusion drawn from the fruit fly study also applies to humans. This can be illustrated neatly by an unplanned ‘natural experiment’ in Germany's recent history. Before reunification, both East and West Germany saw a radical decline in old-age mortality, as is characteristic for most developed countries. In the former GDR, however, mortality was considerably higher than in West Germany. Following unification (1989–1990), old-age mortality in East Germany declined to reach the levels prevailing in the West (Gjonca, Brockmann and Maier, 2000), a development largely attributed to improved health care for the elderly after unification. Thus, interventions even late in life can switch death rates to a lower, healthier trajectory. It's never too late to start prolonging your life (Vaupel, Carey and Christensen, 2003).

Longevity in humans has a relatively low heritability. Studies of twins indicate that a modest 25 per cent of the variation in life spans is attributable to genetic differences among people (McGue et al., 1993; Herskind et al., 1996; Finch and Tanzi, 1997). The discoveries of genetic and environmental factors that contribute to extensions of the lifespan do not fully explain the malleability of aging. Nevertheless, the findings show that there are means and ways of delaying aging.

**The plasticity of aging**

The rise in life expectancy has provoked discussion of the question whether we are approaching a limit to life expectancy, a biologically determined maximum lifespan that inevitably halts further improvements of old-age survival.

A common assumption still widely held is that lifespan cannot be extended beyond a biologically determined limit. The notion of an inevitable maximum lifespan also influences scientific studies of longevity (Fries, 1980; Olshansky, Carnes and Cassel, 1990). Ever since research into longevity began, attempts have been made to determine the maximum life expectancy that humans could reach. The ceilings proposed by various authors differ but all have been exceeded, apart from those proposed most recently (Oeppen and Vaupel, 2002). The assumption of a finite, biological limit to life can be traced back to Aristotle (350 bc). In his treatise ‘On Youth and Old Age, On Life and Death’, Aristotle contrasted two types of death: premature death caused by disease or accident, and senescent death due to old age. He believed that nothing could be done about old age and thus about the end to life. More than 2,300 years later, James Fries quantified Aristotle's distinction in a widely cited article published in the New England Journal of Medicine. If life is not cut short by accident or illness, then the lifespan of man will inevitably approach a potential maximum limit that is fixed for every human but differs from individual to individual (Fries, 1980). According to Fries, the fixed value of the maximum lifespan is normally distributed with a mean of 85 years and a standard deviation of seven years. Fries emphasizes that nothing can be done to alter a person's maximum lifespan as the latter is beyond the influence of environmental, behavioural, or medical intervention currently conceivable. Accordingly, death rates at older ages are intractable. The notion of unavoidable senescent death has been reinforced by
evolutionary biologists who hypothesize that mortality must rise with age as the force of selection against deleterious, late-acting mutations declines (Hamilton, 1966).

The notion of an upper biological limit to lifespan may be commonly accepted, yet there is no empirical evidence of a proximate limit to human longevity. The steady rise in human life expectancy shows no signs of levelling off. Experts repeatedly asserting that life expectancy is approaching a ceiling have repeatedly been proven wrong. If life expectancy were approaching an unavoidable biologically maximum, then the increase in life expectancy should be slowing, especially in countries such as Japan or France, both of which enjoy exceptionally low death rates. This, however, is not the case (Oeppen and Vaupel, 2002; Vaupel, 1997). Mortality is plastic even at advanced ages.

The prevailing causes of rising life expectancy have undergone changes and are complex. Combined, they have nonetheless led to a stable and linear increase in life expectancy since 1840. This will probably also apply to the future. Just as medical breakthroughs – for example, the discovery of antibiotics or advances in organ transplantation – were not foreseen, we do not know what major technological innovations the future will bring to promote long and healthy lives. There is no reason, however, to assume that progress in technological knowledge and its exploitation will come to a halt. It would not make sense to take the standards of today to estimate the conditions influencing life expectancy tomorrow. Future advances in life expectancy will be made as we progress in the prevention, diagnosis, and treatment of deadly age-related diseases (Barbi and Vaupel, 2005).

**Future prospects of longevity**

Because best-practice life expectancy has been increasing by 2.5 years per decade for the past 160 years, one reasonable scenario is that this trend will continue in the coming decades. To date, there is no indication that a change in the trend is in sight. If the trend continues, there may be a country in about six decades’ time with life expectancy beyond the threshold of 100 years (Oeppen and Vaupel, 2002).

An application of this extrapolation in conjunction with methods from time-series analysis to project the gap between best-practice and national life expectancy results in national forecasts that are considerably higher than many official projections. From the use of this method, female life expectancy for Germany, for example, is expected to rise significantly above 90 years by 2050. Official projections, however, do not exceed 87 years (medium scenario). In many countries, official projections assume a deceleration in reductions of death rates. Such projections made in the past have resulted in underestimates of actual increases in life expectancy. These errors distort planning for future pensions, health care, and other social needs as well as the decision-making of individuals drawing up saving plans or planning for retirement. Increases in life expectancy of a few years can produce large changes in the numbers of old and oldest old who will need support and care. In developed countries, centenarians may well become commonplace during the lifetime of people alive today.

**Mortality divergences**

Although health trends have been generally positive throughout the world and remarkable improvements in survival have been achieved in developed and many developing countries (Tuljapurkar, Li and Boe, 2000; Vallin and Meslé, 2005), death rates still vary among countries and even within countries. In the
1970s and early 1980s, many demographers expected a convergence in life expectancies worldwide by assuming gains would be higher for the countries with lower life expectancies (McMichael et al., 2004). A quarter of a century later, however, it is clear that this assumption did not hold. On the one hand, increases in life expectancy of some of the best-performing countries, such as Japan or France, did not show any levelling off at all and life expectancy climbed higher than expected. On the other hand, there have been exceptions to the widespread phenomenon of general mortality decline in the second half of the 20th century. Mortality reversals were observed in the 1980s and 1990s in as many as 42 countries (McMichael et al., 2004; Caselli, Meslé and Vallin, 2002; Vallin and Meslé, 2005) as life expectancy fell. Most of these countries are situated in sub-Saharan Africa or in eastern Europe. Life expectancy in several sub-Saharan countries was more than ten years lower in 2004 than predicted by the UN Population Division about 20 years earlier (United Nations, 1981). Other countries that experienced reversals in life expectancy at the end of the 20th century are North Korea, Haiti, Fiji, the Bahamas, and Iraq. Setbacks apart from those caused by war and famine were not taken into account by early demographers, with the result that future setbacks in national mortality were considered unlikely (McMichael et al., 2004).

In sub-Saharan Africa, HIV/AIDS and other infectious diseases, such as tuberculosis and malaria, caused death rates to rise, and many of the countries involved were additionally faced with economic hardships, political conflicts, and violence between groups or individuals. Russia, like other countries of the former USSR or of eastern Europe, experienced increased mortality among working-age adults, especially among men aged between 20 and 65 (Shkolnikov et al., 1998; Meslé et al., 2003). Adults are normally less vulnerable to mortality increase than are children or the elderly. The drastic political and socio-economic transition increased unemployment rates and income inequalities, and led to weakened safety nets and to psycho-social stress among those most affected, particularly the less educated population groups (Shapiro, 1995; Shkolnikov et al., 1998; Bobak et al., 2000). Adverse male behaviours, such as alcohol abuse, crime, and violence, contributed to male excess adult mortality. In addition, rates of cardiovascular disease and cancer mortality are high in Russia. Some industrialized countries perform less well than others. Since the mid-1980s in the United States, for example, death rates have declined more slowly than in most other developed countries. Until about 1980, the United States enjoyed relatively low death rates for both women and men after aged 65. Since then, however, death rates at older ages have fallen less rapidly than in Japan, France and other countries. The reasons for the slow increase in life expectancy in the United States are not yet well understood.

**Mortality differentials**

The U-shape of the mortality risk trajectory applies to all humans. Nevertheless, remarkable differentials exist by geographical region and along other dimensions. The best-known differential is between females and males. In most developed countries, the difference between female and male life expectancy is between four and seven years. The gap between women and men is typically smaller in less developed countries. It is not clear how much of the gap is biological as opposed to social, in part because biological factors interact with social ones. While men take more health risks (such as smoking), women are more careful about their health (for example, visits to the doctor).
Socio-economic status (SES) and mortality have an inverse relationship: individuals with higher SES usually enjoy lower mortality, regardless of how SES is measured (Goldman, 2001). Although measures of SES are correlated with each other, they address different dimensions: education is related to health behaviour and knowledge of healthy lifestyle, occupation to health hazards of the job, and income to access to health care as well as to the ability to provide a healthy living environment (such as housing conditions).

Marital status is another important mortality determinant. Married individuals usually have lower death rates than do never-married women and men, the widowed, or the divorced. Two different hypotheses have been discussed in the literature to explain this differential. On the one hand, marriage is expected to have a protective effect via pooled financial resources, higher social support, the adoption of healthier lifestyles, and other factors. On the other hand, it is argued that there is a selection effect into marriage: healthy women and men have higher chances of finding a spouse than less healthy individuals (Goldman, 1993).

Abstract

Film-goers discover the films they like by consuming them, and through the exchange of information the demand for motion pictures evolves dynamically. The supply of screens adjusts in response to demand through flexible state-contingent exhibition contracts. This article presents an overview of the economics of motion pictures that focuses on how the demand process affects the distribution of outcomes, how the distribution of outcomes can be quantified with the use of statistical models, and how the industry's organization and business practices can be understood in light of the behavioural and statistical models.

Article

The business of motion pictures is a fascinating laboratory for applied researchers in the social sciences. The glamorous subject matter makes the industry inherently interesting, but more important for empirical research is the availability of project-level data on investment and financial returns. Most studies of investment decisions are conducted at the industry or firm level, so that the researcher observes the return only on a portfolio of projects. In the movie business, the unit of observation is the individual project, and data are collected and reported in fine detail by many industry sources. Early research on the movie business applied microeconomic theory to the industry and made little use of its detailed data and rich institutions. This early literature is important in providing the historical context in which many of the movie industry's business practices emerged. Kindem (1982) has collected in his volume many papers that provide organizational and institutional analyses of the motion-picture industry from its origins through the modern era. More recent papers in this line of applied research provide revisionist analyses of the industry's history and development (Chisholm, 1993; 1997; De Vany
The market for motion pictures is difficult to understand quantitatively, though the intuition is transparent. Film-goers discover the films they like by consuming them, and through the exchange of information the demand for motion pictures evolves over time. Supply adjusts as the available screens respond to demand through flexible state-contingent exhibition contracts. The present article provides an overview of the economics of motion pictures. The focus is on how the demand process affects the distribution of outcomes, how the distribution of outcomes can be quantified, and how this relates to the industry's organization and business practices.

**Movie-goer choices and outcome uncertainty**

Understanding demand is essential if one is to make sense of the movie industry's contracts and business practices. Early viewers of a movie affect the choices of potential viewers – behaviour that goes under the names of herding, contagion, network effects, bandwagons, path-dependence, momentum, and information cascades. The particular models differ in their details, but they are dynamic in that demand depends on revealed demand, or more generally on how group behaviour arises from the interaction of individual decision-makers (Epstein and Axtell, 1996). Initial advantages in movie attendance can lead to extreme differences in outcomes when demand has recursive feedback. De Vany and Walls (1996) showed that box-office revenues have a contagion-like property where the week-to-week change in demand is stochastically dependent on previous demand. A big opening of a bad movie can kill it but a big opening of a good movie can lead to an avalanche of attendance and large revenues. Let's examine the demand for movies more closely to see the origins of extreme success and failure.

Assume for simplicity initially that there was only one movie that could be viewed by one consumer at any one time. Consumers choose in random sequence whether or not to go to the movie. If we further assume that the consumers have a common prior belief about the film's quality, then there is a common probability $p$ that a randomly chosen person will choose to see the film. If we let $X$ be the number attending the film, then $X$ is a binomial random variable; it follows that when consumers share a common prior the film's revenues would follow a binomial distribution. When quality is unknown and priors over quality differ among viewers, $p$ is a random variable. By conditioning on $p$ and integrating over the binomial distribution, we see that each of the $n+1$ possible outcomes is equally likely; adding uncertainty to the priors transforms the distribution of revenue from the binomial to the uniform distribution.

Now consider information sharing, as has been modelled by Jovanovic (1987), where potential consumers can use information revealed during a film's run to refine their prior on its quality; this sort of information includes the opinions of other viewers, such as expert reviewers, advertising, and information from box office reports and queuing at cinemas. De Vany and Walls (1996) let the distribution of customers over screens be multinomial uniform, so the movie search problem – a search for quality with an unknown distribution – is similar to the search for price with an unknown distribution. Viewers who do not know the distribution begin with a uniform prior and adapt from there. The result of this process is the Bose–Einstein distribution which has the property that all of the possible outcome vectors are equally likely! This means the vector in which the attendance at every theatre is equal to zero is as likely as one in which all $n$ trials go to only one theatre and every other vector is...
equally likely (Feller, 1957). The Bose–Einstein distribution has uniform mass over a space of $s+1$-vectors; the $s$-vectors correspond to the revenues of the $s$ theatres and one bin collects those who go to no film.

What is important about the evolution of choice probabilities under the Bose–Einstein choice logic is the way past successes are leveraged into future successes: as soon as individual differences emerge among the films, they are compounded by information feedback into very large differences over the course of a film's theatrical lifetime. A broad opening at many theatres can produce large and rapidly growing audiences, but it also can lead to early failure if the large crowd relays negative information. Movie customers sequentially select movies, and the probability that a given customer selects a particular movie is proportional to the fraction of previous customers who selected that movie. This result obtains because the probabilities are not known and sampling reveals information that causes previous selections to attract new ones.

Quantifying the distribution of movie outcomes

Box-office revenue is asymptotically power law or Pareto distributed (De Vany and Walls, 1999; 2002). One of the attractions of the power law distributions in explaining the movie business is that they allow for the heavy tails and skewness that are characteristic of box-office outcomes. Power laws emerge in many other systems with feedback of the type discussed above (Brock, 1999).

The stable Paretian model

Mandelbrot (1963) proposed the stable Paretian distribution as a general model for natural and social systems; it is applied in economics, finance, biology, geology, physiology, and other sciences (McCulloch, 1996; Uchaikin and Zolotarev, 1999; Mantegna and Stanley, 1995; Levy and Soloman, 1997). The stable distribution is the limiting distribution of all stable processes so that it contains the other well-known stable distributions (Cauchy, Lévy, Gaussian) as special cases. Motion picture profit is well fit by a stable distribution with infinite variance and positive skew (Walls, 2000; De Vany and Walls, 2004). The stable distribution's ability to capture the empirical regularities found in motion picture data and the distribution's statistical foundation on the most general form of central limit theorem make it a natural model of motion picture outcomes. The theoretical reason for thinking that a stable distribution might apply to motion pictures is that Mandelbrot (1963) showed that a dynamic process that is stable under choice, mixture, and aggregation converges in distribution to the stable distribution. If motion picture revenues and costs are discrete time processes with stable increments, then profit will converge to a stable distribution.

Conditional stable distribution

In empirical studies it is possible to model the stable Paretian distribution of movie outcomes conditional on a vector of explanatory variables with the use of McCulloch's (1998) stable regression model in which the index of stability $\alpha$ and the regression coefficients are estimated jointly. The stable
regression model has the familiar form of a linear regression \[ y_i = \beta_0 + \sum_{j=1}^{k} \beta_j x_i + \varepsilon_i \] where the \( \beta \)'s are the coefficients to be estimated and the \( x \)'s are the regressors, but the random disturbance term is assumed to follow a stable distribution with median zero. Estimation of the stable regression model results in an estimate of the regression coefficient \( \beta \)'s as well as an estimate of the characteristic exponent \( \alpha \). The regression coefficients in this model represent what is known about the correlates of film success while at the same time permitting the variance of film success at the box office to be infinite. Estimates of this model show that the distribution of returns conditional on a movie's attributes has infinite variance and that returns to production budgets are substantially larger and returns to stars substantially lower than one would estimate using an improperly specified least-squares model (Walls, 2005b).

**Stretched exponentials**

Concavity in log-log plots of size against rank, also known as a parabolic power law, are interpreted as evidence of increasing returns to information in the demand for motion pictures (De Vany and Walls, 1996; Walls, 1997; Hand, 2001). Frisch and Sornette (1997) propose a multiplicative stochastic process that can explain the deviation of the data relative to a power law distribution, and Sornette (1998) provides rigorous technical details on multiplicative processes leading to power laws and stretched exponentials. Walls (2005a) finds that the stretched exponential distribution fits motion-picture revenue data remarkably well. The stretched exponential distribution does not truncate the upper tail in its estimates of the probability of a movie earning a larger amount than previous movies. The distribution also accounts for the deviation from the strict Pareto power law in a way that does not place artificial restrictions on the possibility that a movie can earn far more than our experience suggests.

**Understanding the movie business**

We now discuss how the behavioural and statistical models help us to understand the way the motion-picture industry operates and how contracts and business practices adjust the supply of theatrical engagements to capture the increasing returns inherent in the demand process.

**The opening**

Stars, large production budgets and national advertising campaigns can place a film on many exhibitor screens when it opens. This can generate high initial revenues and, if viewers like the film and spread the word, it will earn high revenues in the following weeks. But a wide release is vulnerable to negative feedback – if viewers do not like the film, the large opening audience transmits a large flow of negative information, and revenue may decline at a rapid rate. A wide release lowers the gross revenue per theatre, and this may cause exhibitors to drop the film sooner than they would otherwise. The willingness of exhibitors and downstream sources of revenue like cable television, videocassette distributors, pay per view and network television as well as foreign distributors to pay advance guarantees for motion pictures before their theatrical run is a major inducement for distributors to
produce big budget films and promote them heavily. The theatrical market can be less important than other sources of revenues (Rusco and Walls, 2004).

**Decentralization**

Each film's run through the market is sequential in order to exploit information dynamics. The run is self-organized because it decentralizes the decision to extend the run to each theatre and uses only local information to extend or close the run at each location. The initial release is modified over time through this process, and new engagements can be added subject to prior contractual obligations. These contractual features interact to adaptively capture revenue and generate strongly increasing returns from highly successful films. When demand has positive feedback, supply responds flexibly to allow some films to become blockbusters.

**Admission pricing**

Fixed admission prices (across films but within a given customer class or time of day) are a common industry practice. As a result, demand is accommodated by lengthening a film's run. A relatively stationary admission price combined with a count of admissions gives a reliable signal of demand, and this signal is transmitted throughout the industry by real time reporting of box office revenues. This reporting is required in the exhibition contract and encouraged by other means as well. If the admission price were increased to ration excess demand, the number of people who would see the film in the opening weeks would fall and this would reduce the flow of information from this source to potential viewers. This lower rate of information transfer would lead to a shorter run and a lower total level of demand. The ability to extend the run makes an almost perfectly elastic supply response possible, so there is no need for price to rise to ration excess demand. Fixed admission prices lead to a pure quantity signal and an adaptive supply response to accommodate demand discovery.

**Contracting**

Optimal contract theory does not fit the environment of motion pictures where expected values are dominated by the rare and unpredictable events that are so large. The incentive clauses of optimal contract theory are designed to alter the probabilities of favourable outcomes and raise expected values, but the asymmetric information often emphasized by optimal contract theory is not a factor because both principal and agent are in a state of symmetric ignorance about the prospects of a movie owing to the 'nobody knows' property (Caves, 2000).

A difficult problem to solve contractually is how to keep a film on screens long enough for it to build an audience. If an exhibitor takes such a film, it is with the risk that it may build so slowly during his or her run that only exhibitors who show it later will benefit from information feedback. Because the Paramount decrees bar long-term, exclusive showings, it is difficult to guarantee that the exhibitor who takes the risk of introducing the film will benefit if the film later becomes a success (De Vany and Eckert, 1991). When the audience grows recursively, the Paramount contracting restrictions may prevent risk-taking exhibitors from capturing the demand externality which they create.
Extreme events drive the business, so contracts condition pay on rare events with compensation related to the outcome of the movie. Many Hollywood superstar movie contracts contain some form of profit participation (Weinstein, 1998). Many contracts are contingent on theatrical box office revenues, which are readily monitored. In this case, the share of gross revenue paid often is nonlinear, with the share rising at higher outcomes, to reflect the nonlinear dependence of profit on revenue. In a complex contract, there may be several breakpoints where the star's percentage share increases, this nonlinearity reflecting the nonlinearity of profit in revenue.

Film rentals

The exhibition contracts are rich in contingencies that make them highly adaptive: they rely on locally generated information; they set the rental fee in a precise and nonlinear way in response to demand; they share risk between exhibitors and distributors; and they create incentives for exhibitors to show films by granting a measure of exclusivity. The rental price adapts to the state of demand and the rental schedule is nonlinear. Events in the tail are the high-revenue weeks during a movie's theatrical run, and these weeks can occur at any time during the run. During these high-revenue weeks, the rental clause allows the exhibitor to retain his or her (negotiated) cost per week of operation plus ten per cent while allocating the remaining 90 per cent to the distributor (De Vany and Eckert, 1991).

Star power

Movies with superstars have a different distribution of profit from other movies (De Vany and Walls, 2004). The profit distribution for superstar movies is an asymmetric stable distribution with infinite variance. Stars place much more mass in the upper tail of the profit distribution. The probability of extreme catastrophes – losses in excess of $95 million, say – is higher for movies without stars than for movies with stars. This is not at all obvious and may not be observed in a given sample. Putting a star in a movie places more mass on the upper tail and less on the lower tail. Expected profit is positive for star movies and negative for non-star movies. These values are consistent with the fact that probability is skewed to the positive tail in superstar movies and to the negative tail for others. Superstar movies are more profitable and less risky than other movies.

Success breeds success

An interesting property of the stable Paretian distribution discussed above is that conditional expectation does not converge. The tails of stable distributions are Paretian and the conditional probability that \( x \geq x_0 \) is \( \mathcal{P}(x > x_0) = (x_0 / x)^\alpha \). The conditional mean, given that \( x > x_0 \) equals \( \bar{x}_0 = x_0^{\alpha} / (\alpha - 1) \). Since \( \alpha \) is a constant, the conditional expected value of profit depends linearly on \( x_0 \). Conditional on having earned a profit, the expected profit continues to rise with current profit, and this does not end as the movie earns more profit. This is not paradoxical because movies that make it into the upper tail of the profit distribution have been selected from among their competitors. The heavy tails of the stable distribution imply that probability does not decline rapidly enough for the conditional expectation to converge. For the Gaussian or log Gaussian distributions, the conditional expectation converges to a
constant as the conditioning event increases. The linear conditional expectation of the Pareto distribution means that blockbuster movies that have already attained high profit have an expectation of even higher profit, and this prospect does not diminish as profit grows. This captures the idea of demand momentum.

Conclusion

When movie audiences see a movie they like, they make a discovery and they tell their friends about it. This and other information is transmitted to other consumers, and demand develops dynamically as the audience sequentially discovers which movies it likes. Supply adapts to revealed demand through flexible exhibition contracts and other business practices that permit the increasing returns in film demand to be realized.

Multilingualism or linguistic diversity in a heterogeneous society provides extraordinary challenges and room for policies which may have important economic implications in shaping the flows of interregional or international trade, investment and migrations. Given the often uncompromising nature of linguistic conflicts, linguistic policies and, especially, the choice of official languages should take into account the preferences of those groups of individuals whose cultural, societal, historical values and sensibilities could be affected. In evaluating linguistic policies an important role is played by the dynamic nature of language environments driven by individual choices of learning other languages.

Keywords
communicative benefits; linguistic disenfranchisement; linguistic standardization; multilingualism; official languages

Article
Multilingualism or linguistic diversity is an important societal phenomenon that can generate gains or losses resulting from the economic interactions between individuals, regions or countries. The effects of multilingualism have recently come to the forefront of public policy debates. Linguistic issues and, in particular, the treatment of minority languages are almost unparalleled in terms of their explosiveness and emotional appeal, much more so than any other question of resource allocation or responsibility sharing within a polity. As noted by Bretton (1976, p. 447), ‘language may be the most explosive issue universally and over time. This mainly because language alone, unlike all other concerns associated with nationalism and ethnocentrism is so closely tied to the individual self. Fear of being deprived of communicating skills seems to raise political passion to fever pitch.’
Language policies in multilingual societies are beset by the trade-off between standardization and disenfranchisement. Linguistic standardization comprises any set of policies that promote the dominant
use of a unique or several languages while limiting the usage of languages spoken by other population groups. Indeed, linguistic standardization may deliver important benefits in terms of greater ease of communication, reducing costs of translation, increased trade, improved economic performance and administrative efficiency. However, excessive standardization may exacerbate the alienation of large minorities and widen the existing chasm between linguistic communities (Laponce, 2003). A restriction of basic linguistic rights may create disenfranchisement of groups of individuals and cause citizens to lose their ability to communicate in the language of their choice. Standardization, which is often represented by a selection of official languages and allocation of linguistic rights, may alienate those groups of individuals whose cultural, societal and historical values and sensibilities are not represented by the official languages (Laitin, 1989). As Pool (1991) points out, non-official languages may suffer from their ‘minority status’ and limit employment and advancement possibilities of their native speakers. Since in many cases it is not feasible to include all the languages in the set of official ones, a multilingual society must design some language standardization policies (for example, the ‘three-language formula’ in India; Baldridge, 1996) and the implementation of certain standardization measures (De Swaan, 2001; Grin, 2004). However, the explosive and uncompromising nature of linguistic conflicts, the reluctance of linguistic majorities to concede rights to minorities, makes the choice of official languages a challenging and daunting task. Thus, the choice of the set of official languages has to take into account the sensitivity of a society towards possible disenfranchisement of large groups of its citizens (Ginsburgh, Ortuño-Ortín and Weber, 2005) and has to rely on a delicate resolution of the interplay between administrative and cost efficiency, on the one hand, and the rights and desires of various linguistic groups, on the other (Van Parijs, 2005).

To illustrate the individual and aggregate cost and benefits of standardization and disenfranchisement, we consider a society $M$ and the set of languages $L$ spoken in this society. We assume that every citizen $i$ is endowed with a unique native language $n(i) \in L$ and a set of languages $L(i) \subseteq L$ that, to simplify, she commands with identical ease. A linguistic profile of each individual $i$ is the pair $(n(i), L(i))$, and society's linguistic profile is given by $P = \{(n(i), L(i)) : i \in M\}$. A linguistic policy is represented by a set of official languages $K \subseteq L$ that is chosen for administrative, educational, and official communication functions in the society (Pool, 1991; 1996, and the extensive list of references therein; Ginsburgh, Ortuño-Ortín and Weber, 2005.) The choice of the set $K$ represents a linguistic standardization policy. If the set of official languages $K$ is non-empty and smaller than $L$, those members of the society whose native language is not included in $K$ will be disenfranchised and some of their linguistic rights will be denied.

In order to evaluate the costs of disenfranchisement, we assume that every citizen $i$ has utility function $u_i$ defined over all subsets of $L$. We will denote $u_i(K)$ for $i \in M$ and $K \subseteq L$, where citizens with the same linguistic profiles have identical utility functions. It is important to stress that the functions $u_i$ are defined over the set of languages as a whole, rather than being dissected into preferences over single languages. Though citizens may have preferences over single languages, their evaluation of the set of official languages could be crucially affected by inclusion or exclusion of their native language. The aggregate utility (welfare) function for the entire society is given by $W(u, P, K)$, where $u$ is the vector of $u_i$'s.

Our description indicates the special role played by the native languages of citizens in $M$, which can be viewed as the union of linguistic clusters $M_l$, where, for each $l \in L$, $M_l$ consists of citizens whose native
language is 1. Assuming additivity of the aggregate utility, we have \( W(u, P, K) = \sum_{i \in L} \sum_{j \in M} \mu_i^j(K) \). As a simple example, consider the dichotomous function based on the citizens’ native languages (Ginsburgh and Weber, 2005), for which the value of \( u_i^K \) is 1 if i’s native language, \( n(i) \), is included in \( K \), and zero if it is not. The latter group contains individuals who are disenfranchised by the imposed standardized measures. The value taken by the function \( W \) is the number of citizens whose native language belongs to the set \( K \), \( W^1(u, P, K) = \sum_{i \in N} n(i) \in K \). One generalization of the dichotomous approach is to take into account the entire language profile of every citizen rather than her native language only. Then, the value of her utility function is 1 if at least one of the languages spoken by her is included in \( K \) and zero otherwise. Here, the notion of disenfranchisement is limited to those who speak no official language: \( W^2(u, P, K) = \sum_{i \in N} \{ n(i) \cap K \neq \emptyset \} \).

In evaluating citizens’ preferences over subsets of languages one may take into account the similarity or the proximity between languages (see, for example, Dyen, Kruskal and Black, 1992, for a matrix of distances between 95 Indo-European languages). Let \( \delta(l, l') \) be the linguistic distance between two languages \( l \) and \( l' \). Denote the linguistic distance between any two subsets \( T, T' \) of \( L \) as the minimal distance between a language from \( T \) and a language from \( T' \):

\[
\delta(T, T') = \min_{l \in T, l' \in T'} \delta(l, l').
\]

Then, the ‘linguistic welfare’ of the society is function of the distances between citizens’ native languages and the set of official languages \( K \): \( W^3(u, P, K) = w(\delta(n(1), K), \delta(n(2), K), \ldots, \delta(n(M), K)) \), where \( w: \mathbb{R}^M_+ \to \mathbb{R} \) is decreasing in each of its \( M \) arguments. Again, a modified utility function could be defined over the distances between the sets \( L(i) \) and \( K \) instead:

\[
W^4(u, P, K) = w(\delta(L(1), K), \delta(L(2), K), \ldots, \delta(L(M), K)).
\]

Note that enlarging the set of official language is welfare improving in all four specifications above. Thus, if the only goal of the society is to maximize aggregate utility, it should set \( K=L \). However, there are also other considerations to take into account. Difficulties of communication, costs incurred by translation and interpretation, possible errors causing delays and sometimes paralysing multilateral discussions and negotiations impose a non-negligible burden on societies with a large number of official languages (in 2007, the European Union had to manage 23 official languages at a cost over $1.5 billion). Denote then by \( C(K) \) the cost of maintaining the set \( K \) of official languages. Obviously, \( C \) is increasing, but its specific form depends on the intensity of the linguistic regime. There could be various requirements, including a ‘full’ regime that every official document needs to exist in all official languages.

There is thus a trade-off between language standardization (and disenfranchisement of some citizens) and the translation, interpretation and communication costs generated by every additional official language. Formally, the society’s objective is to find a set of languages \( K \) that maximizes the difference between aggregate utility and costs:

\[
\max_{K \subseteq L} W(u, P, K) - C(K).
\]

A solution to this problem is discussed by Grin (2004, p. 201), who argues that there must be an optimum, since ‘it is reasonable to assume that the benefits of diversity increase at a decreasing rate, while its costs increase at an increasing rate’, and is addressed in Ginsburgh, Ortuño-Ortín and Weber (2005).
Language profiles considered so far are assumed given. In fact, they can be remarkably dynamic and change over time as individuals may decide to learn other languages. The reasons that induce citizens to do so can be analysed by examining the benefits and the costs that such learning generates. Benefits are often linked with the increased earning potential, especially in the case of immigrants who acquire the native language of the country in which they live (see, for example, MacManus, Gould and Welsch, 1978; Grenier, 1985; Lang, 1986; Chiswick, 1998; and references in Grin and Vaillancourt, 1997). We consider the Selten and Pool (1991, p. 66) ‘communicative benefits’ approach that frees itself from the restriction that ‘earnings [are] a mechanism and forms a milieu of the incentive to learn languages’. For every language \( l \) consider the set \( M_l \) of its native speakers, whose number is denoted by \( m_l \). Assume for simplicity that \( l = j, k \) and that all citizens speak only their native language, so that the linguistic profile \( L(i) \) consists of \( n(i) \) for every \( i \in M \). Citizens may learn the other language. Denote by \( m_{j,k}(m_{j,l}) \) the number of citizens in \( M_j(M_k) \) who do so. A citizen \( i \in M_j \) who learns language \( k \) incurs a cost \( C(j, k) \), where \( C \) is an increasing function of linguistic distance. Let \( u_j(m_{j,k}, \cdot) \) be the utility of \( i \in M_j \), where the second argument indicates the number of individuals \( i \) can communicate with. We assume that the utility functions are increasing and, moreover, identical for all individuals with the same native language. If \( i \) learns \( k \), it costs her \( C_{j,k} \), but she will be able to communicate with all citizens in \( M_k \). Her gross benefit will be given by \( u_j(m_{j,k}, m_k) \). If \( i \) does not learn \( k \), she will be able to communicate with those in \( M_k \) who learn language \( j \), and her gross (and net) benefit will be \( u_j(m_j, m_k) \). This formulation leads to the following equilibrium condition that makes individuals in \( M_k \) indifferent between learning the other language and deciding not to do so: 

\[
\frac{u_j(m_j, m_k) - C_{j,k}}{u_j(m_{j,k}, m_k)} = \frac{u_j(m_j, m_k)}{u_j(m_{j,k}, m_k)}.
\]

This equation allows us to determine the number of citizens in group \( M_k \) who learn \( j \), and in a similar manner the number of those in group \( M_j \) who learn \( k \) (see Selten and Pool, 1991; Church and King, 1993; Shy, 2001; Gabszewicz, Ginsburgh and Weber, 2005; Ginsburgh, Ortúñ-Ortín and Weber, 2007). By imposing some additional conditions, such as continuity, concavity and super-modularity of the utility functions one can derive some comparative statics results. In particular, one can show that the number of learners of the foreign language \( j \) in country \( k \) is positively correlated with the number of \( j \)-speakers in other countries and negatively correlated with the population size of their own country \( k \) (Lazear, 1999; Ginsburgh, Ortúñ-Ortín and Weber, 2007). These results also show that public policies may be useful in stimulating learning (for a cost–benefit analysis of linguistic policies in Quebec, see, for example, Breton and Mieskowski, 1975, Vaillancourt, 1987; see also Fidrmuc and Ginsburgh, 2007, for policy suggestions in the EU).

In short, the questions raised by multilingualism offer serious challenges and the main reason is that linguistic policies are concerned not only with difficult trade-offs and resource allocation issues, but enter also the area of public policies that touch so closely personal values, beliefs and traditions.

animal spirits; bubbles; extraneous random variables; imperfect asset markets; income effect; increasing returns; indeterminacy; jump variables; missing initial conditions; multiple equilibria in macroeconomics; multiple laws of motion; overlapping generations models; public debt; stable manifolds

Article
The multiple equilibrium literature seeks explanations for excessive economic volatility, persistent poverty, market fads and fashions, and related macroeconomic phenomena that appear to be anomalies in standard models of rational economic behaviour. Terms like animal spirits, sunspots, irrational exuberance, indeterminacy, and bubbles describe situations of multiple equilibrium. All of these ideas assert that future values of macroeconomic states cannot be predicted accurately from current values of these states or from knowledge of economic fundamentals, even if households and firms behave with complete rationality. Most of the economics research community has been sceptical of multiple equilibrium (cf. McCallum, 1990), believing that it undermines the comparative statics and comparative dynamics exercises that are essential for policy evaluation and econometric prediction. Is it unreasonable, ask the sceptics, to know how the economy selects one equilibrium when many are possible, and how the expectations of economic actors settle on that particular outcome?
Economists have to weigh these legitimate reservations against direct evidence from laboratory experiments that beliefs do matter (Duffy and Fisher, 2005) as well as against the continuing difficulties of unique equilibrium models to come to grips with an expanding array of empirical anomalies in many sub-fields of macroeconomics, from excessively volatile asset prices and exchange rates to persistent underdevelopment. This article describes briefly four types of multiple equilibria common in macroeconomics, discusses what causes them, and reviews briefly what they teach us about economic policy.
Typology and examples

Multiple equilibria occur in dynamic economies whenever the laws of motion that describe macroeconomic states over time admit more than one solution sequence or, more broadly, several asymptotic states. The simplest mathematical example is a set valued, piecewise linear, deterministic law of motion for a scalar state variable \( x(t) \), expressed in terms of a vector \( \nu = (A, B, m, a, b) \) of fundamental parameters:

\[
x(t + 1) = f(x(t), \nu) = mx(t) + a \text{ if } 0 < x(t) < A = g(x(t), \nu) = mx(t) + b \text{ if } B < x(t)
\]

(1)

for all \( t = 0, 1, \ldots \), with \( 0 < m < 1, 0 < A < B, 0 < a < b \), and possibly some initial condition \( x(0) > 0 \) fixed by history.

For different values of the parameter vector \( \nu \), eq. (1) illustrates explicitly three major types of multiple equilibria: indeterminacy from missing initial conditions, indeterminacy from multiple laws of motion, and multiple attractors. A fourth type, non-fundamental state variables or sunspots, occurs when we randomly combine the two laws of motion \( f \) and \( g \). All four types are associated with excessively volatile behaviour, that is, with macroeconomic states exhibiting abnormal sensitivity to small changes in fundamentals.

**Missing initial conditions** is the simplest and best-known type of indeterminacy. Suppose, for example, that there is a unique law of motion \( f \), that is, the parameters \( A \) and \( B \) are infinitely large. If \( x(0) \) is an initial price or, more generally, a jump variable that is not predetermined by history but emerges instead from forward-looking markets, then there is a one-dimensional continuum of solutions \( x(t, a) \) to eq. (1) indexed on the indeterminate initial condition \( x(0) \):

\[
\log(x(t, a) - a / (1 - m)) = t \log m + \log(x(0) - a / (1 - m))
\]

(2)

More generally, an indeterminacy with \( S - 1 \) degrees of freedom appears in any dynamic economy when: (a) history predetermines I initial conditions; (b) the law of motion has \( S \) stable eigenvalues; and (c) \( 1 < S \). Equation (2) illustrates the case \( (S, I) = (1, 0) \). A major set of economic examples for this kind of multiplicity comes from overlapping generations models. Fiat money in a dynamically inefficient exchange economy (Wallace, 1980) has an indeterminate steady state with worthless money at which \( (S, I) = (1, 0) \) because history does not fix the initial price of money. Public debt in a dynamically inefficient production economy (Diamond, 1965) leads to an indeterminate steady state, with worthless public debt and \( (S, I) = (2, 1) \) because the price of debt is also a jump variable. Finally, two-sector growth environments (Galor, 1992), in which the distribution of capital between sectors is again a jump variable, exhibit indeterminacy with \( (S, I) = (2, 1) \) whenever the consumption good is more capital-intensive than the investment good.

**Multiple laws of motion** describe a less understood but more pernicious kind of indeterminacy that arises even if there are no jump variables. Examples of this phenomenon are growth models with private information or limited enforcement (Azariadis and Smith, 1998; Azariadis and Kaas, 2008) as well as Markov switching models in time-series econometrics and empirical finance (Hamilton, 1994). To illustrate, let us choose the parameter vector \( \nu \) in eq. (1) so that

\[
(1 - m)B < a < b < (1 - m)A
\]
Then the two laws of motion, \( f \) and \( g \), overlap in the interval \((B, A)\); each of them has a steady state, \( a / (1 - m) \) and \( b / (1 - m) \) respectively, which is a suitable initial condition for the other law. If \( x(t, a) \) and \( x(t, b) \) are dynamic equilibria for the two laws in eq. (2), then for any initial condition \( x(0) \) in the interval \((B, A)\), we can write down a deterministic general solution \( z(t) \) that combines regimes \( f \) and \( g \) in any arbitrary time sequence, that is,

\[
    z(t) = x(t, a) \quad \text{for some } t = x(t, b) \quad \text{for all other } t
\]  

(4)

For each \( x(0) \), we may freely select either regime in each time period. In particular, choosing the same regime every period leads to the steady state of that regime; switching regimes periodically leads to deterministic periodic cycles, as in Grandmont (1985), and so on.

**Sunspot equilibria** are mixtures of multiple deterministic equilibria – static ones as in Cass and Shell (1983) or dynamic ones as in Azariadis (1981) – connected by a non-fundamental or extraneous random variable. Market sentiment, investor beliefs, and consensus forecasts are three examples of extraneous random variables which often take on more colourful names like ‘animal spirits’, ‘sunspots’ or ‘self-fulfilling prophecies’. A simple illustration of a non-fundamental state variable is a lottery \( s(t) \) played each period over the intercept, \( a \) or \( b \), of the two laws of motion in eq. (1). For instance, if \( s(t) \) is a two-state Markov process, then \( s(t) = s(t - 1) \), with probability \( p(a) \) if \( s(t - 1) = a \), and with probability \( p(b) \) if \( s(t - 1) = b \). The general stochastic solution \( Z(t, s(t)) \) to eq. (1) shows how outcomes depend on the non-fundamental macroeconomic state \( s(t) \). Specifically,

\[
    \text{If } s(t - 1) = a, \text{ then } z(t, s(t)) = x(t, a) \quad \text{w. 1 - } p(a) \quad \text{if } s(t - 1) = b, \text{ then } z(t, s(t)) = x(t, a) \quad \text{w. } p \quad p(b)
\]  

(5)

The last type of non-uniqueness, multiple attractors, describes environments with several asymptotic states. Here long-run values of macroeconomic states depend on the corresponding initial values, as in Murphy, Shleifer and Vishny (1989), Azariadis and Drazen (1990), and Matsuyama (1991). We call these environments ‘non-ergodic’ or ones in which ‘history matters’. For example, suppose we pick the parameter vector \( v \) in eq. (1) to eliminate the overlap between regimes \( f \) and \( g \), and obtain one piecewise linear law of motion. Specifically, we replace (3) by

\[
    a < (1 - m) \quad A < (1 - m)B < b
\]  

(6)

Then, for each initial \( x(0) \), the general deterministic solution \( z(t) \) to eq. (1) is a unique step function, which traces the law \( f \) up to \( x = A \), and jumps to the other law.
$g$ at that point. Mathematically,

$$z(t) = x(t, a) \text{ if } z(t-1) < \Lambda \quad \text{or} \quad x(t, b) \text{ if } z(t-1) > \Lambda$$

(7)

Equilibrium here is completely determinate and utterly predictable if history fixes $x(0)$, but the asymptotic state is $a / (1 - m)$ if $x(0) < \Lambda$ and $b / (1 - m)$ if $x(0) > \Lambda$. History matters in this situation because small or temporary shocks to the macroeconomic state $z(t)$ can have substantial and long-lasting consequences if that state is anywhere near the critical value $\Lambda$.

**Causes**

Dynamic inefficiency and dynamic complementarities are the two most common proximate causes of multiple equilibrium in macroeconomic models. Dynamic inefficiency is a property of economies with very patient consumers who are energetic savers at low interest rates. For example, holders of short-term US Treasury bills in the last 50 years seem content with an average real pre-tax annual yield of about one per cent. Very patient savers are willing to invest in bubbles, paying top dollar for assets with low dividends. Bubbles themselves (Tirole, 1985; Shiller, 1989) are notoriously indeterminate objects in their initial conditions and laws of motion; they may deflate now, later or not at all, depending on investor sentiment.

Economies with externalities, increasing returns and, most notably, imperfect asset markets often exhibit complementarities in production or consumption which cause excess demands for consumption goods and productive factors to bend backward instead of sloping downward. The typical outcome is several steady states and several laws of motion or stable manifolds, each one leading to a distinct asymptotic state. In particular, multiple equilibria occur when externalities or increasing returns link the payoffs of each agent with the actions of others, both in strategic environments (Cooper and John, 1988) and in competitive ones (Benhabib and Farmer, 1994). Producers, for example, find it advantageous to raise, hold steady, or lower output in tandem with their industry or the whole national economy.

Imperfect asset markets, especially restrictions on debt and short sales (Bewley, 1986; Kehoe and Levine, 1993; Kiyotaki and Moore, 1997) are an intellectually bountiful and empirically compelling source of complementarities in consumption. This literature motivates restrictions on short sales by the collateral requirements of creditors and, more generally, as a deterrent to debtor default. Short-sales constraints depend on the excess payoff of solvency (which guarantees unfettered participation in future asset markets) over default (which restricts trading in future asset markets). Constraints on short sales are tighter the smaller this excess payoff is because smaller excess payoffs strengthen the temptation to default.

Debt constraints cause two dynamic complementarities in consumption, one through prices and the other through quantities (Azariadis and Kaas, 2007). Either one may be sufficient to overcome the intertemporal substitution effect embedded in the consumer's utility function. Specifically, price changes create a dynamic complementarity when the ordinary income effect is amplified by a relaxation of binding short-sale restrictions. The same outcome is achieved by quantity changes when an anticipated relaxation of future constraints increases the current payoff to solvency, and to continued market participation, thus slackening today's constraints.

**Lessons for policy**

What is the function of economic policy in a deterministic world of many steady states like the one described in eq. (7)? What should policy do in the stochastic world of eq. (5) where non-fundamental variables like beliefs, forecasts, consumer sentiment, ‘sunspots’, or ‘animal spirits’ could be every bit as important as fundamentals? Dynamic economies with several asymptotic states have two special properties: long-run performance depends on the starting state $x(0)$; and
Temporary shocks may have permanent consequences. Any economy that is headed towards an inferior or undesirable steady state may be shocked temporarily until it finds a path leading to a more desirable state. In growth models with many asymptotic states, these shocks are easy to achieve in principle via short-lasting gifts of physical or human capital, by forgiving international debt, and so on. The US-supported Marshall Plan for Europe did exactly that in the 1940s and 1950s. Africa seems in need of a similar plan now but the internal situation in that continent is more problematic than Europe's was at the end of the Second World War. A bigger conceptual, as distinct from political, challenge is to formulate policies appropriate for environments swayed by non-fundamental variables and vulnerable to spurious volatility. If equilibria were well described by the stochastic process of eq. (5), could we find an economic policy to eliminate the unnecessary randomness, and bolster among consumers the belief that the economy is headed toward the more desirable of the two steady states, say, $b/(1 - m)$?

Viewing economic policy as *equilibrium selection* is fairly widespread in the monetary policy literature (Woodford, 2003), and broadly consistent with monetary neutrality. On this view, credible monetary policy may be unable to influence the set of possible long-run equilibria, but it does bear on which one the economy selects. In eq. (5), for example, reactive policy rules may be unable to change the laws of motion $f$ and $g$ but they can still deliver the long-run state $b/(1 - m)$ if they influence the public's beliefs about the long-run likelihood of each state. All it takes to achieve the high state is nudging the two mixing probabilities, $p(a)$ towards zero and $p(b)$ towards 1.

**How to cite this article**

What is the effect of a change in the level of investment? Wicksell (1935) was the first economist to pose this question explicitly in the context of his ‘pure credit economy’. Voluntary or anticipated saving is not a requirement if the banking system is willing to supply the necessary credit to finance an increase of investment demand. The effect of this increase of investment demand is an increase in the level of prices (if the level of output is fixed or given), or output if there is idle capacity and unemployed labour. In his *Treatise on Money* (1930) Keynes analyses the same question. Just as in Wicksell's model, in the *Treatise*, investment is independent of current saving. The effects of a change of investment are studied through the *Treatise*'s ‘Fundamental Equations’ according to which a difference between current (or voluntary) saving and investment will give rise to a change in the price level. It is a pure excess demand effect. Changes in the price level will lead to unforeseen (or windfall) profits or losses which, in turn, will affect producers’ next period decision to produce and employ. Windfall profits will have the effect of inducing producers to increase the level of output; losses will have the opposite effect. The effect may not be as mechanical as described here if new informations (concerning, for example, changes in economic policies) come into the picture.

Book IV of the *Treatise* studies the ‘credit cycle’, that is, the effects of changes in monetary or banking policies on the rate of interest which may have an effect on the decisions to save and invest, and therefore, on the price and output levels. Changes in both the price and output levels are seen as deviations from their long-period or equilibrium counterparts; they are short-period or disequilibrium levels of price and output which, so to speak, oscillate around the equilibrium as defined by the equality between voluntary saving and investment. However, just as in Wicksell's analysis, once the system deviates from the equilibrium position, very little is said in terms of the path towards a new equilibrium;
Multiplier analysis is very much related to the adjustment process described above. The real *differentia* is that it focuses predominantly on the notions of stability and equilibrium of the process. The most important contributors for the development of the multiplier analysis were Kahn (1931), Keynes (1936) and Kalecki (1971).

The multiplier as an exercise in comparative statics

Let us consider the effects of a change in the level of investment which is known to all the relevant agents of the economy. Also let us temporarily assume that producers of consumption goods fully anticipate the effects of this change in investment on the demand for their products. An increase in the level of investment demand implies a greater level of production of capital goods. The degrees of capacity utilization and employment in the capital goods sector increase, thus leading to higher profits and a greater wage bill. Part of the extra profits and wages earned will be spent in consumption goods; the rest will be saved. The share of profits and wages spent in consumption goods are determined respectively by the propensities to consume out of profits and wages. These, according to Keynes (1936, chs 8 and 9), depend on objective factors (other than income) such as the money wage rate and agents’ rates of time-discounting, and subjective factors such as precaution and avarice.

Thus the main effect of an increase in investment is that it induces an increase in consumption, saving, and income. The final effect on the level of income will depend essentially on the propensity to consume of the economy. The greater the propensity to consume, the greater will be the increase in the demand for consumption goods resulting from an initial increase in the income generated in the capital goods sector. The immediate effect on the demand for consumption goods will be given by \( C = cI \) where \( C \) and \( I \) are respectively the levels of consumption and investment, and \( c \) is the weighted average of the propensities to consume out of profits and wages. The immediate effect on the level of income will be given by \( \Delta Y = \Delta I + c \Delta I \). Note that a second round of the multiplier process will lead to an increase in the level of income given by \( \Delta Y = \Delta I + c \Delta I + c^2 \Delta I \). In the limit the effect will be given by \( \Delta Y = \Delta I + c \Delta I + c^2 \Delta I + ... = \left[ \frac{1}{1-c} \right] \Delta I \). The term \( 1/(1-c) \) is called the investment multiplier.

According to Keynes, the multiplier ‘tells us that, when there is an increment of aggregate investment, income will increase by an amount which is \( 1/(1-c) \) times the increment in investment’ (Keynes, 1936, p. 115).

Note that the change in the level of saving (\( \Delta S \)) is given by the propensity to save (\( s=1-c \)) times the level of income, that is, \( \Delta S = s \Delta Y \), which, according to the above analysis, is also equal to the initial change in the level of investment. Thus, through the multiplier mechanism, a change in the level of investment gives rise to an equal level of saving. The multiplier is essentially an equilibrating mechanism. It refers to the adjustment of the economy given an exogenous change, and it determines the equilibrium levels of income and saving associated with different levels of investment demand. It describes the changes in the level of consumption which eventually makes the latter compatible to each level of investment given the propensity to consume of the economy.

The essential difference between the multiplier mechanism and the description of credit cycles found in Keynes’s *Treatise on Money* as well as in the analyses of Wicksell and the Swedish economists (Ohlin...
The multiplier analysis: The New Palgrave Dictionary of Economics

and Lindhal for example), is that it emphasizes the notion of equilibrium. It determines the new equilibrium configuration associated with any change in the level of investment demand rather than only its immediate effects. Because it is an equilibrating mechanism it must also take into account the stability conditions of the process. In terms of the simple static version discussed above, the only stability condition is that the propensity to consume must be smaller than one. If it were greater than one the system would always explode either to a situation of full employment or zero-employment of the labour force and capacity utilization. As noted by Keynes, ‘if the [community] seek to consume the whole of any increment in income, there will be no point of stability and prices with rise without limit’ (Keynes, 1936, p. 117). However, since the propensity to consume is always positive, the multiplier is always greater than one which implies that fluctuations in investment will lead to fluctuations of income of greater magnitude. Thus, the workings of the multiplier mechanism itself may be regarded as a source of instability.

The multiplier as an exercise in dynamics

What makes the analysis of the above section static is the fact that it emphasizes the equilibrium configuration associated with a given (and known) level of investment, and a given propensity to consume. The decision to consumer is rather passive and taking it into account does not really make the analysis dynamic. What is most important, however, is that the decisions to produce are not considered. Production takes time, and therefore decisions to produce involve expectations over a period of time. A dynamic approach to the analysis of the multiplier should emphasize the role of time and expectations associated with the decisions to produce.

What is the appropriate time unit for the analysis of the multiplier process if decisions to produce are to be considered explicitly? Following Keynes we shall take the short period as the appropriate time unit. The short period is associated with ‘daily’ decisions, and daily here stands ‘for the shortest interval of time after which the firm is free to revise its decisions as to how much employment to offer’ (Keynes, 1936, p. 47). Producers make their decisions as to how much to produce based on their short-period expectations.

On the demand side the object of such expectations are either the expected sale-proceeds or the expected price, that is, the price which the producer expects to get for his product at the end of the period of production. Let us take the expected price as the relevant variable, and assume that the producer knows the remuneration rates of the variable inputs and the shape of his cost curve. Given this information we may assume that the producer goes through the following optimization exercise in order to determine the levels of output and employment:

\[ \max_{E[p]} E[p]X - wN \text{ st. } X = F(N, K) \]

where \( E[p] \) is the expected price, \( X \) and \( N \) are the levels of output and employment respectively, \( w \) is the money-wage rate, \( K \) is the stock of capital (assumed to be given), and \( F \) is a production function. The level of employment associated with the expected price must satisfy the following condition:

\[ w / E[p] = F'(N^*) \]

The level of output is obviously \( X^* = F(N^*) \).

Let us assume that the level of investment has been stable for a rather long period of time. Producers of consumption goods know not only the level of investment but also the demand for their products associated with this level. Therefore they are able to form correct expectations concerning the demand for their products, and their price. In short, in each and every period the expected price corresponds to
the market price, that is, \( E[p] = p \). We now let the level of investment increase but assume that the producers of consumption goods either do not know that the change has taken place or the effect of the change on the demand for their products. If the latter is the case, assume that they underestimate the effect on demand. In either case the actual price will be greater than the expected price associated with the predetermined level of output \( (X^*) \), that is, \( p > E[p] \) where \( p \) is the market price. In this example producers will experience a windfall profit given by \( Q = (p - E[p])X^* \). The same exercise could be carried on taking stocks rather than the price as the adjustment variable (see Hicks, 1974, ch. 1).

The process initiated with a change in investment demand could go on for a long period. Producers would continue to get their expectations wrong, profits or losses would appear, new decisions would be taken and so on. Will producers ever get their prices (and production decisions) right? If we assume that the level of investment will not be affected by changes in short-period expectations, and depending on the way producers form their expectations, they will eventually converge to an equilibrium position. If, for example, producers form their short-period expectations in an adaptive fashion, for certain values of the parameters of the expectation function, the system will converge to a position of rest. For other values of the parameters the system will not converge. This only implies that the way producers form their expectations may affect the stability of the multiplier process and the trajectory of the relevant variables.

Does the way producers form their expectations affect the equilibrium configuration? The answer here is no. If the level of investment is assumed to be given and the process is assumed to be stable (which, again, depends on the parameters of the expectation function), the equilibrium configuration will be exactly the same as the one associated with a process in which producers form their expectations in a rational fashion. By ‘rational’ here we mean that expectations are recurrently correct. Keynes was aware of this result: in his lecture notes written in 1937 he argued that his principle of effective demand is substantially the same independently of the way expectations are formed (see Keynes, 1973, pp. 180–1).

**The multiplier and the notion of ‘shifting equilibrium’**

So far we have examined the multiplier mechanism assuming that either the level or the expected level of investment is given. In both the static and dynamic analyses the multiplier tells us the levels of income and saving compatible with a given level or expected level of investment. The advantage of these approaches to the multiplier is that they emphasize the notion of equilibrium, that is, they provide a definite result to the effect of a change in investment.

However, once the notion of equilibrium has become clear, we should turn our attention to the interactive relation between the level of investment and the workings of the multiplier. The level of investment is quite a volatile variable. Long-period expectations (which play a central role in the determination of the level of investment) change for various reasons. They change due to changes in the political or international environments; due to changes in economic policies; or due to objective problems of individual industries which tend to affect the expected performance of other industries of the economy. To different states of long-period expectations there corresponds different levels of investment and, therefore, different ‘levels of long-period employment’ (Keynes, 1936, p. 48). The extent to which short-period expectations are fulfilled may also affect the level of investment. If the actual demand is persistently greater than the expected demand, producers will tend to revise their long-
We may associate the notion of ‘shifting equilibrium’ with the evolution of the economic system as determined by different states of long-period expectations, and therefore, characterized by a sequence of equilibrium configurations of income and saving. By shifting equilibrium Keynes meant ‘the theory of a system in which changing views about the future are capable of influencing the present situation’ (1936, p. 293).

**Distribution and the multiplier**

The relationship between the distribution of income (or the real wage) and the multiplier depends on assumptions about the exogeneity or endogeneity of the real wage. In the *General Theory* Keynes assumed perfect competition *cum* profit maximization and decreasing marginal returns which, for a given money-wage rate, implies that the real wage is endogenously determined. It also implies that the greater the levels of employment and output, the smaller the real wage. This result has an important implication for the workings of the Keynesian multiplier. If we assume – as Keynes and Kalecki usually do – that the propensity to consume out of wages is greater than the propensity to consume out of other types of incomes (profits, interests, and so on), as the level of income increases and the real wage falls, the value of the multiplier decreases. Keynes pointed out to this result in the *General Theory*:

> the increase of employment will tend, owing to the effect of diminishing returns, ... to increase the proportion of aggregate income which accrues to the entrepreneurs, whose ... propensity to consume is probably less than the average for the community as a whole. (1936, p. 121)

Kalecki (1971) assumed constant marginal returns and gave up profit maximization. Instead he assumed that firms determine their prices through a markup over variable costs which, in a closed economy, also determines the real wage. Therefore, according to Kalecki, the real wage is exogenously determined, and does not change as the levels of output and employment change. This means that the multiplier does not change either as the level of output changes; it depends on the propensity to consume out of wages and profits and the level of the markup, both assumed to be constant over the cycle.

multiplier analysis: The New Palgrave Dictionary of Economics

How to cite this article

The phrase ‘multiplier–accelerator’ refers to a combination of a theory of income as determined by investment and a theory of investment as determined by the rate of change of income. The concept of multiplier is usually attributed to Richard Kahn (1931), from whom it was adopted by Keynes and used as a building block for his General Theory. The idea was probably shared by a number of European economists in the Thirties and was certainly known to Michael Kalecki, independently of Keynesian influence.

The theory of multiplier in its pure (and static) form can be described thus. In a capitalist economy, investment can always be realized in real terms. The necessary saving will be made available by means of corresponding variations of the level of income, given the propensity to save. With generally underutilized capacity and labour and fixed prices – the most common hypothesis – real income will take whatever value generates a flow of saving equal to planned investment. Alternatively, in the presence of supply constraints, the level of prices will adjust and deflate consumption expenditure so as to make available the real resources required for investment.

The former, ‘fixprice’ version of this simple relation can be stated in the form of algebraic equations, as follows

\[ Y = C + I, \]

(1)

\[ C = cY, \quad c = 1 - s \]

(2)
where $Y$, $C$, $I$ indicate, respectively, actual income, consumption and investment; $\bar{I}$ is desired investment; $c$ and $s$ are the propensities to consume and to save, respectively.

Elementary manipulation yields:

$$Y = (1/s)\bar{I}$$

where $(1/s)$ measures the multiplier and the causal relation runs from right to left.

The concept of accelerator appeared in the economic literature much earlier than the *General Theory* and was perhaps first developed by Aftalion (1909) and J.M. Clark (1917). It is based on the idea that the relation between productive capacity (somewhat measured by a scalar quantity, the capital stock) and production can vary only within narrow limits and, in a first approximation, may be taken as a constant.

The constancy of the capital–output ratio may be defended on the basis of two main arguments:

(i) Technical coefficients are fixed (or change little) even though the interest rate may vary: in economists’ parlance, the isoquants are L-shaped. Whatever the plausibility of this hypothesis may be from an engineering point of view, it is difficult to accept it on economic grounds. Indeed, when ‘capital’ is a vectorial quantity (i.e. a list of different capital goods), the capital–output ratio depends both on technical coefficients and on relative prices and the rate of interest.

(ii) Technical coefficients vary, within a certain technology, as functions of the rate of interest. If the latter is constant so are the former.

The assumption on (ii) may be accepted or rejected for lack of realism but is formally correct. On the other hand, it is also consistent with the fix-price approach to income determination. In its starkest form, the accelerator (Harrod called it ‘the Relation’) can be described by the equation

$$K = \nu Y,$$

(5)

(where $K$ indicates the capital stock and $\nu$ the desired capital–output ratio) or, in its incremental form
multiplier–accelerator interaction: The New Palgrave Dictionary of Economics

\[ l = \dot{y} \]  
(6)

where an overdot indicates the derivative with respect to time.

The idea came naturally to combine multiplier and accelerator and derive a model ‘complete’ in the sense that, given initial conditions, it determines the time evolution of capital stock and income. This was first attempted in the late 1930s by Harrod (1936, 1939) and, in a more mathematical manner, by Samuelson (1939). In the subsequent years, a substantial part of the literature on cycle and growth was also based on the interaction between multiplier and accelerator.

In order to discuss this idea formally, let us couple equations (4) and (6). We shall obtain

\[ sY = \dot{y} \]  
(7)

and

\[ (\dot{y} / y) = (s / n) \]  
(8)

Equation (8) represents the proportional rate of growth of income as a function of the propensity to save and the acceleration coefficient and was first investigated by Harrod and Domar, after whom it has been named ever since.

The model described by equations (1)–(8) implicitly assumes that equality always holds between demand (=consumption+investment) and supply (=income), as well as between actual and desired consumptions, the results may become drastically different. This line of research was pursued early by Samuelson, Hicks and, in an apparently very different context, Kalecki, and provided the basis for a theory of the trade cycle which prevailed in the economic profession in the early post-World War II years (the best reference is perhaps Phillips, 1954).

Suppose that, while desired and actual consumption are still equal, discrepancies are permitted to exist between demand and supply and between actual and desired investment. We therefore need to replace the relevant equilibrium conditions
multiplier–accelerator interaction: The New Palgrave Dictionary of Economics

and

\[ \dot{Y} = C + I \text{(or equivalently, } sY = I) \]

by adjustment mechanisms which reflect economic agents’ reactions to undesired situations. The most commonly used such adjustments are those of a tâtonnement type, according to which the relevant variables change at a rate proportional to the differences between their desired and actual values. In terms of our model, we have

\[ \dot{Y} = \tau_y [(C + I) - Y] = \tau_y [I - sY], \]

(9)

\[ \dot{I} = \tau_i [\dot{Y} - I], \]

(10)

where \( \tau_y \) and \( \tau_i \) are the (positive) speeds of adjustment of income and investment. The equation (9) can be interpreted as a (typically Keynesian) situation in which, prices being fixed and potential supply unlimited, producers are constrained only by demand and adjust their production in relation to (positive or negative) excess demand.

The system (9)–(10) can be easily transformed into a single second-order differential equation in \( Y \). By choosing the arbitrary unit of measure of time such that \( \tau_i = 1 \) we have

\[ \dot{Y} + [1 + \tau_y s] \dot{Y} + \tau_y sY = 0 \]

(11)
System (11) has a unique position of stationary equilibrium at $Y=0$. (‘Zero’ must be taken here to indicate a level of income determined by factors not considered in the present discussion, such as government expenditure.) Its dynamic behaviour depends on the structural coefficients and may induce decline or growth, in either case with or without fluctuations.

Generally speaking, we may say that the accelerator is an explosive factor in so far as, for given $s$ and $v$ the greater $v$ the more likely it is for the system to grow in time. Moreover, the relative size of the accelerator affects the oscillatory behaviour of the system: if the motion is damped, a large $v$ tends to make the system fluctuate; vice versa, if the motion is explosive, a strong acceleration leads to sustained growth without fluctuations. In agreement with intuitive considerations, large speeds of adjustment tend to produce explosive behaviour, whereas the saving ratio acts as a damper. The effect of these factors on oscillations is more complicated and cannot be ascertained in any obvious way.

A very special and unlikely case arises when we have

$$1 + Ty(s - v) = 0$$

(12)

and the time path followed by the system is a pure sinusoid describing a persistent and perfectly regular cycle, neither damped nor explosive. This of course is a watershed situation which would be destroyed by any small perturbation of the model and is therefore not a suitable idealization of economic cycles. The multiplier–accelerator model constitutes a rough but effective idealization of certain basic mechanisms deemed to determine or influence cycles and growth in a capitalist economy under certain specific circumstances.

Two major extensions of the model, which have made it theoretically more robust (and complicated), should be mentioned in concluding this entry.

First of all, the assumption that the structural coefficients are constant may be dropped and they may instead be treated as functions of the level (or the rate of change) of income, thus making the model nonlinear. Formal investigation of nonlinear multiplier–accelerator models was initiated in the 1950s by Richard Goodwin (1951a and 1951b) and is still a very active area of research. Nonlinear models have two distinct advantages over the linear ones. For one thing, they better correspond to empirical observation of economic facts. Secondly, and most importantly, they can reproduce a far richer (and economically more interesting) diversity of dynamic behaviours. In particular, only they can represent sustained fluctuations of income, i.e. cycles that neither expire nor explode, without requiring very special configurations of parameters for which no economic justification could be found.

A second important extension of the model has been the generalization of some basic results to the multidimensional case. In an economy with an indefinitely large number of sectors the Harrod–Domar equation (7) can be rewritten as

$$[I - A]x = B\dot{x},$$

(13)
multiplier–accelerator interaction: The New Palgrave Dictionary of Economics

where \( A \in \mathbb{R}^{n \times n} \) is the flow input–output matrix, i.e. the generalized propensity to consume; \( B \in \mathbb{R}^{n \times n} \) is the stock input–output matrix, i.e. the generalized accelerator; \( x \in \mathbb{R}^n \) is the vector of production levels; \( I \) is of course the identity matrix.

In analogy to the one-dimensional case we can introduce error-adjustment mechanisms for production and investment, obtaining the system of differential equations

\[
\dot{x} + \{ T_y \, y \, (I - A) + T_y \, T_y \, B \} \, x + T_y \, T_y \, (I - A) \, x = 0 \tag{14}
\]

where \( T_y \) and \( T_i \) are diagonal matrices whose (positive) elements are the speeds of adjustment of production and investment, respectively, in the various sectors.

The analysis of system (13) is obviously more complex than that of (11), even in the linear case, as now the coefficients are of order \( n^2 \). However, it is possible to define multidimensional equivalents of the main explosive and damping factors, and to indicate the conditions for oscillatory behaviour. It is also possible to show that – in perfect analogy to the one-dimensional case – the loss of stability which takes place when the explosive forces (the accelerators) become too strong vis-à-vis the damping forces (saving and lags), leads to cyclical behaviour of the system.

Co-author with J.A. Hobson of the *Physiology of Industry* (1889), Mummery was also a famous mountaineer who wrote a book on climbing in the Alps and the Caucasus and died in the Himalayas in 1895. According to Hobson's own account (*Confessions of an Economic Heretic*, pp. 29–30), it was Mummery who set him on the path to intellectual heresy; considering that Hobson's later economic writings may in many ways be regarded as a development of the theme established in the *Physiology of Industry*, this is a considerable achievement.

Mummery was a businessman who seems to have become acquainted with Hobson by chance while the latter was teaching in Exeter. He managed to convince Hobson, after considerable argument, that the economy contained a serious tendency to over-saving, and that depressions were the expression of this tendency. Unfortunately we do not know how far this idea had developed in Mummery's mind before he met Hobson, or how much each contributed to the published version of the argument. Since Hobson subsequently became a prolific writer on economic matters, one suspects that the meat of the book was his work. It is not certain that Mummery had received much training in economics, and he may have contributed little more than the germ of the idea.

Mun, Thomas (1571–1641)

Walter Eltis

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

balance of payments; balance of trade; East India Company; mercantilism; Mun, T.; specie-flow mechanism

Article

Thomas Mun, the distinguished mercantilist, was born in London in June 1571 and died in July 1641. He was the third son of John Mun, a mercer, whose father, also John Mun, held the office of provost of the moneyers in the Royal Mint and received a grant of arms in 1562. Thomas Mun became an extremely wealthy merchant, and a Director (Member of the Committee) of the East India Company in 1615. In 1624 he had the opportunity to serve as Deputy Governor which he declined, but he remained a director until he died.

The East India Company was much criticized because its trade involved exports of bullion (in order to purchase spices). In 1621 Mun was author of a pamphlet, *A Discourse of Trade, from England unto the East-Indies*, in which he set out the benefits that England derived from this trade. His argument was that the same spices (and he details the amounts) would otherwise have been imported from Turkey at three times the sterling cost, and that the purchase of spices in the Indies thus produced satisfactory results for British consumers, while merchants also benefited, and so ultimately did the balance of trade. On Mun's figures the East India Company exported £100,000 of silver yearly to import silk and spices which sold in England for £500,000 (out of which customs duties took a substantial fraction). But only £120,000 of these goods were actually consumed in England, and the remaining £380,000 were re-exported with the consequence that England gained back considerably more bullion than the original outflow of £100,000. In 1622 he was the leading member of a committee of merchants which submitted evidence to a Commission set up by James I to investigate the causes of the fall in the exchange rate and the loss of specie from which Britain was suffering. Mun was principal author of their first memorandum in 1622, and sole author of later memoranda submitted in 1623. He strongly opposed Malynes’ view that the fall in the exchange rate was attributable to conspiratorial behaviour by foreign merchants, and argued that the balance of *trade* was the principal determinant of specie flows and the exchange rate. His
memoranda resurfaced in 1664, as chapters in his posthumously published magnum opus, *England's Treasure by Forraign Trade, or the Ballance of our Forraign Trade is the Rule of our Treasure*, which Schumpeter has referred to as ‘the classic of English mercantilism’. This was published by his son, John Mun, with the imprimatur and personal approval of Charles II's Secretary of State, Sir Henry Bennet. *England's Treasure* demolished the previous mercantilist literature which advocated detailed interventionist policies to sustain the English money supply and the exchange rate, such as banning gold exports, currency appreciation, lowering the metallic content of the currency, and encouraging the domestic circulation of foreign coin. Mun reiterated the fundamental balance of payments equation that specie flows must be determined primarily by the excess of exports over imports, and therefore insisted that there could not be a sustained loss of gold and silver while there was a trade surplus, while none of the above expedients could prevent a monetary outflow in the face of a sustained deficit. His book hammered home the significance of the balance of payments equation, with numerous examples to demonstrate the impotence of detailed interventionist policies to hold or attract bullion while trade was in deficit. At the same time, he developed examples like those in his earlier *Discourse of Trade*, to show how it was ultimately the domestic consumption of imports and not imports as such that needed to be compared with exports to determine the net balance of trade. Imports by English merchants which were not destined for consumption in England were bound to result in equivalent exports, plus of course merchants’ profits and duties for the King.

Mun went on to explain the relationship between the balance of trade and the excess of home production over consumption, and to distinguish carefully between the financial interests and impact on the trade balance of Merchants, the Commonwealth (the whole population) and the King. Merchants were solely concerned with profit. The Commonwealth determined the trade balance via the relationship between the aggregate expenditures and incomes of the whole population, while the Sovereign's interest in trade depended considerably upon customs and excise, ‘the King by his Customs and Imposts may get notoriously, even when the Merchant notwithstanding shall lose grievously’ (p. 147).

Mun may well have been the first to state the celebrated proposition (which Lord Kaldor made much of in the 1970s) that the current account trade surplus must correspond to the sum of the financial surpluses of the public and private sectors. He set out an example where a King enjoys revenues of £900,000, spends £400,000 and accumulates the resulting budget surplus of £500,000. Then if the trade surplus is merely £200,000, the King will lay up £300,000 more in his Coffers than the whole Kingdom gains from strangers by forraign trade: who sees not then that all the money in such a State, would suddenly be drawn into the Princes treasure, whereby the life of lands and arts must fail and fall to the ruin both of the publick and private wealth? So that a King who desires to lay up much money must endeavour by all good means to maintain and encrease his forraign trade. (pp. 188–9)

Mun believed that the achievement of a trade surplus on which monetary inflows depended would be best achieved where the population moderated consumption, and merchants enjoyed maximum freedom to exploit opportunities for trade. He has been much praised in the secondary literature for his perception that it was the trade balance that determined specie flows. This has been universally judged vastly superior to the previous literature which recommended piecemeal interventionism in financial markets.
According to McCulloch's 1847 *Edinburgh Review* article ‘Mun's book was received as the gospel of finance and commercial policy; and his principles ruled for above a century the policy of England, and much longer that of the rest of Europe’ (p. 450).

Mun's analysis was superseded in 18th-century England because he failed to go a vital stage further and appreciate the potentially self-correcting nature of the balance of payments. This led Hume and his followers to cease to regard the trade balance as a primary policy objective in comparison with the achievement of a growing capital stock, and increasing levels of output and employment, about which Mun was also deeply concerned.

But those who have been satisfied that the trade balance is self-correcting have sometimes failed to appreciate that a continuing deficit is inevitable where consumption (modern writers would say, domestic absorption) exceeds production. They also lost Mun's perception that in a protectionist world, winning trade away from other countries may permit increases in domestic capital and employment with would not otherwise occur.

Mundell, Robert (born 1932)

Charles Engel
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Mundell is best known for his work creating an open-economy version of the IS–LM model. Its special interest lies in the analysis of monetary and fiscal policy. He emphasized the importance of the speed of adjustment in capital markets and the role of fixed versus flexible exchange rates in determining the impact of policy changes and the determination of a desirable monetary–fiscal policy mix. Mundell has also been influential on optimum currency areas, the effect of inflation on portfolio investment, and trade theory.

Keywords

Article

Robert Mundell is one of the key figures in the development of thought in international monetary economics. His work on the IS–LM model in open economies, equilibrium in a world of perfect capital mobility, monetary dynamics in open economies, and optimal currency areas constitutes the core of the research for which Mundell is best known. His work continues to this day to be influential in the analysis of policy decisions in open economies, but an equally important legacy of Mundell's is the role his work played in determining the direction of research in open-economy macroeconomics in the 1960s, 1970s and through to the present. Mundell's work had such a great impact in part because it combined theoretical rigor with elegant presentation. Mundell was awarded the Nobel Prize in 1999 for his analysis of monetary and fiscal policy under different exchange rate regimes and his analysis of
Mundell, Robert (born 1932) : The New Palgrave Dictionary of Economics

optimum currency areas’. Mundell was born in Kingston, Ontario, in 1932. His undergraduate education was undertaken at the University of British Columbia and the University of Washington. He engaged in postgraduate studies at the London School of Economics and received his Ph.D. from MIT in 1956. He taught at Stanford University and the Bologna Center of the School of Advanced International Studies of the Johns Hopkins University, and joined the staff of the International Monetary Fund in 1961. He was a Professor of Economics at the University of Chicago from 1966 to 1971. In 1974 he joined the faculty at Columbia University, where he has spent the remainder of his career.

Mundell is perhaps best known for his work creating an open-economy version of the IS–LM model. Mundell's (1960; 1961; 1962; 1963a) model is still the workhorse model of most undergraduate texts in international macroeconomics. Mundell, like Meade, Metzler, and a few others whose work preceded Mundell's, recognized that the analysis of exchange rates and balance of payments flows must proceed in a monetary general equilibrium framework. Under Mundell's initial formulation, the equilibrium conditions in money markets and goods markets were augmented by an external balance condition. Mundell's concept of external balance was a balance of payments equilibrium, in which the net flow demand for foreign exchange is zero. Demand for foreign exchange comes from importers of goods and from importers of foreign assets. In his initial work, Mundell modelled the demand for foreign assets as a flow that depended on the difference between home and foreign interest rates. As long as there was a positive spread between home and foreign interest rates, capital inflows would persist at a steady rate. Mundell's special interest was in the analysis of monetary and fiscal policy. He emphasized the importance of the speed of adjustment in capital markets and the role of fixed versus flexible exchange rates in determining the impact of policy changes and the determination of a desirable monetary–fiscal policy mix. His framework was extended and used to consider policy issues by academics and central bankers for many years.

One basic insight of these models concerns the difference in the impact of fiscal and monetary policy under fixed and floating exchange rates. Consider a monetary expansion. Under a floating exchange rate, external balance requires a depreciation of the domestic currency. The monetary expansion lowers interest rates, leading to a capital outflow and a decline in demand for the domestic currency. With sticky nominal goods prices (the hallmark of the Keynesian IS–LM analysis), the depreciation makes imported goods more expensive, so expenditure switches to home goods. This expenditure switching effect would not be present if exchange rates were fixed. Indeed, Mundell (1961) makes the point that in the absence of sterilization (see below) the monetary expansion would be reversed over time. That is, under fixed exchange rates, the monetary expansion leads to a balance of payments deficit. Under a balance of payments deficit, as the central bank's foreign reserves decline, the money supply falls. In contrast, an expansionary fiscal policy might have greater impact under fixed exchange rates, when capital mobility is high. In the IS–LM framework, an increase in aggregate demand raises interest rates. This should lead to an inflow of capital and an appreciation of the home currency under flexible exchange rates. But the appreciation switches demand away from home goods, thereby dampening the effect of the fiscal expansion. Under fixed exchange rates, the expenditure switching does not occur. Moreover, in the absence of sterilization operations the balance of payments surplus that ensues from the fiscal expansion will lead to a domestic monetary expansion as the central bank acquires foreign reserves.

Note how the analysis of the effects of fiscal expansions depends on the assumption that capital flows
respond significantly to changes in the interest rate. If capital flows were not significant, the analysis would be reversed. A fiscal expansion leads to an increase in domestic income. Some of that increased income is spent on imports. There may be increased capital inflows because the interest rate has risen domestically, but if these flows are slight then the decline in the trade balance dominates, so the country's balance of payments deteriorates. Under floating exchange rates, then, there will be a currency depreciation that further boosts aggregate demand. That effect is not present under fixed exchange rates, and indeed there could be a contractionary effect of the balance of payments deficit in the absence of sterilization.

Of special note is Mundell's (1963a) version of his model under the assumption of perfect capital mobility, so that the rates of return on home and foreign nominal bonds are equalized. At one level this paper is a simple extension of his earlier work to consider the extreme case in which capital flows infinitely quickly to equalize rates of return. But at another level the model is fundamentally different. In essence this case turns the external balance condition from a flow equilibrium (analogous to the IS curve) into an asset-market equilibrium condition (analogous to the LM curve.) In this model, for asset markets to be in equilibrium households must be satisfied not only with their holdings of money relative to interest-earning assets (LM) but also with their holdings of domestic bonds relative to foreign bonds. This model laid the foundation for virtually all later work in the field that understands the market for foreign exchange to be an asset market.

The key distinction analytically is that the flow of assets plays no role per se in determining equilibrium in this formulation. For example, the trade balance plays no direct role in establishing the equilibrium in the foreign exchange market. In contrast to many models of the 1950s in which the exchange rate adjusted to set the trade balance to zero, here the trade balance plays a role only in its contribution to the net demand for domestic output. The balance of payments simply reflects the central bank's net accumulation of foreign assets. As Obstfeld (2001) points out, the balance of payments is no longer a relevant indicator of external balance in this setting. By modelling the external balance condition as an asset-market equilibrium, Mundell opened the door for subsequent models that considered the role of expectations in determining exchange rates and laid the foundation for models of balance of payments crises under fixed exchange rates in which speculative attacks play a key role.

Subsequent developments in the field have replaced Mundell's ad hoc formulations of behaviour with optimizing models, and have explicitly modelled expectations formation. But Mundell's work was a cornerstone of the development of more sophisticated models, and open-economy macroeconomic models are still often evaluated by comparing their implications with those of the models of Mundell. Dynamics was a key concern of Mundell's. Even within the IS–LM framework, Mundell examined the evolution of output, interest rates, exchange rates and prices. Mundell paid special attention to the dynamic effects of balance of payments ‘disequilibrium’ under fixed exchange rates. When the net private flow demand for foreign exchange is not zero (that is, the sum of the current account and the private component of the capital account is not zero), then, in Mundell's terms, there is balance of payments disequilibrium. Mundell made explicit the distinction between balance of payments flows that were sterilized – so that the monetary base did not change – and policies that allowed the money supply to change automatically when there was balance of payments disequilibrium. Mundell (1961) especially was a precursor of the literature that became known as the ‘monetary approach to the balance of payments’. That literature emphasized the automatic adjustment mechanism when there is no sterilization. Most of that analysis was undertaken in classical-style models in which nominal goods
prices were assumed to be flexible. Indeed, Mundell (1967) was a contributor in that tradition. But what Mundell's (1961) piece makes clear is that it is the assumption of non-sterilization that is key to understanding the dynamics of adjustment. Even in a world of sticky nominal prices, automatic adjustment to balance of payments disequilibrium can occur through adjustment in the money supply. Dynamics were central in Mundell's development of what became known as 'the assignment problem'. The question was whether the central bank should be responsible for external balance and fiscal authorities for internal balance, or vice versa. Mundell's answer was that each policy tool should be assigned to the market in which it has the greater effect, which depends on the speed of adjustment of goods markets relative to capital markets. Mundell modelled policymaking in a realistic world in which policymakers have an imperfect understanding of the state of the economy, and in which macroeconomic adjustment to policy changes is slow. These concerns have all but disappeared from more recent research in macroeconomic policymaking, but Mundell's focus still seems relevant. Moreover, Mundell's work recognizes that policymaking at the national level is not in the hands of a single policymaker, but instead involves the interaction of decisions by central banks and fiscal authorities whose actions and goals may not be perfectly coordinated.

Mundell's (1961) paper on optimum currency areas also is still very influential. This paper determines some conditions under which it is optimal for countries to share a common currency. Mundell's view was that there may be some advantage to sharing currencies in terms of reduced transactions costs. But the adoption of a common currency means, of course, that each country is not free to pursue its own independent monetary policy. That loss may not be so large when factors of production can flow freely between the countries in a currency area. If there is a downturn in one country, adjustment can occur through factor flows towards the country with the stronger economy. But if factor mobility is weak, then there is a case for each country to have its own independent money. In general, in Mundell's framework the optimum currency area is determined by a trade-off between these considerations about factor mobility and considerations involving the transactions costs of having many separate currencies. Mundell's work in this area spawned a large literature that considered other factors that determine whether a set of countries were good candidates for adoption of a single currency.

Mundell is also known for his short paper (1963b) that develops what became known as the 'Mundell–Tobin effect'. Mundell argued that inflation reduced the demand for real money balances. That led to a portfolio shift that could induce greater investment in real capital.

Mundell's (1957) also made a lasting contribution in pure trade theory. This paper examined the effects of factor mobility in the Heckscher–Ohlin–Samuelson model. Factor mobility could be a substitute for goods trade, just as goods trade could substitute for factor mobility (as in the well-known factor-price equalization theorem.)

The Nobel Prize citation notes that ‘Mundell chose his problems with uncommon – almost prophetic – accuracy in terms of predicting the future development of international monetary arrangements and capital markets.’ When Mundell wrote much of his influential work in the early 1960s, much of the world was on a fixed-exchange rate system – although his native Canada had a freely floating exchange rate. Moreover, there were still significant barriers to international flows of capital that had been erected in the 1930s and 1940s, even among advanced industrialized countries. Nonetheless, Mundell focused in much of his work on the contrast between the fixed and floating exchange rate systems, with an emphasis on the role of capital mobility. Only in the early 1970s did most of the advanced world move to floating exchange rates, and obstacles to capital flows were gradually eliminated in the decades...
following Mundell's early writings. His work on optimum currency areas was frequently cited in the economic analysis that preceded the introduction of the euro. Many of Mundell's contributions are collected in *International Economics* (1968). Excellent brief surveys of Mundell's work can be found in Royal Swedish Academy of Sciences (1999) and Obstfeld (2001). Mundell (2001) provides an interesting history of the development of some of Mundell's work.

municipal bonds

James M. Poterba
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Municipal bonds are issued by state and local governments in many nations. In the United States the interest on these bonds is usually exempt from federal income tax, which provides an incentive for taxable investors to hold municipal bonds even if their before-tax yield falls below that of other taxable bonds. This article describes the various types of municipal bonds, the yield spread between taxable bonds and municipal bonds, and the factors that determine the efficiency of the federal income tax exemption as a means of subsidizing capital outlays by state and local governments.

Keywords

alternative minimum tax (USA); bonds; implicit tax rate; municipal bonds; Social Security in the United States

Article

Municipal bonds differ from most other securities because of their special tax status. Interest payments on bonds issued by state and local governments in the United States are exempt from federal income tax. Most states with income taxes also exempt their own interest payments from tax. The federal income tax exemption for municipal bond interest is usually justified on the grounds that it reduces borrowing costs for states and localities, thereby facilitating their investment in public infrastructure.

When the federal income tax was enacted in 1913, there was some question as to the constitutionality of such a federal tax on interest paid by states and localities. In 1988, the Supreme Court affirmed the federal prerogative to tax such interest in the case of South Carolina v. Baker. The tax exemption for municipal bond interest should therefore be viewed in the same way as any other tax expenditure, namely as a political decision about the structure of income taxation.

There are three types of municipal bonds: general obligation bonds, which are backed by the ‘full faith and credit’ of the borrowing jurisdiction; revenue bonds, which are backed by the stream of income from a particular project such as a highway or publicly operated power plant; and private purpose bonds.
which are tax-exempt bonds issued by private borrowers with the authorization of a state or local government. Only general obligation or ‘GO’ bonds have a potential claim on the tax revenues of a state and local government. The interest payments on revenue bonds are dependent on the revenues associated with the project that issued the bonds. Private purpose bonds are typically used to finance private sector projects that are deemed beneficial to the state or local economy or community; in practice these bonds finance a wide range of activities. The market value of outstanding tax-exempt bonds in 2006 was 2.3 trillion dollars according to estimates from the Federal Reserve Board Flow of Funds Accounts. GO bonds account for roughly 40 per cent of outstanding tax-exempt debt.

While municipal bond interest is generally exempt from federal income taxation, the relevant tax rules are complicated in some situations. For example, retirees who receive Social Security benefits must include tax-exempt bond interest in the income concept that is used to determine how much of their Social Security income is included in taxable income. In addition, the interest paid on many private purpose bonds is taxable under the federal alternative minimum tax (AMT). While the AMT affected only 3.5 million taxpayers in 2006, projections suggest that provided there are no changes in the basic structure of the tax, it will apply to more than 20 million taxpayers by 2010. Bonds that are not exempt from the AMT typically offer investors a higher yield than bonds that pay interest that is completely tax exempt.

In part as a result of changes in the tax law, there have been changes over time in the ownership patterns for municipal bonds. Prior to 1986, commercial banks were the primary holders of short-term municipal bonds while households and insurance companies were the primary holders of long-term municipals. The Tax Reform Act of 1986 sharply limited the incentives for banks to hold tax-exempt bonds, and since then the ownership mix has shifted towards households. According to Flow of Funds data for the third quarter of 2006, households were the direct owners of 37 per cent of outstanding municipal bonds. Mutual funds, which are largely owned by households, accounted for another 33 per cent. Commercial banks hold seven per cent, while property and casualty insurance companies hold 14 per cent.

Investors who hold municipal bonds avoid paying income taxes on their interest income, but they pay an ‘implicit tax’ when the pre-tax interest rate on municipal bonds is lower than that on an equally risky taxable bond. The yield spread between taxable and municipal bonds is often summarized by the implicit tax rate. This is the value of $\theta$ for which $(1 - \theta)R_T = R_M$ where $R_T$ is the yield on newly issued Treasury bonds and $R_M$ is the yield on prime grade municipal bonds of comparable maturity. This relationship is only satisfied by newly issued taxable and municipal bonds under the assumption that investors plan to hold these bonds to maturity. Poterba (1986) shows that with forward-looking investors, the implicit tax rate measured from current bond yields reflects not just current marginal tax rates on taxable interest but future marginal tax rates as well. For seasoned bonds, the tax treatment of differences between the purchase price of the bond and the par value complicates the calculation of the implicit tax rate. More generally, when investors sell their bonds before maturity, changes in bond prices may result in taxable capital gains or losses. The definition of the implicit tax rate also assumes that Treasury bonds and prime grade municipals are equally risky, an assumption that some might question. The implicit tax rate on municipal bonds varies across bond maturities at a given point in time, and it varies over time in part as a result of changes in tax rates and tax rules. During the first week of 2007, the interest rate on 30-year GO bonds with an AAA rating was 4.14 per cent, while the yield on a 30-year Treasury bond was 4.59 per cent. The implicit tax rate based on these values is 9.8 per cent, well below the top statutory marginal tax rate on individual investors, 35 per cent. The yield spread between
AAA-rated municipal bonds and AAA-rated corporate bonds is larger, but this comparison raises the challenge of risk adjustment. For the same week, the yield on one-year AAA-rated municipals was 3.53 per cent, while that on one-year Treasury bonds was 4.92 per cent. The implicit tax rate at the one year maturity was therefore 28.3 per cent.

One of the challenges in analysing the municipal bond market is explaining why implicit tax rates are substantially below top statutory rates. Chalmers (1998) discusses various potential explanations and rejects the possibility that differential default risk explains this long-standing pattern. The yield curve puzzle has motivated research on the relative pricing of taxable and tax-exempt bonds. Green (1993) argues for moving beyond yield-to-maturity analysis, such as that underlying the foregoing implicit tax rate computations, and developing a more subtle analysis of the tax-exempt bond market.

The key insight in Green (1993) and several subsequent studies is that fully taxable individual investors are unlikely to regard newly issued tax-exempt bonds and newly issued taxable bonds as competitive investment alternatives. If such investors chose to hold taxable bonds, they should do so by holding bonds that generate income in a way that generates less tax liability than a newly issued bond. The opportunities to earn bond returns that face a lighter tax burden are greater at longer than at shorter maturities, because divergences between the purchase price of a bond and its par value are potentially greater at long maturities. This role of tax-wise investing appears to receive empirical support in yield curve comparisons at different maturities. It may help to explain why implied tax rates in the municipal bond market are often lower for longer-maturity than for shorter-maturity bonds.

Whether the policy of exempting interest on state and local government bonds from federal taxation is an efficient method of encouraging capital formation by states and localities is a long-standing subject of debate. The answer turns on the difference between the implicit marginal tax rate on municipal bonds, which determines the interest saving of state and local government borrowers, and the weighted-average marginal tax rate of municipal bond investors, with weights equal to the tax-exempt interest receipts of each investor. The latter determines the federal government's revenue cost from exempting interest on state and local government obligations from tax. If the revenue cost exceeds the interest saving, it would cost less for the federal government to provide cash transfers to state and local governments equal to the amount of their current interest saving, while taxing interest on their bonds, than to pursue the current policy of tax exemption. In 2002, the weighted-average marginal tax rate for individual investors who received tax-exempt interest was 30.2 per cent. Feenberg and Poterba (1991) describe the calculation of such marginal tax rates. Since the implicit tax rate on 20-year municipal bonds and Treasuries varied between ten and 20 per cent during calendar 2002, the revenue cost of the exemption for households appears to exceed the interest saving for state and local government borrowers.

The progressivity of the federal income tax schedule is a key determinant of the efficiency of policies that exempt interest from taxation. When the yield spread between taxable and municipal bonds is determined by the marginal tax rate of the lowest tax rate investor who holds those bonds, but the revenue cost is determined by the weighted average marginal tax rate of the investors who hold municipal bonds, then the efficiency cost of the tax exemption will be greater when the top marginal tax rates affect many but not all municipal bond investors, and when the top rates are substantially higher than the rates on lower-income households.

When investors have access to taxable and tax-exempt bonds of equal risk, market equilibrium should involve investor clienteles in which investors segment themselves according to their tax rates. High tax
rate investors should hold tax-exempt bonds, while low tax rate investors should hold taxable bonds. In practice, this separation does not occur. Poterba and Samwick (2003) show that among households that hold tax-exempt bonds, 55 per cent also hold taxable bonds. In contrast, only 15 per cent of the households that hold taxable bonds also hold tax-exempt bonds. There are risks inherent to holding municipal bonds, such as the risk of tax change, that are difficult to hedge and may incline investors to diversify their portfolios. This may explain why most investors who hold municipal bonds also hold taxable bonds.

There are many innovative products in the municipal bond market, including variable rate municipals, insured municipal bonds, and zero coupon tax-exempt bonds. The bonds issued by several large issuers, particularly large states and revenue authorities, trade in active after-markets, but the markets for many smaller municipal bond issues are not very liquid.

Abstract

Richard Musgrave is best known for his treatise *The Theory of Public Finance* (1959). His most original and lasting contributions are in taxation theory and public goods theory. His work on tax incidence has been the starting point for all subsequent studies on tax burdens by income classes, and he broke new ground by introducing the concept of equal options as the basis for horizontal equity. His separation of budgetary functions into allocation and distribution branches has acquired increased practical significance as much of the expansion of the public sector has consisted of increased transfer payments.

Article

Born in Koenigstein, Germany, Musgrave was educated at Heidelberg (where he obtained a Diplom Volkswirt in 1933) and at Harvard University (where he obtained his Ph.D. in 1937). After serving at the Federal Reserve System in Washington, he held appointments at a number of leading North American universities and ended his formal teaching career at Harvard, where he was Professor Emeritus. He was an economic adviser to a number of governments, headed foreign tax commissions, and served as editor of the *Quarterly Journal of Economics*.

Richard Musgrave is best known for his outstanding treatise *The Theory of Public Finance*, published in 1959 at a time when social expenditures were growing rapidly throughout the industrial world, and when poverty and social justice had become primary policy concerns. This book, which is comprehensive, has
served as a fundamental source for scholars and as a teaching reference. In it Musgrave summarizes and extends his original contributions to expenditure theory and the theory of taxation, provides an extensive review of the classical literature in public finance, and includes a thorough discussion of fiscal and monetary policy developed from a Keynesian perspective. One of the great strengths of the book is Musgrave’s broad knowledge of the early European masters of public finance, notably Wicksell and Lindahl. By reviewing the classical writers and relating his theory of the public household to their work, Musgrave built an essential bridge between earlier ideas and the development of modern public goods theory.

Musgrave made significant contributions to virtually all areas of public finance. He wrote on the theory of fiscal federalism and revenue sharing, international aspects of taxation, alternative measures of income tax progressivity, land value taxation, the theory of fiscal sociology, and the effects of tax policy on private capital formation, as well as on various aspects of debt and monetary policy. His most original and lasting contributions can be grouped into two categories: taxation theory, which includes three major contributions, and public goods theory, in particular his theory of the public household.

One of Musgrave’s most distinguished contributions to taxation theory is his joint paper with E.D. Domar on the effects of taxes on risk taking (1944). The authors show that taxes on capital income will not necessarily decrease investment in relatively risky ventures once the loss offset provisions of the tax and its income effects are accounted for. In fact, it is quite likely that risk taking will be encouraged by an interest income tax. This article ranks with the half-dozen most influential articles on taxation written since the mid-1950s, and it represents the first application of the theory of choice under uncertainty to taxation. Its conclusions have proved to be quite robust to more general formulations of the theory of risk taking.

Musgrave’s second contribution to taxation theory is his theoretical and empirical work on tax incidence. He has developed most of the general concepts currently used in incidence analysis, and, in one of the first general equilibrium analyses, established the fundamental equivalences between direct and indirect taxes and between general and specific factor taxes. These contributions clarify a much confused issue: whether general excise taxes are shifted forwards to purchasers of taxed commodities or backwards to providers of factor services. They also established the importance of both uses and sources aspects of incidence theory.

Musgrave’s work on the allocation of tax burden (1951) to different income groups is a basic contribution to applied analysis and has been the starting point for all subsequent studies on tax burdens by income classes. More recently (1974) he refined this earlier work and covered the distributive aspects of expenditures as well as taxes. In another important study, The Shifting of the Corporation Tax (1963), with M. Krzyzaniak, Musgrave developed the first econometric estimates of incidence and concluded that the corporate profits tax is shifted forwards, a finding which gave rise to a large literature.

Musgrave extended and refined the normative theory of equitable taxation and its implications for income taxation and the concept of horizontal equity (1959, ch. 8). Later, in 1976, he broke new ground by introducing the concept of equal options as the basis for horizontal equity. Within this framework, two persons are considered to be in equal positions and should be treated equally if they face the same options. Thus, two persons with the same present value of lifetime earnings would be considered equal. One of the important insights of this concept is that under certain assumptions a consumption-based tax system is more equitable than an income tax system: the first treats equals equally while the second discriminates against persons who save relatively more.
The theory of the public household, Musgrave's unifying perspective on public goods, has provided the basis for many of his insights into that fundamental topic. This theory distinguishes between three branches of government – the allocative branch, which provides for social goods and deals with related questions of efficiency, the distribution branch, which modifies the distribution of income as determined by market forces and inheritance, and the stabilization branch, which is concerned with unemployment and overall economic stability.

He stresses that the failure to distinguish between the three different objectives of budget policy will involve unnecessary conflict and inefficient policy design. For instance, different voters may agree on the objective of fiscal stabilization but may fail to enact a proportional cut in taxes in recession if the proposals to combat recession will increase expenditures or change the distribution of income. Hence, one of the practical principles to emerge from the three-budget classification is that expenditure levels and the distribution of income, or tax shares of individual groups, should be determined independently of stabilization objectives. Similarly, the distinction between allocation and distribution leads to the principle that redistribution should be implemented primarily through a tax-transfer process. This will avoid inefficient increases of public expenditures in the name of progressive objectives. The distinction between allocation and distribution has acquired increased practical significance as much of the expansion of the public sector has consisted of increased transfer payments: Social Security and publicly financed medical care. Also, in a wide variety of policy areas, from the regulation of the prices of energy resources to efficient congestion-pricing of urban highways, the conflict between allocation and distribution has led to poor policy design, as he predicted. Compensation systems are needed to offset the redistributive effects of efficient allocation policies.

The value of the distinction between allocation and distribution has been enhanced by the work of Robert Nozick and John Rawls on social justice. Nozick has restated and extended John Locke's doctrine that one is fully entitled to the fruit of one's labour. Rawls developed a very different theory based on a communal claim to the output of high-ability persons. However, the claim structure is voluntarily agreed upon through a social compact, as risk-averse individuals, not knowing their future position, agree behind a veil of ignorance to share their income. This contractual approach to distribution is fully consistent with Musgrave's separation between the allocation and distribution branches.

Musgrave distinguishes between primary and secondary redistribution. Primary redistribution is determined by the social rights that entitle the individual to some share of the social product based on membership in the community, rather than on property ownership or labour supplied. Secondary redistribution is voluntary giving that occurs either through private charities or collective provision. Secondary redistribution is Pareto optimal in that the donor derives more satisfaction from providing the gift to the poor than from additional personal consumption. The mix between primary and secondary redistribution will vary across societies, according to differences in social values. Also, some social rights, or primary redistribution, may be provided in part in the form of goods and services, such as education, training programmes and medical care. This possibility blurs the separation of allocation and distribution functions.

The primary shortcoming of the distinction between allocation and distribution, however, is not the existence of transfers in kind and the subsidization of certain goods, which Musgrave has classified as merit goods (1957; 1959). As stressed by Samuelson, the fundamental issue is that numerous allocations between social and private goods are Pareto efficient, and the choice of an efficient allocation, a task for the distribution branch, has allocative consequences. In a planning solution, then, allocation and
distribution are decided simultaneously, not separately. Musgrave agrees to the formal correctness of this argument but he argues that this approach implicitly assumes that the planner knows individual preferences, and that the question of distribution is dealt with de novo. If, however, the distribution of income is determined primarily by market forces and preferences are not known, a pricing rule or voting rule that induces preference revelation must be designed. The determination of the pricing rule is the allocative function of government. The determination of money income, in conjunction with the pricing rule, is the distributive function. When considered from a broader perspective the separation of budgetary functions into allocation and distribution branches has been invaluable, both as a normative theory and as a description of the way public agencies operate. Experience shows that it is very important to develop coordination between branches of government. Also, Musgrave's three-branch theory clarifies many positive issues, such as the causes of large foreign trade deficits and the demise of central cities in metropolitan areas, as well as the design of policies to deal with these trends.

The establishment of a framework for the systematic solution of fiscal problems is Musgrave's most significant contribution. His work combined theory, institutional and historical information, a deep understanding of prior work and empirical testing. Like a number of other outstanding economists educated during the turbulent 1930s, he emphasized the practical and concrete applications of academic research in the belief that ‘intelligent conduct of government is at the heart of democracy’, and until the end of his life was an active commentator on policy issues. A lovely delineation of his views, along with a contrasting perspective, is found in Buchanan and Musgrave (1999); see also his review of the evolution of ideas on fiscal policy (1987).

music markets, economics of

Frederic M. Scherer
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

With the growth of economic prosperity, the demise of feudalism, and the weakening of Western religious institutions, markets for music have been transformed radically. By the 19th century, freelance composition and performance endeavours outweighed the employment of musicians by churches and noble courts. Further changes came from the invention of electrical and then electronic means of recording and disseminating music. The emergence of copyright for musical works strengthened economic incentives for the composition of music.

Keywords

Baumol's cost disease; copyright; music markets; superstars

Article

On 15 January 1787, Wolfgang Amadeus Mozart wrote from Prague to a friend in Vienna that ‘here [in Prague] nothing is talked about but Figaro; nothing is played, tootled, sung or whistled but [Mozart's Marriage of] Figaro.’ Music was ubiquitous, and Mozart was at the time Prague's favorite composer. More than two centuries later, music is played and listened to incessantly, usually through some electronic medium, in homes, shops, automobiles, trains, and on the streets. But the diversity of composers and forms is much greater. And in the means by which music is created and reaches the ears of its countless appreciators, the market institutions have changed radically.

Early history

The history of musical performance is as old as the history of humanity. A seven-hole Chinese flute has been carbon-dated to the year 7,000 bc. Prehistoric tribes celebrated military events and other special occasions with music from drums, horns, flutes, and a variety of stringed instruments. By the Middle Ages in Europe, the professional performance of music was concentrated in the churches, following traditions inherited from the Judaic temple music of King David, and in the residences of the wealthy, especially the nobility. The Roman Schola Cantorum was founded in the seventh century ad to perform what came to be called Gregorian chant. The first Holy Roman Emperor, Charlemagne (d. 814), imported from Rome a delegation of 12 specialists to propagate the correct use of Gregorian chant in northern Europe. Chapels established in residences of the nobility maintained their own cadre of instrumentalists and singers. Competition between Protestant and Roman Catholic denominations during the 16th century led to innovations in the richness of church music, ranging from the eminently singable hymns of Martin Luther to the polyphonic masses of Giovanni da Palestrina. The musicians employed in noble chapels also provided entertainment at dinners and celebrations, and during the Renaissance period wealthier nobles initiated further specialization, maintaining one group of musicians for chapel and another for secular entertainment. During the second half of the 17th century, a kind of ‘cultural arms race’ emerged among the hundreds of noble courts in Germany, Bohemia, and Austria. Each court competed for prestige through the quality of the musicians and composers it employed to entertain visitors (see Elias, 1969; Baumol and Baumol, 1994).

As a golden age of classical music dawned in the 17th century, much of Europe was organized along feudal lines. There was an active market for the hiring of promising musicians, who travelled far and wide in search of the best employment opportunities. But once a musician was retained by a feudal lord, at least throughout much of the European continent, he
(seldom she) was often bound to continued servitude at the noble's whim and on the noble's terms. Claudio Monteverdi was able to leave his badly paid, demoralizing position with Duke Vincenzo I of Mantua only after his employer's death in 1612. Johann Sebastian Bach was imprisoned for nearly a month in 1717 when he sought to leave the service of the Duke of Weimar. His contemporary Georg Friedrich Händel was advised by friends to reject an employment offer from the King of Prussia (Scherer, 2004, p. 94):

For they well knew, that if he once engag'd in the King's service, he must remain in it, whether he liked it, or not; that if he continued to please, it would be reason for not parting with him; and that if he happened to displease, his ruin would be the certain consequence.

When he was discharged in an economy move during 1769, Niccolò Jommelli was denied permission to take with him copies of the music he had written for the Duke of Württemberg.

Gradually, however, a new set of opportunities materialized for musicians to earn a living as freelance artists. Opera was the forerunner of this new tradition (see Bianconi and Pestelli, 1998). Having pioneered the first modern opera *Orpheo* under ducal auspices at Mantua, Monteverdi migrated to the free city of Venice, where operas were financed by a consortium of wealthy patricians, organized by a hired impresario, and written and performed under contracts individually negotiated with composers, librettists, and soloists. The paradigm spread to other parts of Italy, then to England and parts of Germany, and eventually to other European nations and the United States. Opportunities for the performance of instrumental music at private locales also began to emerge. One predecessor appeared in mercantile London, where King Charles II, embarrassed over his perennial money problems and his inability to pay his court musicians adequately, allowed Henry Purcell and others to perform their music privately in local theaters, taverns, and music halls. In 1697 Thomas Hickford opened a ‘Great Dancing Room’ in London, perfecting the emerging model for private music halls. In 1735 Vauxhall Gardens, south-east across the Thames from today's Victoria Station, began offering open-air summer concerts at admission prices sufficiently modest to draw Londoners of nearly all economic classes (see McVeigh, 1993). These innovations spread to other locations in London and then to many parts of the European continent. By the third decade of the 19th century, private ballrooms had proliferated in Vienna to the point at which they could accommodate some 50,000 music lovers simultaneously, with entertainment provided, inter alia, by 300 musicians under contract to Johann Strauss, sen., and deployed by Strauss in groups of 25. His son Johann was paid $100,000 to conduct his own and others’ compositions at the Boston, Massachusetts, Peace Festival in 1872, performed in a huge wooden shed by an orchestra of 2,000 and chorus of 20,000 before audiences of approximately 100,000 persons.

The transition from church and court employment to freelance music composition is depicted in Figure 1. (Scherer, 2004, pp. 69–71). It summarizes by 50-year birth cohort intervals the principal occupational choices of 646 musical composers of enduring fame born between 1650 and 1849. Strong downward trends are evident for court and church employment along with an upward trend for freelance activity. With double-counting allowed to reflect multiple career phases, we see that the fraction employed in noble courts or regularly subsidized by them fell from 62.4 per cent for composers born between 1650 and 1699 to 19.0 per cent for those born in the first half of the 19th century, by which time the Napoleonic wars had undermined much of the feudal system. For church employment the sharpest decline occurs for composers born in the second half of the 18th century. The fraction earning a significant component of their living through freelance composition and performance activities increased from 35.5 per cent for composers born in 1650–99 to 81 per cent for those born in 1800–49.

**Figure 1**

Trends in composers’ principal modes of employment, 1650–1849
Markets for music are both vertically and horizontally complex. Final demand exists for hearing music performed or for performing it oneself. From that demand are derived a host of other demands: for new musical compositions, for the sheet music through which compositions are disseminated to performers, for training (for example, at conservatories and local schools) in performance, for the concerts and other venues at which music is performed, for the instruments with which it is performed, and for recorded means by which performed music is propagated more widely. The composition, instrument-making, and dissemination stages have for many centuries experienced particularly vigorous innovation. In some subsets, however, such as organ building and violin-making, the technology attained a remarkable degree of perfection as early as the 17th century. Although data permitting a direct statistical test have not been available, the growth of concert-going during the 18th and 19th centuries in tandem with the commercial and industrial revolutions in Europe implies a substantial income elasticity of demand for music consumption. Indirect evidence is presented in Figure 2 (from Scherer, 2004, p. 35), showing trends in the production of pianos in the United States between 1850 and 1939. Values for years other than those on which specific data were available (points) are interpolated. The implied income elasticity of demand is in the range of 2.4 to 4.3, depending upon what other variables are included in multiple regressions. There is a sharp and lasting break in the series during the mid-1920s, when an economic boom was in full swing. The 1909 and 1923 production peaks were not surpassed over the next 60 years, after which imports began to outweigh domestic production. Two coincident events are responsible for the mid-1920s slump: the introduction of electrical phonographs (with fidelity superior to acoustic phonographs marketed successfully in the 1890s) and the advent of radio broadcasting, including the transmission of classical and popular music. Up to that time, the principal
alternative to expensive concert-going (or free summer concerts in urban parks) was the active performance of music within one's home. After the mid-1920s, music could be enjoyed passively at home by listening to radios and phonographs. An era of participatory family musicales began to fade, and a new era dawned.

Figure 2
Trends in US piano production, 1850–1939

The marriage of electronics with music wrought further radical changes in markets for music. Through records, radio, television, and still later, the internet, audiences for musical performance were no longer limited to those who could be assembled to hear a specific concert. The whole world was a stage, with four noteworthy consequences. First, for the world as a whole, musical record sales in 1998 (if we count only those sold legally, consistent with applicable copyrights) amounted to more than four billion units. Second, through amplification live performances could be heard by unprecedented numbers of concert-goers. The Woodstock Festival of August 1969 attracted an estimated 300,000 to 500,000 participants. Third, the expansion of potential audiences enhanced incentives for product differentiation. New musical styles proliferated during the second half of the 20th century at an accelerating pace. Fourth, the prerequisite for success as a vocal performer was no longer a beautiful voice that could carry through the expanse of an opera house. Electronics made popular acclaim attainable for faint voices, and even for performers whose histrionics, dancing ability, costuming, and sex appeal outweighed their vocal talent.

The expansion of markets also intensified a phenomenon already in evidence at the start of the 18th century: superstardom. The received theory (see, for example, Rosen, 1981) asserts that the broader the market for talent is, the higher the income differential tends to be between performers with the greatest ability to please and performers of inferior talent. In 1998, for example, the Three Tenors (Luciano Pavarotti, Placido Domingo, and Jose Carreras) along with their agent received an advance of $18 million for a single performance accompanying the World Cup football finals in Paris, including broadcast and recording rights. Michael Jackson's 'Thriller' album, introduced in 1992, achieved an all-time world high of 46 million unit sales, and in 2002, before he plunged into legal and financial difficulties, Jackson's net financial worth was estimated to be in the order of $300 million. But superstardom was not entirely new. In the early 18th century, the leading opera singers made arduous journeys throughout Europe in quest of the most remunerative engagements. The most famous of them all, the castrato Farinelli (Carlo Broschi), is said to have earned £5,000 during the 1735–36 opera season in London at a time when an English building...
For live musical performances that are neither amplified nor broadcast, another economic law operates, known as ‘Baumol’s cost disease’ (Baumol and Bowen, 1965). Many musical works require a more or less fixed complement of musicians expending a nearly fixed amount of rehearsal and performance time. Thus, labour productivity hardly grows from one century to the next. Meanwhile, most other goods and services experience appreciable rates of productivity growth, permitting those who supply them to earn increasing real incomes over time. For musical performers to stay abreast economically with alternative high productivity growth vocational opportunities, musicians’ hourly pay levels must rise apace commensurately, which means that the costs of live musical performances increase relative to the prices of all other goods and services, threatening possibly severe adverse substitution effects. To maintain a thriving supply of live musical performances, subsidization becomes increasingly necessary – not by noble patrons, as in the 18th century, but by governments (preponderantly in Europe and Asia) or affluent concert-goers and private philanthropists (the United States pattern). For 42 leading US symphony orchestras, all unionized, admissions receipts during the 2002–03 season defrayed on average only 43 per cent of annual budgets. Balancing budgets (which was often not achieved) required voluntary contributions and drawing upon endowments (the latter varying from virtually nothing to $248 million, with a mean of $48 million and median of $19 million). A regression analysis spanning 1980 to 2002 revealed that those orchestras’ budgets were higher, if local population is also taken into account, the greater the concentration of manufacturing, mining, and service corporation headquarters assets was in the relevant metropolitan area. A local corporate headquarters presence subsidized symphony orchestra performance both directly through endowment contributions and through the annual donations of well-paid company officials (Scherer, 2005).

**Music publication and copyright**

For at least three centuries the composers and publishers of new music have complained about the unauthorized use, or ‘piracy’, of their works. The copyright system – having governments confer upon composers and publishers (including record producers) exclusive rights to their productions, which can then be licensed to others upon payment of royalties and/or performance fees – has been the standard means of compromising the maintenance of economic incentives for creative contributions against widespread public dissemination. The first formal copyright law was enacted in England in 1709, but it was interpreted initially not to cover musical works. Extension to musical works came first in 1777 through a lawsuit brought in England by Johann Christian Bach, the son of Johann Sebastian Bach. Musical works were then included under copyright laws passed in the United States, France, various German states, and then, thanks to an initiative led by Johann Nepomuk Hummel and Ludwig van Beethoven culminating in 1837, the German, Austrian, Italian, Czech, and Hungarian territories that previously comprised the Holy Roman Empire. Prior to the enactment of copyright laws, some protection against unauthorized use was provided by ‘privileges’ – ad hoc grants of exclusivity conferred upon composers or publishers by royal sovereigns. Securing such grants required access to the relevant sovereign and, in the politically fragmented territories of the old Holy Roman Empire, the grants were mostly localized and prone to being undermined by competitors producing and selling from another territory. Composers protected their works by contracting with publishers having a reputation for respecting their contracts and keeping manuscripts secret for as long as possible before published versions reached the market. Hand-copying posed a particular threat, for in the early days of the music publishing industry’s rapid growth – for example, around 1800 – a copyist could turn out copies by hand at a unit cost lower than the average front-end set-up costs plus variable costs incurred with mechanical printing for production runs of fewer than 25–40 copies (Scherer, 2004, p. 162). Like his contemporaries, Mozart attempted to prevent hand copyists from pirating his works by keeping the copyists he hired under constant supervision and dividing work on any given manuscript among multiple copyists. Publishers combatted piracy through secrecy, announcing fixed prices lower than copyists’ minimum costs for publications expected to secure a considerable volume (which would now be called ‘limit pricing’), keeping composers’ honoraria low for works of limited or uncertain appeal, and entering into collusive anti-piracy agreements with fellow publishers. Giuseppe Verdi and his publisher Giovanni Ricordi were the first to make aggressive use of the copyright laws enacted in German-speaking and Austrian-controlled regions (for example, northern Italy). Previously, local opera houses had purchased or leased manuscripts at cut-rate prices from copyists. With copyright and a network of local enforcement employees, Verdi and Ricordi were able to extract fees from each house, graduating them in a discriminatory fashion to extract more revenue from those serving large, affluent audiences than those located in small provincial towns. They were also particularly energetic in publishing ‘reductions’ of each separate overture, aria, and chorus, along with bundles covering a full opera, for a diversity of instruments – for example, voice, piano, violin, flute, clarinet, and various ensembles – played by middle-class citizens in their homes. In this way they were able to create a mass market for their works, and as a result Ricordi could pay unprecedentedly large sums for the rights to publish Verdi’s works. Verdi became quite rich, accumulating an estate equivalent to nearly £40,000 at the time of his death in 1901 (when English building craftsmen’s annual income averaged £100) and beginning semi-retirement at his Busseto villa in the fifth decade of his nearly nine-decade life. Verdi’s extensive written correspondence leaves little doubt that, as his fortune grew, he consciously reduced his work effort along a backward-bending supply curve. Few 18th and 19th century composers achieved as much prosperity as Verdi did; the terminal wealth distribution is highly skew. (Gioachino Rossini became even wealthier and, after reaching the age of 37, spent the remaining four decades of his life in retirement.) It is unlikely that the majority of composers found themselves on the backward-bending portion of a labour supply curve. It is not unreasonable to suppose that the spectacular financial successes achieved by a relatively few composers under the copyright laws inspired many others to try their luck at musical composition. An attempt to test this hypothesis quantitatively (Scherer, 2004) was inconclusive, largely because of the difficulty of holding other relevant
variables constant. What can be said, however, is that the lack of copyright laws did not prevent classical music from experiencing its golden age of creativity before copyright protection was available in the most musically productive parts of Europe, that is, before the death of Beethoven in 1827 and Schubert in 1828. Despite this limping recommendation, advocates for copyright have been successful in extending greatly both the length of time for which creative individuals and publishers can be protected and, given a continuing stream of new technological challenges, in the range of media over which copyright applies (see Lessig, 2004).

Muth, John F. (1930–2005)

F. Robert Jacobs

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

John F. Muth, Professor of Operations Management, is known for his seminal work in rational expectations, aggregate planning and production scheduling. He received his Ph.D. from Carnegie Tech and spent most of his academic career at Indiana University. A colleague for over 20 years, in this article we give insight into his eclectic interests and intellectual motivation.

Keywords

aggregate planning; artificial intelligence; innovation cycles; linear decision rule; Muth, J. F.; rational expectations

Article

John F. (Jack) Muth was a brilliant individual, though somewhat awkward socially, and little understood by most people. He was born in Chicago, where his father worked as an accountant at a national accounting firm. Eventually, Jack moved with his parents and two brothers to St. Louis, Missouri. He was very weak as a youngster, suffering from severe asthma and allergies. An avid reader, Jack loved playing the cello and studying mathematics. Jack’s cello-playing days continued through the 1980s, and he was a member of the Bloomington symphony orchestra for many years. He studied industrial engineering at Washington University in St. Louis, and continued with graduate work in mathematical economics at Carnegie Tech in Pittsburgh, Pennsylvania. His thesis advisor was Franco Modigliani, with Herb Simon and Merton Miller serving on his committee. All three individuals would later become Nobel laureates in economics.

While a doctoral student, Muth was the first recipient of the Alexander Henderson Award in 1954 (for his work in economics). While finishing his doctorate, he spent the 1957–8 academic year as visiting lecturer at the University of Chicago, returned to Carnegie Tech as an assistant professor during 1959 to 1961, spent the 1961–2 academic year at the Cowles Foundation at Yale University, and finally returned to Carnegie Tech as an associate professor without tenure from 1962 to 1964. It is said that it took him
very long to graduate because he did not see the need to take a foreign language examination which would have completed requirements for the Ph.D. degree. Eventually, a colleague whose wife was a French instructor joined the faculty. She tutored Muth in French, and he was finally allowed to graduate. He went on to Michigan State as a professor in 1964, and moved to Indiana University in 1969. He stayed at Indiana University until he retired in 1994.

Throughout his entire academic career John Muth loved to challenge conventional thought. He would explore alternative explanations mathematically, his most famous work being three papers that develop the rational expectations hypothesis (1960; 1961; 1981). Later work by Robert Lucas, the economist, popularized the idea of rational expectations, and Lucas received the Nobel Prize for his efforts. Esther-Mirjam Sent has written a comprehensive paper that describes Muth's work on rational expectations from a historical perspective (Sent, 2002).

Many have asked why Muth did not himself further develop his ideas. If you knew him, this is easy to explain. He knew that there were alternative ways to explain the macroeconomic relationships that were the hot topic of the day. All he wanted to do was show an alternative; in essence, to create an academic debate that challenged conventional wisdom. His colleagues at Carnegie Tech were heavily involved in related research, and he wanted to have some fun and add his thoughts at the same time. Whenever he saw an opening to challenge an idea, he enjoyed developing his elegant ideas, often running concise computer simulations to accompany his mathematical models, subsequently writing up his results. He started doing this very early in his academic career.

A true intellectual, Muth had little interest in promoting his ideas through workshops, presentations or other academic portals. He felt his papers would be interpreted and stand the test of time. Being a good friend, I remember on many occasions Jack talking about invitations to speak at international conferences and at schools. These invitations were usually declined, I am sure not because he was uninterested but rather because he felt these activities would take a significant amount of time, he would probably have trouble with his allergies, and he was more interested in working on his current ideas. He always had something that he was actively working on and would talk about these ideas often over a few beers in the late afternoon at Nick's in Bloomington, Indiana, with his friends.

The late 1960s and early 1970s were spent developing industrial scheduling theory in the field of operations management. He wrote about the importance of the ‘aggregate planning’ problem and established it in the literature in 1960 with his colleagues at Carnegie Tech (Holt, Modigliani, Muth and Simon, 1960). It was Muth who established the proof of the linear decision rule in aggregate planning. This effort developed into a series of books published with Gerry Thompson and Gene Groff (Muth and Thompson, 1963; Groff and Muth, 1969; 1972).

He spent the late 1970s through the early 1980s studying artificial intelligence. His main interests were in inference engines and inductive and deductive logic. To my knowledge he published only one paper on the topic (Jacobs, Hancock, Mathieson and Muth, 1991). I often heard him refer to his work on artificial intelligence as his ‘ten-year sink hole’.

Later in the 1980s he began studying innovation cycles. He would often muse on the fact that many of the most innovative ideas were developed by individuals working at home, and how corporations that spent gigantic sums to develop new ideas so often produced only minor incremental innovations. He wrote simple simulation programs that simulated a random progress function, and matched these results with what was documented in the literature, often musing on the fit. He published an important paper in this area in 1989.
During the late 1980s until his retirement in 1994, Muth spend his time teaching undergraduate courses in process design and scheduling. As one might imagine, he was an awkward teacher and often had difficulty coming down to the level of doctoral students, much less undergraduate students. When he realized during this time that he was going to have to teach undergraduate students to see out his career, it was interesting to observe how he worked to improve. He worked with the teaching resource group at the university, who videotaped his lectures and helped him develop a better teaching style. His colleges in the department were amazed when he was listed as a recommended instructor in the student newspaper in the early 1990s, an event that gave him great personal satisfaction.

He loved sailing in the Florida Keys and had a 30-foot Auburn sailboat that was docked in Marathon until he moved it to Cudjoe Key around 1989. The boat was well suited for sailing around the Florida Keys having a shallow keel. He retired in 1994 and initially split his time between Bloomington and the Keys. For a time, he worked as a consultant to the business school to develop the integrative cases used in the undergraduate core curriculum, taking Indiana's integrative core to yet another level, as he had done in economics and in almost any area in which he became involved. From around 2000, he remained permanently in the Keys.

This article has possibly not emphasized enough the impact of Muth's work. He was truly a brilliant intellectual and influenced numerous doctoral students throughout his career at Michigan State and Indiana University. As an aside, he was also an amazing Trivial Pursuits player. You always wanted Muth on your team since he seldom missed a question! Muth also had a private side as an aggressively loyal and caring person to his close friends. He was always willing to spend time to talk through important career decisions, and always willing to comment quickly and brilliantly on a manuscript (although it might cost you a beer).

Finally, a funny story, I can still remember being in the Keys with my wife and children, and visiting Jack when he first bought the Cudjoe Key house. Late one afternoon we were all driving up from Key West with Jack. We stopped at a store to pick up some food for dinner, my wife and I leaving the kids with Jack in the car. When we returned to the car, there we saw Jack teaching our two young daughters how to make ‘unusual noises’ by putting their hands over their armpits and pumping their arms up and down. We all still laugh when we think about that time and the other wonderful times we enjoyed with that nervous little genius who was such a great friend.

Gunnar Myrdal was born in the province of Dalarná in Sweden. He attributed his faith in Puritan ethics and his egalitarianism to his sturdy farming background.

He was a student of the giant figures Knut Wicksell, David Davidson, Eli Heckscher, Gösta Bagge and above all Gustav Cassel. His personal friendship was warmest with Cassel, to whose chair in Political Economy at Stockholm University he succeeded (1933–9).

At first a pure theorist, Myrdal's year in the United States as a Rockefeller Fellow, following the crash of 1929, turned his interests to political issues. On his return to Sweden from America he, with his wife Alva, became active in politics. In 1935 he became a Member of Parliament. Together, they pioneered modern population policy. His involvements in Swedish politics between 1931 and 1938 turned him from a theoretical economist into a political economist and what he himself describes as an institutionalist. In 1938 the Carnegie Corporation selected him for a major investigation of the Negro problem in America, a project which resulted in An American Dilemma (1944a).

He returned to Sweden in 1942 and for five years was again involved in political activities. He headed the committee that drafted the social democratic post-war programme. He returned to Parliament and became a member of the board of directors of the Swedish Bank, chairman of the Swedish Planning Commission, and Minister for Trade and Commerce (1945–7). As Minister he arranged for a highly controversial treaty with the Soviet Union and was also involved in controversy over the dismantling of wartime controls. In 1947 he became Executive Secretary of the United Nations Economic Commission for Europe, to which he recruited an outstandingly able team. After ten years with the Commission in Geneva he embarked on a ten-year study of development in Asia, the result of which was the monumental Asian Drama (1968). In 1973 he was awarded the Nobel Prize in economics jointly with Friedrich von Hayek.
Methodological questions occupied Myrdal's thought throughout his life. They were already present in the young Myrdal's *Political Element in the Development of Economic Theory* (1930, English edition 1953). It was under the influence of the remarkable Uppsala University philosopher Axel Hägerström that he had begun to question the wisdom of the economic establishment.

Myrdal's doctoral dissertation on price formation and economic change (1927) introduced expectations systematically into the analysis of prices, profits and changes in capital values. The microeconomic analysis focused on planning by the firm. Many of these ideas were used in his later macroeconomic work, including *Monetary Equilibrium* (1931, English expanded translation 1939).

Much confusion had been caused by the lack of distinction between anticipations and results. The concepts *ex ante* and *ex post* that Myrdal developed greatly clarified the discussion of savings, investment and income, and their effects on prices. In anticipation, intention and planning, savings can diverge from investment; after the event they must be identical, because the community can save only by accumulating real assets. It is the process by which anticipations *ex ante* are adjusted so as to bring about the bookkeeping identity *ex post* that explains unexpected gains and losses as well as fluctuations in prices. Only in equilibrium are *ex ante* savings equal to *ex ante* investment, so that there is no tendency for prices to change. By introducing expectations into the analysis of economic processes he made a major contribution to liberalizing economics from static theory, in which the future is like the past, and to paving the way for dynamics, in which time, uncertainty and expectations enter in an essential way.

What is common to his three important later books, *The Political Element* (1930), *American Dilemma* (1944a) and *Asian Drama* (1968) is the emphasis on realistic and relevant research, whether on economic problems, race relations, or world poverty, and with it the effort to purge economic thinking of systematic biases.

Starting on the study of Blacks in the United States, he soon discovered that he had to study ‘American civilization in its entirety, though viewed in its implications for the most disadvantaged population group’ (Introduction to *An American Dilemma*, Section 4). The way to reach objectivity was to state explicitly the value premisses of the study. These premisses were not chosen arbitrarily, but were what Myrdal called the ‘American Creed’ of justice, liberty and equality of opportunity. But while these value premisses were chosen for their relevance to American society, they corresponded to Myrdal’s own valuations. The major contribution of the book, which Myrdal regarded as his war service, is the analysis of six decades after Reconstruction as a ‘temporary interregnum’ not a ‘stable equilibrium’, and of the incipient changes, on which the prediction of the Black revolt in the South was based.

Apart from his work on expectations and on racial problems, Myrdal is best known for his critique of conventional economic theory applied to underdeveloped countries.

Through his whole work run five lines of criticism of mainstream economic and social theory. First, his appeal for realism is not a critique of abstraction. His criticism is that irrelevant features are selected and relevant ones ignored (‘opportunistic ignorance’). A second line of criticism has been the narrow or abstract definitions of development, economic growth, or welfare. The actual needs and valuations of people, not the abstractions of statisticians or the empty concepts of metaphysicians, should be the basis for formulating aims. His third line of criticism is directed at the narrow definitions and the limits of disciplines. The essence of the institutional approach, advocated by Myrdal, is to bring to bear all relevant knowledge and techniques on the analysis of a problem. In an interdependent social system there are no economic, political or social problems, there are only problems. His fourth line of criticism is directed at spurious objectivity which, under the pretence of scientific analysis, conceals political
valuations and interests. Myrdal argues that this pseudoscience should be replaced by explicit valuations. He is, of course, aware of the complex nexus between valuations and facts but, ever since his youthful *Political Element*, has constantly fought the inheritance of natural law and utilitarianism, according to which we can derive recommendations from pure analysis. A fifth line of criticism is directed against biases and twisted terminology. He lays bare the opportunistic interests and the ‘diplomacy’ underlying the use of such concepts as ‘United Nations’, ‘international’, ‘values’, ‘welfare’, ‘developing countries’, ‘unemployment’, ‘the free world’. The features against which these lines of criticism are advanced are combined in the technocrat. He isolates economic (or other technical) relations from their social context; he neglects social and political variables and thereby ministers to the vested interests that might otherwise be hurt; he pretends to scientific objectivity and is socially and culturally insensitive. Since the majority of experts, academics and planners are of this type, he has ruffled many feathers.

The question may be asked whether the narrow technocrat cannot be replaced by an approach that introduces social variables openly into the formal model? Myrdal's answer would be, yes and no. In certain areas, a widening or redefinition of concepts can be successful. The productive effects of better nutrition can be studied and the line between investment and consumption be redrawn. The influence of climate, of attitudes, and of institutions can be introduced as constraints or as variables. An agricultural production function can be constructed in which health, education, distance from town, and so on figure as ‘inputs’. ‘Capital’ can be redefined so as to cover anything on which expenditure of resources now raises the flow of output later.

But there are limits to such revisionism. These limits apply both to the analysis of facts and to recommendations of policies. On the factual side, the reformulation runs into difficulties if the connection between expenditure now and ‘yield’ later is only tenuous, as in the initiation of a birth control programme or a land reform.

In the analysis of values, the construction of a social welfare function is not, in Myrdal's view, a logical task. The unity of a social programme of a party is unlike that of a computer program or a logically consistent system, and more like the unity of a personality. It is discovered not only by deductive reasoning but by empathy, imagination, and even artistic and intuitive understanding. Means and ends, targets and instruments, are misleading ways of grasping the valuations of a class, an interest group or a whole society, for their unity is not logical but psychological.

In *Asian Drama* the explicitly formulated valuations are the ‘Modernization Ideals’. A list would include rationality, planning for the future, raising productivity, raising levels of living, social and economic equalization, improved institutions and attitudes, national consolidation, national independence, political democracy, social discipline.

An important idea in Myrdal's arsenal of ideas is that of circular or cumulative causation (or the vicious – or virtuous – circle), first fully developed in *An American Dilemma*. It postulates increasing returns through specialization and economies of scale and shows how small advantages are magnified. The principle goes back to Wicksell who, in *Interest and Prices* (1898), had analysed divergences between the natural and the market rates of interest in terms of upward or downward cumulative processes, until the divergence was eliminated. Wicksell pointed out that, if banks keep their loan rate of interest below the real rate of return on capital, they will encourage expansion of production and investment in plant and equipment. As a result, prices will rise and will continue to rise cumulatively as long as the lending rate is kept below the real rate.

The principle of cumulative causation can be used to show movements away from an equilibrium
position as a result of the interaction of several variables. Myrdal has not always been entirely clear in the formulation of this important principle, and there has been the suggestion that any form of circular or mutual causation or interaction is cumulative and hence disequilibrating. This would be false, for a series of mutually caused events can, after a disturbance, rapidly converge either on the initial or on some other point of stable equilibrium. In order to get instability, a cumulative movement away from the initial situation, the numerical values of the coefficients of interdependence have to be above a critical minimum size. For example, an increase in consumption will raise incomes which in turn will raise consumption, and so on, ad infinitum. But as long as the marginal propensity to consume is less than unity, the infinite series will converge on a finite value.

The notion of cumulative causation was applied by Myrdal most illuminatingly to price expectations (Monetary Equilibrium) and to the relations between regions (Economic Theory and Underdeveloped Regions, 1957; American title: Rich Lands and Poor). He showed how the advantages of growth poles can become cumulative, while the backward region may be relatively or even absolutely impoverished. Myrdal applied the notion of sociological variables, such as the prejudices against Negroes and their level of performance (low skills, crime, disease, and so on); to economic variables; and, above all, to the interaction of so-called ‘economic’ and ‘non-economic’ variables. Thus, the relation between better nutrition, better health and better education, higher productivity and hence ability further to improve health, education and nutrition shows that the inclusion of non-economic variables in the analysis opens up the possibility of numerous cumulative processes to which conventional economic analysis is blind. It also guards against uni-causal explanations and panaceas.

The revolutionary character of the concept of cumulative causation is brought out by the fact that interaction takes place not only within a social system in which the various elements interact, but also in time, so that memory and expectations are of crucial importance. The responses to any given variable, say a price, are different according to what the history of this variable has been. It is this dynamic feature of analysis and its implications for policy that distinguishes Myrdal's approach from that of economists who think in terms of general equilibrium.

In Economic Theory and Underdeveloped Regions (1957), and later in Asian Drama (1968), he used the concepts ‘backwash’ and ‘spread’ effects to analyse the movement of regions or whole countries at different stages of development and the effects of unification. It is a highly suggestive, realistic and fruitful alternative explanation to that of stable equilibrium analysis, usually based on competitive conditions and diminishing returns, and concluding that gains are widely and evenly distributed. Like the Marxists, Myrdal emphasizes the unequal distribution of power and property as an obstacle not only to equity but also to efficiency and growth. But his conclusion is not Marxist. He regards a direct planning of institutions and shaping of attitudes (what Marx regarded as part of the superstructure) as necessary, though very difficult, partly because he believes that attitudes and institutions are inert, and partly because the policies which aim at reforming attitudes and institutions are themselves part of the social system, part of the power and property structure. There are clearly also logical difficulties in operating on variables that are thought to be fully determined within the system.

In Asian Drama Myrdal criticizes the kind of government he calls the ‘soft state’. This critique has sometimes been misunderstood. It is plain that ‘softness’ in Myrdal's sense is quite compatible with a high degree of coercion, violence and cruelty. The Tamils in Sri Lanka, the Indians in Burma, the Chinese in Indonesia, the Hindus in Pakistan, the Moslems in India, the Biharis in Bangladesh – to take six states he calls ‘soft’ – could not claim excessively soft treatment. ‘Soft states’ also go in for military
violence, both internal and external. Their ‘softness’ lies in their unwillingness to coerce in order to implement declared policy goals. It is not the result of gentleness or weakness but reflects the power structure and a gap between real intentions and professions.

Myrdal applied his method to the analysis of inflation combined with widespread unemployment in the developed countries of the West in the 1970s, and either coined or was one of the first to use the term ‘stagflation’. He attributes the situation to the organization of producers as pressure groups, and the dispersion and comparative weakness of consumers, to the tax system which encourages speculative expenditures, to the structure of markets and to the methods of oligopoly administrative pricing, and he condemns inflation as a socially highly divisive force.

The approach favoured by Myrdal is one of neither Soviet authority and force nor of capitalist laissez-faire but of a third way: that of using prices for planning purposes and of attacking attitudes and institutions directly to make them the instruments of reform. His approach has more affinity with those socialists who were dismissed by Marx as utopian. The difficulty is that any instrument, even if used with the intention to reform, within a given power structure may serve the powerful and re-establish the old equilibrium. Even well-intentioned allocations, rationing, licensing and controls may reinforce monopoly and big business. How does one break out of this lock? Myrdal does not draw revolutionary conclusions but relies on the, admittedly difficult, possibility of self-reform that arises, in both the American Creed and in the Modernization Ideals, from the tensions between preferred and proclaimed beliefs and actions.

Both An American Dilemma and Asian Drama are books about the interaction and the conflict between ideals and reality, and about how, when the two conflict, one of them must give way. Much of conventional economic theory is a rationalization whose purpose it is to conceal that conflict. But it is bound to reassert itself sooner or later. When this happens, either the ideals will be scaled down to conform to the reality or the reality will be shaped by the ideals.

Nash equilibrium, refinements of

Srihari Govindan and Robert B. Wilson
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article describes ways that the definition of an equilibrium among players' strategies in a game can be sharpened by invoking additional criteria derived from decision theory. Refinements of John Nash's 1950 definition aim primarily to distinguish equilibria in which implicit commitments are credible due to incentives. One group of refinements requires sequential rationality as the game progresses. Another ensures credibility by considering perturbed games in which every contingency occurs with positive probability, which has the further advantage of excluding weakly dominated strategies.

Article

Game theory studies decisions by several persons in situations with significant interactions. Two features distinguish it from other theories of multi-person decisions. One is explicit consideration of each person's available strategies and the outcomes resulting from combinations of their choices; that is, a complete and detailed specification of the 'game'. Here a person's strategy is a complete plan specifying his action in each contingency that might arise. In non-cooperative contexts, the other is a focus on optimal choices by each person separately. John Nash (1950; 1951) proposed that a combination of mutually optimal strategies can be characterized mathematically as an equilibrium. According to Nash's definition, a combination is an equilibrium if each person's choice is an optimal response to others' choices. His definition assumes that a choice is optimal if it maximizes the person's expected utility of outcomes, conditional on knowing or correctly anticipating the choices of others. In some applications, knowledge of others' choices might stem from prior agreement or communication, or accurate prediction of others' choices might derive from 'common knowledge' of strategies and outcomes and of optimizing behaviour. Because many games have multiple equilibria, the predictions obtained are incomplete. However, equilibrium is a weak criterion in some respects, and therefore one can refine the criterion to obtain sharper predictions (Harsanyi and Selten, 1988; Hillas and Kohlberg, 2002; Kohlberg, 1990; Kreps, 1990).

Here we describe the main refinements of Nash equilibrium used in the social sciences. Refinements were developed incrementally, often relying on ad hoc criteria, which makes it difficult for a non-specialist to appreciate what has been accomplished. Many refinements have been proposed but we describe only the most prominent ones. First we describe briefly those refinements that select equilibria with simple features, and then we focus mainly on those that invoke basic principles adapted from single-person decision theory.

Equilibria with simple features

Nash's construction allows each person to choose randomly among his strategies. But randomization is not always plausible, so in practice there is a natural focus on equilibria in 'pure' strategies, those that do not use randomization. There is a similar focus on strict equilibria, those for which each person has a unique optimal strategy in response to others' strategies. In games with some symmetries among the players, the symmetric equilibria are those that reflect these symmetries. In applications to dynamic interactions the most useful
equilibria are those that, at each stage, depend only on that portion of prior history that is relevant for outcomes in the future. In particular, when the dynamics of the game are stationary one selects equilibria that are stationary or that are Markovian in that they depend only on state variables that summarize the history relevant for the future. Applications to computer science select equilibria or, more often, approximate equilibria, using strategies that can be implemented by simple algorithms. Particularly useful are equilibria that rely only on limited recall of past events and actions and thus economize on memory or computation.

Refinements that require strategies to be admissible

One strategy is strictly dominated by another if it yields strictly inferior outcomes for that person regardless of others’ choices. Because an equilibrium never uses a strictly dominated strategy, the same equilibria persist when strictly dominated strategies are deleted, but after deletion it can be that some remaining strategies become strictly dominated. A refinement that exploits this feature deletes strictly dominated strategies until none remain, and then selects those equilibria that remain in the reduced game. If a single equilibrium survives then the game is called ‘dominance solvable’. An equilibrium can, however, use a strategy that is weakly dominated in that it would be strictly dominated were it not for ties – in decision theory such a strategy is said to be inadmissible. A prominent criterion selects equilibria that use only admissible strategies, and sometimes this is strengthened by iterative deletion of strictly dominated strategies after deleting the inadmissible strategies. A stronger refinement uses iterative deletion of (both strictly and weakly) dominated strategies until none remain; however, this procedure is ambiguous because the end result can depend on the order in which weakly dominated strategies are deleted. A particular order is used for dynamic games that decompose into a succession of subgames as time progresses. In this case, those strategies that are weakly dominated because they are strictly dominated in final subgames are deleted first, then those in penultimate subgames, and so on. In games with ‘perfect information’ as defined below this procedure implements the criterion called ‘backward induction’ and the equilibria that survive are among those that are ‘subgame-perfect’ (Selten, 1965). In general a subgame-perfect equilibrium is one that induces an equilibrium in each subgame. Figure 1 depicts an example in which there are two Nash equilibria, one in which A moves down because she anticipates that B will move down, and a second that is subgame-perfect because in the subgame after A moves across, B also moves across, which yields him a higher payoff than down.

Figure 1

Player A moves down or across, in which case player B moves down or across. Payoffs for A and B are shown at the end of each sequence of moves.
The informal criterion of ‘forward induction’ has several formulations. Kohlberg and Mertens (1986) require that a refined set of equilibria contains a subset that survives deletion of strategies that are not optimal responses at any equilibrium in the set. Van Damme (1989; 1991) requires that if player A rejects a choice X in favour of Y or Z then another player who knows only that Y or Z was chosen should consider Z unlikely if it is chosen only in equilibria that yield player A outcomes worse than choosing X, whereas Y is chosen in an equilibrium whose outcome is better. A typical application mimics backward induction but in reverse – if a person previously rejected a choice with an outcome that would have been superior to the outcomes from all but one equilibrium of the ensuing subgame, then presumably the person is anticipating that favourable equilibrium and intends to use his strategy in that equilibrium of the subgame. In Figure 2, if A rejects the payoff 5 from Down then B can infer that A intends to play Top in the ensuing subgame, yielding payoff 6 for both players.

**Figure 2**

First A and then B can avoid playing the subgame in which simultaneously each chooses between two options.
Before proceeding further we describe briefly some relevant features of dynamic games, that is, games in which a player acts repeatedly, and can draw inferences about others' strategies, preferences, or private information as the game progresses. A dynamic game is said to have 'perfect information' if each person knows initially all the data of the game, and the prior history of his and others' actions whenever he acts, and they do not act simultaneously. In such a game each action initiates a subgame; hence backward induction yields a unique subgame-perfect equilibrium if there are no ties. But in many dynamic games there are no subgames. This is so whenever some person acts without knowing all data of the game relevant for the future. In Figure 3 player C acts without knowing whether player A or B chose down. Figure 3

Player A moves down or across, in which case player B moves down or across. Player C does not observe whether it was A or B who moved down when she chooses to move left or right.
The source of this deficiency is typically that some participant has private information – for example, about his own preferences or about outcomes – or because his actions are observed imperfectly by some others. Among parlour games, chess is a game with perfect information (if players remember whether each king has been castled). Bridge and poker are games with imperfect information because the cards in one player’s hand are not known to others when they bet. In practical settings, auctions and negotiations resemble poker because each party acts (bids, offers, and so on) without knowing others’ valuations of the transaction. Analyses of practical economic games usually assume (as we do here) ‘perfect recall’ in the sense that each player always remembers what he knew and did previously. If bridge is treated as a two-player game between teams, then it has imperfect recall because
Refinements of Nash equilibrium are especially useful in dynamic games. Nash equilibria do not distinguish between the case in which each player commits initially and irrevocably to his strategy throughout the game, and the case in which a player continually re-optimizes as the game progresses. The distinction is lost because the definition of Nash equilibrium presumes that players will surely adhere to their strategies chosen initially. Most refinements of Nash equilibrium are intended to resurrect this important distinction. Ideally one would like each Nash equilibrium to bear a label telling whether it assumes implicit commitment or relies on incredible threats or promises. Such features are usually evident in the equilibria of trivially simple games, but in more complicated games they must be identified by augmenting the definition of Nash equilibrium with additional criteria.

In the sequel we describe two classes of refinements in detail, but first we summarize their main features, identify the main selection criteria they use, and mention the names of some specific refinements. Both classes are generalizations of backward induction and subgame perfection, and they obtain similar results, but their motivation and implementation differ.

1. The criterion of sequential rationality

The presumption that commitment is irrevocable is flawed if other participants in the game do not view commitment to a strategy as credible. Commitment can be advantageous, of course, but if commitment is possible (for example, via enforceable contractual arrangements) then it should properly be treated as a distinct strategy. Absent commitment, some Nash equilibria are suspect because they rely implicitly on promises or threats that are not credible. For example, one Nash equilibrium might enable an incumbent firm to deter another firm from entering its market by threatening a price war. If such a threat succeeds in deterring entry then it is costless to the incumbent because it is never challenged; indeed, it can be that this equilibrium is sustained only by the presumption that the incumbent will never need to carry out the threat. But this threat is not credible if, after entry occurs, the incumbent would recognize that accommodation is more profitable than a price war. In such contexts, the purpose of a refinement is to select an alternative Nash equilibrium that anticipates correctly that entry will be followed by accommodation. For instance, the subgame-perfect equilibrium in Figure 1 satisfies this criterion.

Refinements in the first class exclude strategies that are not credible by requiring explicitly that a strategy is optimal in each contingency, even if it comes as a surprise. (We use the term ‘contingency’ rather than the technical term ‘information set’ used in game theory – it refers to any situation in which the player chooses an action.) These generally require that a player’s strategy is optimal initially (as in the case of commitment), and that in each subsequent contingency in which the player might act his strategy remains optimal for the remainder of the game, even if the equilibrium predicts that the contingency should not occur. This criterion is called ‘sequential rationality’. As described later, three such refinements are perfect Bayes, sequential, and lexicographic equilibria, each of which can be strengthened further by imposing additional criteria such as invariance, the intuitive criterion and divinity.

2. The criterion of perfection or stability

The presumption that commitment is irrevocable is also flawed if there is some chance of deviations. If a player might ‘tremble’ or err in carrying out his intended strategy, or his valuation of outcomes might be slightly different from others anticipated, then other players can be surprised to find themselves in unexpected situations. Refinements that exploit this feature are implemented in two stages. In the first stage one identifies the Nash equilibria of a perturbation of the original game, usually obtained by restricting each player to randomized strategies that assign positive probabilities to all his original pure strategies. In the second stage one identifies those equilibria of the original game that are limits of equilibria of the perturbed game as this restriction is relaxed to allow inferior strategies to have zero probabilities.

Refinements in the second class also exclude strategies that are not credible, but refinements in this class implement sequential rationality indirectly. The general criterion that is invoked is called ‘perfection’ or ‘stability’, depending on the context. In each case a refinement is obtained from analyses of perturbed games. This second class of refinements is typically more restrictive than the first class due to the stronger effects of perturbations. As described later, two such refinements are perfect and proper equilibria. These are equilibria that are perturbed slightly by some perturbation of the players’ strategies. A more stringent refinement selects a subset of equilibria that is truly perfect or stable in the sense that it is perturbed only slightly by every perturbation of players’ strategies. This refinement selects a subset of equilibria rather than a single equilibrium because there need not exist a single equilibrium that is essential in that it is perturbed slightly by every perturbation of strategies. A stringent refinement selects a subset that is hyperstable in that it is stable
Nash equilibrium, refinements of : The New Palgrave Dictionary of Economics

against perturbations of both players' strategies and their valuations of outcomes, or against perturbations of their optimal responses; and further, it is invariant in that it is unaffected by addition or deletion of redundant strategies. The crucial role of perturbations in the second class of refinements makes them more difficult for non-specialists to understand and appreciate, but they have a prominent role in game theory because of their desirable properties. For example, in a two-player game a perfect equilibrium is equivalent to an equilibrium that uses only admissible strategies. In general, refinements in the second class have the advantage that they satisfy several selection criteria simultaneously. After this overview, we now turn to detailed descriptions of the various refinements.

Refinements that require sequential rationality

In dynamic games with perfect information, the implementation of backward induction is unambiguous because in each contingency the player taking an action there knows exactly the subgame that follows. In chess, for example, the current positions of the pieces determine how the game can evolve subsequently. Moreover, if he anticipates his opponent's strategy then he can predict how the opponent will respond to each possible continuation of his own strategy. Using this prediction he can choose an optimal strategy for the remainder of the game by applying the principle of optimality – his optimal strategy in the current subgame consists of his initial action that, when followed by his optimal strategies in subsequent subgames, yields his best outcome. Thus, in principle (although not in practice, since chess is too complicated) his optimal strategy can be found by working backward from final positions through all possible positions in the game.

In contrast, in a game with imperfect information a player's current information may be insufficient to identify the prior history that led to this situation, and therefore insufficient to identify how others will respond in the future, even if he anticipates their strategies. In poker, for example, knowledge of his own cards and anticipation of others' strategies are insufficient to predict how they will respond to his bets. Their strategies specify how they will respond conditional on their cards but, since he does not know their cards, he remains uncertain what bets they will make in response to his bets. In this case, it is his assessment of the probability distribution of their cards that enables construction of his optimal strategy. That is, this probability distribution can be combined with their strategies to provide him with a probabilistic prediction of how they will bet in response to each bet he might make. Using this prediction he can again apply the principle of optimality to construct an optimal strategy by working backward from the various possible conclusions of the game.

Those refinements that select equilibria satisfying sequential rationality use an analogous procedure. The analogue of the probability distribution of others' cards is a system of 'beliefs', one for each contingency in which the player might find himself. Each belief is a conditional probability distribution on the prior history of the game given the contingency at which he has arrived. Thus, to whatever extent he is currently uncertain about others' preferences over final outcomes or their prior actions, his current belief provides him with a probability distribution over the various possibilities. As in poker, this probability distribution can be combined with his anticipation of their strategies to provide him with a probabilistic prediction of how they will act in response to each action he might take – and again, using this prediction he can apply the principle of optimality to construct an optimal strategy by working backward from the various possible conclusions of the game.

There is an important proviso, however. These refinements require that, whenever one contingency follows another with positive probability, the belief at the later one must be obtained from the belief at the earlier one by Bayes' rule. This ensures consistency with the rules of conditional probability. But, importantly, it does not restrict a player's belief at a contingency that was unexpected, that is, had zero probability according to his previous belief and the other players' strategies.

In Figure 3, in one Nash equilibrium A chooses down, B chooses across, and C chooses left. This is evidently not sequential because if A were to deviate then B could gain by choosing down. In a sequential equilibrium B chooses down and each of A and C randomizes equally between his two strategies. The strategies of A and B imply that C places equal probabilities on which of A and B chose down. The weakest refinement selects a perfect-Bayes equilibrium (Fudenberg and Tirole, 1991). This requires that each player's strategy is consistent with some system of beliefs such that (a) his strategy is optimal given his beliefs and others' strategies, and (b) his beliefs satisfy Bayes' rule (wherever it applies) given others' strategies. A stronger refinement selects sequential equilibria (Kreps and Wilson, 1982). A sequential equilibrium requires that each player's system of beliefs is consistent with the structure of the game. Consistency is defined formally as the requirement that each player's system of beliefs is the limit of the conditional probabilities induced by players' strategies in some perturbed game, as described previously. A further refinement selects quasi-perfect equilibria (van Damme, 1984), which requires admissibility of a player's strategy in continuation from each contingency, excluding any chance that he himself might deviate from his intended strategy. And even stronger are proper equilibria (Myerson, 1978), described later. This sequence of progressively stronger refinements is typical. Because proper implies quasi-perfect implies sequential implies perfect-Bayes, one might think that it is sufficient to always use properness as the refinement. However, the prevailing practice in the social sciences is to invoke the weakest refinement that suffices for the game being studied. This reflects a conservative attitude about using unnecessarily restrictive refinements. If, say, there is a unique sequential equilibrium that uses only admissible strategies, then one refrains from imposing stronger criteria.

Additional criteria can be invoked to select among sequential equilibria. In Figure 4 there is a sequential equilibrium in which both types of A move left and B randomizes equally between middle and bottom, and another in which both types of A move right and B chooses middle. An alternative justification for the second, due to Hillas (1998), is shown in Figure 5, where the game is restructured so that A either commits initially to left or they play the subgame with simultaneous choices of strategies. The criterion of subgame...
perfection selects the second equilibrium in Figure 4 because in Figure 5 the subgame has a unique equilibrium with payoff 6 for A that is superior to his payoff 4 from committing to left.

Figure 4
Nature chooses whether player A's type is A1 or A2 with equal probabilities. Then A chooses Left or Right, in which case player B, without knowing A's type, chooses one of three options.

Figure 5
The game in Figure 4 restructured so that either A commits to Left regardless of his type, or plays a subgame with simultaneous moves in which he chooses one of his other three type-contingent strategies. The payoffs 6,4 to A and B from the unique Nash equilibrium of the subgame are shown with an asterisk.
These refinements can be supplemented with additional criteria that restrict a player's beliefs in unexpected contingencies. The most widely used criteria apply to contexts in which one player B could interpret the action of another player A as revealing private information; that is, A's action might signal something about A's type. These criteria restrict B's belief (after B observes A deviating from the equilibrium) to one that assigns positive probability only to A's types that might possibly gain from the deviation, provided it were interpreted by B as a credible signal about A's type. The purpose of these criteria is to exclude beliefs that are blind to A's attempts to signal what his type is when it would be to A's advantage for B to recognize the signal. In effect, these criteria reject equilibria that commit a player to unrealistic beliefs. Another interpretation is that these criteria reject equilibria in which A...
Nash equilibrium, refinements of: The New Palgrave Dictionary of Economics

is ‘threatened by B’s beliefs’ because B stubbornly retains these beliefs in spite of plausible evidence to the contrary.

The simplest version requires that B’s belief assigns zero probability to those types of A that cannot possibly gain by deviating, regardless of how B responds. The intuitive criterion (Cho and Kreps, 1987) requires that there cannot be some type of A that surely gains from deviating in every continuation for which B responds with a strategy that is optimal based on a belief that assigns zero probability to those types of A that cannot gain from the deviation. That is, an equilibrium fails the intuitive criterion if B’s belief fails to recognize that A’s deviation is a credible signal about his type. They apply this criterion to the game in Figure 6, which has two sequential equilibria. In one both types of A choose left and B chooses down or up contingent on left or right. In another both types choose right and B chooses up or down contingent on left or right. In both equilibria B’s belief in the unexpected event (right or left respectively) assigns probability greater than 0.5 to A’s type A1. The intuitive criterion rejects the second equilibrium because if A2 were to deviate by choosing left, and then B recognizes that this deviation credibly signals A’s type A2 (because type A1 cannot gain by deviating regardless of B’s response) and therefore B chooses down, then type A2 obtains payoff 3 rather than his equilibrium payoff 2.

Figure 6
A signalling game in which Nature chooses A's type A1 or A2, then A chooses left or right, and then B, without knowing A's type, chooses up or down

Cho and Kreps also define an alternative version, called the ‘equilibrium domination’ criterion. This criterion requires that, for each continuation in which B responds with a strategy that is optimal based on a belief that assigns zero probability to those types of A that cannot gain from deviating, there cannot be some type of A that gains from deviating. More restrictive is the criterion D1 (Banks and Sobel, 1987), also called ‘divinity’ when it is applied iteratively, which requires that, if the set of B’s responses for which one type of A gains from deviating is larger than the set for which a second type gains, then B’s beliefs must assign zero probability to the second type. The criterion D2 is similar except that some (rather than just one) types of A gain. All these criteria are weaker than the never weak best reply criterion that requires an equilibrium to survive deletion of a player’s strategy that is not an optimal reply to any equilibrium with the same outcome. In Figure 6 this criterion is applied by observing that the second equilibrium does not survive deletion of those strategies of A in which type A2 chooses left.

A lexicographic equilibrium (Blume, Brandenburger and Dekel, 1991a; 1991b) uses a different construction. Each player is supposed to rely on a sequence of ‘theories’ about others’ strategies. He starts the game by assuming that his first theory of others' strategies is true, and uses his optimal strategy according to that theory. He continues doing so until he finds himself in a situation that cannot be explained by his first theory. In this case, he abandons the first theory and assumes instead that the second theory is true – or if it too cannot
Nash equilibrium, refinements of: The New Palgrave Dictionary of Economics

The construction of a perfect equilibrium (Selten, 1975) illustrates the basic method, which uses two steps.

1. For each small positive number \( \varepsilon \), one finds an \( \varepsilon \)-perfect equilibrium, defined by the requirement that each player's strategy has the following property: every one of his pure strategies is used with positive probability, but any pure strategy that is an inferior response to the others' strategies has probability no more than \( \varepsilon \). Thus an \( \varepsilon \)-perfect equilibrium supposes that every strategy, and therefore every action during the game, might occur, even if it is suboptimal.

2. One then obtains a perfect equilibrium as the limit of a convergent subsequence of \( \varepsilon \)-perfect equilibria.

One method of constructing an \( \varepsilon \)-perfect equilibrium starts by specifying for each player \( i \) a small probability \( \delta_i \leq \varepsilon \) and a randomized strategy \( \sigma_i \) that uses every pure strategy with positive probability – that is, the strategy combination \( \sigma \) is 'completely mixed'. One then finds an ordinary Nash equilibrium of the perturbed game in which each player's payoff from each combination of all players' pure strategies is replaced by his expected payoff when each player \( i \)'s pure strategy is implemented only with probability \( 1-\delta_i \) and with probability \( \delta_i \) that player uses his randomized strategy \( \sigma_i \) instead. In this context one says that the game is perturbed by less than \( \varepsilon \) toward \( \sigma \) – we use this phrase again later when we describe stable sets of equilibria. An equilibrium of this perturbed game induces an \( \varepsilon \)-perfect equilibrium of the original game.

An alternative definition of perfect equilibrium requires that each player's strategy is an optimal response to a convergent sequence of others' strategies for which all their pure strategies have positive probability – this reveals explicitly that optimality against small probabilities of deviations is achieved, and that a perfect equilibrium uses only admissible strategies. In fact, a perfect equilibrium of the agent-normal-form induces a sequential equilibrium of the dynamic version of the game. Moreover, if the payoffs of the dynamic game

Refinements derived from perturbed games

The other major class of refinements relies on perturbations to select among the Nash equilibria. The motive for this approach stems from a basic principle of decision theory – the equivalence of alternative methods of deriving optimal strategies. This principle posits that constructing a player's optimal strategy in a dynamic game by invoking auxiliary systems of beliefs and the iterative application of the principle of optimality (as in perfect-Bayes and sequential equilibria) is a useful computational procedure, but the same result should be obtainable from an initial choice of a strategy, that is, an optimal plan for the entire game of actions taken in each contingency. Indeed, the definition of Nash equilibrium embodies this principle. Proponents therefore argue that whatever improvements come from dynamic analysis can and should be replicated by static analysis of initial choices among strategies, supplemented by additional criteria. (We use the terms 'static' and 'dynamic' analysis rather than the technical terms 'normal-form' and 'extensive-form' analysis used in game theory.) The validity of this argument is evident in the case of subgame-perfect equilibria of games with perfect information, which can be derived either from the principle of optimality using backward induction, or by iterative elimination of weakly dominated strategies in a prescribed order. The argument is reinforced by major deficiencies of dynamic analysis; for example, we mentioned above that a sequential equilibrium can use inadmissible strategies. Another deficiency is failure to satisfy the criterion of invariance, namely, the set of sequential equilibria can depend on which of many equivalent descriptions of the dynamics of the game is used (in particular, on the addition or deletion of redundant strategies).

On this view one should address directly the basic motive for refinement, which is to exclude equilibria that assume implicitly that each player commits initially to his strategy – since Nash equilibria do not distinguish between cases with and without commitment. Thus one considers explicitly that during the game any player might deviate from his equilibrium strategy for some exogenous reason that was not represented in the initial description of the game. Recognition of the possibility of deviations, however improbable they might be, then ensures that a player's strategy includes a specification of his optimal response to others' deviations from the equilibrium. The objective is therefore to characterize those equilibria that are affected only slightly by small probabilities of deviant behaviours or variations in preferences. This programme is implemented by considering perturbations of the game. These can be perturbations of strategies or payoffs, but actually the net effect of a perturbation of others' strategies is to perturb a player's payoffs.

In the following we focus on the perturbations of the static (that is, the normal form) of the game but similar perturbations can also be applied to the dynamic version (that is, the extensive form) by applying them to each contingency separately. This is done by invoking the principle that a dynamic game can also be analysed in a static framework by treating the player acting in each contingency as a new player (interpreted as the player's agent who acts solely in that contingency) in the 'agent-normal-form' of the game, where the new player's payoffs agree with those of the original player.

The construction of a perfect equilibrium (Selten, 1975) illustrates the basic method, which uses two steps.
are generic (that is, not related to each other by polynomial equations) then every sequential equilibrium is also perfect. A stronger refinement selects *proper* equilibria (Myerson. 1978). This refinement supposes that the more inferior the expected payoff from a strategy is, the less likely it is to be used. The construction differs only in step 1: if one pure strategy S is inferior to another T in response to the others' strategies then S has probability no more than ε times the probability of T. A proper equilibrium induces a sequential equilibrium in every one of the equivalent descriptions of the dynamic game.

A perfect or proper equilibrium depends on the particular perturbation used to construct an ε -perfect or ε -proper equilibrium. Sometimes a game has an equilibrium that is *essential or truly perfect* in that any σ can be used when perturbing the game by less than ε toward σ, as above. This is usual for a static game with generic payoffs because in this case its equilibria are isolated and vary continuously with perturbations. However, such equilibria rarely exist in the important case that the static game represents a dynamic game, since in this case some strategies have the same equilibrium payoffs. This occurs because there is usually considerable freedom about how a player acts in contingencies off the predicted path of the equilibrium; in effect, the same outcome results whether the player ‘punishes’ others only barely enough to deter deviations, or more than enough. Indeed, for a dynamic game with generic payoffs, all the equilibria in a connected set yield the same equilibrium outcome because they differ only off the predicted path of equilibrium play. One must therefore consider sets of equilibria when invoking stringent refinements like truly perfect. One applies a somewhat different test to sets of equilibria. When considering a set of equilibria one requires that every sufficiently small perturbation (within a specified class) of the game has an equilibrium near some equilibrium in the set. Some refinements insist on a minimal closed set of equilibria with this property, but here we ignore minimality.

The chief refinement of this kind uses strategy perturbations to generate perturbed games. Kohlberg and Mertens (1986) say that a set of equilibria is *stable* if for each neighbourhood of the set there exists a positive probability ε such that, for every completely mixed strategy combination σ, each perturbation of the game by less than ε toward σ has an equilibrium within the neighbourhood. Stability can be interpreted as truly perfect applied to sets of equilibria and using the class of payoff perturbations generated by strategy perturbations. Besides the fact that a stable set always exists, it satisfies several criteria: it uses only *admissible* strategies, it contains a stable set of the reduced game after deleting a strategy that is weakly dominated or an inferior response to all equilibria in the set (these assure *iterative elimination of weakly dominated strategies* and a version of *forward induction*), and it is *invariant* to addition or deletion of redundant strategies. However, examples are known in which a stable set of a static game does not include a sequential equilibrium of the dynamic game it represents. This failure to satisfy the backward induction criterion can be remedied in various ways that we describe next.

One approach considers the larger class of all payoff perturbations. In this case, invariance to redundant strategies is not assured so it is imposed explicitly. For this, say that two games are equivalent if deletion of all redundant strategies results in the same reduced game. Similarly, randomized strategies in these two games are equivalent if they yield the same randomization over pure strategies of the reduced game. Informally, a set of equilibria is hyperstable if, for every payoff perturbation of every equivalent game, there is an equilibrium equivalent to one near the set. Two formal versions are the following. Kohlberg and Mertens (1986) say that a set S of equilibria is *hyperstable* if, for each neighbourhood N of those strategies in an equivalent game that are equivalent to ones in S, there is a sufficiently small neighbourhood P of payoff perturbations for the equivalent game such that every game in P has an equilibrium in N. A somewhat stronger version is the following. A set S of equilibria of a game G is *uniformly hyperstable* if, for each neighbourhood N of S, there is a δ larger than any equilibrium in the N -neighbourhood of any game equivalent to G has an equilibrium equivalent to one in N. This version emphasizes that uniform hyperstability is closely akin to a kind of continuity with respect to payoff perturbations of equivalent games. Unfortunately, both of these definitions are complex, but the second actually allows a succinct statement in the case that the set S is a ‘component’ of equilibria, namely, a maximal connected set of the Nash equilibria. In this case the component is uniformly hyperstable if and only if its topological index is non-zero, and thus *essential* in the sense used in algebraic topology to characterize a set of fixed points of a function that is slightly affected by every perturbation of the function. This provides a simply computed test of whether a component is uniformly hyperstable.

Hyperstable sets tend to be larger than stable sets of equilibria because they must be robust against a larger class of perturbations, but for this same reason the criterion is actually stronger. Within a hyperstable component there is always a stable set satisfying the criteria listed previously. There is also a proper equilibrium that induces a sequential equilibrium in every dynamic game with the same static representation – thus, the criterion of *backward induction* is also satisfied. Selecting a stable subset or a proper equilibrium inside a hyperstable component may be necessary because there can be other equilibria within a hyperstable component that use inadmissible strategies. Nevertheless, for a dynamic game with generic payoffs, all the equilibria within a single component yield the same outcome, since they differ only off the path of equilibrium play, so for the purpose of predicting the outcome rather than players' strategies it is immaterial which equilibrium is considered. However, examples are known in which an inessential hyperstable component contains two stable sets with opposite indices with respect to perturbations of strategies.

The most restrictive refinement is the revised definition of stability proposed by Mertens (1989). Although this definition is highly technical, it can be summarized briefly as follows for the mathematically expert reader. Roughly, a closed set of equilibria is (Mertens-) *stable* if the projection map (from its neighbourhood in the graph of the Nash equilibria into the space of games with perturbed strategies) is essential. Such a set satisfies all the criteria listed previously, and several more. For instance, it satisfies the *small-worlds* criterion (Mertens, 1992), which requires that adding other players whose strategies have no effect on the payoffs for the original players has no effect on the selected strategies of the original players. The persistent mystery in the study of refinements is why such sophisticated constructions seem to be necessary if a single definition is to satisfy all the criteria simultaneously. The clue seems to be that, because Nash equilibria are the solutions of a fixed-point problem, a fully adequate refinement must ensure that fixed points exist for every perturbation of this problem.
The state of the art of refinements

The development of increasingly stronger refinements by imposing ad hoc criteria incrementally was a preliminary to more systematic development. Eventually, one wants to identify decision-theoretic criteria that suffice as axioms to characterize refinements. The two groups of refinements described above approach this problem differently. Those that consider perturbations seek to verify whether there exist refinements that satisfy many or (in the case of Mertens-stability) most criteria. From its beginning in the work of Selten (1975), Myerson (1978), and Kohlberg and Mertens (1986), this has been a productive exercise, showing that refinements can enforce more stringent criteria than Nash (1950; 1951) requires. However, the results obtained depend ultimately on the class of perturbations considered, since Fudenberg, Kreps and Levine (1988) show that each Nash equilibrium of a game is the limit of strict equilibria of perturbed games in a very general class. Perturbations are mathematical artefacts used to identify refinements with desirable properties, but they are not intrinsic to a fundamental theory of rational decision making in multi-person situations. Those in the other group directly impose decision-theoretic criteria – admissibility, iterative elimination of dominated or inferior strategies, backward induction, invariance, small worlds, and so on. Their ultimate aim is to characterize refinements axiomatically. But so far none has obtained an ideal refinement of the Nash equilibria.

Nash program

Roberto Serrano
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article is a brief survey on the Nash program for coalitional games. Results of non-cooperative implementation of the Nash solution, the Shapley value and the core are discussed.

Keywords

cooperative games; core; Edgeworth, F.; Nash program; Nash solution; non-cooperative games; Shapley value; subgame perfect equilibrium; Walrasian outcome

Article

In game theory, ‘Nash program’ is the name given to a research agenda, initiated in Nash (1953), intended to bridge the gap between the cooperative and non-cooperative approaches to the discipline. Many authors have contributed to the program since its beginnings (see Serrano, 2005, for a comprehensive survey). The current article concentrates on a few salient contributions. One should begin by introducing some preliminaries and providing definitions of some basic concepts.

Preliminaries

The non-cooperative approach to game theory provides a rich language and develops useful tools to analyse strategic situations. One clear advantage of the approach is that it is able to model how specific details of the interaction may affect the final outcome. One limitation, however, is that its predictions may be highly sensitive to those details. For this reason it is worth also analysing more abstract approaches that attempt to obtain conclusions that are independent of such details. The cooperative approach is one such attempt.

Here are the primitives of the basic model in cooperative game theory. Let $N = \{1, \ldots, n\}$ be a finite set of players. For each $S$, a non-empty subset of $N$, we shall specify a set $V(S)$ containing $|S|$-dimensional
payoff vectors that are feasible for coalition $S$. Thus, a reduced form approach is taken because one does not explain what strategic choices are behind each of the payoff vectors in $V(S)$. In addition, in this formulation, referred to as the characteristic function, it is implicitly assumed that the actions taken by the complement coalition (those players not in $S$) cannot prevent $S$ from achieving each of the payoff vectors in $V(S)$. There are more general models in which these sorts of externalities are considered, but for the most part the contributions to the Nash program have been confined to the characteristic function model. Given a collection of sets $V(S)$, one for each $S$, the theory formulates its predictions on the basis of solution concepts.

A solution is a mapping that assigns a set of payoff vectors in $V(N)$ to each characteristic function $(V(S))_{S \subseteq N}$. Thus, a solution in general prescribes a set, although it can be single-valued (when it assigns a unique payoff vector as a function of the fundamentals of the problem). The leading set-valued cooperative solution concept is the core, while the most used single-valued ones are the Nash bargaining solution and the Shapley value.

There are several criteria to evaluate the reasonableness or appeal of a cooperative solution. One could start by defending it on the basis of its definition alone. In the case of the core, this will be especially relevant: in a context in which players can freely get together in groups, the prediction should be payoff vectors that cannot be improved upon by any coalition. Alternatively, one can propose axioms, abstract principles, that one would like the solution to have, and the next step is to pursue their logical consequences. Historically, this was the first argument to justify the Nash solution and the Shapley value. However, some may think that the definition may be somewhat arbitrary, or one may object that the axiomatic approach is ‘too abstract’. By proposing non-cooperative games that specify the details of negotiation, the Nash program may help to counter these criticisms. First, the procedure will tell a story about how coalitions form and what sort of interaction among players is happening. In that process, because the tools of non-cooperative game theory are used for the analysis, the cooperative solution will be understood as the outcome of a series of strategic problems facing individual players. Second, novel connections and differences among solutions may now be uncovered from the distinct negotiation procedures that lead to each of them. Therefore, a result in the Nash program, referred to as a ‘non-cooperative foundation’ or ‘non-cooperative implementation’ of a cooperative solution, enhances its significance, being looked at now from a new perspective. Focusing on the features of the rules of negotiation that lead to different cooperative solutions takes one a long way in opening the ‘black box’ of how a coalition came about, and contributes to a deeper understanding of the circumstances under which one solution versus another may be more appropriate to use.

The Nash bargaining solution

A particular case of a characteristic function is a two-player bargaining problem. In it, $N = \{1, 2\}$ is the set of players. The set $V(\{1, 2\})$, a compact and convex subset of $\mathbb{R}$, is the set of feasible payoffs if the two players reach an agreement. Compactness may follow from the existence of a bounded physical pie that the parties are dividing, and convexity is a consequence of expected utility and the potential use of lotteries. The sets $V(\{i\})_{i \in N}$ are subsets of $\mathbb{R}$, and let $d_i = \max V(\{i\})$ be the disagreement payoff for player $i$, that is, the payoff that $i$ will receive if the parties fail to reach an agreement. It is assumed that $V(\{1, 2\})$ contains payoff vectors that Pareto dominate the disagreement payoffs. A solution assigns a feasible payoff pair to each bargaining problem.
This is the framework introduced in Nash (1950), where he proposes four axioms that a solution to bargaining problems should have. First, expected utility implies that, if payoff functions are rescaled via positive affine transformations, so must be the solution (scale invariance). Second, the solution must prescribe a Pareto efficient payoff pair (efficiency). Third, if the set $V(\{1, 2\})$ is symmetric with respect to the 45 degree line and $d_1 = d_2$, the solution must lie on that line (symmetry). Fourth, the solution must be independent of ‘irrelevant’ alternatives, that is, it must pick the same point if it is still feasible after one eliminates other points from the feasible set (IIA). Because of scale invariance, there is no loss of generality in normalizing the disagreement payoff to 0. We call the resulting problem a normalized problem.

Nash (1950) shows that there exists a unique solution satisfying scale invariance, efficiency, symmetry and IIA, and it is the one that assigns to each normalized bargaining problem the point $(u_1, u_2)$ that maximizes the product $v_1v_2$ over all $(v_1, v_2) \in V(\{1, 2\})$. Today we refer to this as the ‘Nash solution’.

The use of the Nash solution is pervasive in applications and, following the axioms in Nash (1950), it is usually viewed as a normatively appealing resolution to bargaining problems.

In the first paper of the Nash program, Nash (1953) provides a non-cooperative approach to his axiomatically derived solution. This is done by means of a simple demand game. The two players are asked to demand simultaneously a payoff: player 1 demands $v_1$ and player 2 demands $v_2$. If the pair $(v_1, v_2)$ is feasible, so that $(v_1, v_2) \in V(\{1, 2\})$, the corresponding agreement and split of the pie takes place to implement these payoffs. Otherwise, there is disagreement and payoffs are 0. To fix ideas, let us think of the existence of a physical pie of size 1 that is created if agreement is reached, while no pie is produced otherwise. Thus, player $i$'s demand $v_i$ corresponds to demanding a share $x_i$ of the pie, $0 \leq x_i \leq 1$, such that player $i$'s utility or payoff from receiving $x_i$ is $v_i$.

The Nash demand game admits a continuum of Nash equilibria. Indeed, every point on the Pareto frontier of $V(\{1, 2\})$ is a Nash equilibrium outcome, as is the disagreement payoff point if each player demands the payoff corresponding to having the entire pie. However, Nash (1953) introduces uncertainty concerning the exact size of the pie. Now players, when formulating their demands, must have to take into account the fact that with some probability the pair of demands may lead to disagreement, even if they add up to less than 1. Then, it can be shown that the optimal choice of demands at a Nash equilibrium of the demand game with uncertain pie converges to the Nash solution payoffs as uncertainty becomes negligible. Hence, the Nash solution arises as the rule that equates marginal gain (through the increase in one's demanded share) and marginal loss (via the increase in the probability of disagreement) for each player when the problem is subject to a small degree of noise and demands/commitments are made simultaneously.

Rubinstein (1982) proposes a different non-cooperative procedure. In it, time preferences – impatience – and credibility of threats are the main forces that drive the equilibrium. The game is a potentially infinite sequence of alternating offers. In period 0, player 1 begins by making the first proposal. If player 2 accepts it, the game ends; otherwise, one period elapses and the rejector will make a counter-proposal in period 1, and so on. Let $\delta \in [0, 1)$ be the common per period discount factor, and let $v_i(\cdot)$ be player $i$'s utility function over shares of the pie, assumed to be concave and strictly monotone. Thus, if player $i$ receives a share $x_i$ in an agreement reached in period $t$, his payoff is $\delta^{t-1}v_i(x_i)$. Perpetual disagreement has a payoff of 0.
Using subgame perfect equilibrium as the solution concept (the standard tool to rule out non-credible threats in dynamic games of complete information), Rubinstein (1982) shows that there exists a unique prediction in his game. Specifically, the unique subgame perfect equilibrium prescribes an immediate agreement on the splits \((x, 1-x)\) – offered by player 1 – and \((1-x, 1-x)\) – by player 2 – which are described by the following equations:

\[
\begin{align*}
\nu_1(y) &= \delta \nu_1(x) \\
\nu_2(1-x) &= \delta \nu_2(1-y) .
\end{align*}
\]

That is, at the unique equilibrium, the player acting as a responder in a period is offered a share that makes him exactly indifferent between accepting and rejecting it to play the continuation: the bulk of the proof is to show that any other behaviour relies on non-credible threats.

As demonstrated in Binmore, Rubinstein and Wolinsky (1986), the unique equilibrium payoffs of the Rubinstein game, regardless of who is the first proposer, converge to the Nash solution payoffs as \(\delta \to 1\). First, note that the above equations imply that, for any value of \(\delta\), the product of payoffs \(\nu_1(x)\nu_2(1-x)\) is the same as the product \(\nu_1(y)\nu_2(1-y)\). Thus, both points, \((\nu_1(x), \nu_2(1-x))\) and \((\nu_1(y), \nu_2(1-y))\), lie on the same hyperbola of equation \(\nu_1\nu_2 = K\) and, in addition, since they correspond to efficient agreements, both points also lie on the Pareto frontier of \(V\{1, 2\}\). Finally, as \(\delta \to 1\), one has that \(x \to y\) so that the two proposals (the one made by player 1 and the other by player 2) converge to one and the same, the one that yields the Nash solution payoffs. Thus, credible threats in dynamic negotiations in which both players are equally and almost completely patient also lead to the Nash solution.

The Shapley value

Now consider an \(n\)-player coalitional game where payoffs are transferable in a one-to-one rate among different players (for instance, because utility is money for all of them). This means that \(V(S)\), the feasible set for coalition \(S\), is the set of payoffs \((x_i)_{i \in S}\) satisfying the inequality \(\sum_{i \in S} x_i \leq v(S)\) for some real number \(v(S)\). This is called a transferable utility or TU game in characteristic function form. The number \(v(S)\) is referred to as the ‘worth of \(S\)’, and it expresses \(S\)’s initial position (for example, the maximum total utility that the group \(S\) of agents can achieve in an exchange economy by redistributing their endowments when utility is quasi-linear).

Therefore, without loss of generality, we can describe a TU game as a collection of real numbers \((v(S))_{S \subseteq N}\). A solution is then a mapping that assigns to each TU game a set of payoffs in the set \(V(N)\), that is, vectors \((x_1, \ldots, x_n)\) such that \(\sum_{i \in N} x_i \leq v(N)\). In this section, as in the previous one, we shall require that the solution be single-valued. Shapley (1953) is interested in solving in a fair way the problem of distribution of surplus among the players, when taking into account the worth of each coalition. To do this, he resorts to the axiomatic method. First, the payoffs must add up to \(v(N)\), which means that the entire surplus is allocated (efficiency). Second, if two players are substitutes because they contribute the same to each coalition, the solution should treat them equally (symmetry). Third, the
solution to the sum of two TU games must be the sum of what it awards to each of the two games (additivity). Fourth, if a player contributes nothing to every coalition, the solution should pay him nothing (dummy).

The result in Shapley (1953) is that there is a unique single-valued solution to TU games satisfying efficiency, symmetry, additivity and dummy. It is what today we call the Shapley value, the function that assigns to each player \( i \) the payoff

\[
Sh_i(N, \nu) = \sum_{S, i \in S} \frac{(|S| - 1)!(|N| - |S|)!}{|N|!} \times [\nu(S) - \nu(S \setminus \{i\})].
\]

That is, the Shapley value awards to each player the average of his marginal contributions to each coalition. In taking this average, all orders of the players are considered to be equally likely. Let us assume, also without loss of generality, that \( \nu(\{i\}) = 0 \) for each player \( i \).

Hart and Mas-Colell (1996) propose the following non-cooperative procedure. With equal probability, each player \( i \in N \) is chosen to publicly make a feasible proposal to the others: \((x_1, \ldots, x_n)\) is such that the sum of its components cannot exceed \( \nu(N) \). The other players get to respond to it in sequence, following a pre-specified order. If all accept, the proposal is implemented; otherwise, a random device is triggered. With probability \( 0 \leq \delta < 1 \), the same game continues being played among the same \( n \) players (thus, a new proposer will be chosen again at random among them), but with probability \( 1 - \delta \) the proposer leaves the game. He is paid 0 and his resources are removed so that, in the next period, proposals to the remaining \( n-1 \) players cannot add up to more than \( \nu(N \setminus \{i\}) \). A new proposer is chosen at random among the set \( N \setminus \{i\} \), and so on.

As shown in Hart and Mas-Colell (1996), there exists a unique stationary subgame perfect equilibrium payoff profile of this procedure, and it actually coincides with the Shapley value payoffs for any value of \( \delta \). (Stationarity means that strategies cannot be history dependent.) As \( \delta \to 1 \), the Shapley value payoffs are also obtained not only in expectation but independently of who the proposer is. One way to understand this result, as done in Hart and Mas-Colell (1996), is to check that the rules of the procedure and stationary behaviour in it are in agreement with Shapley's axioms. That is, the equilibrium relies on immediate acceptances of proposals, stationary strategies treat substitute players similarly, the equations describing the equilibrium have an additive structure, and dummy players will have to receive 0 because no resources are destroyed if they are asked to leave. It is also worth stressing the important role in the procedure of players' marginal contributions to coalitions: following a rejection, a proposer incurs the risk of being thrown out and the others of losing his resources, which seem to suggest a 'price' for them.

**The core**

The idea of agreements that are immune to coalitional deviations was first introduced to economic theory in Edgeworth (1881), who defined the set of coalitionally stable allocations of an economy under
the name ‘final settlements’. Edgeworth envisioned this concept as an alternative to Walrasian
equilibrium (Walras, 1874), and was also the first to investigate the connections between the two
concepts. Edgeworth's notion, which today we refer to as ‘the core’, was rediscovered and introduced to
game theory in Gillies (1959). Therefore, the origins of the core were not axiomatic. Rather, its simple
definition appropriately describes stable outcomes in a context of unfettered coalitional interaction. (The
axiomatizations of the core came much later: see, for example, Peleg, 1985; 1986; Serrano and Volij,
1998).

For simplicity, let us continue to assume that we are studying a TU game. In this context, the core is the
set of payoff vectors \( \mathbf{x} = (x_1, \ldots, x_n) \) that are feasible, that is, \( \sum_{i \in N} x_i \leq v(N) \), and such that there does
not exist any coalition \( S \subseteq N \) for which \( \sum_{i \in S} x_i < v(S) \). If such a coalition \( S \) exists, we shall say that \( S \)
can improve upon or block \( \mathbf{x} \), and \( \mathbf{x} \) is deemed unstable. The core usually prescribes a set of payoffs
instead of a single one, and it can also prescribe the empty set in some games.

To obtain a non-cooperative implementation of the core, the procedure must embody some feature of
anonymity, since the core is usually a large set and it contains payoffs where different players are treated
very differently. Perry and Reny (1994) build in this anonymity by assuming that negotiations take place
in continuous time, so that anyone can speak at the beginning of the game instead of having a fixed
order. The player that gets to speak first makes a proposal consisting of naming a coalition that contains
him and a feasible payoff for that coalition. Next, the players in that coalition get to respond. If they all
accept the proposal, the coalition leaves and the game continues among the other players. Otherwise, a
new proposal may come from any player in \( N \). It is shown that, if the TU game has a non-empty core (as
well as any of its subgames), the stationary subgame perfect equilibrium outcomes of this procedure
coincide with the core. If a core payoff is proposed to the grand coalition, there are no incentives for
individual players to reject it. Conversely, a non-core payoff cannot be sustained because any player in a
blocking coalition has an incentive to make a proposal to that coalition, who will accept it (knowing that
the alternative, given stationarity, would be to go back to the non-core status quo). Moldovanu and
Winter (1995) offer a discrete-time version of the mechanism: in their work, the anonymity required is
imposed on the solution concept by looking at order-independent equilibria.

Serrano (1995) sets up a market to implement the core. The anonymity of the procedure stems from the
random choice of broker. The broker announces a vector \( (x_1, \ldots, x_n) \), where the components add up to \( v(N) \). One can interpret \( x_i \) as the price for the productive asset held by player \( i \). Following an arbitrary
order, the remaining players either accept or reject these prices. If player \( i \) accepts, he sells his asset to
the broker for the price \( x_i \) and leaves the game. Those who reject get to buy from the broker, at the called
out prices, the portfolio of assets of their choice if the broker still has them. If a player rejects but does
not get to buy the portfolio of assets he would like because someone else took them before, he can
always leave the market with his own asset. The broker's payoff is the worth of the final portfolio of
assets that he holds, plus the net monetary transfers that he has received. Serrano (1995) shows that the
prices announced by the broker will always be his top-ranked vectors in the core. If the TU game is such
that gains from cooperation increase with the size of coalitions, the set of all subgame perfect
equilibrium payoffs of this procedure will coincide with the core. Core payoffs are here understood as
those price vectors where all arbitrage opportunities in the market have been wiped out. Finally, yet
another way to build anonymity in the procedure is by allowing the proposal to be made by brokers
outside of the set $N$, as done in Pérez-Castrillo (1994).

Nash, John Forbes (born 1928)

Joel Watson
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Nash originated general non-cooperative game theory in seminal articles in the early 1950s by formally distinguishing between non-cooperative and cooperative models and by developing the concept of equilibrium for non-cooperative games. Nash developed the first bargaining solution characterized by axioms, pioneered methods and criteria for relating cooperative-theory solution concepts and non-cooperative games, and also made fundamental contributions in mathematics. Nash was the 1994 recipient of the Bank of Sweden Prize in Economic Sciences in Memory of Alfred Nobel, jointly with John C. Harsanyi and Reinhard Selten.

Article

The context of for Nash's work: von Neumann and Morgenstern

Nash's contributions to the theory of games were fundamental to the development of the discipline and its interface with applied fields of study. This section provides is a short account of the state of affairs before Nash's work. For a more detailed account, see the suggestions for further reading at the end of this article.

The first significant step in mathematical modelling of strategic situations was Augustin Cournot's (1838) book on oligopoly, where Cournot presented models of firm interaction that were analysed using what we now call Nash equilibrium. But Cournot did not attempt, or perhaps even recognize, how the analysis might generalize. Further, in the ensuing years confusion persisted regarding whether it would be appropriate for a firm to incorporate a response by its rivals when considering whether to change its own action. The concept of strategic independence – that the players' strategies can be considered to be
Game theory became a discipline with the work of John von Neumann (1928), which was incorporated into the path-breaking book by von Neumann and Oscar Morgenstern (1944; 1947). In the book, von Neumann and Morgenstern formally defined both the extensive form (tree-based) and normal form (strategy-based) representations of games, related by the notion of a strategy; they studied for the first time a general class of games, defining solutions and proving existence using fixed-point methods; they introduced the idea of analysing how coalitions of players can take advantage of binding agreements; and they provided a theory of utility and decision-making under risk (the expected utility criterion). With one book, game theory was created and put on solid footing.

Von Neumann and Morgenstern were interested in developing a positive theory of behaviour in games – for any given game, a ‘solution’. In a nutshell, their analysis progresses as follows:

1. Formulate a solution concept for two-player zero-sum games, which have the defining property that, for each strategy profile (one strategy for each player), the players' payoffs sum to zero. Such a game is special because the only economic concern is distributional; in other words, the game models a situation of pure conflict between the players, where one player's winnings come at the other's expense.

2. Analyse \( n \)-player zero-sum games by assuming that coalitions of players could bind together and play as a team against the other players. This requires assuming that coalitions can communicate before the game and make binding agreements on how to play. The value of forming a coalition is calculated in reference to the implied zero-sum game that the coalitions play against one another, which ultimately is a two-player game to which the solution from Part 1 above is applied.

3. To evaluate a non-zero-sum, \( n \)-player game, imagine the existence of a fictitious player \( n+1 \) whose payoff is defined as negative of the sum of the other players' payoffs. This creates a zero-sum game to which the preceding applies.

For an illustration of von Neumann and Morgenstern's analysis of two-player zero-sum games (Part 1 above), consider a simple example. Suppose that players 1 and 2 interact in the normal form game depicted in the following table.
Player 1 selects between strategies A, B, and C. Simultaneously, player 2 chooses between X, Y, and Z. The players' payoffs, which might as well be in
monetary terms, are shown in the cells of the table, with player 1’s payoff written first. Note that this is a zero-sum game in that, in each cell of the table, the players’ payoffs sum to zero.

Von Neumann and Morgenstern motivated their solution concept by considering sequential variations of games in which one player would move first and then the other player, having seen what the first selected, would respond. Their key concept is what is generally known as a ‘maximin strategy’, also called a ‘security strategy’. A security strategy for a given player is a strategy that gives the highest guaranteed payoff level; that is, it maximizes the minimum that the player could get, where the minimum is calculated over all of the strategies of the other player.

In the example, B and C are both security strategies for player 1 because, regardless of what player 2 does, player 1 gets a payoff of at least 1 when using either of these strategies, whereas it is feasible for player 1 to obtain a lower payoff (0 or −2, in particular) by selecting strategy A. For player 2, Y and Z are security strategies and they guarantee a payoff of at least −1.

Von Neumann and Morgenstern’s general analysis focuses on mixed strategies (probability distributions over pure strategies) in finite two-player games, to which the maximin definition extends. They prove that the players’ security levels (the amounts that the security strategies guarantee) sum to zero. Thus, when each player selects his security strategy, each player obtains exactly his security level payoff. Further, when one player selects his security strategy, the other player can do no better than select her own security strategy; that is, the two players’ security strategies are optimal responses to each other. Security strategies also describe optimal play in zero-sum games that are played sequentially. For example, if player 1 had the privilege of selecting among A, B, and C after observing player 2’s choice, both players would still select security strategies. Finally, security strategies are interchangeable in that the preceding conclusions hold equally well for any combination of security strategies, for instance (B, Y) as well as (B, Z).

Although von Neumann and Morgenstern had developed a theory that applied to all finite games, their theory is essentially empty for non-zero-sum games. For example, in converting a two-player game into a three-player game by adding the fictitious player 3, von Neumann and Morgenstern basically change the rules of the game for the original two players, who now can make binding agreements. The resulting prediction is that the two players will bind themselves to a strategy profile that maximizes the sum of their payoffs, with each player getting at least his security level. Von Neumann and Morgenstern’s theory is therefore incomplete and unsatisfying on two fronts. First, for non-zero-sum games, it offers no treatment of rationality in the absence of binding commitments. Second, it offers no way of predicting the outcome of a two-player bargaining problem beyond Francis Ysidro Edgeworth’s (1881) contract curve and it relies on transferable utility. Nearly all interesting economic examples involve efficiency concerns and hence are not zero-sum in nature, so economics had little to benefit from game theory until another significant step could be made in the modelling of rational behaviour.

### Nash’s contributions

Nash’s contributions to the emerging discipline of game theory were equally as bold as were von Neumann and Morgenstern’s and, in terms of applicability, even more significant. Nash’s main contributions were made in a series of four papers published between 1950 and 1953 and summarized in this section. In his articles in the *Proceedings of the National Academy of Sciences* in 1950 and the *Annals of Mathematics* in 1951, which reported his dissertation research, Nash (a) introduced and made clear the distinction between cooperative and non-cooperative games – the latter being games in which players act independently (that is, without the assumption about coalitions that von Neumann and Morgenstern adopted) – and (b) defined a solution concept for non-cooperative games. The first four paragraphs from Nash’s *Annals of Mathematics* article describe the context and the contribution succinctly:

Von Neumann and Morgenstern have developed a very fruitful theory of two-person zero-sum games in their book *Theory of Games and Economic Behavior*. This book also contains a theory of n-person games of a type which we would call cooperative. This theory is based on an analysis of the interrelationships of the various coalitions which can be formed by the players of the game.

Our Theory, in contradistinction, is based on the absence of coalitions in that it is assumed that each participant acts independently, without collaboration or communication with any of the others.

The notion of an *equilibrium point* is the basic ingredient in our theory. This notion yields a generalization of the concept of the solution of a
two-person zero-sum game. It turns out that the set of equilibrium points of a two-person zero-sum game is the set of all pairs of opposing 'good strategies.'

In the immediately following sections we shall define equilibrium points and prove that a finite non-cooperative game always has at least one equilibrium point. We shall also introduce the notions of solvability and strong solvability of a non-cooperative game and prove a theorem on the geometrical structure of the set of equilibrium points of a solvable game. (1951, p. 286)

Nash's equilibrium concept became known as 'Nash equilibrium'. It and the cooperative/non-cooperative distinction were cited by the Royal Swedish Academy of Sciences in awarding Nash the Nobel Prize.

In more mathematical and modern language, here are the definitions of best response (in Nash's words, a 'good strategy') and Nash equilibrium. Consider any game defined by a number \( n \) of players; a strategy set \( S_i \) for each player \( i = 1, 2, \ldots, n \); and, for each player \( i \), a payoff function \( u_i: S \rightarrow \mathbb{R} \), where \( S \) is the set of strategy profiles. The strategy sets may be defined as mixed strategies for some underlying set of pure strategies, in which case the payoff functions, as expectations, are linear in the mixed strategies. For a player \( i \), we write ‘\(-i\)’ to refer to the other players. Given a strategy vector \( s_{-i} \) for the other players, player \( i \)'s strategy \( s_i \) is called a best response if player \( i \) can do no better than to select \( s_i \); that is, we have \( u_i(s_i, s_{-i}) \geq u_i(s'_i, s_{-i}) \) for every strategy \( s'_i \) of player \( i \). Then strategy profile \( s^* = (s_1^*, s_2^*, \ldots, s_n^*) \) is called a Nash equilibrium if every player is best responding to the others—that is, if for each player \( i \), it is the case that \( s_i^* \) is a best response to \( s_{-i}^* \).

For an illustration of Nash equilibrium and its relation to security strategies, consider the game depicted in the following table.
Observe that, in this game, C and Y are the players' security strategies, so a naive application of von Neumann and Morgenstern's maximin theory (absent...

Nash, John Forbes (born 1928) : The New Palgrave Dictionary of Economics

Nash's argument, and fascinating theoretical result, established the profession's understanding of the connection between cooperative and non-cooperative equilibrium in the non-cooperative model justifies wide use of the cooperative solution as a reasonable shorthand for the actual non-cooperative setting. More significantly, Nash argued that the relation between the cooperative solution concept and the Nash bargaining solution is the forerunner to the enormous literature on equilibrium refinements. Nash's limit argument was the primary subject of Nash's Nobel co-recipients. Amazingly, Nash showed that the limit is unique and coincides with the prediction of his axiomatic model; that is, the limit is the Nash bargaining solution. Nash observed that the demand game has generally an infinite number of equilibria, revealing a coordination aspect to the bargaining problem. But Nash went further in developing a brilliant method to 'escape from this troublesome non-uniqueness' by looking at the limit of 'smooth' approximations of the demand game. That the game has multiple Nash equilibria demonstrates the general economic problem of coordination, in particular the possibility that the players will coordinate on the less efficient Nash equilibrium. Other games, such as the Prisoner's Dilemma, have only inefficient equilibria and thus reveal a fundamental tension between individual and joint incentives.

Nash's intuitive concept of equilibrium facilitated the analysis of all non-cooperative games, opening the door to widespread application of game theory. Indeed, Nash equilibrium has become the dominant solution concept for the analysis of games. Through an ingenious fixed-point argument, Nash also proved the existence of an equilibrium point in every finite game. Further, in his dissertation (1950) Nash offered two interpretations of the concept, one based on rational reasoning by individual players and the other describing stability of the distribution of strategies chosen by a population of individuals who interact over time. The latter is a precursor to the methodology of the literature on learning in games and to the modern theories of evolutionary stability in biology (John Maynard Smith, 1984). Nash's 1951 Annals of Mathematics article also contains a section that defines 'dominance' (meaning one strategy yields a strictly higher payoff than another, regardless of what the other players do) and explains how an iterated dominance procedure can be used to rule out strategies that are not equilibria. Thus, Nash also made observations that would resurface in the concept of 'rationalizable strategic behaviour' (B. Douglas Bernheim, 1984; David Pearce, 1984), the main non-equilibrium notion of rationality. Nash even was among the first to perform game experiments, as his co-authored article in the volume Decision Processes (Kalisch et al., 1954) attests.

In his 1950 Econometrica article, Nash tackled the two-person bargaining problem with the objective of determining a unique solution (a precise 'value') that eluded von Neumann and Morgenstern. Nash took a cooperative-theory approach by positing a system of four axioms that reasonably characterize properties one might expect the outcome of a bargaining process to exhibit: (a) a notion of equal bargaining power, (b) invariance to inessential utility transformations, (c) efficiency, and (d) independence of the solution to the removal of so-called irrelevant alternatives. Nash proved that a particular function of parameters (which maximizes the product of surpluses) is exactly characterized by the axioms. The analysis showed that it is possible to reasonably identify a precise outcome of a bargaining process. It also initiated the axiomatic method for the analysis of bargaining (where theorists explore how different axioms characterize various functional solutions), starting a literature that thrived for several decades. The Nash bargaining solution is still the dominant solution in applied economic models.

Nash's second paper on bargaining (the 1953 Econometrica article) took another major step by connecting the non-cooperative and cooperative approaches to strategic analysis. At the heart of this theoretical exercise is an underlying non-cooperative game, which gives a set of feasible payoffs, and a technology for the players to make binding commitments about the mixed strategies that they will play in the underlying game. In the model, players first simultaneously make threats, which are mixed strategies they are bound to play if they do not reach an agreement. Then the players interact in a non-cooperative bargaining game in which they simultaneously make payoff demands – this stage is now called the 'Nash demand game'. If their payoff demands are feasible in the underlying game, then the players obtain their demanded payoffs; otherwise, the players get what their threats imply.

Nash observed that the demand game has generally an infinite number of equilibria, revealing a coordination aspect to the bargaining problem. But Nash went further in developing a brilliant method to 'escape from this troublesome non-uniqueness' by looking at the limit of 'smooth' approximations of the demand game. Amazingly, Nash showed that the limit is unique and coincides with the prediction of his axiomatic model; that is, the limit is the Nash bargaining solution. Nash's limit argument was the forerunner to the enormous literature on equilibrium refinements, an area of research that thrived decades later and was the primary subject of Nash's Nobel co-recipients. More significantly, Nash argued that the relation between the cooperative solution concept and the equilibrium in the non-cooperative model justifies wide use of the cooperative solution as a reasonable shorthand for the actual non-cooperative setting.

Nash's argument, and fascinating theoretical result, established the profession's understanding of the connection between cooperative and non-cooperative
models and initiated the literature on what is now called the ‘Nash program’.

After completing the work in game theory just described, Nash made fundamental contributions in pure mathematics – contributions that, in terms of mathematical depth and originality, were of an even higher order of sophistication and importance. According to leading mathematician John Milnor, Nash's subsequent mathematical work is far more rich and important [in this mathematical sense]. During the following years he proved that every smooth compact manifold can be realized as a sheet of a real algebraic variety, proved the highly anti-intuitive C1-isometric embedding theorem, introduced powerful and radically new tools to prove the far more difficult C1-isometric embedding theorem in high dimensions, and made a strong start on fundamental existence, uniqueness, and continuity theorems for partial differential equations. (Milnor, 1998, p. 1330)

It is not appropriate to provide here details on Nash's pure mathematics work (nor is it possible, due to the limitations of the author's fields of expertise).

Nash's personal life

Nash's character became legendary with the publication of a biography by Sylvia Nasar (1998) and a 2001 feature film produced by Brian Grazer and Ron Howard. Nash's remarkable personal journey began in Bluefield, West Virginia, where he was born and raised. He explored mathematics and conducted science experiments as a child, and attended Carnegie Institute of Technology, where the mathematics department discovered in him a budding genius. Nash's ideas on bargaining that were published as ‘The Bargaining Problem’ (1950) were developed while he was an undergraduate student at Carnegie, during the only economics course he took, on international trade.

Nash studied mathematics in the graduate program at Princeton University, where, as his biography describes, he was boorish, cocky, and a renowned adversary in strategic contests. At Princeton, Nash added to his prodigious achievements, finishing his dissertation – the work on non-cooperative games and equilibrium that would bring him the Nobel Prize – in his second year. (Nash also invented the board game Hex, a game independently created by Danish mathematician Piet Hein.) Nash taught at Princeton for one year and then took a position at Massachusetts Institute of Technology, where he was on the faculty until 1959. There he conducted the research that won him great acclaim in the mathematics community.

Nash's genius in advancing game theory and mathematics was paired with deep personal challenges. In 1959 Nash began experiencing the severe mental disturbances of paranoid schizophrenia. He resigned from MIT and began a phase of life marked by delusional thinking, an escape to Europe, repeated hospitalizations, unsuccessful medical treatments, and then a long, disengaged presence at Princeton. In the mid-1980s Nash miraculously began to emerge from the delusional haze in what he describes as a gradual rejection of psychotic thinking on intellectual grounds (Nash, 1995). After a quarter century of detachment, Nash's life regained a measure of normality.

Nash's legacy in game theory and economics

There is no simple way of quantifying the enormous reach of Nash's ideas. The notions of Nash equilibrium, the Nash bargaining solution, the Nash demand game, and the Nash program have found such widespread acceptance and application that it has become customary, and perhaps even appropriate, for researchers to forgo formally citing Nash's articles when utilizing these concepts. Nash ideas helped to propel game theory from a mathematical sub-field into a full discipline, with major use and application in not only economics, where it is the main and worthy alternative to the competitive-market framework, but also in theoretical biology, political science, international relations and law.

Beyond its theoretical content, Nash's work also made a stylistic departure from that of von Neumann and Morgenstern, whose book methodically records definitions, examples, and analysis for numerous special cases in the process of developing general theory. Nash, in contrast, used the terse style of the mathematician, presenting his ideas with minimal obscuring features. His 1950 *Proceedings of the National Academy of Sciences* entry, for instance, is generously allotted two pages and could have been typeset on one. The benefit of focusing on the basic mathematical concepts is that it allows for a broad
range of interpretations and extensions. For example, there are several motivations for Nash equilibrium, including as a condition for self-enforcement of a contract (which is an important topic in the current literature). A hallmark of excellent theoretical modelling is precise and straightforward expression of assumptions and conclusions, with their relation shown in the most simple and elegant way possible.

Mathematician Milnor, after offering the assessment of Nash's work in pure mathematics that is quoted above, continues with by saying: ‘However, when mathematics is applied to other branches of human knowledge, we must really ask a quite different question: To what extent does the new work increase our understanding of the real world? On this basis, Nash's thesis was nothing short of revolutionary’ (1998, p. 1330). Two leading game theorists of today say ‘Nash's theory of non-cooperative games should now be recognized as one of the outstanding intellectual advances of the twentieth century’ (Myerson, 1999, p. 1067) and ‘His work lay the foundation of non-cooperative game theory, now the predominant mode of analysis of strategic interactions in economics, political science, and biology’ (Crawford, 2002, p. 380).

When viewed from the perspective of five short decades, game theory has caused a revolution in economics and other fields of study. It was with the work of John Nash that the flame so exquisitely ignited by von Neumann and Morgenstern became the torch that would eventually set the social sciences ablaze.

Bibliography

Items indicated with an asterisk provide good further background reading on John F. Nash, Jr. Also, the Scandinavian Journal of Economics, vol. 97, issue 1 (1995), contains articles on John Nash and his co-Nobel Prize recipients, John C. Harsanyi and Reinhard Selten. For a complete list of Nash's publications, including his papers in pure mathematics, see Milnor (1998).

With antecedents as far back as the late 17th century, national accounting is a product of the Great Depression, the Second World War and the subsequent period of recovery and economic growth. Soon after the war, country experiences and international harmonization processes interacted, eventually leading to a complete accounting framework with the 1993 SNA/ESA 1995. Until the mid-1970s, national accounting experienced a kind of golden age, after which greater difficulties arose, in terms of the increased complexity of economic life, widened social concerns and theoretical challenges. In that context, impressive achievements and a sense of frustration have coexisted.

**Article**

National accounting is a product of the 20th century, more precisely of the Great Depression, the Second World War and the subsequent period of recovery and economic growth. However, two and a half centuries earlier, estimates of national income had started with William Petty and Gregory King in England, and Vauban and Boisguilbert in France. This innovation in England, by the end of the 17th century, has been attributed to ‘the spirit of the age’ (Phyllis Deane, 1955), ‘an age of great intellectual vigour, scientific curiosity and inventiveness’ (Richard Stone, 1986). This early work had two main purposes: on the one hand, taxation and fiscal reforms, and on the other the assessment of the nations’ comparative economic strength in an age when England, France and the Netherlands were frequently at war. Exceptionally, King, an outstanding pioneer, made consistent estimates of various economic magnitudes (income, expenses, increase or decrease in wealth, and so on) for a series of years. However, as a rule, national income was estimated as an isolated magnitude using various methods. Estimates were intermittent and extended slowly (according to Studenski, 1958, national income had been estimated at least once for only eight countries by the end of the 19th century, and for some 20 by 1929. From 1850, earlier in England, evaluations of fortune or wealth, more numerous, were disconnected from national income estimates.

From national income estimate to national accounting

The influence of the First World War was limited, with some exceptions (for example, an NBER 1909–19 series in current and constant dollars published by Wesley Mitchell et al. in 1921–22). The 1929 crisis was a turning point. Official demand appeared (US Senate, 1932; Carson, 1975, p. 156) leading to a 1934 report prepared by Simon Kuznets and his assistants (National Income 1929–1932, in current prices, by type of economic activity and distributed income). Estimates were then extended to expenditures (final consumption and capital formation) by Clark Warburton. In a number of countries – the Netherlands (Jan Tinbergen), Sweden, Denmark (Viggo Kampmann) – large programs were developed, such as the one resulting in National Income in Sweden 1861–1930 published in 1937 by Erik Lindahl, Einar Dahlgren and Karin Koch. Working on his own, Colin Clark in the United Kingdom extended his previous 1932 estimates to a quite comprehensive coverage (National Income and Outlay, 1937).

The 1930s were a period of maturation in economics, apart from the conceptual and methodological deepening directly involved in this stream of quantitative estimates. The stimulus to quantitative macroeconomics given by Keynes's General Theory (1936) provided the theoretical basis for the estimation of interdependent economic aggregates, for the relationships between income and expenditure and between saving and investment were central to his argument. Such interrelationships had not previously been absent from economic theories (think of Quesnay's Tableau économique, Marx's reproduction schemes or Walras's general equilibrium analysis). However, after the Great Depression, such concepts and their statistical representations became central to macroeconomic concerns and policies. Keynes's works were focused on macroeconomic relations, but others sought representations of the economic system as a whole in different ways. Ferdinand Grüning in Germany (1933) analysed the economic circuit at a level later called ‘mesoeconomic’, half-way between the macro and micro levels. Wassily Leontief's research (1941) introduced input–output analysis at the level of homogeneous industrial groups, with a much broader view, in terms of general equilibrium, than the descriptive
national accounting, history of: The New Palgrave Dictionary of Economics
detailed balances of relations between branches (industries) prepared by P.I. Popov (1926) in the Soviet Union. The idea of an accounting approach for the economy as a whole, similar to the business accounting approach, was introduced either as a tool for improving national income estimates (as by Morris A. Copeland, following an intuition of Irving Fisher) or as part of a new proposed economic organization (André Vincent in France, Ed Van Cleeff in the Netherlands). The idea of micro/macro relationships was present in much of this work. Coming from a very different perspective, Ragnar Frisch developed an axiomatic, bottom-up representation of economic circulation.
The Second World War was the second, decisive, turning point. National accounting, often called at the beginning social accounting, crystallized in a direct response to the problem of war finance in the UK, as explicitly stated in the April 1941 White Paper (UK Treasury, *An Analysis of the Sources of War Finance and Estimate of the National Income and Expenditure in 1938 and 1940*). This was backed up by a technical paper by James Meade and Richard Stone in 1941. A more elaborated ‘social accounting’ system was soon proposed by Stone in an appendix to *Measurement of National Income and The Construction of Social Accounts* (published by the United Nations in 1947). Inspired by business accounting, it included sector accounts grouping accounting entities and their transactions organized according to a sequence of sub-accounts, with a set of detailed definitions and the discussion of many unsettled issues. Although it covered neither balance sheets nor a detailed analysis of the productive system, this accounting system was well ahead of its time. Actually, before and during the war, the United States was in advance in both national income and related aggregates estimates and their use, as for instance in the 1942 feasibility study of the Victory Program led by Kuznets or the analysis of the inflationary gap (Carson, 1975, p. 174–7). However, the National Income Division of the Commerce Department, with Milton Gilbert, evolved towards a simple accounting framework rather than a developed accounting system.
Though they encountered many difficulties and though it was a very uneven development, mostly due to deficiencies in statistical information and staffing, national accounting experienced a kind of golden age in the three decades following the war. Economic reconstruction and growth policies, the large increase in the economic role of government and the welfare state, the extension of international cooperation (for example, the Marshall Plan and, later, the Common Market in Europe), with the consequent emphasis on measuring of the rate of growth, led to a great demand for national accounts. This comprised the requirements of Keynesian macroeconomic demand management for short-term economic budget forecasts and longer-term projections needed for various types of indicative planning (the latter being particularly important in France). The development of econometric techniques and national accounts estimates reinforced each other. This trend towards greater use of national accounting data was general, even though the economies involved ranged from basically liberal economies such as the United States to more controlled economies such as France, the Netherlands and Norway.

International harmonization and extensions
Country experiences interacted with the process of international harmonization very early. Discussion between Canada, the UK and the USA took place in September 1944. There was a meeting of a League of Nations Committee, for which Stone prepares a memorandum, in December 1945. Stone played a prominent role in the first generation of standardized systems (OEEC, 1950; 1952; United Nations, 1959).
This first attempt at standardization across the Western world as a whole, however, was too limited in scope, and was very far from the ambitions of the 1945 accounting scheme. Conceived as a simplified model for countries that were only beginning to develop their national accounts, it could not meet the needs of countries that were already more advanced, such as Scandinavian countries (Odd Aukrust in Norway, Ingvar Ohlsson in Sweden) or even a country like France. Under the impulse of Claude Gruson, France was, in the 1950s, in order to implement far-reaching economic policies, beginning the process of building a comprehensive and ambitious system of its own, integrating accounts for economic agents, input–output tables and financial transactions in a way that was more integrated than the Copeland's money-flows accounts in the United States.

Until the end of the 1960s the Western stage was characterized by the existence of a variety of national systems that were difficult to reconcile, even among those countries that adopted, in principle, the same comprehensive concept of production, including non-market government services. The new French system adopted a narrower concept of production, limited to market goods and services. The Soviet Union and its satellites used the even more restricted concept of material production, limited to goods and the so-called material services (mostly the transport of goods), following the old tradition of Smith and Marx. However, during the 1960s intense international discussions took place, on the basis of the wide range of national experiences in Europe and North America and the demands of international organizations. The result was the adoption of a second generation of standardized systems, the 1968 System of National Accounts (SNA) and the new European System of Accounts (ESA 1970), prepared on the basis of a report by Stone for the UN (the OECD deleting its system) and a French expert for the European Community. The European Community, thinking the 1952 system was too narrow and unsuited to harmonizing the accounts of its original six members and to meeting the needs of Community policies, had decided in 1964 to establish its own system.

The new system (they can be described as a single system, for SNA and ESA were very close) was closer to Stone's 1945 inspiration and to the French, Scandinavian and British systems than to the 1952 standardized system, in terms of coverage (in particular of input–output tables and financial accounts), integration and institutional orientation. The main weakness remained the absence of balance sheets, despite the pioneering work of Raymond Goldsmith in the United States at the beginning of the 1960s. Fixed capital formation was limited to tangible assets and the relation between income and changes in wealth was not fully shown.

The System of Balances of the National Economy, built around the material product concept, was also standardized, though little innovation was involved, through the framework of the Council of Mutual Economic Assistance, and then published by the United Nations (1971). Careful comparisons between the SNA and the Material Product System (MPS) were carried out in the UN European Economic Commission in Geneva.

France decided to leave its own peculiar system and join, via ESA 1970, the international system, this being achieved by 1976. The USA was not actively involved in the elaboration of the 1968 SNA, keeping its National Income and Product Accounts, whose accounting and conceptual framework had evolved little since 1947.

A quarter of a century later, a third generation of normalized systems has taken the trend towards a universal system a step further. The 1993 SNA/ESA 1995 closed the accounting framework by including balance sheets and completing the accumulation accounts with the introduction of a revaluation account (holding gains and losses) and an account for other types of capital gains and losses. Intangible capital
formation was partly accounted for. In the current accounts, the analysis of income distribution was deepened (primary income distribution, secondary distribution, and redistribution in kind), actual final consumption was differentiated from final consumption expenditures, via the re-routing of social transfers in kind from government to households. This clarification of the accounting relation between income and changes in wealth (net worth) has deep implications (see below).

Nearly full integration was achieved between the SNA and the International Monetary Fund manuals (Balance of Payments, Government Finance Statistics, Monetary and Financial Statistics). The MPS disappeared at the beginning of the 1990s with the collapse of the Soviet Union and the fast transition of China towards a market economy. Paradoxically, the USA followed a slower path towards adopting the SNA framework.

During this long process of extension and harmonization of the accounting framework, the substance of the accounts changed dramatically in comparison with what was involved when the focus was on estimating national income. The product aggregate soon became the most important one, on a par with the expenditure aggregate. The income aggregate not only lost its position of being the single aggregate, but was often given a secondary position. From that, a series of consequences resulted.

The factor cost method of valuation, when still in use, was reduced to a lower rank than the market price valuation (in spite of the recurrent objection of ‘double counting’). The latter was much more convenient for the valuation of expenditure and the analysis of consumer behaviour. In an integrated framework, the market price valuation was then applied also to the product aggregate (domestic product takes progressively the first place) and much later on to the income aggregate. In the 1993 SNA, full recognition was given to the concept of national income at market prices, which is in fact the new name given to the earlier concept of national product (which was not actually a product but an income concept).

Partly for similar reasons, gross concepts have generally come to be preferred in practice, even though net concepts, that is, after deduction of consumption of fixed capital (depreciation in the usual business terminology), were considered closer to what was generally understood by the idea of national income. Both gross and net concepts of product, income and expenditure are finally considered part of the SNA/ESA.

The analysis and measurement of production and flows of products (goods and services), both in current value and in volume, have been given an increasing importance in relation to the integration of supply and use or input–output tables (a characteristic feature of the 1968 SNA/ESA 1970). This is increasingly done using the framework of annual tables. The integration with income estimates is less clear in practice, though the concept of value added, a significant improvement, and not only in words, on the old expression ‘net output’ or ‘net product’, provides the necessary link.

In this context, thanks to Stone’s contribution, significant improvements in valuation concepts were made in the 1968 SNA. This widens and differentiates the usual notion of market prices. Basic prices, excluding net taxes on products, were introduced on the output side, resulting in the measurement of value added at basic prices. All taxes, minus subsidies, on products are then introduced. On the use side, acquisition prices are defined as purchasers' prices including only non-deductible taxes.

Measures in constant prices (described as volume measures), combining quantity and quality changes, also changed significantly. The trend was from globally deflating national income using a single price index in the 1930s, to deflating each of the main items in the balance of products (output, final consumption, and so on) using specific indices, and finally to an integrated system of price and volume...
measures, at a detailed level, using an input–output framework when annual tables were available (with Denmark, France, the Netherlands and Norway leading here). Double deflation, of output and inputs respectively, was used for value added in this context. International manuals by Stone (1956; 1968 SNA, ch. 4) and Peter Hill (1972; United Nations, 1979) recommended such an approach. Later on the 1993 SNA/ESA 1995 recommended replacing the traditional fixed base indices with chain indices, preferably Fisher volume and price indices or acceptable alternatives.

Much more complex, both conceptually and practically, international comparisons of volume levels of aggregates were the object of an International Comparison Project (ICP), launched in 1968, after the pioneering research of Colin Clark (1940) and Gilbert and Irving Kravis (1954) at the OEEC. Purchasing power parities, more significant than exchange rates, were calculated. The results of the ICP, however, were not as widely implemented or as widely accepted as national volume measures, something that is unfortunate in a globalized world.

Beyond the progressive completion of its integrated framework, attempts were made to broaden the scope of national accounting by developing semi-integrated additional constructs, such as the satellite accounts whose idea was introduced (by Vanoli) by the end of the 1960 (for example, accounts for social protection, health, education, and environmental protection). In such an approach, the fully integrated system itself becomes the central framework (the expression often used, ‘core accounts’, is ambiguous).

Social accounting matrices (SAMs) were designed by Stone and Alan Brown in 1962, in order to achieve more flexibility than was possible using the usual account presentation. Though the word ‘social’ here means only ‘for the whole economy’, it gave rise to a certain ambiguity. SAMs are sometimes presented as a kind of alternative framework.

In the late 1980s, the Dutch proposed an ambitious ‘system of economy-related statistics’ as a way of organizing a vast array of statistics. A ‘core system’, narrower than the SNA central framework, was linked with ‘system modules’, such as social and environmental modules. This proposal had some similarity with the unsuccessful attempt by Stone, in the first half of the 1970s, to design for the United Nations a system of social and demographic statistics. It echoes the growing importance given to the micro–macro linkages (for example, Richard and Nancy Ruggles, 1986), in parallel with the increased availability of micro-databases.

Concern for statistical coordination had, of course, been present in national accounting from the very beginning.

**New challenges since the mid-1970s**

The achievements of national accounting, in the face of an enormous development of statistics, have been impressive. However, many countries are still far from fully implementing the international system (for example, few countries prepare integrated balance sheets), and economic and social conditions have changed drastically, especially since the mid-1970s. As a result national accounting, often questioned, sometimes radically, has had to face new challenges.

Since around 1980, after the supply shocks of the 1970s and the decreasing role played by macroeconometric models, national accounting has no longer been supported by the Keynesian paradigm. Some people even think it is obsolete. However, the demand for national accounts continues...
to grow, even if it also changes. Predominantly short-term concerns have led to a pressing demand for quarterly accounts, and even sometimes for a monthly GDP, resulting in conflicts between timeliness (early estimates are required) and accuracy. Though more accurate, through successive revisions, annual accounts seem less used and their results are less commented upon.

In the opposite direction, computable general equilibrium models have multiplied since the mid-1970s as a means of studying policies aimed at structural change. Without any concern for the setting up of time series, they are based on the accounts of a single year supplemented, as required, by other data dictated by the models' specificities and purposes. Although they use the somewhat misleading SAM terminology, they actually need national accounts bases.

It remains true, however, that for the study of structural and social policies economists and social researchers, since the last two decades of the 20th century, have generally preferred to make use of micro-simulation models. The role of national accounts data is relatively reduced in this context.

In contrast, a considerable extension of the institutional and political role of national accounting took place during the 1990s, mostly in Europe. Certain aggregates (GDP or GNP) had been used fairly early for administrative purposes such as country contributions to international organizations, eligibility thresholds to preferential World Bank loans, regional allocation of European structural funds, and the ‘Fourth own budgetary resource’ of the Community budget. However, the debate over accession criteria to the European Economic and Monetary Union (the creation of the euro) marked a qualitative jump in the consideration of national accounting by policymakers and public opinion. Most Maastricht criteria were defined in reference to the ESA (ratios of public deficit and public debt to GDP). The ESA became compulsory for member states of the European Union. This marked the culmination of the European statistical strategy adopted in the 1960s. Closely related to the international statistical systems, like the SNA, European statistical tools are in effect very often legally based.

The policy uses of the ESA necessitate effective harmonization of the content of the accounts. A procedure of verification and evaluation of the comparability and representativeness of GDP is established. Full harmonization is, however, difficult. Because conceptual and statistical issues and political considerations intervene, especially in the procedure for identifying excessive deficits, specific cases have to be studied, sometimes through a rather difficult process. Here, and in issues such as the ratio between compulsory levies and GDP, national accounts appear at the forefront of sensitive political concerns. While it clearly shows their importance, this situation may also have less positive aspects for the national accounts. There is the possibility of political pressures, though this is rare; there may be lack of flexibility; official obligations and procedures can be very time-consuming and, as a result of limited human resources, European national accountants may become insufficiently involved in research work.

No similar policy-led process is taking place at the world level. However the need for regulation on a global scale is increasingly felt. Monitoring and intervention aimed at remedying local and regional crises and at preventing systemic crises falls to the International Monetary Fund, in agreement with the principal economic powers. Hence the growing role of the IMF in the supply, by member states, of timely and well-documented harmonized information. In the last decade of the 20th century, the Fund set up a system of standards to guide countries in data dissemination, including meta-information concerning various characteristics of the data. The structuring role of national accounts has been particularly highlighted. The Fund has conducted assessment missions in order to evaluate the quality of countries' national accounts and data systems.
the background of economies which have become much more complex, and hence more difficult to
describe and measure, than was the case in the three decades following the Second World War. The
number and sophistication of available products have grown; changes in product quality have become
more rapid; the share of services, generally more difficult to measure, especially in volume, has
increased. The effects of technical change, opening the global economy, the transformation of
enterprises and groups, refinements of price policies and consumer behaviour, continuing financial
innovations, frequent extension of informal activities, and so on have caused a tendency for economic
information systems to maladjust. Hence many controversies arise, notably on price and volume
measurements of capital goods – quality change based on performances (Robert Gordon) or on resource
cost (the traditional solution championed by Edward Denison) – or measurement of consumption goods
and services, where the Boskin Report in the United States (Boskin, Dulberger and Griliches, 1996)
argued that the price increase was overestimated.

Significant methodological progress has been in areas such as the measurement of quality change of
durable goods based on the change in their performance, the US having taken the lead. However the
field is huge, and research is mostly concentrated on information and communication technology
products. The measurement of financial and insurance services is in progress. Intangible assets are
increasingly investigated. For non-market services, the necessary focusing on direct output–volume
measurement instead of the traditional input–volume approach opens, at the start of the 21st century,
another wide field of research. It soon appears that the relationship between the concepts of output and
outcome must be clarified. On the other hand, some very important issues, like interest and inflation, the
treatment of R&D expenditures and the extraction of subsoil resources, have remained outstanding for a
long time, defying consensus, though relevant solutions do exist.

After a long emphasis on the relationship between production, income and expenditure, national
accounting concerns have in recent decades been extended to the full set of relations between
production, income, accumulation and wealth. This raises complex issues concerning the analysis and
measurement of capital, particularly intangible assets, and consequently income. By the end of the 20th
century business accountants faced similar difficulties with the emerging international accounting
standards, moving from historical cost, which national accounting always rejected, to fair value
valuation of assets.

Thus, national accounting is fighting for a better coverage of its traditional object at the same time that,
at least since the early 1970s, new social concerns have given rise to requests for aggregate monetary
indicators synthesizing broader sets of phenomena. There remain things that national accountants cannot
do. One is the provision of a welfare indicator, a function that Kuznets assigned to national income, and
which gave rise, in the 1940s, to an intense debate involving John Hicks and Paul Samuelson that
reached negative conclusions. (William Nordhaus and James Tobin, 1973, later tried to provide such a
measure with their ‘measure of economic welfare’. ) Another is the measurement of an environmentally
adjusted domestic product. The suggestions in this direction included in the 1993 United Nations
Handbook, Integrated Environmental and Economic Accounting, do not reach a consensus and are not
implemented. There was then a move towards wanting a sustainable product or income measure, but this
does not make any answer easier, though Hicks's concept of income (the maximum amount that can be
consumed in a period while expecting total wealth to be unchanged at the end of it) has increasingly
been advocated in recent decades.

Most difficulties relate to the observation and measurement of non-market non-monetary flows and
stocks. Economists propose at least partial measurement solutions, within the framework of standard economic theory, using, for instance, contingent valuation methods (which raises problems of combination with actual exchange values, transfer of results and aggregation), or theoretical constructs with idealized conditions, seeking to justify a possible interpretation of net domestic product in terms of both welfare and sustainability. Other approaches, however, lean towards synthetic indicators combining both monetary and non-monetary variables. Tensions between social concerns, theoretical issues and observation constraints of actual economies are increasingly at stake.

National Bureau of Economic Research

Malcolm Rutherford

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The National Bureau of Economic Research was founded in 1920 and has been regarded as one of the leading research organizations in economics ever since. This entry deals briefly with the founding of the NBER, its early research on national income and business cycles, its later research directions and contributions, and some of the more important changes in organization and direction that have occurred up to 2007.

Keywords

Article

The National Bureau of Economic Research (NBER) was founded in January 1920, and from the moment of its founding was seen as one of the leading independent research organizations in economics in the world (Fabricant, 1984).

The NBER was established as an independent, non-partisan, research organization focused on empirical investigation. The original research orientation was towards ‘basic’ knowledge of the economy, but was, nevertheless, clearly intended to inform and improve the policymaking process. More recently the research focus has shifted to become more explicitly applied and policy orientated, but empirical work is still central to the bureau's mission. From the first, its Board included a large number of directors from various universities, scientific associations and other organizations. This and the system of manuscript review were designed to ensure the scientific impartiality of its work. These aspects of bureau organization still exist today.
The idea for an independent research bureau in economics sprang from discussions between Malcolm Rorty and N.I. Stone in 1916. Rorty was a statistician with AT&T, Stone an economist working as an arbitrator and economic advisor. Their policy views clashed but they could agree on the need for more reliable information. They involved Wesley Mitchell (Columbia), Edwin Gay (Harvard), and John R. Commons (Wisconsin, and then President of the American Economic Association). The First World War interrupted progress, but the experience of the war made the lack of quantitative information concerning the economy even more apparent, and by the AEA meeting of December 1919 all the necessary elements were in place.

The NBER began with a research agenda directed at the measurement of the size and distribution of national income, and the problem of business cycles. Wesley Mitchell was the first director of research, Edwin Gay the first president, while Rorty and Stone were members of the Board of Directors. Funding was obtained for a small research staff, originally consisting of Mitchell, Willford King, Frederick Macaulay and Oswald Knauth. The major financial contributors were the Commonwealth Fund, followed by the Carnegie Corporation, and, after 1923, the Laura Spelman Rockefeller Memorial Foundation (and its successor organization, the Social Science Division of the Rockefeller Foundation). The NBER also sold subscriptions and engaged in research commissioned by the President's Conference on Unemployment. In 1921 and 1922 the NBER published its first national income estimates: *Income in the United States: Its Amount and Distribution*. This was followed in 1923 by *Business Cycles and Unemployment*, produced by a special staff of the NBER for the President's Conference on Unemployment.

The NBER grew and prospered during the 1920s and early 1930s. The senior research staff were paid a modest stipend by the bureau, but generally held university appointments in the New York area. The bureau also employed research assistants and received funding for research fellowships and for statistical laboratory and library facilities. The research staff came to include Leo Wolman, F.C. Mills, Simon Kuznets, Arthur Burns and Solomon Fabricant. The bureau's research expanded to include Wolman's work on trade union membership, a substantial project on the topic of labour migration (undertaken by Harry Jerome, who was ‘borrowed’ from Wisconsin), F.C. Mills's extensive series of price studies, as well as further work on national income and business cycles. Mitchell produced the first of his projected volumes on business cycles, *Business Cycles: The Problem and its Setting*, in 1927. The bureau also continued its association with the President's Conference on Unemployment by contributing the research for *Recent Economic Changes in the United States* (1929). Kuznets took over the work on national income from King in 1931, and from 1933 he was ‘loaned’ to the Department of Commerce to work on the construction of official national income estimates. The first result of Kuznets's efforts was his report *National Income, 1929–32*, published in 1934.

A financial crisis in 1932 resulted in significant retrenchment at the bureau, which had suffered loss of income due to the Depression and faced uncertainty over the future of Carnegie support. The crisis was overcome thanks to the flexibility shown by Edmund Day of the Social Science Division of the Rockefeller Foundation, but Day expressed concerns with the bureau – its dependence on Rockefeller funding, its domination by a staff drawn heavily from Columbia University, and its lack of interaction with the broader academic community (Rutherford, 2005).

Rockefeller continued to fund the NBER core programmes on national income, business cycles, price and price relationships, the labour market, and savings and capital formation. The bureau also took on a programme of financial research funded by the Association of Reserve City Bankers and headed by
Ralph Young. Mitchell and Burns developed what became known as the ‘NBER method’ of specific and reference cycles to deal with the variations they found between cycles, but the project became ever larger. By the late 1930s the bureau's financial position had recovered and staff numbers again grew substantially, with Milton Friedman joining as an assistant to Kuznets in 1937 (he took over Kuznets's work on *Incomes from Independent Professional Practice*), Moses Abramovitz and Julius Shiskin arriving in 1938, and Geoffrey Moore, among numerous others, in 1939.

Day's concerns were not without results. A Universities National Bureau Committee was established in 1935 to examine the potential of NBER–university cooperation. Out of this came the Conference on Income and Wealth (headed by Kuznets) and the Conference on Prices (headed by Mills). The first of these was particularly successful, producing the series Studies in Income and Wealth from 1938 onwards. In addition, Joseph Willits joined the bureau in 1936 as executive director, to deal with administration and fund raising. In 1939, Willits was appointed as Director of the Division of Social Science of the Rockefeller Foundation, and the NBER enjoyed strong support from Rockefeller until Willits left that position in 1954 Rutherford 2005.

Mitchell retired as Director of Research and was succeeded by Arthur Burns in 1945. Kuznets and Burns disagreed over the future direction of the bureau. Kuznets wished to shift the research emphasis to long-run growth, while Burns wished to maintain the focus on business cycles. Kuznets was to pursue his interests through the Conference on Income and Wealth with the financial support of the Social Science Research Council. Burns stayed as Director of Research until appointed to the Council of Economic Advisers in 1953. He was succeeded by Solomon Fabricant. Burns, however, returned to the bureau as President in 1957 and regained much of his previous authority within the organization.

In 1946, Burns and Mitchell published *Measuring Business Cycles*, the result of almost 20 years of effort on the business-cycle project, and the much delayed second volume of the three that were planned. The final, theoretical, volume was never completed. *Measuring Business Cycles* drew sharp criticism from Tjalling Koopmans of the Cowles Commission for its failure to utilize a formal model. Although Koopman's 1947 characterization of the work as 'measurement without theory' is a misrepresentation of the Mitchell–Burns programme, there can be no doubt that Burns and others at the bureau were sceptical of what might be achieved by the econometric methods being pioneered at Cowles. Also at this time Burns was engaged in a criticism of Keynesian economics as represented by Alvin Hansen. For Burns, Keynesian theorizing was too speculative and not sufficiently well grounded empirically (Burns, 1946).

The period from the late 1940s through to the mid-1960s was a mixed time for the bureau. Some excellent projects were undertaken. Milton Friedman and Anna Schwartz began their work on US monetary history in 1948, a project that took until 1963 to publish. Friedman did other important work, particularly on consumption theory. Abramovitz worked on inventories and business cycles. George Stigler, who had joined the bureau staff in 1943, worked on output and employment trends. Geoffrey Moore refined the system of leading indicators for business cycles, and Morris Copeland developed the analysis of money flows, later to become flow of funds accounts. All the same, the focus of the bureau's efforts had become less sharp; it was conducting much work of lesser value, and running into considerable financial difficulty. Once Willits left Rockefeller, those at Rockefeller were not so sympathetic to the bureau's plight. With the exception of a programme on international economic relations, Rockefeller declined to continue funding the NBER, and in 1958 the bureau turned to the Ford Foundation. Ford established a review committee of Gardiner Ackley, Richard Ruggles, and George Stocking. They criticized the bureau, but recommended that Ford provide funding, which they did. This
allowed the bureau to continue, with relatively few changes until 1965. The research conducted over this period covered a wide range of projects that were loosely grouped into the categories of economic fluctuations, economic growth, wages and other incomes, the economic impact of government and international economic relations.

In 1965, Solomon Fabricant retired as Director of Research and was replaced by Geoffrey Moore, which was seen by many as a decision by the bureau to stay pretty much on its existing track. At the same time, Ford embarked on a major review of the bureau, again with a committee, but this time consisting of Emile Despres, R.A. Gordon, Lawrence Klein, Lloyd Reynolds, Theodore Schultz, George Shultz and James Tobin. This committee was sharply critical of the bureau, its leadership, project selection and research methods. Burns resigned as President and was replaced by John Meyer of Harvard. Meyer took over many of the functions previously held by the Director of Research, created two Vice Presidents of Research, and reorganized the bureau's efforts into specific programmes under their own Directors. Meyer also shifted the focus of the bureau's research into a number of new areas of social policy importance such as urban economics, health, human resources, education, environmental standards, the economics of the family, and crime and punishment. A number of important NBER studies were published during Meyer's term on subjects such as these by Theodore Schultz, Gary Becker, William Landes, Jacob Mincer and Victor Fuchs. Work on cycles was carried on, but no longer using the older NBER methods (Rutherford, 2005).

Meyer left the bureau in 1977 and was replaced as President by Martin Feldstein, also of Harvard. Feldstein has remained as President except for a few years when he was with the Council of Economic Advisors (1982–4), and Eli Shapiro took over. Feldstein brought about further changes at the bureau, doing away with the senior research staff employed directly by the bureau, and changing the bureau into an organization designed to promote and coordinate research being conducted by university-based ‘research associates’ funded largely by National Science Foundation and other research grants. This rearrangement vastly increased the bureau's involvement with the larger academic community. The focus has remained on empirical and policy-related research. Feldstein added programmes on issues such as aging, and asset pricing, and reinvigorated the NBER programmes on macroeconomics and on taxation. As of 2007, the NBER lists 17 major research programmes each involving 20 or more NBER research associates and each with its own director(s). These include aging, asset pricing, children, corporate finance, education, economic fluctuations and growth, health, industrial organization, international finance, labour, law and economics, monetary economics, productivity and public economics. In addition are smaller working groups working on another 16 topics from behavioural finance to the Chinese economy. The Conference on Income and Wealth also continues. Details of these programmes, those involved, and their publications can be found on the NBER website. The NBER's Research Associates now number about 600, and the NBER working paper series is a major research outlet. Links to the original NBER emphasis on measurement and business cycles are still to be found, however, notably in the NBER's data collection and in the Business Cycle Dating Committee.

Abstract

This article emphasizes how classical, neoclassical and real Keynesian economic theories are related to accounts of national income and its distribution. The more traditional parts of the analysis focus on rates of growth, capital accumulation and real net rates of return to capital, factorial distributions of income, and capital-theoretic problems in constructing matching national income accounts. More modern neo-Keynesian and monetary approaches are examined to account for theoretical roles played by money and banking in determining output, national income and technical progress. The effects of measures of banking output on modern national income accounts are stressed.

Article

Comprehensive systems of national accounts consist today of traditional national income, expenditure and product accounts, input output or production accounts, financial transactions and revaluation accounts (Rymes, 1992) and national balance sheets. While many parts of this modern system are expressed in current and constant prices, national income, its factor and individual income distributions are meaningfully expressed only in current prices. Constant price, or ‘quantity’, indexes are used to measure ‘real’ expenditures over time and across nations, in productivity studies both partial and for all factors again over time and across industries and countries (see Erwin W. Diewert's contributions in ILO, 2004, and IMF, 2004). Indeed, much of modern economic history can now be written in terms of the nominal and real economic accounts over time.

Yet, to date, no one has put together a comprehensive examination of the whole accounting system seen from a particular set or sets of economic theory. Theorists, such as J.R. Hicks, Richard Stone, Wassily Leontief and James Meade, and quantitative economic historians such as Simon Kuznets have made notable contributions to national accounting and have been so recognized with Nobel Prizes. The general lack of emphasis on the connection with economic theory, however, causes the poor student of economics to find the structure of the official accounts a bewildering maze of ‘uses and resources’, which seem more the product of much worthwhile international compromise than the development of the accounts from basic principles of economic theory. Anyone who has tried to teach economics students with the assistance of the 1993 System of National Accounts (SNA 1993, Washington, DC.; Commission of the European Communities; International Monetary Fund; OECD; United Nations; and the World Bank (sic)) will not find in all the bureaucratic compromises of admittedly needed reconciliation and international comparisons those flashes of illumination which economic theories can give. A recent OECD publication (Blades and Lequiller, 2006) further illustrates dangers of the lack of economic theory. It never adequately explains the economic meaning behind consumers ‘real’ expenditures and producers ‘real’ outputs making up GDP, though such knowledge must be held if the reader is to understand the very useful warnings about ‘real shares’ and additivity problems associated with index numbers. Thus it is sad to read one of the best practitioners of national accounting today asserting ‘… the conceptual foundations of the present model of the national accounts are...
being progressively undermined by the shifting quicksand of economic theory…’ (Ward, 2006, p. 327). Of course, Ward describes other eroding forces, but to give economic theory priority of place in conceptually undermining the accounts seems to me an error resulting from a despairing denigration of economic theory.
I concentrate here on how economic theory contributed to and conditioned national income accounting developments and to some extent how problems in constructing national accounts condition good economic theory. The central theme of this article, then, is the interplay between economic theory and national income accounting. Modern readers, especially students, once they see the interconnection between the accounts and economic theory, should find the national accounts as fascinating and exciting as I do and will each become, I hope, a ‘… passionate accountant’ (Lathen, 1974, p. 183).

Classical and neoclassical national income theories

David Ricardo argued the principal problem of political economy was the determination of the laws governing the distribution of national income among the classes of society (Ricardo, 1971, vol. 1, p. 5). His question was a major concern of classical economic theorists and it has returned to some pre-eminence among economists today (Milanovic, 2005). Consider the following set of extremely simple national income and expenditure accounts set out for a market economy to examine classical economic theory.

\[
\begin{array}{ccc}
\text{Incomes} & \text{Expenditures} \\
WL & PC & C \\
RP_K & PK & K \\
RP_N & PN & N \\
D_N & PN & N \\
\end{array}
\]
where National Income (Y) is shown as identically equal to National Final Expenditures (E) or Product. Examining the accounts for one country among many, one must distinguish between National Income and Domestic Product whereas, of course, World Income (WI) and World Expenditure or Product (WP) will be the same. Some economists regard the Domestic Product concept as more useful since it extracts from effects of the international redistribution of returns to capital. (For a contrary opinion, see Beckerman, 1987.) More technical but telling objections can be raised against the Domestic Product concept when it is expressed in constant price terms in a world experiencing technical change in which international trade takes place in intermediate inputs of production.

Why however, does Y identically equal E? If we imagine the accounts were for an even simpler world where there was no capital, then the equality among the circular flows would be clear. Owners of labour would sell their time to producers and the value of their expenditures for the goods produced would cover the cost of the producers. For an extensive discussion of circular flows and the crucial capital-theoretic problems in national accounting, see Hulten (2006).

On the Expenditure side of the accounts, \( P_{CK}K \) refers to the rates of depreciation or using up of capital in production. On the Expenditure side of the accounts, \( P_{CK}K \) is the values of the final consumption of the society, which, to many economists, is the be all and end all of economics. \( P_{CK}K \) represents the values of the gross capital formation taking place in the society. It is gross in that no allowance is taken of the fact that the new capital goods being produced may or may not be sufficient to replace the wear and tear on existing capital goods. Y and E refer then to Gross National Income and Expenditure respectively. One of the major theoretical problems in contemporary theory and classical and contemporary national income accounting is the meaning of capital and the conception and measurement of ‘maintaining capital intact’. Even today, despite advances in accounting and economic theory, it is difficult if not almost impossible empirically to measure well the ‘wear and tear’ on capital in modern economic systems. Where depreciation arises from obsolescence, so severe are the problems of measurement that almost all economists today use Gross Domestic Income (Product) or Expenditure as the principal aggregate for economic analysis. National income analysis, then, is greatly hampered by the fact that good estimates of capital consumption and the depletion of natural agents of production, again to say nothing of the degradation of the environment, are generally not available.

If we did have such estimates, the National Accounts just set out could be revised further to appear as

\[
Y = E
\]
where \( P_K (G - D)K = P_K nK \) is net capital formation, with \( n \) being the rate of growth so that one would be able to see how important net returns were to capital in net national income, which also in this case is said to measure 'sustainable' consumption.

The importance of the capital problem extends to the measurement of labour income as well. Today, wages are paid not so much for the application of pure labour time but for the services of the human capital accumulated by the individuals through expenditures on education, health and even the raising of families. On such capital expenditures, though there is a direct link between the forgoing of present consumption and the accumulation of capital by the individuals, the difficulties of measuring the depreciation on intangible human capital in the so-called knowledge economies are as bad as, if not worse than, those for physical capital. Yet the problem of measuring the returns to human capital gripped the classical economists as well.

One could argue that the consumption of the workers was not final at all, but was perhaps just sufficient to maintain the labour force either at a particular level or at a certain growth rate. Suppose we could extend all of the capital measurement thinking previously outlined to the classical and modern neoclassical treatment of labour. We could write off the consumption of the workers as required inputs into the maintenance of the labour force. Much of PC would vanish along with WL. The above accounts could be then even further dramatically reduced to

\[
\begin{align*}
\text{Incomes} & = & \text{Expenditures} \\
WL & \text{PC} \\
RP_K K & P_K (G - D)K = P_K nK \\
RP_{NN} & \\
Y^*N & = \equiv E^*N
\end{align*}
\]
The extreme classical Ricardian stationary state comes into focus, where the economy is said to have converged to a position where savings and accumulation have been pushed to the point where \( R \), the net rates of return, are positive but so low that net savings and the rate of growth of net capital stock and national income, \( n \), would be zero.

Though classical economists were aware that capital accumulation was unlikely to occur in given states of technology, the modern treatment of technical progress is to assume that it serendipitously occurs or, more interestingly, is an endogenous function of the rate of capital accumulation. If, however, technical progress were steadily occurring, then the long-period equilibrium of modern classical analysis and theory comes into view. If we ignore land and landholders, and if the consumption of the capitalists were some function of their income and the rate of return so that \( PC^* = c(R, RPK) \), then national income for steady growth, the modern variant of the Ricardian stationary state, becomes...

\[
\begin{align*}
\text{Incomes} & \quad \text{Expenditures} \\
\text{RP}_K K & \quad \text{PC}^* \\
\text{RP}_N N & \quad \text{PK}(G - D)K = \text{PK}nK \\
\hline
\text{Y**N} & \equiv \quad \text{E**N}
\end{align*}
\]

where \( PC^* \) is the consumption of the capitalists (and landholders).
that is, the economy may be said to have converged to an equilibrium where rates of return to capital exceeds the rate of growth of the income of the economy arising from technical progress, \( n' \), if the fraction of returns to capital saved, \( s \), is less than 1. If one assumes that the rate of technical progress is a function of \( R \), then the whole structure of the classical and neoclassical national income accounts can be boiled down to reflect basic theories

\[
\begin{align*}
R_{PK} - c((R)R_{PK}) &= \equiv Pn'K \\
(1 - c((R)R_{PK})) &= \equiv Pn'K \\
s(R)R &= \equiv n'
\end{align*}
\]

where the net rates of return to capital, the intertemporal prices in modern economies, are seen by the simplest accounts to be a function of the rates of saving, or intertemporal choice, and rates of technical change, itself the product of investing and expected rates of return, \( R^* \), themselves seen as some function of \( R \). Thus, we see that, when asking questions about the distribution of national income, the national accounts can be set out to illuminate the forces of growth which play vital roles in determining national income. It can also be seen that Ricardo's question about the determinants of the factorial distribution of national income lies at the very heart of modern economic analysis, of both the neoclassical and neo-Ricardian growth varieties (see Barro and Sala-i-Martin, 1995, in particular the chapter on growth accounting; and Pasinetti, 1995). While economic theories may be said to generate the accounts designed to illuminate them, we have seen that they also illuminate the great theoretical difficulties and aggregation problems associated with Professor Hulten's questions about capital theory.

Readers should please note that I am largely by-passing the severe capital-theoretic difficulties alluded to by him. One of Hulten's observations that ‘... all aspects of capital ultimately are derived from the decision to defer current consumption in order to enhance or maintain expected future consumption’ (2006, p. 195) means that capital is not a factor of production independently of the ‘willingness to wait’ and that multifactor productivity advance should be conceived as the improvement in the efficiency of working and waiting, \( n' \), rather than an improvement in the efficiency of labour and capital. The deep theoretical questions involved in measuring capital, the growth of nations and the aggregation questions may be resolved to some extent by the application of Leontief's disaggregated production and capital accumulation accounts (see Cas and Rymes, 1991; Rymes, 1997).
Keynesian theory

The Keynesian revolution clashed with classical and neoclassical theories and led to some of the modern ‘advances’ in national income accounting. Indeed, some national accountants argue that, partly as a result of Keynes and other theorists such as Jan Tinbergen, modern national accounting started in the 1930s (Bos, 2003; 2006). At the same time economic theory started paying increased attention to institutional forms such as corporations and governments. Under these influences, our simplified national accounts now appear as

\[
\begin{array}{cc}
\text{Incomes} & \text{Expenditures} \\
WL & P_{CC} \\
\Omega & P_{K\Delta K} \\
\hline \\
Y & \equiv \\
\hline \\
E & \end{array}
\]

where the net returns to capital and net rents on natural agents of production are largely replaced by corporate profits, \( \Omega \), which generally have measures of depreciation of limited economic meaning, and may or may not well reflect the distribution of interest to bondholders and dividends to shareholders with almost certainly no account being taken of capital gains and losses, and where the switch away from national income to gross national product reflects concern with unemployment rather than the level and the distribution of national income. When the revaluation accounts are added to the standard income accounts, theory again comes to the forefront.

Suppose that modern corporations distribute none of the profits or returns to capital they earn as dividends to their shareholders, ignoring for simplicity the payment of interest to bondholders, but reinvest their profits in the acquisition of capital goods for their firms. The value of the shares held by shareholders (and bought and sold among them) rise along with increases in the corporate stock of capital. It would appear from the national accounts as if the corporations did the saving whereas they may be used to test theories which have the corporations as mere intermediaries, whose investment decisions reflect the wishes of their shareholders.

The neo-Ricardian and Keynesian theories can be put together for the determination of not just the level but also the distribution of national income. If good estimates of the wear and tear on capital are available, one can revert from gross to net income and develop arguments addressed to the question of whether corporate firms and governments can affect the level and the distribution of national income. Here the national accounts can contribute to our knowledge of the extent to which individual households can be said to ‘see through’ corporate firms and governments in such matters as the Ricardian equivalence theorem (see Gillespie, 1980; 1991). To do this, the accounts must be prepared with the various theories of institutional forms in mind; otherwise they may be dismissed with some derision by contemporary theorists (Prescott, 2006).

When the personal distribution of national income is considered, national income accounts must be supplemented by longitudinal surveys of the distribution of income and wealth.
among individuals and families, the latter of which can be taken as representing constellations of individuals through time. Here again the theory of why certain families have such time preferences as to permit them to form dynasties requires much work if national income is to be so disaggregated so that those forces playing upon it may be extended to portray and explain individual and dynastic distributions of income and wealth.

Controversies among modern monetary theories and national accounting

Recent developments in monetary theory present great challenges to national accounting. Some monetary theories, those based fundamentally on the quantity theory of money, assert that once-over changes in ‘costless’ fiat money cannot have effects on such real phenomenon as national income, whereas continuous changes in such monies, affecting continuous changes in price indexes, may have rather dramatic effects. Yet, as national balance sheets and wealth accounts show, outside fiat monies are becoming increasingly marginal. How is national income affected by these matters?

National income reflects differences in the underlying classical, neoclassical and Keynesian theories. Keynesian models of unemployment rest upon the empirical and theoretical unimportance of outside or fiat money. Friedman argues, against the Keynesian position, that with real capital gains (losses) accruing to holders of money because of Keynesian disequilibria, real national income will tend to equilibrate at classical economic levels. Thus, if money wage rates and prices are falling because of unemployment, then, according to Friedman, the real income of people, holding given amounts of outside fiat money, will be positive, and will rise faster and faster and become bigger and bigger the more quickly prices fall, thus causing the unemployment to vanish even if there were some adverse effects on expenditures while the deflations were going on (Friedman, 1976, pp. 319–21). As monetary economies are characterized by less and less outside or fiat money, the less and less important is the Friedman counter to Keynes. The question which must be asked is this: is it meaningful to introduce capital gains and losses associated with deflations and inflations and the holding of fiat money into the revaluation accounts associated with national income estimates when, under modern monetary and central banking theory, such holdings, at least in the form of reserves with central banks, are vanishing?

The basic problem with the current national accounts is that we do not have meaningful measures of the output of private banks nor, even more importantly, of the output of central banks. If we applied the current method of imputation for the output of banks to modern central banks, their output would be seen to be zero (Rymes, 2004). Since the banks are the principal producers of transactions services and affect monetary production technologies, it follows that the inability of the national accounts to arrive at satisfactory measures of the output of banks in general means that they cannot measure satisfactorily production in monetary economies (see Fixler and Reinsdorf, 2006). Thus, though one of the central questions dividing Keynesian and neoclassical analyses and the effects of monetary developments on the concepts and measures of national income cannot be currently understood using the current national income accounts, even deeper questions emerge. Does the growth of banks and central bank policies affect capital accumulation, technical progress and national income? We simply do not know now!

Conclusion

The national income accounts have played central roles in the development of economic theory and analysis. Concepts and measures must be improved and developed to reflect better the fact that we live in monetary economies where we do not understand and do not accordingly measure well the outputs of banks and central banks, capital inputs, accumulation and technical progress, all which affect the distribution of national income. Ricardo’s question still needs answers. Our current theories and measures of national income need work. Readers and students should therefore realize that there is much exciting and profitable theoretical and empirical study remaining to be done in national income accounting.

Acknowledgements

I am indebted to Dr Harry Postner, with whom I collaborated in preparing a paper given at a session we organized on ‘National accounts and the teaching of economics’ at the 1998 meetings of the International Association for Research in Income and Wealth (IARIW), for his continued criticisms of my work. The most dispiriting finding of that session was how few departments around the world maintained courses in national accounting as part of their curricula. I think the reason is that official national accounting places too little emphasis on connecting with modern economic theories and accordingly lose too much academic contact. I alone am responsible for this basic theme in this article. I also record with much gratitude the extremely critical and penetrating comments on the initial draft made by Professor Duncan McDowall of the history department at Carleton. Professor McDowall took valuable time away from writing a history of the Canadian national accounts to comment on my manuscript. I am also much obliged to Professor Mark Bils whose suggestion for tightening the monetary part of the argument was useful indeed. Finally, I thank Michael James for making my article far more readable than I could.

The term ‘national system of political economy’ stems from a filiation of American and German ideas that arose in opposition to the universalist character of classical economics and were designed to promote public policies serving the economic development of the nation. The development was visualized as one that would yield a balance of agriculture and industry and make the most of a country's potential economic strength. The term ‘American system’ occurs as early as 1787 in No. 11 of *The Federalist*, where Alexander Hamilton launches this appeal to his readers: ‘Let the thirteen states, bound together in a strict and indissoluble Union, concur in erecting one great American system, superior to the control of all transatlantic force or influence and able to dictate the terms of the connection between the old and the new world.’

Hamilton's more detailed proposals regarding the ways and means to construct the American system can be found in his great state papers, written when he served as Secretary of the Treasury in President Washington's cabinet, and dealing with manufactures, a national bank, and the public debt. With the help of these three instruments he wished to emancipate the new nation from the rural economy of its forefathers, one that Thomas Jefferson, Hamilton's great antagonist, attempted to preserve. Among Hamilton's specific devices to promote industrial development, bounties, or subsidies, stood out. Later writers emphasized protective tariffs rather than bounties. These writers included Daniel Raymond, a Baltimore attorney, whose *Thoughts on Political Economy* of 1820, while not elaborating the notion of a national system in so many words, made a substantial contribution to the later interpretation of the term by introducing the concept of 'capacity' to produce goods, identified by him with national wealth. Raymond placed on government the duty of utilizing and enlarging this capacity by a policy of protection. His plea for protective tariffs was supported both by the infant-industry argument and the employment argument, in conjunction with which Raymond wrote...
explicitly of ‘full employment.’

The next step in elaborating the concept of a national system was taken by Frederick List, the German writer and promoter, who in 1827 during his residence in the United States published *Outlines of American Political Economy*. Like Hamilton, List writes of the ‘American system’, which was to realize its potential with the help of tariff protection. This work was written and distributed at the behest of a Pennsylvania manufacturers association whose members clamoured for tariff protection. Composed ostensibly in the form of letters addressed to a leading protectionist, the work appeared serially in the *National Gazette* of Philadelphia and was reprinted by more than 50 other newspapers. When published in pamphlet form, it was distributed in ‘many thousand’ copies, as List later reported. It was sent to the members of Congress and was apparently helpful in securing the adoption of the Tariff Act of 1828.

In an abortive attempt to win a prize, List wrote in French in 1837 an essay on *The Natural System of Political Economy*, which remained, however, unpublished until 1927, when it was printed in French and German. An English translation appeared only in 1983. This work anticipates in a number of respects List's principal work, *National System of Political Economy*, in which the national-system doctrine reached its full flowering. This work was published in German in 1841; an English translation, sponsored by protectionist interests in the United States, appeared in 1856, and another one, published in England, in 1885. The work, while substantial enough in itself, was intended to be the first part of a larger project, which, however, was never completed. Of the English translations, the earlier one omits the preface, while the later one contains extracts from the preface but omits the introductory chapter that provides a summary of the work.

In the *National System*, List finds fault with the classics for a variety of reasons. He takes them to task for having constructed a system of thought that is permeated by individualism and cosmopolitanism but neglects the nation. According to List, the community of nations is not a homogenous group but made up of members that find themselves at different stages of their development. List then goes on to construct a stage theory which visualizes progress from the agricultural stage to one in which agriculture is combined with industry, and to still another one in which agriculture, industry, and trade are joined together. List tends to equate agriculture with poverty and low level of culture, whereas industry and urbanization bring wealth and cultural achievement. The classics, with their homogenized picture of the world which neglected national differences, would tend to perpetuate the underdeveloped status of the United States and continental Europe vis-à-vis the highly developed Britain. According to List, each stage, or each nation at its respective stage, requires a different set of economic doctrines, whereas the classics claimed universal validity for their doctrines.

At heart, List wanted to improve on Providence by turning all people into Englishmen. To allow the underdeveloped countries of his time to participate in the march toward higher stages, attention would have to be paid to their productive capacities. The development and utilization of these was a task that List placed squarely on the national governments. In this connection List called for liberal political institutions, for the construction of what is now known as social overhead, especially in the form of transportation facilities, for balanced growth and for tariff protection for infant industries (not for agricultural products). The free-trade orientation of the classics List was willing to endorse as valid for the future, when all nations had utilized their potential and attained the most progressive stage. Then free trade would be combined with universal peace and a world federation.

There are a number of questions that List left unanswered. To begin with the most often heard objection to the infant-industry argument for protection, what tests are there to identify infant industries and to
mark their eventual attainment of maturity, when protection presumably is to terminate? Moreover, List
did not explain how the type of economic warfare that he envisaged would prepare the ground for
universal peace. Nor did he show awareness of the likelihood that, once all nations had progressed to
what he called the normal state one nation would again get ahead of the others, perhaps for reasons of
technological advances, a matter treated with so much insight by Hume in his analysis of the migration
of economic opportunities.
List had been a protectionist of sorts already in his young years in his native Germany. His protectionist
leanings came to the fore in the United States, where he encountered an even richer potential for
economic development and where changing economic conditions were more rapid and conspicuous.
Here List's strictures on the classics fell on fertile ground because so many features of their dismal
science did not seem to fit into the American environment, especially Malthus's population doctrine and
Ricardo's theories of subsistence wages, diminishing returns, and free trade. Thus List's work coalesced
with the works of native American critics of the classics, especially of Henry Carey, who developed
theories of increasing rather than diminishing returns and of rising wages and profits and declared that
each successive addition to the population brings a consumer and a producer. According to Samuelson,
Carey's 'logic was often bad and his prolix style atrocious. But his fundamental empirical inferences
seem correct for his time and place' (p. 1,732). Beginning in 1848, Carey became an ardent exponent of
protectionism. By this time List was dead and it is uncertain to what extent, if any, Carey was indebted
to List's thought. Neither of the two developed his proposal for tariff protection in isolation but as parts
of a wider system of thought, of a theory of economic development in the case of List and of a theory of
a harmoniously ordered society in the case of Carey.
Among political leaders in the United States Henry Clay is often mentioned as an architect of the
American system, in which the industrial east and the agrarian west were allied in a powerful union. He
pleaded for such a system in a famous speech in 1824, in which he supported protective tariffs as
instruments of industrial development. Later still, in 1870, Francis Bowen, an early teacher of
economics at Harvard, would publish American Political Economy, in which he supported tariff
protection and which caused him to lose his teaching job in economics, the president easing him into the
presumably less controversial field of history.
In Germany, List's ideas had a profound and lasting influence. He promoted the customs union, which
by 1844 covered almost all of Germany, and agitated for railroad construction and tariff protection. The
very name of economics in Germany, Nationalökonomie, conveys associations with List. Some German
interpreters of the history of economics have compared List with Marx. Both had utopian visions of a
society to come in the fullness of time. Both made much of a fusion of theory and practice and of
economics and politics. Both are linked by their reputation as rebels who opposed the established order.
It is an interesting trivium that in 1841 List turned down an offer to serve as the editor of a newspaper
that was to be published under the name of Rheinische Zeitung, a post that Marx filled the following
year.
List's thought has an affinity with the historical schools and institutional economists, who had ideas of
their own about the possibility of universally valid economic doctrines. The word 'system', cleansed of
its protectionist implications, continued to play a key role in the writings of such 20th-century German
economists as Walter Eucken and Werner Sombart. An equally faint echo of the Hamiltonian idea can
be discerned in the current usage of the word in conjunction with the study of comparative economic
systems.

natural and warranted rates of growth

J.A. Kregel
Edited by Steven N. Durlauf and Lawrence E. Blume

Article

The concepts of the natural and warranted rates of growth of national income, associated with the work of R.F. Harrod and E.D. Domar, were first developed in the 1930s and 1940s as part of the rethinking of the theory of economic fluctuations generated by Keynes's *General Theory*. Somewhat paradoxically, they formed an initial impetus for the theories for long-run steady growth elaborated in the 1950s and 1960s.

In the early 1930s Harrod criticized the static nature of economic analysis, suggesting that it be supplemented by a ‘dynamic’ theory: static theory determined the levels of variables, dynamic theory should explain the ‘rates of change’ of the variables taken at a point in time. Harrod's first attempt at dynamic theory, *The Trade Cycle* (1936), appeared almost simultaneously with Keynes's book, which Harrod considered limited to statics, even though it argued that the system could achieve equilibrium at less than full employment, because it dealt with the equilibrium *levels* of output and employment. After a lengthy correspondence with Keynes (cf. Keynes, 1973, pp. 151ff), Harrod published a new version of his theory, ‘An Essay on Dynamic Theory’, (1939) in which he formulated a ‘dynamic equilibrium’ for income, $Y$, defined as the ‘warranted rate of growth’ $g_w=(dY/dt)/Y$, to complement Keynes's static equilibrium. Due to the outbreak of war the theory did not attract attention until he presented it in a series of popular lectures (Harrod, 1948) after the war.

In Keynes's theory any level of output and employment, including full employment as a special case, was a potential equilibrium; the actual equilibrium was determined by the point of effective demand given the general state of expectations expressed in the propensity to consume, the marginal efficiency of capital and liquidity preference. Harrod was thus led to analyse a ‘dynamised version of Keynes’ … effective demand’ (Harrod, 1959), defined as the rate of growth produced by the rate of investment chosen by entrepreneurs which is warranted in the sense of maintaining a rate of expansion of effective demand which is consistent with entrepreneurial expectation and with individuals' autonomous decisions to save. The level of income, $Y_0$, prevailing at any point in time in the actual development of the economy will be determined by the entrepreneurs' expectations of the rate of growth of income $(dY/dt)/Y_0$. On the basis of the expected $dY/dt$ they will decide the investment necessary to satisfy this expected...
expansion in demand. This decision is made on the basis of the ‘capital coefficient’ (which Harrod called \( C \), but is now generally written as \( v \)), \( I_0 = v(dY/dt) \), defined as the total money expenditure that must be made on new investment projects to create an additional £ of output. The public’s decisions to spend and save expressed as \( S = sY_0 \) will then determine the actual increase in income via the multiplier \( (dI/dt)/s = dY/dt \). Entrepreneurs’ expectations will only be confirmed if \( v(dY/dt) = sY_0 \) which when rearranged produces Harrod’s famous growth equation \( g_w = (dY/dt)/Y_0 = s/v \), with \( SY_0 = I/Y_0 \) which is Keynes’s equilibrium. The rate of expansion of income is thus warranted and since entrepreneurs’ expectations have been confirmed they are presumed to expect income to continue to expand at that rate. Thus, given \( Y_0 \) and \( s \) there is a set of expectations which produces a dynamic equilibrium rate which will describe an expansion of income through time of \( Y = Y_t \exp(g_w t) \).

For Harrod, the analytical importance of his dynamics was to be found in the proposition that while in static analysis any departure from equilibrium produced centripetal forces driving the variable back to its equilibrium value, in dynamic analysis any movement away from equilibrium (in this case the warranted rate of growth of income) would set up centrifugal forces which would move the system further away from its equilibrium position. For example, if income were growing at the warranted rate and investment rose above the warranted rate, \( I_t > I_0 \exp(g_w t) \), income would expand at a higher rate, inventories would be drawn down and additional investment would be required to restore them to normal; the expectations which produced the warranted rate would be revised upwards as investment would appear insufficient relative to the expansion in sales, leading to further increases which would eventually surpass available labour and resources. Thus, instead of returning to the equilibrium rate, \( g_w \) an inflationary boom in which expectations would eventually be disappointed by shortages of supply, leads to a collapse of investment and expectations. Since the dynamic equilibrium is unstable, Harrod thus concludes that the warranted rate of growth is inherently unstable.

Just as in Keynes’s theory, there is no reason for the warranted rate to be associated with full employment, nor is there any reason for a disturbance of the system from a dynamic equilibrium to lead to a full employment rate. Disturbances will in general lead to a series of erratic booms and slumps of variable duration with respect to the warranted rate. The full employment rate of growth does however play a role in this cyclical process by setting a limit beyond which it is impossible for the economy permanently to grow, either in equilibrium or disequilibrium. If the rate of growth of potentially employable labour, given by the rate of population growth, is \( n = (dN/dt)/N \), the full employment rate of growth representing the maximum sustainable growth rate would be \( g = n = s/v \) unless technical progress expanded output per man employed. When available technical progress is used to increase labour productivity by \( \tau = (d(Y/N)/dt)/Y/N \) the maximum sustainable rate, which Harrod called the ‘natural’ rate, would be \( G = n + \tau \). The natural rate will only be an equilibrium position, i.e. a warranted rate, if households save the required proportion of income \( s_r \) which given the optimal introduction of new production techniques producing \( v_r \), is required to produce \( g_N = s_r/v_r = n + \tau \). Since there is no economic mechanism that links \( s \) and \( v \) to \( n \) and \( \tau \) the natural rate is unstable, but for different reasons than if it happened by chance to be a warranted rate.

Thus, for any actual state of the economy there will be a value for \( g_w \leq g_N \) which is given by the values of \( Y_0, v \) and \( s \) determined by the past history of the economy. There can, of course, be only one value for \( g_w \) since there cannot be more than one value of \( Y_0, s \) or \( v \) for any given point in time. If the economy
grows at some other rate, say $g_a$, then $Y$ will not expand along the warranted path $Y_t = Y_0 \exp(g_w t)$, so that the rate which would be required to produce warranted growth from any subsequent point in time, $t$, would depend on the actual values of $Y_t$, $s$ and $v$.

For example, if $g_a > s/v$, then $s_a > s$ and investment will continue to increase $g_a$ until the upper limit of $g_n$ is surpassed. This may be conceivable, for example in the period after a deep slump, but physical bottlenecks and increases in money wages due to labour market shortages will eventually lead to inflationary boom and a subsequent collapse back into a slump which will cause incomes and investment to fall, causing $s_a$ to fall. At any time in this process it would be possible to calculate on the basis of the level of income, $Y_t$, and associated $s$ and $v$, the rate of investment which, if adopted would produce warranted equilibrium growth from that time onwards. Although it is highly unlikely that the economy would adopt this rate, it serves as a benchmark with which to compare the actual behaviour of the economy and thus to predict the direction of its subsequent cyclical movements.

There will thus be a different, but unique, value of $g_w$ for every actual position of the system as it develops through time. Only if $g_w$ is in fact attained will the economy exhibit stable, non-cyclical growth, while departures from the rate will not set up self-correcting movements to instantly restore it. These two aspects of Harrod's theory have caused much misunderstanding. The fact that there is only one ‘unique’ or ‘knife-edge’ equilibrium growth path for any given $t$ and condition of the system has led some economists to consider this as the main cause of instability. Yet Harrod himself considered ‘instability’ to be an inherent property of the general concept of dynamic equilibrium as represented by the warranted growth rate. Since there would be only one warranted rate for any given condition of the economy it could be used to explain the cyclical behaviour of the economy if $g_a$ diverged from $g_w$. But in Harrod's theory there would be a new warranted rate for every new combination of $Y$, $s$ and $v$ thrown up by the actual growth of the economy; $g_w$ was only unique because each point in time was characterized by unique conditions. The role of the instability property of the warranted rate, given the natural rate, was to explain how the system would move when it was not growing at its dynamic equilibrium rate.

Domar (1946, 1947), writing after the publication of the General Theory, reacted to a specific problem in Keynes's theory, pointing out that the very investment expenditure that provides the demand for the output of existing productive capacity implies increased productive capacity in future periods. Investment as a means of increasing aggregate demand is thus a ‘mixed blessing’, for if the investment sufficient to prevent unemployment today creates excess capacity tomorrow then even more investment will be required tomorrow. Long-run unemployment could be avoided only by increasing investment at an increasing rate. To analyse this problem it was inevitable that Domar recast Keynes's analysis in terms of rates of change.

Domar approached the problem by separating the influence of investment on aggregate demand and on productive capacity or supply. Keynes had already provided the analysis of demand in terms of the multiplier ($k = 1/s$) giving the expansion in demand resulting from increasing investment as $dY/dt = k(dI/dt)$. On the supply side, however, since all of net investment, and not only the increase, expands productive capacity Domar amends Keynes's approach and considers the fraction of the labour force employed as a function of the ratio of income to potential productive capacity rather than as a simple function of income. Defining $\alpha$ as the net value added produced by a £ of net investment, potential

\[ \alpha = \frac{\text{net value added}}{\text{net investment}} \]
productive capacity will then increase by $\alpha I$ where $I$ is the aggregate cost of new investment projects. On the micro level, however, some new capacity will be competing with older capacity, and since some investment projects will be carried out on the basis of expectations which will not be realized, Domar defines $\sigma$ as the ‘potential social average productivity of investment’ for the economy. The divergence between $\alpha$ and $\sigma$ (as well as the assumption that $\alpha < \sigma$) thus represents errors in investment decisions, investment outpacing the growth in the labour force or investments incorporating inappropriate technology. The supply-side effect is thus $\frac{dY_S}{dt} = \sigma I$. The answer to Domar's question of whether there is a constant rate of growth of investment at which the demand will rise sufficiently rapidly to offset the effect of investment on supply is thus found where $\frac{dY_d}{dt} = \frac{dY_S}{dt}$ or where $k(\frac{dI}{dt}) = \sigma I$. This equality can be rewritten as $\frac{(dI/dt)}{I} = \sigma / k$ which Domar calls the ‘required’ rate of growth of investment.

Domar's assumption that unemployment is determined by the relation of income to potential capacity means that the ‘required’ rate implies full capacity utilization and thus full employment. The failure of the economy to grow at this rate implies excess capacity. If productive potential arising from net investment $\sigma I$ is defined as $P$, $\sigma = \frac{(dP/dt)}{I}$, then a coefficient of utilization determined by the relative expansion of demand and capacity can be defined as, $\theta = \frac{(dY_d/dt)}{(dP/dt)}$. Since $dY_d/dt = k(\frac{dI}{dt})$ and $dP/dt = \sigma I$, $\theta$ can be written as $\frac{(dI/dt)}{I} \cdot \frac{1}{k/\sigma}$ assuming that $\alpha = \sigma$. If investment is expanding at the required rate $(\frac{dI/dt)}{I} = \sigma / k$, $dY_d/dt = dP/dt$ and $\theta = 100$ per cent capacity utilization. Domar's required rate is thus equivalent to Harrod's natural rate of growth $(sr/vr)$ when $\alpha = \sigma$ since $k = 1/s$ and $\sigma = \frac{(dY/dt)}{I} = 1 / vr$, $\sigma / k = s / vr$.

Domar's analysis of divergence of the actual growth rate from the 'required' rate also produces an analysis of instability, for when $(dI/dt)/I$ is below $k/\sigma$ the required rate, $dY_d/dt$ is less than $dP/dt$, so part $(1 - \theta)$ of new productive potential is unused. This excess capacity thus implies the existence of unemployment. A higher rate of growth of investment would be required to eliminate the excess capacity and unemployment, but since current productive capacity is already excess to needs, entrepreneurs are more likely to try to reduce than to increase their desired capacity by lowering $(dI/dt)/I$, which will increase rather than decrease both unemployment and excess capacity, producing a slump. Thus, in difference from Harrod's analysis, the natural rate is a unique equilibrium or 'knife edge' rate as well as being unstable. For Domar, instability is not linked to the conceptual definition of dynamic equilibrium by means of a warranted rate, but rather to the 'paradox' that is the dynamic equivalent to the Keynesian paradox of saving: given $s$, the elimination of excess capacity, whether it is caused by the effects of investment on the expansion of demand or productive capacity, requires more capital to be built, while a shortage of productive capacity requires a reduction in the rate of growth of investment. This result is parallel to Harrod's statement to the effect that a general glut of commodities is due to entrepreneurs producing too little rather than too much.

While both Harrod and Domar sought to use the concepts of warranted and natural or required rates as an aid to understanding the cyclical implications of Keynes's analysis, and despite the differences in their approach, their work served to form the basis of what came to be known as the 'Harrod–Domar' theory of steady growth. By interpreting the variables $s$ and $v$ as being given exogenously the theory produced what Kaldor (1951) called 'Harrod's problem', or as Joan Robinson (1965, p. 52) put it:

Given $s$,... and $v$,... $g$ is determined. There is only one value of $g$ which (provided it does
natural and warranted rates of growth: The New Palgrave Dictionary of Economics

not exceed \( n \) is not impossible. The uniqueness of \( g \), not any question about the stability of the corresponding growth path, created the problem of the ‘knife edge’.

This ‘problem’ was ‘resolved’ by introducing differential savings propensities from wages and profits to make \( s \) a variable determined by the distribution of income, which would allow multiple long-period unemployment growth equilibria, as in the post-Keynesian theories of growth and distribution. Alternatively (cf. e.g. Solow, 1970, ch. 2), if movements in relative prices of capital and labour services are allowed to produce substitution of capital for labour, as in an aggregate production function, then \( v \) would become variable over time and lead to the full employment of both factors, despite Domar’s (1952, pp. 23–6) explicit warning that the introduction of a Cobb–Douglas production function to solve this problem would lead directly to this traditional pre-Keynesian result.

These two conflicting interpretations of the applicability of Keynes’s unemployment equilibrium in the long period, soon enlarged to include the wider question of capital theory, created a debate in which steady state theories overwhelmed the interests of both Harrod and Domar in the implications of Keynes’s theory for the problem of economic fluctuations and dynamics.

natural experiments and quasi-natural experiments

J. DiNardo
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Natural experiments or quasi-natural experiments in economics are serendipitous situations in which persons are assigned randomly to a treatment (or multiple treatments) and a control group, and outcomes are analysed for the purposes of putting a hypothesis to a severe test; they are also serendipitous situations where assignment to treatment ‘approximates’ randomized design or a well-controlled experiment.

Keywords

experiment; natural experiments; quasi-natural experiments; randomization; regression discontinuity design; returns to schooling; social experiments; treatment effect

Article

The term ‘natural experiment’ has been used in many, often, contradictory, ways. It is not unfair to say that the term is frequently employed to describe situations that are neither ‘natural’ nor ‘experiments’ or situations which are ‘natural, but not experiments’ or vice versa.

It will serve the interests of clarity to initially direct most of our attention to the second term – experiment. A useful, albeit philosophically charged definition of an experiment ‘is a set of actions and observations, performed in the context of solving a particular problem or question, to support or falsify a hypothesis or research concerning phenomena’ (Wikipedia, 2006).

With such a broad definition in hand, it may not be surprising to observe a wide range of views among economists about whether or not they perform experiments. Vernon Smith, for example, in experimental methods in economics, begins with the premise that ‘historically, the method and subject matter of economics have presupposed that it was a non-experimental … science more like astronomy or meteorology than physics or chemistry’ (emphasis added). As he makes clear, his observation implies that today, economics is an experimental science. Bastable's article on the same subject in the first edition of The New Palgrave overlaps only superficially with Smith's and divides experiments along the lines suggested by Bacon: experimenta lucifera, in which ‘theoretical’ concerns dominate, and experimenta fructifera, which concern themselves with ‘practical’ matters. In sharp contrast to Smith, Bastable concludes that experimenta lucifera are ‘a very slight resource’ (1987, p. 240) in economics.

These two views of experiment, however, do not seem helpful in understanding the controversy regarding natural experiments. ‘Experiment’ in our context is merely the notion of putting one's view to the most ‘severe’ test possible. A good summary of the the spirit of experiment (natural or otherwise) comes from the American philosopher Charles Sanders Peirce (and see Mayo, 1996 for a nice exposition of this and related points):

[After posing a question or theory], the next business in order is to commence deducing from it whatever experimental predictions are extremest and most unlikely … in order to subject them to the test of experiment.

The process of testing it will consist, not in examining the facts, in order to see how well they accord with the hypothesis, but on the contrary in examining such of the probable consequences of the hypothesis as would be capable of direct verification, especially those consequences which would be very unlikely or surprising in case the hypothesis were not true.

When the hypothesis has sustained a testing as severe as the present state of our knowledge … renders imperative, it
will be admitted provisionally … subject of course to reconsideration. (Peirce, 1958, 7.182 (emphasis added) and 7.231 as cited in Mayo, 1996)

The philosophy of experimentation in natural science

In the emergence of modern natural science during the 16th century, experiments represented an important break with a long historical tradition in which observation of phenomenon was used in theories as a way to justify or support a priori reasoning. In Drake's (1981) view: ‘The Aristotelian principle of appealing to experience had degenerated among philosophers into dependence on reasoning supported by casual examples among philosophers and the refutation of opponents by pointing to apparent exceptions not carefully examined.’ In the useful historical account provided by Shadish, Cook, and Campbell (2002) it is suggested that this ‘break’ was twofold: first, experiments were frequently employed to correct or refute theories. This naturally led to conflict with political and religious authorities: Galileo Galilei's conflict with the Church and his fate at the hands of the Inquisition is among the best-known examples of this conflict. Second, experiments increasingly involved ‘manipulation’ to learn about ‘causes’. Passive observation was not sufficient. As Hacking (1983, p. 149) says of early experimenter Sir Francis Bacon: ‘He taught that not only must we observe nature in the raw, but that we must also “twist the lion’s tail”, that is, manipulate our world in order to learn its secrets.’ Indeed, at some level in the natural sciences there has been comparatively little debate about the centrality of experiment – ironically, it has typically been only philosophers of science who have downplayed the importance of experiment. Hacking (1983) makes a strong case that philosophers typically have exhibited a remarkably high degree of bias in minimizing their importance in favour of ‘theory’. Until the 19th century, the term experiment was typically reserved for studies in the natural sciences.

In the low sciences such as economics and medicine, the role of experiment is been the subject of extensive debate, much tied up with the debate on whether all the types of experiments possible in real science are possible in economics as well as with debates about the many meanings of the word ‘cause’.

A key distinction between much real science and economics involves the centrality of ‘randomization’. No randomization is required, for example, to study whether certain actions will produce nuclear fission, since ‘control’ is possible: if a set of procedures applied to a piece of plutonium – under certain pre-specified experimental conditions – regularly produces nuclear fission, as long as agreement exists on the pre-specified conditions and on what constitutes plutonium, and so on, it is possible to put the implied propositions to the type of severe test that would gain widespread assent – all without randomization. Put in a different way, randomization is required only when it is difficult to put a proposition to a severe test without it.

A related issue is whether a study of ‘causes’ requires some notion of ‘manipulation’. Most definitions of ‘cause’ in social science involve some notion of ‘manipulation’ (Heckman, 2005) – Bacon's ‘twisting of the tail’, so to speak. In physics, by way of contrast, some important ‘causes’ do not involve manipulation per se. One might argue that Newton's law of gravitation was an example of a mere empirical regularity that became a ‘cause’. Indeed, when proposed by Newton, Leibnitz objected to this new ‘law’: in the prevailing intellectual and scientific climate where the world was understood in terms of ‘mechanical pushes and pulls’, this new law seemed to require the invocation of ‘occult powers’ (Hacking, 1983). (There is an element of irony in Leibnitz's objection. Leibnitz is believed by some to be the object of Voltaire's satire as the character Dr Pangloss in Candide of whom it is said that he 'proved admirably that there is no effect without a cause … in this the best of all possible worlds’ – a very different notion of causation! Voltaire, 1759, ch. 1.)

In this article, we take the view that, even if manipulation were not necessary to define causality, manipulation is central to whether it is possible to discuss the idea intelligibly in social sciences and whether some kind of ‘severe test’ is possible (DiNardo, 2007). Some philosophers have sought to define science around issues related to ‘control’, arguing that the phenomena economists try to investigate are impossible to study scientifically at all. Philosophers have articulated numerous reasons for the difference between social and natural science. A few examples may be helpful: Nelson (1990, pp. 102–6) argues, for example, that the objects of enquiry by the economist do not constitute ‘a natural kind’. Put very crudely, the issue is the extent to which all the phenomena that we lump into the category ‘commodity’, for example, can be refined to some essence that is sufficiently ‘similar’ so that a scientific theory about commodities is possible in the same way as a ‘body’ is in Newtonian mechanics. This is often discussed as the issue of whether the relevant taxonomy results in ‘carving nature at the joints’. Hacking (2000) introduces the notions of ‘indifferent kinds’ – the objects in the physical science – atoms, quarks, and so on with ‘interactive’ kinds – the objects of study in medicine or the social sciences. We might interact with plutonium or bacteria, but neither the plutonium nor the bacteria are aware of how we are classifying them or what we are doing to them. This can be contrasted with ‘interactive kinds’ that are aware and for which ‘looping’ is possible. For example, mental retardation might lead to segregation of those so designated. This segregation might lead to new behaviours which then might not fall under the old label, and so on. Consequently, investigation of such phenomena might be likened to ‘trying to hit a moving target’. Searle (1995) on the other hand, notes that the objects of interest in social science while epistemologically objective, are ontologically subjective. While the loss of 100 dollars may be very ‘real’ to someone, the notion of money requires...
groups of individuals to accept money as a medium of exchange. Again, the existence of atoms does not require us to recognize their existence.

**Randomization: an attempt to evade the problems of imperfect ‘control’**

If one accepts the centrality of manipulation (or something like it), it will not be surprising that the application of principles of experimentation to humans who have free will, make choices, and so on entails a host of issues that, inter alia, sharply constrain what might be reasonable to expect of experiments, natural, or otherwise. If it is not possible, desirable, or ethical to ‘control’ humans or their ‘environment’ as it sometimes is in the natural sciences, is it possible to learn anything at all from experiment broadly construed? Randomization in experiments developed in part to try to evade the usual problems of isolating the role of the single phenomenon in situations. In the 19th century, it was discovered that by the use of ‘artificial randomizers’ (such as a coin toss) it was possible, in principle, to create two groups of individuals which were the same on average apart from a single ‘treatment’ (cause) which was under (at least partial) control of the experimenter. Hacking (1988, p. 427) has observed that their use began primarily in contexts ‘marked by complete ignorance’: the economist F. Y. Edgeworth was early to apply the mathematical logic of both Bayesian and ‘classical’ statistics to a randomized trial of the existence of ‘telepathy’. Although economists played an important role in the development of randomization, economists as a whole were quite slow to embrace the new tools. In an echo of debates that faced natural sciences in the 1600s, this was due in part ‘because the theory [of economics] was not in doubt, applied workers sought neither to verify nor to disprove’ (Morgan, 1987, pp. 171–2).

Over time, the term ‘experiment’ evolved to include both experiments of the ‘hard sciences’ where a measure of control was possible as well as situations in which artificial randomizers were used to assign individuals (or plots of land, and so on) to different ‘treatments’. A key role was played by R. A. Fisher (1935) and his seminal *Design of Experiments* as well subsequent publications which discussed the theory and practice of using artificial randomizers to learn about causes.

There are at least two key limitations of randomized experiments relative to experiments where ‘scientific’ control is possible:

- Without real control, one only has a weak understanding of the ‘cause’ in question. For instance, one can do a randomized controlled trial of the effect of aspirin on heart failure while understanding nothing of the mechanism by which aspirin affects the outcome. Moreover, it is clear that the experiment is ‘context specific’. One’s generalization about atoms in a laboratory often extends to atoms in other contexts in a way not possible in social science.
- Any single experiment – even under the ideal situation – does not always reveal the true answer. In the logic of randomized design, the usual inference procedure is merely one that would give the right answer on average if the experiment were repeated. At best, the true answer is just a ‘long-run tendency’ in repeated identical experiments.

**Social experiments: why not do a ‘real’ randomized trial?**

Even without these limitations, there is a long list of reasons why economists frequently have little interest in randomized trials. The most important reason is that many of the real randomized experiments (often called ‘Social experiments’) of which one could conceive (or have been implemented), are immoral or unethical. At a most basic level, the decision as to who ‘performs an experiment’ and who ‘decides’ or is recruited to be experimented upon often reflects deep-seated social injustice. Even Brandeisian (see below) experiments take on a sinister cast – state governments surely do not consider the interests of all their citizens equally. Indeed, historically the conduct of experiments on persons has told us as much or more about the structure of society than anything else: one well-known example is the series of ‘experiments’ conducted by the US Public Health Service from 1932 to 1972 on about 400 poor black men who had advanced syphilis. One aim of the experiment was to determine the effect of untreated syphilis. To this end, the medical doctors misrepresented themselves to the subjects (the sons and grandsons of slaves), claiming to provide free medical care. For example, when penicillin became the standard of care, the subjects were deliberately not provided with the medication: rather, the doctors were content to observe the horrific progress of the disease as some went blind or insane.

Another set of reasons is practical – experiments are costly to administer. Another reason is attrition: often people drop out of such experiments (often in non-random ways), greatly complicating the problem of inference. A distinct, although sometimes related, reason is that the results of social experiments involving randomization are sometimes difficult to interpret. One often cited reason is that those recruited to participate in such experiments may be different from those for whom the policy is ultimately intended. In even the simplest experiments, ‘compliance’ is imperfect. Not everyone assigned to a treatment takes it up – indeed, it is often the case that analysis is made on an ‘intent to treat’ basis. That is, those ‘assigned’ to treatment are compared to those assigned to the control whether or not those assigned to treatment actually ‘took’ the treatment. Another often cited reason is that what is likely when a social experiment is conducted with a small number of persons might be very different when applied to much larger numbers of persons. Persons, unlike atomic particles, enjoy free will. In the world of persons, the ‘experiment’ does not necessarily stop after the
experimenters have made their observations. For example, even in the context of a true randomized experiment, those denied treatment often have the opportunity to find it elsewhere (see Heckman and Smith, 1995, with references, for one discussion of the merits of randomized trials in the social science).

Types of natural experiments

Thus far we have seen that the word ‘experiment’ can be used in two very different senses: one to denote situations where real ‘control’ is possible and second involving artificial randomizers. As a consequence, the term ‘natural experiment’ has been used in very different senses. I now turn to the origins of the term and the different ways the term has been used, although we focus on natural experiments most frequently arising in economics.

Natural experiments in natural science

An early use of the term ‘natural experiment’ in English describes an investigation into the functioning of ‘nature’. The term comes from a translation Saggi di naturali esperienze fatte nell’Accademia del Cimento published in Italian in 1667 which appeared in an English translation by Richard Waller in 1684 as Essays of natural experiments made in the Academie del Cimento (Waller, 1684). The short-lived Accademia del Cimento was founded in Florence in 1657 by the Medici brothers, Prince Leopold and Grand Duke Ferdinand II, and the Saggi record a small subset of the large number of experiments by the Cimento that involved such issues as ‘smells do not traverse Glass’, and ‘the failure to confirm Existence of Atoms of cold’ (1684, p. xx). Although the experiments of the Academy included trials involving humans, they did not involve randomization. Indeed, the legacy of these investigations into humans is more relevant to the study of 16th-century culture and authority relations than 16th-century science. (Trippy, 1994, for example, discusses an investigation into a ‘gentler’ laxative that could ‘satisfy’ the needs of Grand Duke Ferdinand II as well as those of the many ‘delicate persons’ who visited or had dealings with the court that involved experimentation on individuals described variously as ‘a mercenary’, ‘a vagrant’, ‘the Little Moor’, and so on.)

Over time, in the hard sciences, the term natural experiment has also come to describe both cases where ‘nature’ provides an experiment that resembles the controlled situation that scientists would like observe but are unable to create themselves. An unsuccessful experiment may help make the point clear: in a famous quote by Albert Einstein to Erwin Findlay Freundlich (who was attempting to assess the whether path of a ray of light was affected by gravity), Einstein wrote: ‘If only we had a considerably larger planet than Jupiter! But nature has not made it a priority to make it easy for us to discover its laws.’ (‘Wenn wir nur einen ordentlich grösseren Planeten als Jupiter hätten! Aber die Natur hat es sich nicht angelegen sein lassen, uns die Auffindung ihrer Gesetze bequem zu machen’, (as cited in Ashtekar et al., 2003; translation from the New York Times, 24 March 1992).

Natural experiments as serendipitous randomized trials

In contrast to the natural experiment of the hard sciences, the term natural experiment is often used by economists to denote a situation where real randomization was employed, without the intent of providing a randomized experiment. For example, between 1970 and 1972 men from specific birth cohorts were conscripted into the US military by way of a draft lottery. Each day of the year was randomly assigned a number which (in part) determined whether or not one was at risk of being inducted into the military service to fight in the US war on Indochina. As a consequence, men of specific birth cohorts born only a day apart, for example, had very different risks of serving in the military. In Hearst, Newman and Hulley (1986), the authors asked whether the war continued to kill after the warrior returned home. The authors compared, among other things, the suicide rates among individuals who on average were ex ante similar, but who had very different probabilities of having completed military service.

The example is sufficiently simple to make a number of points about the limitations of natural experiments. If one can assume that the mere fact of having such a birth date put one at high risk of military duty, and that having a birth date raised (or did not lower) any person’s risk of serving in the military, then it is possible to use something akin to two stage least squares (2SLS) to estimate an ‘average’ effect of military service for those who were induced to serve in the military by the draft lottery. However, Hearst, Newman and Hulley (1986) are quick to observe that whether or not one actually served in the military, the mere fact of having been put at risk of the lottery might have had an effect on delayed mortality. In econometric terms, this would be a violation of the ‘exclusion restriction’ of 2SLS. If such is the case, it is apparent that a comparison of men with high-risk birthdays to those with low-risk birthdays will be an admixture of the effect of the military service on later mortality and any direct effect of the lottery itself. An additional problem is the possibility of non-random selection induced by men dying while at war. This was judged to be small due since the fraction of US soldiers who died while serving in action was a small fraction of the total.

Returning to how one might go from an estimate generated in this way to more general inference, one has a number of other obstacles. For example, the delayed mortality effects of military service on those induced to serve by an unlucky birth date might be
different from the effect on those who volunteered to fight in the war. If the effects are very different, it would obviously be incorrect to use estimates generated by those induced to serve to extrapolate to the broader population of interest. More generally, our ability to generalize the valid results of an experiment is much more limited when we can only manipulate the cause indirectly (as in the example above) than when we can manipulate the cause directly: there is often the possibility of important differences between persons who take up the treatment as a result of having been encouraged to participate and those who were similarly encouraged but did not take up the treatment.

The regression discontinuity design as a natural experiment

One research design that involves the ‘serendipitous’ randomization of individuals into a treatment is called the regression discontinuity design. Since it is a relatively ‘clean’ example of something that approaches a truly randomized experiment without involving explicit randomization, it provides a good illustration of the strengths and weaknesses of natural experiments. (For an analysis of the relationship between the regression discontinuity design and randomized controlled trials see Lee, 2007.) For illustration, let us consider DiNardo and Lee’s (2004) analysis of the causal effect of ‘unionization’ on firms in the United States. The naive approach would be to compare unionized firms to non-unionized firms.

The basis of the regression discontinuity design is the existence of a ‘score’ or a ‘vote’ which assigns persons to one treatment or another. In the US context, workers at a firm can win the right to form a labour union by means of a secret ballot election. If 50 per cent plus one of the workers votes in favour of the union, the workers win the right to be represented by a union; less than that, and they are denied such rights.

To understand how this works, consider elections at two different sets of work sites that employ large numbers of workers. In one set, 0.5+Δ of the workers vote in favour of the union and win the right to bargain collectively where Δ is some small number. In another set, slightly less than 50 per cent vote in favour of the union, and are denied the right to bargain collectively. The vote share in these sites is 0.5 − Δ. Suppose we have large amounts of data on such elections and can accurately estimate the average outcome (say the fraction of firms that continue to exist 15 years after the vote).

Using almost exactly the same set-up as before, we compare those places where the union wins with those where the union loses:

\[
E[\bar{v}_{\text{Union}} - \bar{v}_{\text{No Union}}] = E[\gamma|\text{vote} = 0.5 + \Delta] - E[\gamma|\text{vote} = 0.5 - \Delta]
\]

If firm survival is described by the same ‘model’ as in above, where now \( T = 1 \) denotes winning the right to bargain collectively, we get:

\[
E[\bar{v}_{\text{Union}} - \bar{v}_{\text{No Union}}] = \beta + \left( E[f(X)|\text{vote} = 0.5 + \Delta] - E[f(X)|\text{vote} = 0.5 - \Delta] \right) + \left( E[\epsilon|\text{vote} = 0.5 + \Delta] - E[\epsilon|\text{vote} = 0.5 - \Delta] \right)
\]

The ‘trick’ is that if we choose Δ to be small enough (that is, close to zero), then

\[
E[f(X)|\text{vote} = 0.5 + \Delta] \approx E[f(X)|\text{vote} = 0.5 - \Delta] \text{ and } E[\epsilon|\text{vote} = 0.5 + \Delta] \approx E[\epsilon|\text{vote} = 0.5 - \Delta]
\]

and we get a ‘good’ estimate of the ‘effect of unions’ in the same sense that we get a good estimate of the effect of a treatment in a randomized controlled trial. That is, if we focus our attention on the difference in outcomes between ‘near winners’ and ‘near losers’ such a contrast is formally equivalent to a randomized controlled trial if there is at least some ‘random’ component to the vote share. For example, sometimes people take ill on the day of the vote – if that happens randomly in some sites, two sites that would have had the same final vote tally had everyone shown up are now different. When such differences are the difference between recognition or not, one has the practical equivalent of a randomized controlled trial. The mere existence of a ‘score’ that discontinuously exposes one to a treatment is not enough. This design would not be appropriate, for example, to analyse the causal effects of US Congressional votes on various issues. Substantial ‘manipulation’ – that is, through negotiation, and so on – of the final vote tally is common and
suggests that individuals near but on opposite sides of the threshold are not otherwise similar (see regression-discontinuity analysis). A few moments’ reflection will make clear both the appeal of such experiments and their limits. Advocates of a natural experiment approach point to the fact that the implicit randomization involved in this design means that we can be more confident with such a comparison than a naive comparison that merely compares unionized to non-unionized firms. This would almost certainly confound the true ‘effect’ with pre-existing differences in unionized and non-unionized firms with ‘unionization’. Advocates will also point to the fact that the experiment is relevant to a potential policy – say lowering the threshold required to win representation rights by a small amount.

Detractors will observe many limitations. Is the effect of a union that is set into a place by a 51 per cent vote the same as the effect of a union where the workers vote unanimously? Possibly not. Stipulating the validity of the estimate, is it reasonable to suggest that the effect of unionization would be the same if all workplaces were allowed to vote on a union? Probably not. Is it possible that a union at one work site affects other work sites? What about the effect on the firm’s competitors? Indeed, it is even possible to question the premise that a union is a ‘treatment’ at all. Does it make sense to talk of a single effect of a labour union when there is such heterogeneity in what the notion ‘labour union’ represents? While the anarcho-syndicalist Industrial Workers of the World (IWW) of Joe Hill (a famous militant IWW member and subject of a well-known folksong) and the American Federation of Labor and Congress of Industrial Organizations (AFL-CIO) of George Meany (a conservative ‘anti-communist’ who was its president for many years) were both labour unions, they had virtually contrary aims and wildly different political structures.

More generally, ‘causes’, ‘treatments’, and so on are much more fragile objects for the types of things usually interesting to economists than the types of things interesting to natural science. The concepts of natural science are often capable of quite substantial refinement in a way that concepts in the human sciences rarely are.

‘Natural natural experiments’?

As I have already mentioned, the term ‘natural experiment’ has been used in several different ways inconsistent with our definition. It seems pointless, however, to claim that our definition is the ‘true’ or correct one. We shall therefore consider some cases that use the term which do not obviously involve randomization of a treatment or something that approximates such randomization. Rosenzweig and Wolpin (2000) for instance, have coined the expression ‘natural natural experiments’ to denote a wide range of studies involving the use of twins. The emphasis on the word ‘natural’ is intended to highlight the role of nature in providing the variation. Twins have been of inordinate interest to the social scientists since they seem to offer the possibility of ‘controlling’ for ‘genetics’. Consider one case of interest to economists, ‘returns to schooling’. Does acquiring an additional year of school result in higher wages in the labour market? How much higher? To fix ideas consider a simple model of the sort:

\[ y_{ij} = \beta S_{ij} + a_j + \epsilon_{ij}. \]

We are interested in some outcome, say hourly wages, and the causal effect of years of schooling \( S \). It will greatly simplify the discussion if we assume that all persons ‘treated’ with ‘schooling’ experience the same increase in their wages – that is, the treatment effect is a constant across individuals. We have gathered a random sample of \( j = 1, \ldots, J \) ‘identical’ (monozygotic) twins (\( i = 1, 2 \)). The term \( a_j \) is not directly observable but includes everything that the twins have in common – genetics, environment, and so on. The error term \( \epsilon_{ij} \) includes everything that the twins do not have in common and cannot be observed as well as the effects of misspecification, and so on. Though this simple set-up can be greatly elaborated (see Ashenfelter and Krueger, 1994, for a clear exposition) the essential idea is that the difference between the twins purges the outcome of the \( a_j \) term so that an ordinary least squares regression of the difference in wages \( \Delta y_{ij} \) on \( \Delta S_{ij} \) yields a good estimate of

\[ \hat{\beta} \text{ is a good estimate of } \beta + \frac{\text{Var}(\Delta \epsilon, \Delta S)}{\text{Var}(\Delta S)}. \]

The first term is the goal of such studies. The second term points to the possibility that there are other influences which might be correlated both with schooling and that affect the outcome. The second term can be interpreted as the slope coefficient from the following hypothetical ordinary least squares (OLS) regression, where \( \delta \) is the slope of the ‘best-fitting’ line in this expression.
When will $\hat{\beta}$ to be a good estimate of the returns to schooling $\beta$? The conditions are essentially the same as for the randomized controlled trial: if we can treat the assignment of schooling to the two twins as if it were determined by a random coin toss then differences in the level of schooling between the two twins – $\Delta S_{ij}$ – will be independent of differences between the two twins in unobserved influences on wages – $\Delta \varepsilon_{ij}$. Detractors of this approach doubt that such an assumption is plausible. In simple language, if the twins are so ‘identical’ why do they have different levels of schooling? Perhaps the parents noticed that one twin was more interested or had more ‘aptitude’ for schoolwork than another. If that were the case, estimates of the returns to schooling would be confounded with differences in the aptitude for schooling despite the fact that we had ‘controlled’ for a large number of other factors. The key difference between this case and what I have identified as a natural experiment is the lack of an obvious approximation to randomization. Bound and Solon (1999) discuss, inter alia, a host of difficulties in treating twin differences as experimental variation. I do not discuss twins studies that utilize twins as a ‘surprise’ to family size which have some element of randomization.

Other research designs, quasi-experiments

Finally, I should make note of the fact that some authors use the term natural experiment more broadly than I have construed it here. Meyer (1995, p. 151) for instance, considers natural experiments the broad class of research designs ‘patterned after randomized experiments’ but not (generally) involving actual randomization. One term often used for such situations is ‘quasi-experiment’. The relationship between these quasi-experiments and the natural experiments I have been describing is quite varied and ranges from those whose difference from the standard of randomized assignment is merely a matter of ‘degree’ to those in which assignment to treatment differs so much from the standard of randomization that it is really a difference in ‘kind’.

Most of these quasi-experiments are variants of a ‘before and after’ where an observation is made before and after a treatment. Often a before–after comparison for one set of observations (the treatment – $T$) is compared to another set (the control – $C$). A typical set-up might compute a treatment effect by taking the difference in two differences:

$$\text{Treatment Effect} = \{\overline{V}_T, \text{after} - \overline{V}_T, \text{before}\} - \{\overline{V}_C, \text{after} - \overline{V}_C, \text{before}\}.$$  

For this reason, such quasi-experiments are described as using ‘difference-in-differences’ approach to identifying a causal relationship. In the United States, the fact that the state (or city) governments have some liberty to enact laws independently of the federal government, for example, has led to a great deal of research using ‘Brandeisian’ experiments. The term comes by way of US Supreme Court Justice Louis Brandeis, in the case New State Ice v. Liebmann:

There must be power in the States and the Nation to remould, through experimentation, our economic practices and institutions to meet changing social and economic needs. … It is one of the happy incidents of the federal system that a single courageous State may, if its citizens choose, serve as a laboratory; and try novel social and economic experiments without risk to the rest of the country. (U.S. Supreme Court New State Ice Co. v. Liebmann, 285 U.S. 262 (1932))

To give one such example, consider DiNardo and Lemieux’s (2001) evaluation of the effect of changing the age at which it is legal to purchase alcohol or the consumption of marijuana. At the beginning of the 1980s states generally enforced two types of legal regimes. In one set, alcohol could not be legally sold to those under the age of 21. In another, the legal minimum drinking age (LMDA) was 18. In the mid-1980s, the federal government put a great deal of pressure on those states with LMDA of 18 to raise them to 21 and by the end of the 1980s, in all states drinking age was 21.

The assignment of drinking age statutes to the states at the beginning of the 1980s could not be considered ‘approximately’ random. Utah, for example, which is home to a large number of adherents to the Mormon religion – which proscribes alcohol use – had a 21-year drinking age at the beginning of the 1980s. However, due to a federal policy implemented in the mid-1980s of eventually denying federal highway funds to states with legal minimums less than 21 years old, something perhaps approximating an ‘experiment’ can be arrived at by comparing changes in alcohol or marijuana consumption during the 1980s in those states which
were forced to change (and changed early) with those who were forced to but raised their drinking age later. Let \( \Delta y_t \) denote the change in the fraction of 18–21 year olds who reported smoking marijuana in the previous 30 days from 1980 to 1990 in states that had 18-year-old drinking ages that were increased, and \( \Delta y_c \) denote the similar change in states whose drinking age was always 21. Then an estimate of the effect of the drinking age might be:

\[
\Delta y_t - \Delta y_c = \text{Effect of LMDA.}
\]

Although randomization is not employed per se, the credibility of these exercises can be at least partially evaluated. For instance, if the outcome of interest has been approximately constant in both the treatment and control groups for a long time preceding the change in legal regime, the estimate is generally more credible. Less credible is the case in which the outcomes in the control group and the treatment group are quite variable over time, the control group and the treatment group do not follow similar patterns before the proposed experiment, or when both are true.

Controversies: concluding remarks

Natural experiments and their like have been at the heart of much work in economics. Nonetheless, they are the subject of considerable debate. One of the most cited limitations of natural experiments – by both supporters and detractors – is that such experiments are context specific. Indeed, one frequently encountered ‘strength’ of natural experiments is that it often concerns the evaluation of an actual policy. There are limitations, however. If we assume that the experiment is ‘internally valid’ we still have to ask: how do we generalize from one experiment to the broader questions of policy? The foregoing has suggested that it is difficult. There are at least three broad classes of reasons:

1. While a natural experiment might provide a credible estimate of some particular serendipitous ‘intervention’, this may have only a weak relation to the type of interventions being contemplated as policies. Many of the potential reasons for a weak relationship are similar to those encountered in social experiments (among other things, for example, the effect of a treatment in a demonstration programme might be quite different from the outcome that would obtain if the treatment were applied more broadly or to different persons).
2. Some interesting questions are unanswerable with such an approach because serendipitous randomized experiments are few and far between. The extent to which this criticism is warranted, of course, depends on the availability of alternative ways of putting our views to a severe test.
3. More generally, without a ‘theory’, estimates from natural experiments are uninterpretable.

I am sympathetic with all three criticisms although (3) deserves some qualification. While it has been argued that even in the natural sciences it is impossible to have ‘pre-theoretical’ observations or experiments, Hacking (1983) makes a strong case that experimentation has a life of its own, sometimes suggesting ideas in advance of theory, other times the consequence of theory, and sometimes testing theories. Much of this debate in the natural sciences revolves around the notion of what constitutes a ‘theory’. Whatever the validity of the view that one cannot experiment in advance of ‘theory’ in the natural sciences, in the social sciences, it is clear that no theory has the same standing as, say, general relativity in physics. This is the sense in which Noam Chomsky observes that ‘as soon as questions of will or decision or reason or choice of action arise, human science is pretty much at a loss’ (Magee, 2001, p. 184). Indeed, the standing of randomized experiments – in some fields of enquiry regarded as ‘the gold standard’ of evidence – is a great deal lower than the best experiments of natural science; they are most often useful in situations otherwise marked by ‘complete ignorance’ (Hacking, 1988). In short, while the human sciences might have the same ambition as natural science, the status of what we know will almost surely be quite limited.

Nonetheless, one does not need a ‘correct’ theory to hand, nor an understanding as rich as that found in some of the natural sciences to find an experiment useful. At the risk of over-using such metaphors, the fact that the Michelson–Morley experiments were in part about testing for the existence of ‘ether’ did not make them uninteresting. Experiments are just ways to use things we (think we) understand to learn about something we do not. And while the sorts of ‘natural’ experiments ‘serendipitously’ provided by society may be very limited and are often the product of unhappy social realities, they can sometimes perhaps serve a small role in enhancing our understanding.

Any assessment of the usefulness of natural experiments depends on how one judges the power of other methods of enquiry. Such a discussion is well beyond the scope of this article. Nonetheless, not discounting their many limitations, one benefit of natural
I have tried to highlight is that for some they might open up the possibility of revising their beliefs in light of evidence or suggest new ways to think about old problems, however limited. A key aspect of experiments (natural or otherwise) is the willingness to put one’s ideas ‘to the test’. Often, careful study of a natural experiment, however limited, may also make one aware of how complicated and difficult are the problems we call ‘economics’. Even if the success we might have in generalizing natural experiments more broadly may be quite limited, if they bring nothing but humility to the claims social scientists make about much we actually understand, that alone would justify an interest in natural experiments.

Article

In the *Wealth of Nations* Smith says that

> when the price of any commodity is neither more nor less than what is sufficient to pay the rent of the land, the wages of labour, and the profits of the stock employed in the raising, preparing and bringing it to market, according to their natural rates, the commodity is then sold for what may be called its natural price. (Smith, 1776, p. 72)

In the same chapter he explains that in economic theory this particular price level is important because it is a sort of benchmark for the actual price of the commodity, its market price (p. 73). The market price is different from the natural price but tends to move towards it all the time because of competition between producers. ‘The natural price, therefore, is, as it were, the central price, to which the prices of all commodities are continuously gravitating’ (p. 73). Smith's concept of natural price and his description of the competitive mechanism which guarantees that the market prices tend to move towards it became an important element in classical political economy. Smith's analysis was entirely subscribed to by Ricardo (Ricardo, 1821, pp. 88–91), and was a central point in the classical theory of value and in the price theories of some neoclassical economists.

Smith's notion of natural price is part of a more general analysis of the normal and regular causes which determine the value of commodities. Smith's theory can be divided into three main aspects. First of all, there is the definition of natural price, which is made up of three component parts, wages, profits, and...
In Chapter 6 of the *Wealth of Nations*, Smith explains that the price of all commodities resolves itself into wages, profits and rent, as soon as we abandon the ‘early and rude state of society which precedes both the accumulation of stock and the appropriation of land’ (Smith, 1776, p. 65). The price must also repay the raw materials and the capital equipment consumed in production, but the prices of these commodities are also made up of the wages, profits and rent required in their own production (p. 68). Thus ultimately the price of each product is entirely made up of those three parts, which include the incomes of workers, landlords and capitalists who take part in the final production of the good and also the incomes of all those who have indirectly contributed to produce it in previous years. The techniques of production of a commodity have an important influence on its natural price, because they determine the relative shares of profits, rent, and wages. But the natural price also depends on the distribution of income, that is to say, on the level of the natural rates at which wages, rent and profits must be paid. According to Smith, each rate is determined on a different market and this depends on several circumstances. Therefore the natural price of each commodity is determined by the methods of production and by the exogenously given values of the rates which remunerate the three classes which take part in production. It is worth noticing that for Smith, society is made up of different classes, labourers, landlords and capitalist entrepreneurs, whose economic functions are clearly separated. When all the commodities that make up the output of society are assessed according to their natural prices, the part of this value given by wages is the capital stock of society (p. 110), while rent and profits make up the net product, or surplus.

The second feature of Smith's price theory is the description of the reasons why the natural price is the price level which prevails in the long run, and around which market prices gravitate. This price mechanism is an important element in the notion of natural price because it guarantees that the permanent causes of value are those which influence the natural price, while market price deviations are due to temporary circumstances. The market price fluctuates and may differ from the natural price, but there are forces which compel it towards the natural price. The factors affecting natural prices must be regarded as the permanent and fundamental forces that determine the value of produced commodities, quite independently from the day-to-day changes in their market prices. This second part of Smith's analysis of natural prices contains several concepts. First, there is the notion of effectual demand which is used to explain the differences between natural and market prices. Effectual demand is the ‘demand of those who are willing to pay the natural price of a commodity’ (p. 73). Of course a change in this price affects the effectual demand. The quantity produced and brought to the market may be lower (or higher) than the effectual demand, in which case the market price of the commodity will be higher (or lower) than the natural one. This mechanism explains why there are differences between natural and market prices.

The second step in Smith's analysis of the gravitation of market prices around natural prices consists in the competitive mechanism itself. Here, too, several logical stages may be distinguished. (a) For Smith the fact that the market price is higher than the natural one implies that at least one of the three parts which make up the price of a product is higher than it would have been if its contribution to production was remunerated according to its natural rate; it seems reasonable to assume that profits are the share which takes advantage of the favourable market conditions (but the process works in the same way if wages and rent are higher than their natural rates). (b) Entrepreneurs are aware of the existence of these different rates of profit in the different sectors of the economy. (c) There are no barriers to the free circulation of capital, thus entrepreneurs move towards the most remunerative sectors; this is the crucial
aspect of Smith's analysis of competition (see Sylos-Labini, 1976). (d) These capital movements lead to an increase in the output of the products which yield the highest rates of profit. (e) Since the quantity produced and brought to the market of these products increases while the effectual demand in unchanged, the market price falls. This does not mean that there is a downward-sloping demand schedule. In Smith's price theory there is no continuous differentiable inverse relationship between quantities and prices, as is found in neoclassical economics (Garegnani, 1983).

Free competition tends to bring about a uniform rate of profit throughout the economy. Hence the concept of natural price is related to the existence of a single rate of profit on the capital invested in all sectors, and is regarded by Smith as ‘a centre of repose and continuance’ for the actual market price (Smith, 1776, p. 75).

The view that it is possible and useful to separate the day-to-day fluctuations in market prices from the stable and permanent causes of the value of commodities can be traced back to the 16th century. It was part of Scholastic tradition to believe that there was a logical distinction between the actual price of a product and its true value. The former price can vary quite a lot according to the state of trade, while the value is always the same. Von Pufendorf believed that the value, or just price, of a commodity depended mostly on the difficulty of acquiring and producing it (Pufendorf, 1688, pp. 684–9). Theoreticians of the just price regarded it as the level to which actual prices ought to conform. They gave no indication of any spontaneous mechanism which should guarantee that market values would adapt to these just levels.

As a student, Adam Smith read the works of von Pufendorf, and his teacher, Francis Hutcheson, wrote a book entitled A System of Moral Philosophy in which the distinction between value and price was restated along very similar lines (Hutcheson, 1754–5, pp. 53–5). At the end of the 17th century, Dudley North and John Locke maintained that regulations and government interventions could not affect the price of commodities, which depended on market conditions (North, 1691, Preface; Locke, 1691, pp. 4, 11, 13).

Some years before the publication of the works of Locke and North, Sir William Petty regarded the cost of production of commodities as the main cause determining their true value. Ultimately all commodities are produced by two common denominators, land and labour, and their exchange values are in proportion to the quantities of these non-produced goods which have been employed in their production (Petty, 1662, p. 44). The value of goods is regulated by the physical cost of production, which is regarded as the true measure of the difficulty of acquiring them. For Petty, the natural price depends upon the amount of labour required to produce a commodity with the best available technique (pp. 50–1). Richard Cantillon developed Petty's analysis of land and labour as the original components of the value of each commodity. He transformed the amount of labour employed in production into an equivalent quantity of land. Thus, the value of each commodity is given by the quantity of land which has been directly and indirectly used in its production (Cantillon, 1755, p. 29). This is the intrinsic value of the products, and their market price fluctuates around it (pp. 28–30). Moreover, Cantillon presented the well-known theory of the ‘three rents’; the farmer receives two thirds of the products of land, one third is required to pay workers' wages and other expenses, the second third is the profit from his enterprise; the final third accrues to landlords as rent (p. 43).

Quesnay and the Physiocrats also distinguish the permanent value of commodities from their market price. For Quesnay, the fundamental price is the lowest level of the selling price for the producer. This value is the minimum level of the market price: it is the sum of all the expenses incurred by the
natural price: The New Palgrave Dictionary of Economics

cultivator in the production of a commodity, and there is a loss when the market price is lower than this value (Quesnay, 1757, p. 555). The fundamental value of commodities is stable and varies quite slowly, on the other hand market prices change rapidly. Quesnay concentrated his attention on the fundamental price of primary commodities, which included the technical costs of production plus the annual rent paid to the landlords (1757, p. 555; Quesnay, 1756, p. 443). Quesnay believed that two elements contribute to determining the fundamental value of agricultural products: farming techniques, which determine the physical cost of production, and the rule which fixes the distribution of income, at least in the form of rent. The inclusion of an element, rent (which is part of the country's surplus), in the fundamental value of a commodity is an important step towards Smith's concept of natural price. Now the permanent value of commodities is not only the result of technical conditions but also of the social rules and customs which determine the distribution of the net product.

Quesnay used the term ‘natural price’ to indicate the state of prices when free and unobstructed competition in all the markets regulates the exchanges between buyers and sellers (Quesnay, 1766, pp. 829–30). In this case the actual exchange value of the products of land is a *bon prix*, it exceeds the fundamental price and leaves the farmer with a profit (Quesnay, 1757, p. 529). Quesnay provided a good explanation of the reasons why the market price cannot be lower than the fundamental one, but there is no indication of the existence of market forces which lead the actual price towards the *bon prix*. In Quesnay's value theory the notion of fundamental price is only a sort of threshold which fixes the lowest market price, but profits are still not part of the fundamental price.

In 1767 Sir James Steuart published *An Inquiry into the Principles of Political Oeconomy* in which he made at least two important contributions to the classical theory of value. The first was the notion of the real, or intrinsic, value of the goods. He says that two things make up the price of a product, ‘the real value of a commodity and the profit upon alienation’ (Steuart, 1767, p. 159). The real value is the cost of production, which depends upon the average techniques which have been adopted and which establishes the amount of time needed to produce a commodity. The ‘profit upon alienation’ is the positive difference between the actual price and the real value (1767, p. 159). Thus profits are not part of the value of commodities, but according to Steuart ‘such profits subsisting for a long time, they insensibly become consolidated, or as it were, transformed into the intrinsic value of the goods’ (1767, p. 193, Steuart's italics). Thus, in the normal condition of the market, the value of commodities must also include entrepreneurs' profits, which are a permanent feature of the exchange value of goods. Steuart's second contribution to price theory is the concept of effectual demand; this notion indicates the demand of consumers who can actually pay for a product and is clearly distinguished from wants and desires (1767, pp. 151–3). Steuart's analysis does not provide a theory of profit capable of explaining the level which becomes consolidated in the intrinsic value of commodities. The normal value is not yet defined in a way which explains the existence of a regular element of profit in the exchange value of commodities.

In the *Obsérvations sur le mémoire de Saint Péray*, Turgot distinguished the fundamental and market price of commodities. The first concept is defined as the cost of production, which includes wages, raw materials and interests on the capital advanced. The fundamental value is fairly stable, while the exchange value is ruled by supply and demand and ‘it has a tendency to approach it (the fundamental price) continually, and can never move away from it permanently’ (Turgot, 1767, p. 120, n. 16). There is an important difference between Quesnay's and Turgot's use of the term ‘fundamental price’. Turgot's
The notion does not simply indicate the lowest level of the market price, but is the value to which this price must tend. Turgot included a regular profit among the necessary expenses of production (Meek, 1973, p. 17). Turgot's interest on the capital advanced is not only a depreciation allowance but includes profit for the entrepreneur. In Réflexions sur la formation et la distribution des richesses (1766) Turgot clearly says that the return to the capitalist entrepreneur must be divided into three main categories: 'depreciation of the capital', 'wages of superintendence and direction as well as the risk premium' and 'pure return on his capital which he could have earned if he had not employed it in industry' (Groenewegen, 1971, p. 333; see Turgot, 1766, pp. 152, 154). Now profits are an essential part of the permanent value of commodities, but above all Turgot's notion of profit is different from those of Steuart and Quesnay. Profit is defined as a rate on the capital invested. This definition of profits is quite different from that of profit upon alienation, according to which profits are influenced by market conditions where the products are sold. For Turgot, on the contrary, the rate of profit depends mainly on competition between capitalist producers who act with a view to obtaining the highest possible rate of profit. This mechanism explains the existence of a continuous tendency towards the equalization of rates of return in all of the capital.

In the Lectures on Jurisprudence which Adam Smith gave at Glasgow in the academic year 1762–3, we already find the distinction between natural and market price, together with the description of the mechanism by which the latter price gravitates around the natural value (Smith, 1762–3, pp. 353 ff.). Smith's analysis of competition among producers explains that natural prices are bound with the existence of a uniform rate of profit in all the sectors of the economy. The existence of this uniform rate has been traditionally adopted to describe the prices which prevail in the long run, when it is possible to abstract from all the accidental causes which influence market prices. In Smith's economics, technology and income distribution are the permanent forces which determine the value of natural prices.

In classical economics, the notion of natural price is necessary to build up an abstract analysis of the main features of the economy. This notion helps to single out the main characteristics of the capitalistic process of development and their relationships to changes in the distribution of income. Thus the concept of natural price is part of the study of the long-term changes in economic systems, which derive from capital accumulation. Natural price is an essential element of the classical method of analysis, which investigates the features of the long-term positions of the economy, when demand does not affect prices and income distribution (Garegnani, 1976, section 1).

In Chapter 4 of On the Principles of Political Economy and Taxation, Ricardo subscribes to Smith's theory of natural prices (1821, pp. 88–92). He was interested in the analysis of the permanent changes in income distribution, and was not interested in the temporary deviation of market prices from their natural value.

However, there is a major difference between Smith's and Ricardo's theories of profit. Smith says that profits and wages are determined on separate markets and that the natural price is the sum of these shares plus rent, while Ricardo says that the rate of profit and the real wage are inversely related. Marx's notion of prices of production shares many of the features of Smith's natural price; both concepts are associated with the existence of a uniform rate of profit in all sectors of the economy (see Marx, 1894, pp. 153–8). Moreover, Marx accepted Ricardo's analysis of the reasons why market prices fluctuate around natural ones (1894, p. 179). Like Ricardo, he believed that real wages and the rate of profit vary in opposite directions. In his 1951 Introduction to The Works and Correspondence of David
Ricardo, Sraffa clearly singled out the implications of Ricardo's theory of profit determining commodities natural value. Sraffa explicitly mentioned the concepts of natural price and prices of production in presenting his theory of price determination and retained the notion of a uniform rate of profit throughout the economy (Sraffa, 1960, pp. 9, 6).

In the *Principles of Economics* (1920), Alfred Marshall referred to Smith's natural price, for which he substituted the notion of normal price (Marshall, 1920, p. 289). In his discussion of the causes which influence the value of commodities he said that in general, market values are deeply affected by demand, while normal prices depend on the cost of production of commodities. The former price prevails in the short run, but 'the longer the period, the more important becomes the influence of cost of production on value' (1920, p. 291). Normal prices are determined by the persistent causes of value, and are not influenced by fitful and irregular events (1920, pp. 304–5). It should be pointed out that Marshall's notion of cost of production is not the same as the notion put forward by Ricardo and Marx. Moreover, he was sceptical about the existence of a tendency towards the equalization of the rates of profit in all economic activities (1920, pp. 506–7, 512). Nevertheless inside each branch of trade there can be a fair rate of profit which must be reckoned as a component element of the normal price (1920, pp. 513–14).

The terms ‘natural rate’ and ‘market rate’ of interest were introduced by Wicksell (1898; 1906) to denote an equilibrium value and the actual value of the real rate of interest. Wicksell applied these concepts to explain the inter-equilibrium movement of money and prices using the hypothesis of maladjustments in the interest rate. Wicksell's work made the nexus between money creation, intertemporal resource allocation disequilibrium and movements in money income the dominant theme in macroeconomics for three decades. However, Keynes's conclusions over the saving–investment problem in the General Theory led to the abandonment of the concept of ‘natural’ rate of interest.

Article
The main analytical elements of Knut Wicksell's Interest and Prices can be found in the works of earlier writers. Wicksell was familiar with Ricardo's distinction between the direct and indirect transmission of monetary impulses. Although unknown to Wicksell in 1898, Henry Thornton had provided a clear account of the cumulative process in 1802, as had Thomas Joplin of the saving–investment analysis somewhat later (cf. Humphrey, 1986).

Yet Wicksell did not just coin the terms ‘natural rate’ and ‘market rate of interest’. His development (1898; 1906) of these ideas made the nexus between money creation, intertemporal resource allocation
natural rate and market rate of interest: The New Palgrave Dictionary of Economics

disequilibrium and movements in money income the dominant theme in macroeconomics for three decades until it was submerged in Keynesian economics. His starting point was the quantity theory, understood as the proposition that in the long run the price level will tend to be proportional to the money stock. His objective was to explain how both money and prices come to move from one equilibrium level to another. This inter-equilibrium movement became his famous ‘cumulative process’. The maladjustment of the interest rate was the key hypothesis in Wicksell’s explanation.

The ‘market rate’ denotes the actual value of the real rate of interest while the ‘natural rate’ refers to an equilibrium value of the same variable. The latter term by itself divulges Wicksell’s engagement in the ancient quest for a ‘neutral’ monetary system, that is, a system neutral in the original sense that all relative prices develop as they would in a hypothetical world without paper money. Wicksell asserted three equilibrium conditions that the interest rate should satisfy; the first of these was that the market rate should equal the rate that would prevail if capital goods were lent and borrowed in kind (in natura).

This criterion was later shown by Myrdal, Sraffa and others not to have an unambiguous meaning outside the single input–single output world of Wicksell’s example. The further development of Wicksellian theory, therefore, centred around the two remaining criteria: saving–investment coordination and price level stability.

The interest rate has two jobs to do. It should coordinate household saving decisions with entrepreneurial investment decisions and it should balance the supply and demand for credit. If the supply of credit were always to equal saving and the demand for credit investment, the two conditions could always be met simultaneously. But there is no such necessary relationship between saving and investment on the one hand and credit supply and demand on the other. In Wicksell’s system the banks make the market for credit; they may, for instance, go beyond the mere intermediation of saving and finance additional investment by creating money; the injection of money drives a wedge between saving and investment; this could only be so if the banks set the market rate below the ‘natural’ value required for the intertemporal coordination of real activities. The resulting inflation and endogenous growth of the money supply would continue as long as the banking system maintained the market rate below the natural rate. Wicksell analysed the case of a ‘pure credit’ economy in which the cumulative process could go on indefinitely, but he also pointed out that, in a gold standard world, the banks would eventually be checked by the need to maintain precautionary balances of reserve media in some proportion to their demand obligations.

Wicksell used the model to explain long-term trends in the price level and was critical of those who, like Gustav Cassel, used it to explain the business cycle. Nonetheless, subsequent developments of his ideas went altogether in the direction of shorter-run macroeconomic theory. In Sweden, Erik Lindahl (1939) and Gunnar Myrdal (1939) refined the conceptual apparatus, in particular by introducing the distinction between ex ante plans and ex post realizations and thereby clarifying the relationship between Wicksellian theory and national income analysis. The attempts by the Stockholm School to improve on Wicksell’s treatment of expectations were less successful, however, producing a brand of generalized process-analysis in which almost ‘everything could happen’. In Austria, Ludwig von Mises and Friedrich von Hayek focused on the allocational consequences of the Wicksellian inflation story. The Austrian overinvestment theory of the business cycle became known to English-speaking economists primarily through Hayek’s Prices and Production (1931). In expanding the money supply, the banks hold market rate below natural rate. At this disequilibrium interest rate, the business sector will plan to accumulate capital at a rate higher than the planned saving of the household
sector. If the banks lend only to business, the entrepreneurs are able to realize their investment plans whereas households will be unable to realize their consumption plans (‘forced saving’). The too rapid accumulation of capital (which also has the wrong temporal structure) cannot be sustained indefinitely. The eventual collapse of the boom may then be exacerbated by a credit crisis as some entrepreneurs are unable to repay their bank loans.

The Austrian ‘monetary’ theory of the cycle has been overshadowed first by Keynesian ‘real’ macrotheory and later by monetarist theory. One problem with it is the firm association of inflation with overinvestment. The US stagflation in the 1970s, for example, will not fit. The reasons lie largely in the changes that the monetary system has undergone. Most obviously, commercial banks now lend to all sectors and not only to business. More importantly, however, inflation in a pure fiat regime does not tend to distort intertemporal values in any particular direction (although it may destroy the system's capacity for coordinating activities over time): it simply blows up the nominal scale of real magnitudes at a more or less steady or predictable rate. In contrast, the Austrian situation that preoccupied Mises and Hayek in the late 1920s was one of credit expansion by a small open economy on the gold standard. Given the inelastic nominal expectations appropriate to this regime, the growth of inside money would be associated with the distortion of relative prices and misallocation effects predicted by the Austrian theory.

In England, Dennis Robertson and J. Maynard Keynes both worked along Wicksellian lines in the 1920s. The novel and complicated terminology of Robertson's *Banking Policy and the Price Level* (1926) may have made the work less influential than it deserved. Keynes's *Treatise on Money* (1930), although also remembered as a flawed work, nonetheless remains important as a link in the development of macroeconomics from Wicksell to the *General Theory*.

In the *Treatise*, Keynes, like Wicksell, assumes that the process starts with a real impulse, that is, a change in investment expectations. Unlike Wicksell, he focuses on deflation rather than inflation. For Keynes with his City experience, the interest rate was determined on the Exchange rather than set by the banks. Consequently, a deflationary situation with the market rate exceeding the natural rate can only arise when bearish speculation keeps the rate from declining. When saving exceeds investment, therefore, money leaks out of the circular spending flow into the idle balances of bear-speculators. Thus the analysis stresses declining velocity rather than endogenously declining money stock. At this stage of the development of Keynesian economics, the banks are already edging out of the theoretical field of vision and the original connection of natural rate theorizing with criteria for neutral money is by and large severed.

The model of the *Treatise* still assumes that, when market rate exceeds the natural rate, the resulting excess supply of present goods will cause falling spot prices but not unemployment of present resources. Although the focus is on a disequilibrium process, at a deeper level the theory is still comfortingly classical. As long as the economy remains at full employment, the bear-speculators who are maintaining the disequilibrium are forced, period after period, to sell income-earning securities and accumulate cash at a rate corresponding to the difference between household saving and business sector investment. Automatic market forces, therefore, are seen to put those responsible for the undervaluation of physical capital under inexorably mounting pressure to allow correction of the market rate. And the longer those agents acting on incorrect expectations persist in obstructing the intertemporal coordination of activities, the larger the losses that they will eventually suffer.

In the *General Theory*, Keynes starts the story in the same way: investment expectations take a turn for
natural rate and market rate of interest: The New Palgrave Dictionary of Economics

the worse – ‘the marginal efficiency of capital declines’; the speculative demand for money prevents the interest rate from falling sufficiently to equate ex ante saving with investment. But at this point the General Theory takes a different tack: the excess supply of present resources, which is the immediate result of the failure of intertemporal price adjustments to bring intertemporal coordination, is eliminated through falling output and employment. Real income falls until saving has been reduced to the new lower investment level.

This change in the lag-structure of Keynes’s theory (‘quantities reacting before prices’) is not necessarily revolutionary by itself. But Keynes combines it with the assumption that the subsequent price adjustments will be governed, in Clower’s terminology, not by ‘notional’ but by ‘effective’ excess demands. For the economy to reach a new general equilibrium, on a lower growth path, interest rates should fall but money wages stay what they are. Following the real income response, however, saving no longer exceeds investment so there is no accumulating pressure on the interest rate from this quarter; at the same time, unemployment does put effective pressure on wage rates. Interest rates, which should fall, do not; wages, which should not, do. From this point, Keynes went on to argue that nominal wage reductions would not eliminate unemployment unless, in the process, they happened to produce a correction of relative prices (an eventuality that he considered unlikely). This argument was the basis for his ‘revolutionary’ claim that a failure of saving–investment coordination could end with the economy in ‘unemployment equilibrium’.

Prior to the General Theory, writers in the Wicksellian tradition had generally treated ‘saving exceeds investment’ and ‘market rate exceeds natural rate’ as interchangeable characterizations of the same intertemporal disequilibrium. The basic proposition could be couched equally well in terms of quantities as in terms of prices. In the General Theory, Keynes moved away from this language. Constructing a model with output and employment variable in the short run was a novel task and Keynes, as the pioneer, was unsure in his handling of expected, intended and realized magnitudes. Thus his preoccupation with the ‘necessary equality’ of saving and investment (ex post) was to produce endless confusion over interest theory. If saving and investment are always equal, the interest rate cannot be governed by the difference between them; nor can the interest rate mechanism possibly coordinate saving and investment decisions. To Keynes, two things seemed to follow. One was the substitution of the liquidity preference theory of the interest rate for the loanable funds theory; the other was the abandonment of the concept of a ‘natural’ rate of interest (Leijonhufvud, 1981, pp. 169 ff.)

These were not innocent terminological adjustments. The brand of Keynesian economics that developed on the basis of the IS–LM model had only a shaky grasp at the best of times of the intertemporal coordination problem originally at the heart of Keynes’s theory. The Keynesian position shifted already at an early stage back to the pre-Keynesian hypothesis of money wage ‘rigidity’ as the cause of unemployment. This switched the focus of analytical attention away from the role of intertemporal relative prices (the market rate) in the coordination of saving and investment to the relationship between aggregate money expenditures and money wages. This brand of ‘Keynesian’ theory which excludes the saving–investment problem (that is, excludes the market-natural rate problem) could hardly be distinguished from Monetarism in any theoretically significant way.

Monetarism gained enormously in influence during the inflationary 1970s. But its period of dominance was brief. This was so in part because, in its New Classical form, it was both theoretically implausible and empirically weak. In part, however, it was swept aside by a wave of innovations in payments technology and in forms of short-term credit that undermined the stability of the relationship between
the money stock and income which had been the very linchpin of monetarist doctrine. Most recently, this has led to a return to a basically Wicksellian doctrine of what monetary policy should aim to accomplish and how it should be conducted. Leading central banks are now committed to targeting the inflation rate (rather than the price level) and use the interest rate as their primary instrument for pursuing that goal. This policy doctrine has been elaborated in the book by Woodford (2003) which borrows its title from Wicksell.

natural rate of unemployment

Michael J. Pries
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Milton Friedman defined the natural rate of unemployment as the level of unemployment that resulted from real economic forces, the long-run level of which could not be altered by monetary policy. Macroeconomic policymakers continue to view the natural rate as a key benchmark due to the belief that monetary policy can counter short-run deviations of the unemployment rate from the natural rate. It is important, however, that policymakers focus as much attention on understanding the real determinants of the natural rate, and the policies that can affect it, as they do on trying to identify and counteract deviations from it.

Article

In his 1968 presidential address to the American Economics Association, Milton Friedman famously defined the natural rate of unemployment as

… the level that would be ground out by the Walrasian system of general equilibrium equations, provided there is imbedded in them the actual structural characteristics of the labor and commodity markets, including market imperfections, stochastic variability in demands and supplies, the cost of gathering information about job vacancies and labor availabilities, the costs of mobility, and so on. (1968, p. 8)
This definition is incomplete, however, because it conspicuously lacks any mention of inflation. A more complete definition emerges from the remainder of Friedman's presidential address, in which he extensively examined the relationship between the unemployment rate and inflation. He argued that, whereas the natural rate of unemployment is determined by the real factors described in the passage quoted above, deviations from the natural rate are monetary phenomena: ‘I use the term “natural” for the same reason Wicksell did – to try to separate real forces from monetary forces’ (Friedman, 1968, p. 9).

The unemployment–inflation trade-off

Friedman’s ‘natural rate hypothesis’ maintained that ‘… there is a ‘natural rate of unemployment’ which is consistent with the real forces and with accurate perceptions; unemployment can be kept below that level only by an accelerating inflation; or above it only by accelerating deflation’ (Friedman, 1976, p. 458). This view of the relationship between the unemployment rate and inflation grew out of the experiences of the previous decades. In 1958, Phillips had observed a negative empirical relationship between the unemployment rate and the growth rate of wages (Phillips, 1958). Understanding that high wage growth would ultimately translate into inflation, policymakers believed that there was a stable trade-off between unemployment and inflation that they could exploit. In other words, monetary and fiscal policy could be used to drive down unemployment at the cost of a certain degree of inflation. Experience showed, however, that the relationship was not stable. As individuals started to anticipate the inflation that resulted from attempts to exploit the trade-off, stimulative policy ceased to lower unemployment. Consequently, the Phillips curve appeared to have shifted outward, with higher inflation accompanying higher unemployment.

Friedman provided an explanation for this apparent shift. Over the long run, there is an unemployment rate determined by real factors that cannot be affected by monetary policy: the natural rate. In the short run, unanticipated inflation can temporarily push the unemployment rate below its natural rate. If workers do not perceive the higher inflation, then they will respond to higher nominal wages by increasing labour supply; similarly, employers who do not immediately perceive the higher inflation will respond to a higher price for their product by demanding more labour. This temporarily lowers unemployment, but the unemployment rate returns to its natural level when workers and employers begin to perceive the inflation. As emphasized in the literature on rational expectations (for example, Lucas, 1973) that followed Friedman, inflation has no impact on real variables like the unemployment rate once individuals have already built the level of inflation into their expectations. In other words, as expectations about inflation change, the Phillips curve shifts.

Although the absence of any long-run trade-off between inflation and unemployment has gained wide acceptance, the possibility of a short-run trade-off has kept the natural rate of unemployment at the centre of policymaking. In particular, policy rules such as the Taylor rule (see Taylor, 1999) maintain that central banks can stabilize the inflation rate by assessing where the economy stands relative to economic benchmarks such as the natural rate of unemployment, ‘potential output’, or the ‘natural rate of interest’. When unemployment is high relative to the natural rate, and when output is below potential output, the policy rules call for stimulative monetary policy.

However, several important questions arise when one contemplates the usefulness of the natural rate of unemployment as a policy benchmark. First, although the natural rate clearly cannot be observed
directly, can it be estimated with enough accuracy to be useful for policy? Or do movements in the
natural rate itself make it too difficult to distinguish the natural rate and deviations from the natural rate
in a sufficiently timely manner to be useful for policymakers? Second, rather than focusing so much on
deviations from the natural rate, should policymakers also focus on policies that would alter the natural
rate, either at low frequencies or perhaps even at business cycle frequencies? What would those policies
be?

Identifying the natural rate

Although the natural rate is often simplistically described as the long-run average unemployment rate,
economists widely recognize that this rate varies over time. Friedman (1968, p. 9) was clear on this
point:

To avoid misunderstanding, let me emphasize that by using the term ‘natural’ rate of
unemployment, I do not mean to suggest that it is immutable and unchangeable. On the
contrary, many of the market characteristics that determine its level are man-made and
policy-made…. Improvements in employment exchanges, in availability of information
about job vacancies and labor supply, and so on, would tend to lower the natural rate of
unemployment.

Friedman (1968, p. 10) further argued that the mutability of the natural rate of unemployment
significantly reduces its policy usefulness:

What if the monetary authority chose the ‘natural’ rate – either of interest or
unemployment – as its target? One problem is that it cannot know what the ‘natural’ rate
is. Unfortunately, we have as yet devised no method to estimate accurately and readily the
natural rate of either interest or unemployment. And the ‘natural’ rate will itself change
from time to time.

Since Friedman's work, however, economists have achieved additional understanding of some of the
factors that contribute to low-frequency fluctuations in the natural rate of unemployment. It is now
generally understood that demographic changes can have a significant impact on the natural rate of
unemployment (see Shimer, 1998). For instance, young workers experience substantially more job
turnover than more experienced workers, with the spells between jobs often spent in unemployment.
Accordingly, when younger workers make up a larger fraction of the workforce (as they did in the 1970s
when the baby boom generation entered the workforce in significant numbers), unemployment will be
higher on average. Nevertheless, it is not clear whether this greater understanding of the factors that
affect the natural rate can be translated into an estimate of the natural rate that is accurate enough to be
useful for policy. Often changes in the natural rate can only be detected with a significant lag, after
which time a policy response may actually increase volatility by causing the economy to overshoot its
target.
Further complicating the question of the natural rate's usefulness as a policy benchmark is the question
of whether even higher-frequency (that is, business cycle) fluctuations in the unemployment rate could in fact represent movements in the natural rate. For example, modern search theory views unemployment fluctuations at business cycle frequencies as movements in the natural rate, in the sense that they result from real rather than monetary forces. Evidence from data on job flows shows that jobs are constantly being reallocated across firms, industries, geographical regions, and so on (see Davis, Haltiwanger and Schuh, 1996). Moreover, periods of above-average unemployment rates tend to coincide with an increased level of this reallocative activity. In this sense, unemployment rate fluctuations at business cycle frequencies can be viewed as the outcome of real phenomena of the type described in Friedman's famous quote – that is, as cyclical movements in the natural rate. This emphasis on the real determinants of movements in the unemployment rate is part of the broader view that a significant portion of economic fluctuations reflects real factors as opposed to monetary phenomena. The vast real business cycle literature has explored this proposition since the seminal paper by Kydland and Prescott (1982). Hall (2005b) argues that real fluctuations, and the difficulty of distinguishing them from monetary phenomena, render useless the various benchmark concepts such as the natural rate of unemployment, potential output, and the equilibrium real interest rate.

Optimality of the natural rate and policies to alter it

If real sources of unemployment fluctuations are in fact as important as monetary sources, then the proper response by monetary policymakers to the fluctuations is much less clear. However, even if unemployment fluctuations are primarily driven by real factors, it would be incorrect to conclude that either the level or fluctuations of the natural rate are optimal. Accordingly, there may be a role for policy to improve welfare by affecting the natural rate (either at low frequencies or perhaps even at high frequencies). This suggests that research on the optimality of the natural rate, and on policies that can affect it, is as important as research aimed at detecting and proposing policies to counteract deviations from it.

The idea that the natural rate can be either too high or too low has been a primary focus of modern search and matching models of the labour market. In those models, the process whereby workers and firms meet may be subject to various externalities. When a worker chooses to search for a job, it has a positive externality on the probability that employers will find a suitable worker and a negative externality on the probability that other workers will find a job. Employers' search decisions cause similar externalities.

Hosios (1990) analyses the conditions under which, in a broad class of search and matching models, the various externalities result in an unemployment rate that is either too high or too low. He finds that in general there is no economic force that draws the unemployment rate towards its optimal level. One suspects that the wage might play that role. When employers decide whether to open job vacancies (the number of which ultimately determines the unemployment rate), they anticipate the wages that they will have to pay and the profits that they will earn when they form an employment relationship. However, the level of those wages and the resulting profits are determined after the fact by bargaining between workers and firms who have been matched, and who are not contemplating the impact that their bargain has on firms posting new vacancies. If the wages that result from bargaining are too low (high), firms anticipate this and create many (few) vacancies, and the unemployment rate is inefficiently low (high).
As a complement to this more theoretical examination of the optimal level of the natural rate, there is a more applied literature that tries to understand cross-country differences (particularly between continental Europe and the United States) in the average unemployment rate and how those differences relate to various policies. For example, Hopenhayn and Rogerson (1992) examine the impact of firing costs on unemployment and on productivity. They find that, in addition to increasing average unemployment, firing costs reduce productivity by impeding the reallocation of workers towards more productive employers. Ljungqvist and Sargent (1998) argue that the interaction between generous unemployment insurance in many western European countries and an increased turbulence in labour markets can explain the secular rise in European unemployment rates relative to the US rate over the last several decades.

In addition to this work on the determinants of average unemployment rates in the long run, recent work has also focused on trying to better understand the sources of non-monetary movements in the unemployment rate over the business cycle, and whether they are efficient. What real factors contribute to spikes in unemployment, and why is the subsequent recovery so slow? Pries (2004) argues that the slow recovery occurs because workers who lose their job in the initial spike may pass through several short-lived jobs, and several intervening unemployment spells, before ultimately settling into more stable employment. In this environment, policies that try to accelerate a recovery may be counterproductive if they encourage worker–firm pairs to hang on to low-quality matches. Shimer (2005), on the other hand, argues that the slow recovery of the unemployment rate during economic downturns results from a significant reduction in posted vacancies and, consequently, a decline in workers' job-finding rates. More research is needed to understand the causes of the decline in posted vacancies. The canonical Mortensen–Pissarides (1994) matching model, in which wages are flexibly renegotiated as part of a Nash bargaining solution, struggles to produce a sizeable decline in vacancies during recessions. In the model, wages fall considerably during economic downturns, and the lower wages mean that firms still find it quite profitable to post vacancies. This model's failure to deliver the observed cyclicity in vacancies leads Hall (2005a) to suggest that in fact wages are much less flexible than assumed in Mortensen–Pissarides (1994). If so, then should the fluctuations be seen as monetary in nature, and is stimulative monetary policy the correct policy response? Or are tax incentives for investment, which may spur the creation of new jobs, a better policy response? As with countercyclical monetary policy, tax incentives may take effect with a lag and exacerbate fluctuations.

Milton Friedman's assertion in 1968 that there is a natural rate of unemployment that is determined by real economic forces and is impervious to monetary policy has become relatively uncontroversial. Nevertheless, important unresolved questions about the natural rate remain. What is the optimal natural rate? To what extent do unemployment rate fluctuations reflect movements in the natural rate as opposed to deviations from it? What policies, if any, are appropriate for counteracting movements in the natural rate or deviations from it?

consumption externalities; cost–benefit analysis; demand theory; Dupuit, A.-J.; jointness of consumption; Navier, L.; Pigou, A.; public goods; public works; Samuelson, P, on public goods; subjective utility; utility measurement

Article

A French engineer and economist, Louis Marie Henri Navier was a pioneer in the construction of suspension bridges, and is also known as the creator of that branch of mechanics known as structural analysis. In his economic inquiries, he sought a practical measure of public utility that provided the springboard for Dupuit's pioneer contributions to demand theory. Orphaned at the age of nine, Navier was adopted by his great-uncle, the celebrated architect–engineer, Émiland-Marie Gauthey (1732–1806), who likely inspired his adopted son to follow in his illustrious footsteps. Navier died prematurely at the age of 51, thus cutting short a distinguished career of public service.

Navier was one of the earliest formulators of a cost–benefit rule to guide the construction of public works. His rule advocates expenditures on public works if the total benefit derived – in the form of before–after cost savings – exceeds the total recurring costs of the new construction. In choosing recurring costs over total costs as the element to be covered by tolls, Navier was showing a greater appreciation of consumption externalities than Pigou (1947, p. 3n.), who wrote more than a century later. In fact, Navier's rule is a somewhat less sophisticated version of Stephen Marglin's (1967, pp. 22–4) ‘myopic rule’ of public investment.

Navier's rule was the proximate cause of Dupuit's innovative attempt to establish demand based on subjective utility. Dupuit (1844) objected to Navier's attempt to measure utility on two grounds: (a) in competitive markets the proper measure of utility of the quantity of goods and services consumed is not the reduction of transport costs but rather the reduction of production costs; (b) increases in the quantity taken at lower prices do not all have the same utility, but rather take on smaller values as more is consumed. Thus, Dupuit's rule overcame the limitations of Navier's rule, and, in addition, launched the
neoclassical theory of demand. Kölm (1968) argues that, in the context of public finance, Dupuit's rule moves us closer to Samuelson's (1954, pp. 387–9) decision rule regarding public goods. However, a valid comparison of Dupuit's performance with Samuelson's must recognize that Samuelson employed a highly restrictive definition of a public good and the assumption of true consumption jointness – aspects missing from Dupuit's analysis or from Navier's.

The concept of neighbourhood has long been a topic of popular discourse and a subject of academic interest. Despite this attention, there is little agreement on what the term ‘neighbourhood’ means. The American Heritage Dictionary (Pickett, 2000) simply defines a neighbourhood as ‘a district or an area with distinctive characteristics’.

‘A district or an area’ is not very specific, and social scientists (outside of economics) have struggled for decades to define more precisely the geographic boundaries of neighbourhoods (Keller, 1968). Beyond the fact that neighbourhoods are sub-jurisdictional units, characterized by some degree of social cohesion, there is no accepted standard. The report prepared by the National Commission on Neighborhoods (1979, p. 7) stated that ‘each neighborhood is what the inhabitants think it is’. Yet the evidence suggests that such subjective perceptions vary greatly (Keller, 1968).

For economists, who generally focus on externalities when considering neighbourhoods, an individual's neighbourhood should theoretically extend as far as the individuals or facilities that affect her satisfaction with the community (Segal, 1979; Galster, 1986). In practice, economists and other social scientists studying neighbourhoods in the United States typically use census tracts to proxy for neighbourhoods. Including between 2,500 and 8,000 people on average, census tracts are close in size to what most envision as a neighbourhood and have the practical advantage of supplying demographic and economic data from the decennial census. In Australia and Europe, census data are typically available at sub-jurisdictional levels, defined by electoral wards or postcodes, and in some cases, smaller enumeration or collection districts (Overman, 2002; Bolster et al., 2004; Drever, 2004). Increasingly, researchers in the United States and Europe are able to link individual census data and other national...
household surveys to geographic identifiers, and they are experimenting with smaller and more flexible
neighbourhood definitions (Bolster et al., 2004; Ioannides, 2004; Bayer, Ross and Topa, 2005).
As for the term ‘distinctive characteristics’, economists identify several types of goods or services
delivered by neighbourhoods. First, neighbourhoods offer distinct physical amenities, ranging from the
style and condition of local housing to the number and quality of local parks. Second, neighbourhoods
embody a particular set of ‘neighbours’, who have a distribution of income, human capital, and racial
characteristics. Third, neighbourhoods often approximate local public service delivery areas such as
attendance zones for public elementary schools, which often vary significantly in performance, even
within the same jurisdictions. Fourth, neighbourhoods provide accessibility to shopping and employment
opportunities. Finally, economists increasingly view neighbourhoods as possessing a stock of social
capital, or norms and networks that facilitate interaction and can help residents work together to address
problems like crime (Glaeser, 2000).
Social scientists have been preoccupied with the evolution and nature of neighbourhoods for decades.
Modern academic discourse on neighbourhoods has its roots in the Chicago School of the 1920s. These
University of Chicago sociologists hypothesized that cities naturally grow outward in a series of
concentric rings. Through this growth, a neighbourhood life cycle emerges, from richer residents to
poorer, as more affluent residents opt for newer, less dense and quieter areas (Park, Burgess and
McKenzie, 1925).
Economists came later to the study of neighbourhoods, also initially drawn by an interest in the
transition of neighbourhoods from high to low income and from predominantly white to predominantly
minority residents. Muth (1972) and Sweeney (1974) propose variations of the filtering model, which,
similar to the Chicago School theory, posits that neighbourhoods decline because, as their housing ages
and deteriorates, higher-income residents exit, opting for newer neighbourhoods with newer housing.
Other economists focused instead on the role of racial or class preferences in driving neighbourhood
change (Bailey, 1959). In his simple, elegant model, Schelling (1971) shows that, if households care
about the composition of their neighbours, then small changes in demographic make-up can lead to the
rapid tipping of a neighbourhood from one group to another.
Another strand of economic literature examines the relationship between various neighbourhood
attributes and housing prices, typically using hedonic regression analysis (Kain and Quigley, 1970;
Bartik and Smith, 1987). Mills and Hamilton (1994) argue that economists have historically failed to
identify the external effects of housing quality and neighbourhood conditions. But more recent research
finds strong evidence that housing prices are lower in areas with higher crime, lower-quality schools,
dilapidated housing and vacant lots, and fewer homeowners (Grieson and White, 1989; Black, 1999;
Coulson, Hwang and Imai, 2003; Schwartz, Susin and Voicu, 2003; Schwartz et al., 2005). As for the
impacts of racial composition, more recent papers find that a neighbourhood's housing prices are
negatively correlated with the percentage of black residents (Yinger, 1976; Kiel and Zabel, 1996; Myers,
2004).
Finally, following Wilson (1987), economists have more recently turned to the study of how
neighbourhoods and social interactions in them influence resident behaviour and outcomes.

Nemchinov, Vasily Sergeevich (1894–1964)

M.C. Kaser

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

linear programming; mathematical economics; Nemchinov, V. S.

Article

Born the son of a State Bank messenger in Grabovo, Russia, on 2 January 1894; died in Moscow on 5 November 1964. Nemchinov graduated from the Moscow Commercial Institute between the February and October Revolutions of 1917, but joined the Communist Party only in 1940 on appointment as Director of the K.A. Timiryazev Agricultural Institute, the Statistics Faculty of which he had headed since 1928. He showed courage in prohibiting from his Institute the pseudo-genetics ('Michurinism') of T.D. Lysenko, but when at Stalin's instigation mainstream genetics were condemned in 1948 he was forced from the directorship. The Academy of Sciences (to which he had been elected in 1946) then made him chairman of its Council for the Study of Productive Resources, a post retained (with a chair at the party's Academy of Social Sciences) until his fatal illness. In 1958 he established the first group in the USSR to study mathematical economics (from 1963 the Central Economic Mathematical Institute) and was posthumously awarded a Lenin Prize for elaborating linear programming and economic modelling for the USSR.

The research embodied in Nemchinov (1926; 1928) was distorted to justify Stalin's coercion of the peasantry: his data on rural social stratification gave cover to 'liquidation of the kulaks as a class' (though Nemchinov had avoided the term 'kulak'); his measurement of absolute gross harvest (Nemchinov, 1932) was used to extort deliveries from collective farms. As soon as Stalin died, Nemchinov campaigned for the publication of official statistics and for more sophisticated techniques to utilize them – cybernetics had been damned as a pseudo-science serving capitalist interests. His organization of experimental national and regional input–output tables led him to question the meaningfulness of administered pricing, and his last book (1962) sought, as his widow put it (Nemchinova, 1985, pp. 202–21), ‘a broad-based system of social valuations … as a single, internally consistent set of values’.

The neoclassical growth model captures the basic trade-off between saving and investment. It has proven to be a useful tool to study development paths, and the interactions of technology shocks, money and fertility choices with growth.

Keywords

competitive equilibrium; convexity; endogenous growth; fertility; human capital accumulation; infinite horizons; innovation; marginal rate of transformation; neoclassical growth theory; optimal development paths; optimal quantity of money; optimal taxation; population growth; recursive equilibrium; representative agent; Solow–Swan growth model; technical change; technology shocks; transversality condition; turnpike property

Article

This article complements neoclassical growth theory. It discusses some developments of the neoclassical growth theory that endogenize the saving rates.

Infinite horizons

The planning problem

The standard neoclassical growth model assumes that the planning horizon is infinite. One justification is that forward-looking parents act ‘as if’ they were to live forever. To see this, assume that each individual lives for one period and has exactly one descendant. The utility of a member of generation 0 is given by

\[ U_0 = u(c_0) + \beta u_1, \] (1)
where $u$ is an increasing, continuous and concave function of consumption at time $t$, $c_t$. Iterating on this expression yields

$$U_0 = \sum_{t=0}^{\infty} \beta^t u(c_t), \quad \beta = \frac{1}{1 + \rho}, \quad \rho > 0,$$

which shows that altruism implies that the effective planning horizon for each individual is infinite.

In the simplest one-sector version of the model, the technology is summarized by

$$c_t + x_t \leq z^f(k_t), \quad t = 0, 1, \ldots$$

$$k_{t+1} \leq (1 - \delta_k)k_t + x_t, \quad t = 0, 1, \ldots$$

$$k_0 > 0, \text{ given},$$

where $k_t$ is the stock of capital per person available at the beginning of period $t$, $x_t$ is gross investment, $z$ is a measure of productivity, and $\delta_k$ is the depreciation rate of capital. The function $f$ is assumed to be increasing, continuous and strictly concave.

The planning problem corresponds to the maximization of the utility criterion (2), subject to the feasibility constraints (3). The analysis of this problem was initially carried out by Ramsey (1928), Cass (1965) and Koopmans (1965). A thorough analysis of the model can be found in Stokey and Lucas (1989).

The model has sharp predictions for the properties of an optimal development path. The relevant first-order conditions (in the interior case) require that the marginal rate of substitution between consumption at time $t$ and $t+1$ equal the marginal rate of transformation,
\[
\frac{u(c_t)}{\beta u(c_{t+1})} = 1 - \delta_k + zf'(k_{t+1}), \; t = 0, 1, \ldots
\]

(4)

and a transversality condition which is naturally interpreted as requiring that the value, at time 0, of the stock of capital at time \( T+1 \) converge to 0 as \( T \to \infty \). Formally, the condition is

\[
\lim_{T \to \infty} \beta^T u'(c_T)k_{T+1} = 0.
\]

Some properties of the solution are as follows:

1. There exists a unique steady state; that is, there are constant sequences of consumption, investment and capital that satisfy (3) (except at time 0) and (4). From (4) it follows that, in the steady state, the marginal product of capital equals the sum of the discount rate, \( \rho \), and the depreciation factor, \( \delta_k \).

\[
\rho + \delta_k = zf'(k^*)
\]

(5)

which determines capital per worker. The steady state level of consumption is given by

\[
c^* = zf(k^*) - \delta_k k^*.
\]

(6)

2. For any \( k_0 > 0 \), the solution to the problem converges to the steady state. Convergence is monotone.

3. In general, the savings rate – defined as \( 1 - c_t / zf(k_t) \) – is not constant, or even monotone. This distinguishes the optimal neoclassical growth model from the Solow–Swan version that assumes exogenous (and generally constant) saving rates.

The steady state is the model's prediction about the long-run levels of capital, consumption and investment. From the point of view of a theory of growth there are some interesting results:

1. The steady state level of output per worker is independent of the form of the utility function.

2. If a fixed level of government consumption, \( g \), is introduced in the model, the steady state condition (5) remains unchanged. The new steady state level of consumption is \( c^* = zf(k^*) - \delta_k k^* - g \). Thus the
model predicts that, in the long run, permanent increases in government spending have no impact on output per worker, and they crowd out private consumption one for one, with no effect on investment.

The basic model has been extended in many dimensions. In the case of multiple sectors, existence of optimal paths has been established very generally. Burmeister (1980) provides conditions for the existence and uniqueness of steady states with many capital goods.

The properties of optimal paths depend on the specification of the economic environment. In the case of a discounted twice differentiable utility and dominance diagonal of a matrix of first-order conditions, it is possible to show that the turnpike property holds (see the excellent survey in McKenzie, 1986). Formally, McKenzie shows that if \( \{k_t\} \) is an optimal path starting from \( k_0 \), then, for every capital stock \( k_0' \) near \( k_0 \) the associated unique optimal path converges exponentially to \( \{k_t\} \).

The monotonicity properties of optimal paths do not extend to the multicapital or multisector case. In general, optimal paths can display cycles (see Burmeister, 1980) and even more complex behaviour. To illustrate this let the feasible technology set be described as

\[
c_t \leq T(k_t, k_{t+1}),
\]

and let the (indirect) utility function over capital stocks be

\[
\nu(k_t, k_{t+1}) = u(T(k_t, k_{t+1})).
\]

With this notation, the planning problem reduces to

\[
\max_{\{k_{t+1}\}_{k=0}^{\infty}} \sum_{t=0}^{\infty} \beta^t \nu(k_t, k_{t+1}).
\]

Let's denote a candidate solution by a function \( g \) where

\[
k_{t+1} = g(k_t).
\]

Boldrin and Montrucchio (1986) showed that – under standard conditions – given any twice differentiable function \( g \), there exists a pair \((v, \beta)\) so that the associated planner's problem has \( g \) as its optimal policy function. Since \( g \) can exhibit arbitrary complex dynamics, the result shows that in order to endow the theory with predictive power it is necessary to ‘force’ the chosen specification to quantitatively match moments of the (actual) economy.
under study. Most recent research using the neoclassical growth model disciplines the choices of functional forms and parameters by requiring that they predict behaviour consistent with the empirical evidence.

Equilibrium growth

Even though the analysis of the growth model was motivated by normative considerations, under the stated assumptions the planner's solution of the growth model coincides with the competitive equilibrium of the economy. The argument – using the traditional definition of a competitive equilibrium – follows from Debreu (1954). In macro applications – the field in which the model has proved to be most useful – it is more natural to define a competitive equilibrium using the notion of recursive equilibrium first introduced by Prescott and Mehra (1980).

In order to account for wages, let the production function be given by

\[ y \leq zF(k, \eta), \]

where \( F \) is concave and homogeneous of degree one, and it satisfies

\[ f(k) \equiv F(k, 1). \]

Even though there are many alternative ways of defining an equilibrium, it is easiest to consider the case in which there are rental spot markets for capital and labour, and the households trade consumption, labour and capital services and one-period bonds. The problem solved by the representative household is

\[ \max \sum_{t=0}^{\infty} \beta^t u(c_t) \]

subject to

\[ b_{t+1} + c_t + x_t \leq w_t n_t + q_t k_t + (1 + r_t) b_t, \quad t = 0, 1, \ldots \]

\[ k_{t+1} \leq (1 - \delta_k) k_t + \chi_t, \quad t = 0, 1, \ldots \]

and the initial conditions, \([(1+r_0)b_0, k_0]\), given. As stated, this problem has no solution since the budget set is unbounded. Different alternative assumptions on how to deal with debt at infinity have been used to guarantee that the problem is well defined. The most general specification is to rule out Ponzi games by imposing that the present value of debt be nonnegative. Formally, any solution must satisfy
\[
\lim_{T \to \infty} \prod_{j=0}^{T} \frac{1}{1 + r_j} b_{T+1} \geq 0.
\]

which is the analogue – in the market setting – of the transversality condition in the planning problem. Firms solve a static problem

\[
\max_{k_t, n_t} 2F(k_t, n_t) - q_t k_t - w_t n_t.
\]

A competitive equilibrium is an allocation \([\{c_t\}, \{n_t\}, \{x_t\}, \{k_t+1\}]_t=0\), a price system \([\{q_t\}, \{w_t\}, \{r_t+1\}]_t=0\) and a sequence of bond holdings \([b_t+1]_t=0\), such that:

1. Given the price system, the allocation solves the maximization problems of households and firms.

Given that Debreu (1954) shows that the solution to the planner's problem can be decentralized as a competitive equilibrium, the first-order conditions (on the assumption of interiority and differentiability) corresponding to the maximization of utility and profits imply that equilibrium prices (as a function of the planner's allocation) are given by

\[
q_t = z f'(k_t),
\]

\[
(7a)
\]

\[
w_t = z f'(k_t) - k_t z f''(k_t),
\]

\[
(7b)
\]

\[
r_t+1 = q_t+1 - \delta_k.
\]

\[
(7c)
\]
It is possible to state the implications of the neoclassical growth model more intuitively using equilibrium prices. The consumer's optimal choice between consumption and saving requires that

\[
\frac{u(c_t)}{\beta u(c_{t+1})} = 1 + r_t + \delta_k,
\]

that is, that the marginal rate of substitution between present and future consumption equal to (gross) interest rate. Optimality on the part of firms requires that the marginal product of labour be equal to the wage rate and that the marginal product of capital equal the cost of capital, \( r_t + \delta_k \).

The basic neoclassical growth model (and some of the extensions mentioned) has had a significant impact on how economists view the process of development and the role of markets supporting optimal development paths. It is clear that there is nothing special about dynamic problems that make it more (or less) likely for competitive markets to fail to deliver optimal allocations. In the basic model of this note, Theorems I and II of welfare economics apply.

**Applications**

Some of the most notable extensions are as follows.

**Technology shocks**

Brock and Mirman (1972) studied a version of the neoclassical growth model in which the representative agent maximizes the expected value of the discounted flow of utility, and the technology is as in the deterministic growth model except that the technology level, \( z_t \), is replaced by a stochastic process \( \{z_t\} \). Brock and Mirman assumed that the process \( \{z_t\} \) is i.i.d. They established the existence of a solution and they showed that, under standard concavity assumptions, the resulting stochastic process of the capital stock has a unique invariant measure, which is the stochastic analogue of the steady state in the deterministic version of the problem. They also showed that the optimal policy function which determines \( k_{t+1} \) as a function of \( k_t \) and \( z_t \) is monotone. The results were extended to the case of serially correlated shocks by Donaldson and Mehra (1983).

This research has provided the theoretical foundations for a large literature that analyses the impact of economic fluctuations on savings and growth. When the model is extended to include an elastic labour supply, this is a natural setting in which to study cyclical movements of employment. For an introduction to this literature see Cooley (1995).

**Human capital and development**

The neoclassical growth model, extended to allow for human capital accumulation, is a natural candidate to understand the role that technological differences play in accounting for differences in output per worker. In the standard specification – using a Cobb–Douglas specification for \( f \) – it follows that output per worker is given by
where $\alpha$ corresponds to capital share, and $\bar{Y}_0$ (and all the $\bar{Y}_j$ in this section) is a constant. This version of the theory implies that the elasticity of output per worker with respect to $z$ is $1/(1-\bar{\alpha})$. Since accepted estimates of $\alpha$ cluster around 0.33 – which, approximately, correspond to the share of national income that accrues to capital – the elasticity is estimated to be approximately 1.5. If this model is to explain the differences in output per worker between the richest and poorest countries (which are of the order of 15–20 to 1), it must assume fairly large differences in productivity that exceed the best available estimates.

Klenow and Rodríguez-Claire (1997) (see also, Bils and Klenow, 2000) consider a production function of the form

$$y = z^{1/(1-\alpha)}\bar{Y}_0$$

and they use the specification $h^c = e^{\psi s}$, where $s$ corresponds to years of schooling to estimate the role of human capital. In this case, the equilibrium level of output per worker is given by

$$y = z^{1/(1-\alpha)} e^{\psi s} \bar{Y}_1$$

Klenow and Rodríguez-Claire find that the implied $\nu$ is not large. They conclude that productivity differences account for much of the differences in output.

Manuelli and Seshadri (2007a) endogenize the human capital decision. They adopt Ben Porath's (1967) specification. In discrete time, their model assumes that human capital evolves according to

$$h_{t+1} = z h_t + (1 - \delta h) h_t$$

where $n_t h_t$ is the fraction of the available time allocated to producing human capital, and $x_{ht}$ denotes market goods used in the production of human capital. In this setting, $h^c = (1-n) h$. It is possible to show that, in the steady state,
output per worker is given by

$$\gamma = z^{\gamma_2}/[(1-\alpha)(1-\gamma_2)]\gamma_2.$$ 

This version of the model implies that the elasticity of output with respect to the productivity parameter $z$ is $\gamma_2 / [(1-\alpha)(1-\gamma_2)]$. Manuelli and Seshadri use life age–earnings profile evidence to estimate that $\gamma_1=0.63$ and $\gamma_2=0.30$. This results in an elasticity of output per worker with respect to productivity of 6.5. This high elasticity implies that productivity differences have a large impact on (endogenously chosen) human capital. As a result, even small productivity differences are consistent with large variations in output per worker. The relative importance of human capital and productivity is an active area of research. More work is needed before the roles of technology and education in accounting for differences in output can be accurately estimated.

The role of taxation

The neoclassical growth model has been widely used to analyse the effect of specific tax policies and to derive properties of optimal tax systems.

Consider a version of the model in which labour is elastically supplied. Let the period utility function be given by $u(c, \cdot)$, where $\cdot$ is interpreted as leisure. In an economy in which consumption, capital income and labour income are taxed (at constant rates) it follows that the steady state is characterized by

$$\rho = (1 - \tau^k)(F_k(k, n) - \delta_k)$$ (8a)

$$u_c(c, 1-n) = u_c(c, 1-n)F_n(k, n)\frac{1 - \tau^n}{1 + \tau^n}$$ (8b)

$$F(k, n) = c + \delta_k k$$ (8c)
\[ \rho = (1 - \tau^b) r^b. \]  
(8d)

From a formal point of view the system of eqs (8) contains four equations in four unknowns. Let
\[ \Phi(c, \ell) = \frac{\mu(c, 1 - \ell)}{\mu(c, 1 - \ell)}, \] and assume that \( \Phi (c, \ell) \) is increasing in \( c \) and decreasing in \( \ell \). In this case, it is possible to show that:

1. An increase in the tax rate of capital income, \( \tau^k \), decreases the amount of capital, but has ambiguous effects on employment.
2. An increase in tax rate on labour income (consumption) decreases both \( k \) and \( n \).

The effect of taxes on employment and growth is a subject that continues to receive substantial attention. In the mid-1980s Chamley (1986) and Judd (1985) asked the following question: If a government has to finance a given (say, constant) stream of consumption, and if the only available taxes are distortionary taxes (for example, in the previous example, set \( \tau^c = 0 \) and add government spending to (8c)), how should those taxes be chosen? Chamley and Judd showed that the optimal tax system is such that, in the steady state, capital income taxes are zero while labour income taxes are positive.

This result is delicate in the sense that it does not hold if some of the assumptions are slightly modified. For example, if the function \( F \) is strictly concave, and pure profits cannot be taxed away, then the optimal long-run tax rate on capital income need not be zero. Similarly, if there are different types of labour (for example, high and low skill) and it is possible for the planner to distinguish between them, then the zero taxation result is overturned. For other examples see Correia (1996) and Jones, Manuelli and Rossi (1997).

**Money and growth**

Since the neoclassical growth model satisfies the assumptions of the convex economy studied by Debreu (1959), it is impossible to find an equilibrium in which a non-interest earning asset (for example, money) has positive value in equilibrium. In order to introduce money, the neoclassical growth model has been modified in a variety of ways. One of the first attempts corresponds to Sidrauski's (1967) analysis of a monetary model. Sidrauski studied the case in which money enters the utility function, as a reduced form that captures the services provided by money balances.

In Sidrauski's formulation (adapted to discrete time), the consumer problem is

\[ \max \sum_{t=0}^{\infty} \beta^t u(c_t, m_{t+1} / p_t) \]

subject to
where \( m_t \) is nominal money balances chosen by the household, \( M_t \) is the economy-wide per capita money supply (that the individual takes as given), \( p_t \) is the price level, \( B_t \) is the nominal value of one period bonds purchased at time \( t-1 \), and \((1+i_t)\) is the gross nominal interest rate. The specification of the budget constraint reflects the assumption that the government exogenously increases the stock of money through lump-sum transfers. The first order conditions for this problem are (imposing the standard equilibrium conditions)

\[
\begin{align}
\lambda_t & = \beta \lambda_t [1 - \delta k + zf'(k_{t+1})], \\
(9c)
\end{align}
\]

and feasibility. In this version of the model, money is superneutral in the steady state. In the steady state eq. (9c) reduces to eq. (5a) and, hence, the rate of money growth has no impact on the long-run level of output. This result is not robust. If labour is supplied elastically, inflation has (in general) real effects through its impact on the marginal rate of substitution between real money balances and leisure. The one case in which money is still neutral is when the utility function is separable in real money balances (see Fischer, 1979). In an economy in which nominal money balances grow at the (gross) rate \( 1+\pi \), the nominal interest rate is given by

\[
1 + i = (1 + \rho)(1 + \pi),
\]
Fertility and growth

The neoclassical growth model can be easily extended to the case of exogenous population growth and exogenous technical change. It has also been used to understand the interplay between economic forces and fertility decisions (see Barro and Becker, 1989; Becker and Barro, 1988).

To illustrate the relationship between growth and fertility, assume that individuals live for just one period and that each agent gives birth to $\eta$ offspring. The utility function of a member of generation $t$ is given by

$$U_t = u(c_t) + \beta \eta_t^{(1-\varphi)} U_{t+1}, \quad 0 \leq \varphi \leq 1,$$

where $\eta_t$ is the number of children. When $\varphi > 0$, these preferences display imperfect altruism as increases in the number of children result in lower marginal contribution of the last child to utility.

It is assumed that each child costs $\upsilon$ units of labour, and the per capita labour endowment is normalized to 1. The planner's problem for this economy can be expressed as

$$\max_{c_t, \eta_t} \sum_{t=0}^{\infty} \beta^t N_t u(c_t),$$

subject to

$$c_t + \eta_t(a + k_{t+1}) \leq zF(k_t, 1 - \eta_t\upsilon) + (1 - \delta)k_t, \quad k_0 > 0, N_{t+1} \leq N_t \eta_t^{(1-\varphi)}, \quad N_0 = 1.$$

Thus, from a formal point of view, endogenous fertility plays the role of another good, $N_t$, which is ‘produced’ with a linear technology with current fertility as its only input. This is a special case of a two-sector model. Barro and Becker showed that if the utility function is of the form $u(c) = c^\sigma$ – a standard specification – the model can have multiple steady states, with some stable and some unstable.

The model has been used to study the effect of changes in child mortality on fertility (see Doepke, 2005), the impact of introducing social security (see Boldrin and Jones, 2005), and the relationship between fertility, growth
and human capital (see Manuelli and Seshadri, 2007b). In general, the ability of the model to match the evidence depends on the specific parameterization used, and finding the appropriate specification is an active area of research.

## Finite lifetimes

What are the properties of the neoclassical growth model if economic agents have short – relative to the economy – horizons? The simplest case is study an economy in which individuals live for two periods, and have preferences defined over first- and second-period consumption. This model was originally analysed by Diamond (1965), and an excellent textbook treatment can be found in Azariadis (1993).

Each agent inelastically offers one unit of labour in his first period, and $e \leq 1$ units in his second period. The representative agent problem is

$$\max U(c_t^t, c_{t+1}^t)$$

subject to

$$c_t^t + (1 + r_{t+1})^{-1}c_{t+1}^t \leq w_t + (1 + r_{t+1})^{-1}w_{t+1}e,$$

where $c_j^t$ denotes consumption at time $t$ of an individual born in period $j$, and $w_t$ is the wage rate. Feasible allocations satisfy

$$c_t^t + c_{t-1}^t + x_t \leq zF(k_t, 1 + e), k_{t+1} \leq (1 - \delta)k_t + x_t, t = 0, 1, \ldots$$

where, as before, we assume that $F$ is homogeneous of degree 1.

Since the solution to an individual optimization problem is completely summarized (in the two period setting) by its saving function, let

$$s_t = s(w_t, w_{t+1}, r_{t+1})$$

(10)

denote saving by a member of generation $t$. Firms, as in the case of infinite horizons, are assumed to solve static problems. Equilibrium input prices, satisfy the appropriate version of (7).
An equilibrium in this economy consists of sequences of capital stocks and prices such that individuals and firms optimize and markets clear. A simple (and intuitive) condition that characterizes all the equilibria is the requirement that saving by the young at time $t$ equal the capital stock at the beginning of period $t+1$. Formally, this corresponds to

$$k_{t+1} = s(\bar{w}(k_t), \bar{w}(k_{t+1}), \bar{r}(k_{t+1})), \tag{11}$$

where,

$$\bar{w}(k) = zF_2(k, 1 + \varepsilon), \bar{r}(k) = zF_1(k, 1 + \varepsilon) - \delta_k.$$

For a given $k_0$, any sequence that satisfies (11) and that does not violate other feasibility conditions (for example, $k_t \geq 0$) is an equilibrium sequence of capital stocks. The other components of an equilibrium (for example, consumption and prices) can be readily obtained from the household and firm optimization problems.

Even though this set-up (with only one type of consumer) appears very close to the infinite horizon model, its implications are quite different. An (incomplete) list of the most interesting properties includes the following:

1. Even if $\varepsilon = 0$ (young individuals are net savers), and if both consumption goods are normal, the equilibrium need not be unique. A sufficient condition for uniqueness is that the two goods be gross substitutes. This corresponds to the saving function being an increasing function of the interest rate.
2. If $\varepsilon = 0$ and saving is increasing in the interest rate, eq. (11) can be solved for $k_{t+1}$. Let the solution be denoted $k_{t+1} = G(k_t)$. Then, if $G'(0) > 1$, this map can have and odd number $(2j + 1)$ of nontrivial steady states, of which $j + 1$ are asymptotically stable and $j$ are unstable. If $G'(0) < 1$ there may be an even number of nontrivial steady states.
3. If $\varepsilon = 0$ and saving is not increasing in the interest rate, eq. (11) can be solved for $k_{t+1}$ only locally. The major impact of this is that stable steady states need not be separated by unstable steady states.
4. Equilibrium paths of capital may display cycles and, depending on the specification, chaotic dynamics.
5. Equilibria – even stationary equilibria – need not be optimal.

This last result shows that when the individual horizon differs from the economy's horizon, then optimal saving at the individual level need not imply optimality in the aggregate, even in the absence of the standard arguments (for example, externalities) for market failure.

To illustrate what can go wrong, consider an economy in which $U$ is strictly quasi-concave and that, in a stationary equilibrium, the stock of capital is such that $\bar{r}(\bar{k}) = zF_1(\bar{k}, 1) - \delta_k < 0$. Let the levels of consumption in young and old age be denoted $(\bar{r}_1, \bar{r}_2)$. The key condition is that the gross interest rate be less than the gross rate of population growth, which is assumed to be 1 in this example. Consider next the problem of maximizing the utility of a given generation subject to the constraint that allocations be constant and the stock of capital also remains constant. Let $k^*$ be the solution to
max \( U(c_1, c_2) \)

subject to

\[ c_1 + c_2 \leq zF(k, 1) - \delta_k k. \]

Let the solution of this problem be \( (c_1^*, c_2^*, k^*) \). Given that \( k^* \) is such that \( zF_1(k^*, 1) - \delta_k k = 0 \), it follows that \( k^* < \bar{k} \). Since \( (\bar{c}_1, \bar{c}_2, \bar{k}) \) is feasible, it must be the case that \( U(c_1^*, c_2^*) > U(\bar{c}_1, \bar{c}_2) \). Thus all generations, starting with generation 1, are better off under this alternative allocation. What about the initial old? Since they only care about consumption they are also better off as fewer resources are allocated to investment.

To summarize, when individual horizons are shorter than the economy’s horizon, even the simplest specification of the neoclassical growth model can result in very complicated equilibrium paths.

Concluding comments

For many years, the neoclassical growth model has been the workhorse of researchers interested in fluctuations and growth. The model is not without weaknesses. Perhaps the most important is its inability to explain long-run growth: in the steady state the growth rate is exogenous. Endogenous growth models – versions of which are very close to the neoclassical growth model – can be used to understand the effects of policies and shocks on long-run growth. Currently, there are isolated attempts to integrate both views. This has been done for versions of the models that assume convex technologies. For example, endogenous growth models have been used to eliminate the need for arbitrary detrending in the study of business fluctuations (see, for example, Jones, Manuelli and Siu, 2005). The versions of the models that have been studied so far are, of necessity, the simplest ones. It is too early to tell whether the integration of the two strands will succeed.

A large literature on endogenous growth departs from the assumption of convex technologies and no external effects. This body of research views innovation as a form of public good, and emphasizes the role of institutions (for example, how property rights are protected) in determining growth. Since these assumptions amount to departures from the convexity assumptions of the neoclassical model, competitive equilibria are no longer optimal, and this alternative view suggests that a variety of interventions are needed to attain optimality. Thus, the major difference relies on the presence (or absence) of departures from the assumption that technologies form a convex cone.

If the neoclassical growth model is narrowly interpreted (as in this article) as assuming that government policies are exogenous (and markets are competitive), then it follows that the fundamental cause of cross-country differences in output are differences in policies. More recently, the analysis of the determinants of development has emphasized the role of (endogenous) institutions and geography. Endogenizing the institutional structure seems like a natural next step in the development of the theory. However, serious theoretical limitations of our understanding of social choice theory in dynamic settings has limited progress so far. The direct role of geography is easily incorporated into the framework. However, to the extent that the geographic dimension is viewed as influencing (or determining) institutions and or policies, the same limitations apply.

In summary, the neoclassical growth model is still the basic framework to study questions that require
understanding differences across countries, regions or individuals, in the level of some economic variable. The main challenge for future research is to develop a theory of social choices (policy choices) that is consistent with the dynamic framework.

How to cite this article

Neoclassical growth theory is mostly that of the equilibrium of a competitive economy through time. It stresses capital accumulation, population growth and technical progress. It distinguishes momentary equilibrium (when the capital stock, the working population and technical know-how are fixed) from long-run equilibrium (when none of these elements is given). Long-run equilibrium is not a sequence of momentary equilibria, since it embodies the rational expectations of agents. The theory has little to say about the ‘animal spirits’ that may determine an economy's potential growth rate, but provides a good base camp for sallies into the study of particular economies.

Article

Neoclassical growth theory is not a theory of history. In a sense it is not even a theory of growth. Its aim is to supply an element in an eventual understanding of certain important elements in growth and to provide a way of organizing one's thoughts on these matters. For instance, the question of whether technical progress is bound to be associated with unemployment cannot be decisively answered by the
The neoclassical growth theory begins by pinpointing those considerations on which an answer depends. Most of the theory is that of the equilibrium of a competitive economy through time. In particular, attention is paid to the accumulation of capital goods, growth in population and technical progress. Two kinds of equilibria are distinguished. One is the short period or momentary equilibrium of the economy when the stock of capital goods, the working population and technical knowledge can be taken as fixed. The other is the long-run equilibrium when none of these three elements are taken as given. It is important to understand that while long-run equilibrium implies momentary equilibrium for all dates it is not the case that a sequence of momentary equilibria constitutes a long-run equilibrium. For the latter has the property that the actions of agents taken at a given date in the light of their expectations of events at subsequent dates are not regretted when these dates arrive. In other words, it is what we would now call a rational expectations equilibrium. Harrod (1939) called a path of an economy with this property the warranted path.

In principle a warranted path (say of output or output per man) could be quite irregular. Indeed it could be cyclical (Lucas, 1975). But except in very simple models such generality is intractable and most of the attention has been devoted to long-run equilibria which are steady-state or quasi-stationary. (If a variable $x(t)$ obeys the dynamic equation $x(t) = e^{gt}x(0)$ then $\dot{x}(t) = x(t)e^{-gt} = x(0)$ is a constant, that is $x$ is stationary.) This is one of the reasons why the theory is not really a theory of growth. It is also unwise to identify the steady state – say, the steady state rate or growth in output per head – with historical trends in the variable. That would require a good deal more argument than the theories provide. A steady state equilibrium is simply an extension of stationary equilibrium (an equilibrium in which the stock of capital goods, the population and technical knowledge are all constant). But it allows this now to include accumulation and technical change.

It is of interest to ask whether a steady state equilibrium is possible and if it is, whether a sequence of short period equilibria guides the economy to it. There is also another qst: do all warranted paths eventually become steady states? (See Hahn, 1987.) However the literature on these matters is sometimes confused and confusing. Short period equilibrium plainly depends on agents' expectations and so if they are not postulated to be always correct there are many possible evolutions of such equilibria. In fact except for Harrod's (1939) pioneering discussion of actual growth paths and one or two others, little attention has been paid to the expectational problem. Instead the path of the economy has been studied on the hypothesis that what is saved is also invested without explicit attention to what this implies for expectations concerning prices and interest rates. When that is made explicit it turns out that only warranted paths have been examined and not a sequence of short period equilibria. This procedure has been also adopted by the ‘new macroeconomics’ (e.g. Lucas, 1975).

Connected with this is the treatment of investment and savings. The latter are usually taken to be either proportional to income or to come only from profits. Savings are not explained by the optimizing choices of households. This, however, is against the spirit of neoclassical economics. In order to improve on conventional savings theory one either takes a world which one can study ‘as if’ agents were infinitely long lived or one considers an economy of overlapping generations first studied by Samuelson (1958). Neither of these moves is discussed in what follows. But I re-emphasize that until savings behaviour has been explained the theories are not fully neoclassical.

Investment behaviour is a more difficult matter. Since the bulk of the theory is one of the warranted path, the marginal return to any investor is always equal to the marginal cost of investment. Thus
investment is never regretted and is simply explained by it not being profitable to undertake more or less investment than is thus warranted. But difficulties arise if the warranted path and particularly the steady state is not unique, and also if investment is in some sense the carrier of technical progress. ‘Animal spirits’, as Keynes called entrepreneurial investment propensities, may be determinants of the rate of growth which the economy is capable of. Equally important is the circumstance that investment behaviour will be of prime importance in the evolution of a sequence of short run equilibria. neoclassical theory has little to offer on these matters and is open to criticism on these grounds.

This brings me back to the beginning. As will be seen from what follows neoclassical theory states quite precisely what kind of economy in what kind of state is being considered. This economy and this state may be considered to be of low descriptive power. That, however, needs empirical argument and neither proponents nor opponents have produced any clinching ones. But an equally interesting question is whether the theory provides a good base camp for sallies into the study of particular economies. For instance, does it allow us to find just that feature of such an economy which is at variance with the postulates of the theory and thence to a modification of the latter, step by step? To this question at the moment the answer must be yes.

There is one last matter. The theories here discussed have provided the arena for much controversy concerning the logical coherence of neoclassical theory in general (Robinson, 1965; Harcourt, 1969). This controversy is not here discussed. For what it is worth it is this writer's view that neoclassical theory has survived this controversy unscathed. But the emphasis here is on 'logical'. There is little to be said for those economists who have taken the question of the descriptive merit of the theory as having been decisively settled in its favour.

1. **The simple model**

1.1. **The single good economy. no technical progress**

Consider an economy in which a single good is produced by means of itself and labour. The good can also be consumed. The stock of it devoted to production is denoted by $K$ and called capital. The stock does not depreciate either through use or the passage of time. Further notation is as follows: $Y$ is output, $L$ is the amount of labour used in production, $L^0$ is the labour force, $V = \frac{Y}{L}, K = \frac{K}{L}, e = \frac{L}{L^0}$. 

**Assumption 1.1:** The production possibilities of the economy can be represented by a $C^2$ production function.

$$Y = F(K, L)$$

with the following properties:

1. (a) For all $h > 0$: $hY = F(hK, hL)$. (Constant Returns to Scale)
2. (b) $f'(k) > 0$, $f''(k) < 0$ for $k \in [0, \infty]$. Also $f'(0) = \infty$, $f'(\infty) = 0$
Assumption 1.2: The working population \( L^0 \) grows at a constant geometric rate 
\[ \lambda \text{ [i.e. } L^0(t) = L^0(0)e^{\lambda t}\] .

Assumption 1.3: A constant fraction \( s \) of output is not consumed.
It will thus be a condition of equilibrium that output which is not consumed is invested:

\[
sf(k(t)) = s y(t) = \frac{\dot{K}(t)}{L(t)} = \dot{k}(t) + k(t) \frac{\dot{L}(t)}{L(t)}.
\] (1.2)

Definition 1.1: The economy is said to be in steady state equilibrium if \( k(t) \) and \( e(t) \) are constants, profits are maximized and (1.2) holds.
If \( e(t) \) is constant then

\[
\frac{\dot{L}(t)}{L(t)} = \frac{\dot{L}^0(t)}{L^0(t)} = \lambda.
\]

Using this and the condition \( \dot{k}(t) = 0 \) in (1.2) yields

\[
\lambda = \frac{sf(k)}{k}
\] (1.3)

as a condition for steady state equilibrium. Harrod (1939) called \( sf(k)/k \) the warranted rate of growth and we shall abbreviate by writing
Clearly $w(k)$ gives us the rate of growth of output required to keep investment and savings equal to each other in steady state. On the other hand, $\lambda$ is the rate of growth of employment which is needed to keep the proportion employed (possibly = unity) constant. Harrod called it the *natural rate of growth* of output for it tells us the rate at which output grows at a constant $e$.

Now by A.1.1.(b) one has $W(0) > \lambda$ and $W(\infty) < \lambda$ so there exists $k^*$ satisfying (1.3). Since $W'(k) < 0$ everywhere, $k^*$ is the only value of the capital labour ratio satisfying 1.3. But then for profit maximization, the real wage $w^*$ and the real interest rate, $\rho$ in steady state equilibrium are:

$$w^* = f(k^*) - k^*f'(k^*) \text{and } \rho^* = f'(k^*).$$

(1.4)

So the steady state equilibrium exists and is uniquely characterized by (1.4) and

$$\lambda = W(k^*)$$

(1.5')

Now return to (1.2) and consider the path $k(t)$ out of steady state but with $e(t)$ constant at $e$. In our new notation we find

$$\frac{\dot{k}}{k} = \left[ w(k) - \lambda \right]$$

(1.5)

by dividing (1.2) by $k$ and rearranging. Now let

$$\frac{s^*_f(k)}{k} \equiv w(k).$$
so that $V(k)$ is a measure of the deviation of the warranted from the natural rate of growth. One has:

\[ V(k) \geq 0 \text{ for all } k \text{ and } V(k^*) = 0. \]  

(1.6)

Also using (1.5):

\[ \dot{V}(k) = [w(k) - \lambda] w'(k) \dot{k} = [w(k) - \lambda]^2 k w'(k) < 0 \text{ for all } k > 0 \text{ and } k^* \neq k. \]  

(1.7)

These two results together with the Inada conditions suffice for the conclusion:

For all $k(0) \geq 0$, \( \lim_{t \to \infty} k(t) = k^* \).

We sum up:

**Proposition P.1.1:** An economy satisfying A.1.1 – A.1.3 has the following properties:

1. (a) There exists a unique steady state equilibrium
2. (b) The path of the economy along which savings are always equal to investment and the proportion of the workforce employed is constant ($e$ is constant) approaches the steady state equilibrium as $t \to \infty$.

1.2 Discussion of the model

There are many lacunae in the theory just presented and we shall be able to fill in some of these below. But first I discuss what can be learned from it.

Harrod (1939) writing in a Keynesian spirit held the view that a steady state equilibrium might not exist. He was particularly interested in the possibility that the warranted growth rate was always above the natural rate. In that case output would have to grow faster than is physically possible in order for
investment to take up the savings generated and that is not possible. There would be a permanent
tendency to depression. For many commentators this view of Harrod's rested implicitly on an assumed
production function of the form:

\[ y = \min \{ \alpha K, \beta L \} \quad (1.8) \]

that is on fixed coefficients of production (see e.g. Solow, 1956). However, a careful reading of Harrod
suggests that he rather based his argument on the Keynesian liquidity trap. That is he thought that
monetary forces set a positive lower bound on the rate of interest which thus on neoclassical theory set
an upper bound on \( k \) and so, given \( s \), a lower bound on \( w(k) \).

This argument, however, is suspect. It is the real and not the nominal interest rate which governs
(together with the real wage) the choice of \( k \). Liquidity preference may set a lower bound on the nominal
interest rate (the cost of holding money) but not on the real rate. Thus suppose \( r \) is the nominal interest
rate. Then

\[ \rho = r - \frac{\dot{p}}{p} \]

where \( p \) is the price of the good. Then if \( r \) is at its minimum level \( \zeta \) we have from (1.4)

\[ \left( \frac{\dot{p}}{p} \right)^* = \zeta - f'(k^*) \quad (1.9) \]

as a condition of steady state equilibrium. By assumption \( f'(k^*) < \zeta \) so for such an equilibrium one
requires a constant inflation rate:

\[ \left( \frac{\dot{p}}{p} \right)^* > 0. \]
So provided we can graft a monetary sector onto the simple model it would seem that the liquidity trap is not an obstacle to the existence of steady state equilibrium. But this argument reveals a central weakness in the reasoning which supports P.1.1(b). For suppose at a historically given \( k \) one has \( w(k) > \lambda \). If we impose the condition that savings are equal to investment, then indeed there would be pressure on resources and one could tell a story to explain the generation of the required inflation rate of (1.8). But we have no good reason for imposing that condition. By doing so we are not really asking: what actually happens?, that is, what is the actual growth rate?, but rather we are implicitly postulating that the inflation rate is always such that excess savings for \( k \) constant are taken up by capital deepening (\( \dot{k} > 0 \)). But why should this be so? If, for instance, the economy grew at \( \lambda \) then there would be excess supply of the good and normal arguments would lead us to suspect falling prices. But these would raise the real rate of interest and raise \( w(k) \) above \( \lambda \) even further. The steady state equilibrium even if it exists is an unstable ‘knife-edge’ (Harrod, 1939).

(b) Solow's celebrated paper (1956) established P.1.1. But Solow was mistaken in his belief that it disposed of Harrod's knife-edge. The latter does not deal with paths on which the condition: savings = investment at a constant \( e \) has been imposed. That is Harrod did not postulate that the actual path was an equilibrium path. In this he was right since there is no good explanation of the Solow condition.

(c) An alternative procedure leading to P.1.1(a) even if 1.8 is the form of the production function is to drop A.1.3 (Hahn, 1951; Kaldor, 1955; Robinson, 1965). This is done by supposing that the saving ratio out of profits is higher than that out of wages. Now if there are fixed coefficients of production (1.8) the equilibrium conditions (1.4) have no meaning since marginal products are not defined. This leaves it open to determine the real wage and interest rate by the requirement that they should generate that distribution of income between wages and profits which makes the warranted growth rate equal to the natural rate. From (1.8) one finds

\[
\frac{\gamma}{K} = a, \quad \frac{\gamma}{L} = b \quad \text{and} \quad k = \frac{b}{a} \equiv \beta \text{ say}.
\]

Let \( s_0 \) be the saving propensity out of wages and \( s_1 \) the saving propensity out of profits, with \( s_0 < s_1 \). Then the aggregate saving propensity, \( s \), of the economy is given by

\[
\frac{s_1 p}{a} + s_0 \frac{w}{b} = s.
\]

Imposing the condition \( s \alpha = \lambda \) (the warranted rate = natural rate) yields
\[ s_1 \rho + s_0 \frac{w}{\delta} = \lambda \]  
(1.10)

But also

\[ \frac{\rho}{a} + \frac{w}{\delta} = 1 \]  
(1.11)

so that we have two equations to determine what \( w^* \) and \( \rho^* \) must be in steady state equilibrium. A special case arises when \( s_0 = 0 \) (no saving out of wages) and \( s_1 = 1 \) (no consumption out of profits). Then

\[ \rho^* = \lambda \]  
(1.12)

is the condition of equilibrium. The reader should avoid interpreting (1.12) as saying that \( \lambda \) 'determines' the rate of profit. Equation (1.12) tells us what \( \rho \) must be if there is to be steady state equilibrium.

Once again a version of P.1.1(a) survives. Also stability fares slightly better than in (a). For if the actual growth rate is less than the warranted rate (because \( w \) and \( \rho \) have the 'wrong' values), and the latter is greater than \( \lambda \) then investment will be less than savings and competition between firms may lead to lower prices, higher real wages and so a fall in \( s \). This will lower the warranted rate and bring it closer to \( \lambda \) as well as reducing the investment-savings gap. This may be so but what has just been said is not a proof. Indeed, as for instance Meade (1966) has shown, falling profitability may reduce the willingness to invest and so lead the system away from steady state equilibrium.

(d) Of course, (1.8) is not a plausible production function. Suppose we combine the savings assumption of (c) with a neoclassical production function satisfying A.1.1. Then certainly (1.4) must hold in equilibrium. But (1.3) will now read

\[ (s_1 + s_0) f'(k) + s_0 \frac{f(k)}{k} = \lambda \]  
(1.13)
from which we can find \( k^* \). (Since

\[
 s_1 \rho \frac{K}{Y} + s_0 \frac{wI}{Y} = s.
\]

So

\[
 s_1 \rho + s_0 \frac{w}{k} = s \frac{Y}{k} = \lambda.
\]

Then substitute from (1.4) for \( \rho \) and \( w \). So while the saving hypothesis will be reflected in the steady state value of \( k \) it will leave the equality between marginal productivity and factor rewards as an equilibrium condition. Indeed without this, the steady state values of \( w \) and \( \rho \) would be unknown. This is so even under the ‘classical’ savings assumption that \( s_0 = 0 \). The equation derived from (1.13) is then

\[
 s_1 f'(k) = \lambda
\]

and it tells us what \( k \) must be in order to generate a profit rate which, given the savings hypothesis, generates just the right amount of savings required for a growth in the capital stock at the rate \( \lambda \). Thus the savings hypothesis has no direct bearing on the neoclassical equilibrium condition that the rate of profit must equal the marginal product of \( k \).

(e) If workers save and invest their savings at the current rate of return on capital then the foregoing arithmetic needs to be changed. This was first noticed by Pasinetti (1962) whose paper gave rise to a number of others (Meade and Hahn, 1965; Modigliani and Samuelson, 1966).

Let \( \sigma = s_1 - s_0 > 0 \). Let \( \mu \) be the fraction of \( k \) owned by capitalists – that is by agents who have no income from work. Then savings per employed worker are given by

\[
 s_0 f(k) + \sigma f'(k) \mu \kappa.
\]

So in steady state equilibrium one requires
\[
\frac{s_0 f(k)}{k} + \sigma f'(k) \mu = \lambda.
\]  
(1.14)

From which

\[
\frac{\mu f'(k) k}{f(k)} = \frac{1}{\sigma} \left[ \frac{\lambda k}{f(k)} - s_0 \right].
\]  
(1.15)

The left-hand side measures the capitalists' share in income which cannot be negative. But there is nothing which guarantees a solution to (1.15) with \( \lambda k \geq s_0 f(k) \). Pasinetti (1962) simply made the latter (with strict inequality) a condition of the model. But God may have made the world otherwise. In fact there are two possibilities. Suppose (1.15) has an admissible solution. One notes that in steady state one must have

\[
1 - \mu = \frac{s_0 \left[ f(k) - \mu k f'(k) \right]}{\lambda k}.
\]  
(1.16)

That is the ratio of workers' capital to total capital must equal the ratio of their savings to total savings which in steady state equilibrium is equal to \( \lambda k \). Solving (1.16) for \( \mu \) yields

\[
\frac{\lambda k - s_0 f(k)}{k [\lambda - s_0 f'(k)]} = \mu.
\]  
(1.17)

Solving (1.14) for \( \mu \) yields
Equating (1.17) to (1.18) then yields

\[
\lambda k - s_0 f(k) \frac{1}{\sigma f'(k)} = \mu. \tag{1.18}
\]

So even though workers save, the long run equilibrium rate of profit bears the same relation to \(\lambda\) as it does under the classical savings hypothesis. Note that \(\lambda k > s_0 f(k)\) is here required as before. In particular write (1.18) as

\[
\max \left[ 0, \frac{\lambda k - s_0 f(k)}{k} \right] \frac{1}{\sigma f'(k)} = \mu. \tag{1.18'}
\]

Then this always has an admissible solution. If that gives \(\mu = 0\) then from (1.14)

\[
\frac{s_0 f(k)}{k} = \lambda. \tag{1.20}
\]

Harrod solution. It should now be emphasized that \(\mu = 0\) does not mean that capitalists own no capital. All it means is that their share in total capital is zero.

Modigliani and Samuelson (1966) have shown how a warranted growth path may converge to \(k^*\) given by (1.12) or to \(k^{**}\) given by (1.20) depending on the technology and savings propensities.

(f) It will have been noticed that the whole of the above discussion has been conducted for \(L/L^0\) constant and not \(L/L^0 = 1\); that is the steady state is consistent with permanent unemployment. This should cause no surprise since the assumption of constant returns to scale and of constant savings propensities makes all equilibrium conditions independent of scale. If there is unemployment in a steady state
equilibrium it can be argued with equal lack of real sense that either the capital stock is too low or that the real wage is too high. The present model is not suited to a discussion of whether falling interest rates and or money wages as long as there is unemployment would lead the economy to a steady state with full employment.

1.3 The single good economy with technical progress

Growth theory without technical progress seems pretty useless. Yet no really satisfactory account exists of the determinants of technical progress, at least no such account based solely on considerations of economic theory exists. (Schumpeter (1934) is probably still the most interesting attempt but it excludes the possibility of steady state equilibrium.) What follows is therefore rather ad hoc and mechanical. Technical progress shifts the production function through time and so in its most general form when technical progress is \textit{disembodied}, one writes

\begin{equation}
Y(t) = F[K(t), L(t), t]
\end{equation}

and retains the assumption of constant returns to scale for each \( t \). Progress is disembodied if it can be taken full advantage of by the stock of the good (capital) accumulated in the past and by the same kind of labour. Even with this strong assumption we need more structure to build a model and accordingly postulate that all technical progress is \textit{factor-augmenting}, that is (1.21) can be written as

\begin{equation}
Y(t) = F[\alpha(t)K(t), \beta(t)L(t)] \quad \text{with} \quad \alpha(t) \geq 0, \beta(t) \geq 0 \quad \text{all} \ t.
\end{equation}

Let

\begin{equation}
\hat{K}(t) = \alpha(t)K(t), \hat{L}(t) = \beta(t)L(t)
\end{equation}

and

\begin{equation}
\hat{k}(t) = \frac{\hat{K}(t)}{\hat{L}(t)}, \hat{\gamma}(t) = \frac{Y(t)}{\hat{L}(t)}.
\end{equation}
Then the equilibrium real interest rate is given by \( \alpha f' [\dot{k}(t)] \) when \( \ddot{y}(t) = f [\dot{k}(t)] \).

In steady state equilibrium the real interest rate is constant. Let the operator \( E \) applied to a function \( g(x) \) denote its elasticity

\[
Eg(x) = \frac{g'(x)}{g(x)} x
\]

Then for the real interest rate to be constant one requires:

\[
\frac{\dot{\alpha}}{\alpha} + \left\{ Ef' [\dot{k}(t)] \right\} \left[ \frac{\dot{\alpha}}{\alpha} - \frac{\dot{\beta}}{\beta} + \frac{\dot{k}}{K} \right] = 0.
\]

(1.22)

Suppose first that \( \alpha(0) = \beta(0) = 1 \) and that \( \alpha(t) = 0 \) all \( t \), \( \dot{\beta}(t) = b \beta(t) \) all \( t \). Technical progress is purely labour augmenting (at a constant rate) or Harrod-Neutral. Clearly \( \beta(t) = e^{bt} \). Hence (1.22) will be satisfied if

\[
\frac{\dot{k}(t)}{k(t)} - b = 0 \text{ or } \frac{\dot{k}}{K} = b + \lambda.
\]

(1.23)

Let \( n = b + \lambda \) and call it the natural rate of growth. If savings are proportional to income, equilibrium requires

\[
\frac{\alpha(0) s f [\dot{k}(t)]}{\dot{k}(t)} = n
\]

(1.24)
which can be uniquely solved for $\hat{k}^*$ when the production function is concave and satisfies the Inada conditions. By (1.23), $\dot{k}(t) = 0$ and so we conclude that (i) the capital output ratio and the real interest rate are both constant and (ii) the real wage and the capital labour ratio ($k$) are rising at the rate $b$. But the wage per efficiency unit of labour and capital per efficiency unit of labour are both constant. Hence we are essentially in the same situation as that discussed for the absence of technical progress.

Next suppose that $\bar{\alpha}(t) = a \bar{\alpha}(t)$ and $a = b$. Technical progress is said to be *Hicks-neutral*. Then (1.22) becomes

$$a + \left\{E f'[k(t)] \right\} \frac{\dot{k}}{k} = 0.$$  

(1.22')

Suppose that the production function is characterized by an elasticity of substitution equal to minus one. Then since with Hicks-neutrality one can write: $\gamma = e^{bt} f[K(t), L(t)]$ one has that $KF_k/F$ is constant when $K$ is changed but $F$ is constant (if one is moving along an isoquant). This implies

$$Ef'[\hat{k}(t)] = -1$$

and so once again (using (1.22')) one obtains (1.23). A constant rate of profit and a constant share of profits then implies a constant capital output ratio. In other words, Harrod-neutrality is equivalent to Hicks-neutrality with a unit elasticity of substitution (Robinson, 1938). Uzawa (1961) has shown that only a Cobb–Douglas production function will give this equivalence.

If $a \neq b$ technical progress is 'biased' in favour of the higher of $a$ and $b$. However, there is no fundamental reason why technical progress should be of the factor-augmenting type nor, if it is, why it should proceed at a steady rate. Hence technical progress makes the idea of steady state equilibrium somewhat unconvincing.

However, there have been attempts to formulate a theory which focuses on endogenous economic forces that may cause technical progress to be of a certain kind (Kennedy, 1964; Samuelson, 1965). These attempts are not notably successful or convincing and will only be sketched.

Given a factor-augmenting production function which exhibits constant returns to scale, one can write the minimum unit cost function as

$$\zeta = c[q(t)/\alpha(t), w(t)/\beta(t)]$$
where $q(t)$ is the rental of capital of $w(t)$ the wage. Let $s_K$ and $s_L$ respectively be the shares in unit cost of capital and labour. Then from elementary Duality Theory (e.g. Varian, 1978), if $\dot{w}(t) = \dot{q}(t) = 0$:

$$\frac{\dot{c}}{c} = - [s_K a(t) + s_L b(t)]$$

(1.25)

where $b(t) = \dot{b}(t) / \beta(t)$, $a(t) = \dot{a}(t) / \alpha(t)$. The idea now is as follows. Firms can choose to ‘produce’ $a(t)$ and $b(t)$ according to a ‘production possibility’ function.

$$T[a(t), b(t)] = g[b(t)] - a(t) \geq 0$$

(1.26)

and the pairs $(a, b)$ satisfying (1.26) form a convex compact set with a differentiable boundary. Also $g'(b) < 0$. If the firm's objective is to minimize $\dot{c} / c$ subject to (1.26) it will choose $b(t)$ so as to satisfy

$$-g'[b(t)] = \frac{s_L}{s_K}.$$

(1.27)

As Samuelson (1965) has noted, (1.27) is not some novel theory of income distribution unrelated to the Neo-classical one. The latter was needed in the definition of $c$ and the derivation of (1.25).

Now $s_L / s_K$ will depend on the relative prices of efficiency units. Since $g(\cdot)$ is monotone (1.27) can be inverted:

$$b(t) = (g')^{-1}(s_L / s_K)$$

and so we write
The equations (1.26) and (1.28) are two differential equations in $\alpha(t)$, $\beta(t)$ and relative factor prices. It is easy to show that

$$h'(1 - \sigma) \geq 0$$

where $\sigma$ is the elasticity of substitution.

If one can take $w/q$ constant then one proceeds as follows.

Substituting from (1.28) one obtains the differential equation

$$b(t) - a(t) = \frac{d \log \left( \frac{\beta(t)}{\alpha(t)} \right)}{dt} = b(t) - g[b(t)] = v[b(t)] \text{ say.}$$

Substituting from (1.28) one obtains the differential equation

$$\frac{d \log \left( \frac{\beta(t)}{\alpha(t)} \right)}{dt} = v\left( h\left[ \frac{w \alpha(t)}{q \beta(t)} \right] \right).$$

(1.29)

This equation gives the evolution of relative factor augmentation. If for some $[\alpha / \beta]^*$ one has a critical point of $v$ and (1.29) is convergent then there will be a constant relative rate of labour augmentation so $b(t) - a(t) \to 0$. (This does not necessarily imply that $b(t)$ and $a(t)$ become constant.) In that situation innovations are derived to be Hicks-Neutral. Even if the rate of innovation is then constant we know that this will not be consistent with steady state unless the elasticity of substitution is unity. But Samuelson (1965) has shown that the stipulated convergence of (1.29) requires an elasticity of substitution which is less than one in absolute value.

All of this is on the assumption $w/q = \text{constant}$. In fact we know from our earlier discussion that $w/q$ will depend on $\hat{k}(t)$ so we can replace the r.h.s. of (1.29) by:
We then need a differential equation for the evolution of $k(t)$ which we can obtain from the appropriate warranted growth path. Samuelson (1965) has studied the case: $\dot{k}(t) = 0$. The literature can be consulted for further detail. At this level of aggregation the story is hardly persuasive nor can much be said in favour of the objective function which has been stipulated. On the other hand, all of this is a considerable advance on meaningless claims like: 'high wages induce labour-saving innovation' first exposed by Fellner (1961). After all, the marginal return per unit cost of the factor is the same for all factors in equilibrium. None the less one must conclude that the theory of induced innovations and their relations to growth have a long way to go yet.

1.4 The one sector model with embodied technical progress

In this section two related ideas are considered. The first is that capital and labour are substitutable \textit{ex ante} (‘putty’) before investment has been congealed in concrete machines but it is not substitutable \textit{ex post} (‘clay’) once the investment has been made. The second is that technical progress does not benefit old machines; it is embodied in the latest machines. These two ideas are related but can be combined in various ways. Thus one can have embodied technical progress with (traditional) putty–putty (Solow, 1970) or with clay–clay (Solow et al., 1967). One can also have disembodied technical progress as in the previous section with putty–clay. The main lessons are perhaps best learned by combining embodied technical progress with putty–clay. The classic reference here is Bliss (1968).

Some of the technicalities of the analysis now called for are somewhat involved and what follows is more in the nature of a summary of the economic implications.

An investment undertaken at date $\theta$ gives rise to machines of vintage $\theta$. If at that date the investment is $I(\theta)$ and employment is $L(\theta, \theta)$, output per man is $y(\theta, \theta)$ and given by

$$y(\theta, \theta) = e^{\theta f(k(\theta))} \text{ where } k(\theta) = l(\theta) / L(\theta, \theta) e^{2\theta}.$$ 

Let $f(\cdot)$ satisfy Assumption 1.1. The output per man on vintage $\theta$ at date $t \geq \theta$ is written as $y(t, \theta)$. It is assumed that as long as output is produced on vintage $\theta$ that

$$y(t, \theta) = y(\theta, \theta).$$
This departs somewhat from the ‘clay’ assumption. It will be noticed that Harrod-neutral technical progress has been assumed. It can be shown (Bliss, 1968) that this is necessary for a steady state equilibrium to exist. Any firm in this technological environment will make its investment and employment decisions in the light of long term expectations. For once machines have been installed they no longer share in technical progress yet the latter will raise real wages and reduce quasi-rents on old machines. These will be scrapped when quasi-rents have fallen to zero so that the economic life of the machines is endogenous to the economic process. The economic life is relevant to the investment decision and hence expectations of the course of real wages are relevant. In the theory it is assumed that all expectations are always correct. None of these considerations apply to the case of disembodied technical progress with putty-putty.

If \( w(t) \) is the real wage at \( t \) then if \( \gamma(t, \theta) - w(t) > 0 \) it will pay the firm to set \( L(t, \theta) = L(\theta, \theta) \) because of (1.30). It will set \( L(t, \theta) = 0 \) when \( \gamma(t, \theta) - w(t) = 0 \). These conditions determine the economic life of a machine. It is easy to show that if \( T \) is the economic life of a machine that it must be constant in steady state equilibrium. The value of \( T \) is determined by the condition \( w(t) = \gamma(t - T, t - T) \), that is, the wage equals its average product on the last vintage in use. When that is the case the firm is indifferent whether it employs labour on that vintage or not. If it does employ some then if the economy had a little more or less labour it would be employment on the last vintage in use which is varied and so \( w(t) \) would measure labour's marginal social product. If no labour is employed of the last vintage then a small reduction in labour would mean reducing employment on the next oldest vintage. If there is a continuum of vintages then the economy would still lose just \( \gamma(t - T, t - T) \).

Now let \( n = a + \lambda \) as in (1.2). We are looking for a steady state equilibrium as before in which output and investment grow at the rate \( n \) because gross savings are proportional to income. As before also the ratio of capital to labour measured in efficiency units of the latest vintage (i.e. \( k(\theta) \)) should be constant. So if \( Y(t) \) is aggregate output at \( t \) and \( Y(\theta, \theta) \) total output with capital of vintage \( \theta \) we have

\[
Y(t) = \int_{t-T}^{t} \gamma(\theta, \theta) L(\theta, \theta) \, d\theta = \int_{t-T}^{t} \gamma(\theta, \theta) \, d\theta = \frac{e^{nt}Y(t - T, t - T)(1 - e^{-nT})}{n}.
\]

(1.31)

If \( I(\theta) \) is investment at \( \theta \) then \( I(t) = e^{nt}I(t - T) \) and that must equal \( sY(t) \). So using (1.31) and writing \( v = \gamma(t - T) / I(t - T) \) we obtain
The left-hand side of (1.32) is again Harrod's warranted growth rate. But the rate at which the economy is capable of expanding indefinitely now depends on \( T \), the economic life of equipment and that is an economic variable and not a parameter like \( n \). One must, of course, show that (1.32) has a solution. If as in Solow et al. (1967) the technology is clay–clay then \( v \) is given as fixed. Profit maximization together with the condition that the present value of quasi-rents equals the cost of the investment which gives rise to them at the scrapping, fix the equilibrium value of \( T \). It is then possible that Harrod's view that (1.32) has no solution is valid. This is a fortiori true if the solution of (1.32) requires \( s > 1 \).

One can show that the real interest rate (= profit rate) must be constant in steady state equilibrium (see Bliss, 1968). However, the relation between the latter and the equilibrium value of \( T \) is not straightforward and depends on the elasticity of substitution. That is because in steady state the scrapping condition is \( t = \frac{1}{a \log (\text{inverse of share of wages in vintage } (t - T))} \) and the share will depend on the elasticity of substitution. One can also show that if a steady state exists that the warranted growth path of the economy will approach the steady state. This is even the case with clay–clay.

All in all the simple neoclassical model survives ‘the bolting down’ of concrete machines and embodied technical progress rather well. That does not mean that the resulting model is satisfactorily ‘realistic’. What it does mean is that the theory is a good deal more robust than critics once thought it to be. This is also illustrated by the following episode in the related theory of technical progress.

Kaldor took the view that it was not possible to distinguish between finding another ‘page in the book of blueprints’ (Robinson, 1965), i.e. movements along the production function and finding a new page, i.e. innovations. He proposed that all that could be observed was a relation between the rate of growth in labour productivity and investment per man. This relation he called the ‘technical progress function’ and justified by the view that every act of investment led to learning. He and Mirrlees (1962) constructed a model on this basis. However, except for the assumption that firms required investment ‘to pay for itself’ in a predetermined period, the results of the model were not notably different from the ones already discussed. (A linear technical progress function can be integrated into a Cobb–Douglas production function. A non-linear one of the right shape has the advantage of making steady state equilibrium investment be at the rate at which the capital output ratio is constant, i.e. Harrod-neutrality is a consequence and not a hypothesis of the model.)

Arrow (1962) kept the production function (he uses clay–clay) but made technical improvement depend on the total investment undertaken over the past. This was again justified by learning. The steady state again is one of Harrod-neutral progress which is explained endogenously. There are now obvious external benefits from investment but otherwise the ‘learning by doing’ steady state equilibrium is of the kind we have already discussed.

### 2 Two sector growth models
One considers an economy with a consumption good and an investment good sector. This was first proposed by Uzawa (1961) and then gave rise to a very large literature (e.g. Solow, 1962; Inada, 1963; Takayama, 1963). We shall discuss only the case where both sectors have ‘well behaved’ constant returns to scale production functions, capital does not depreciate and there is no technical progress. For the latter see Diamond (1965).

2.1 Steady state

It is well known (e.g. Samuelson, 1957; Mirrlees, 1969) that given these assumptions, the equilibrium relative prices of the two goods are determined once \( \rho \) (the real interest rate) is determined. So with a classical saving hypothesis we know that steady state requires:

\[
\rho = \lambda
\]

and so \( q \) the price of the investment good in terms of the consumption good can be written as \( q(\lambda) \). If \( w \) is the wage in terms of consumption good, \( y_c \) is output per man employed in the consumption good sector and \( \mu = \frac{L_c}{L} \) is the proportion of the labour force employed in that sector, the classical savings assumption yields the equilibrium condition

\[
w = y_c \mu \quad \text{or} \quad \mu = \frac{w}{y_c}.
\]

(Demand for consumption good equals supply.) But \( w/y_c \) is a unique function of \( \rho \). For by profit maximization the marginal product of capital in the consumption sector must equal \( \rho q = \lambda q(\lambda) \). So \( \lambda \) determines a unique capital/labour ratio and so a unique share of wages in the consumption sector. Hence we can write \( \mu = \mu(\lambda) \). If \( k \) is the overall capital labour ratio, \( k_c \) and \( k_I \) the capital/labour ratios in the consumption and investment sectors respectively then

\[
k = \mu k_c + (1 - \mu) k_I
\]

It is plain that \( k \) is uniquely determined by \( \lambda \).

Matters are somewhat more complicated with a proportional saving function and we shall not derive all the results in full. Let \( v \) be the capital output ratio in value terms. In steady state, as usual, we require \( s = \forall \lambda \). The question now is whether putting \( v = s \forall \lambda \) uniquely determines \( k, k_c, k_I \) and hence the rate of profit and real wage. The answer is: no.

Let \( \psi \) be the wage rental ratio. A rise in that ratio will lower \( q \) if the consumption goods sector is more labour intensive than the investment goods sector. Hence \( k_c \) and \( k_I \) will be raised and \( v \) will be lowered. But the value of investment output is a constant fraction \( s \) of the value of output and \( q \) is lower so that output of investment good must rise relatively to that of consumption good and so \( \mu \) must be lower (
1 - \psi is higher). Hence \( k \) will be higher (since \( k_1 > k_c \)) and this will tend to increase \( \nu \). It follows that \( \nu \) can have the same value at different \( k \)'s and \( \psi \)'s. This is really the story of what Professor Robinson (1965) called the Wicksell effect. To get uniqueness one needs the not very persuasive assumption: \( k_c > k_I \) always, or some assumption on the elasticities of substitution (Takayama, 1963).

2.2 Stability

The question may be asked whether a sequence of short period equilibria of the economy starting with an arbitrary \( k(0) \) at time \( t = 0 \) lead the economy to steady state equilibrium.

At any moment of time \( k \) is given from the past. A short period equilibrium is a division of the capital stock and of the labour between the two sectors such that at the resulting prices all markets clear and profits are maximised. The resulting investment good output will augment the capital stock. At the next moment there will also be more labour so we know the new value of \( k \). So given \( k(0) \) it looks as if we could deduce \( k(t) \) for all \( t > 0 \) and so study the convergence to steady state.

But this is only true if momentary equilibrium is unique. If it is not then there will be a variety of paths the system can follow and we do not know which it will be. More seriously in this case we may have, say, there equilibria for some \( k \) and only one for another \( k' \). In that case at the point at which we ‘lose’ equilibria there is a ‘catastrophe’ (in the technical sense). For this see Inada (1963).

Now consider the proportional savings assumption. It says that consumption and investment are proportional to aggregate income, that is, the distribution of income has no effect on the demand for either good. But this is just the case for which non-intersecting community indifference maps exist (see Gorman, 1953) and in that case momentary equilibrium must be unique: it is given by the tangency of the transformation curve between investment and consumption good and the indifference curve. So in this case momentary equilibrium is unique.

But this is not true for the classical saving function where it is clear that demand does depend on the distribution of income so that in general no community indifference maps exist and there may be multiple momentary equilibria. Once again more detailed assumptions concerning elasticities of substitution or \( k_c > k_I \) can rescue the situation. They really amount to the postulate of a certain kind of gross-substitutability (Hahn, 1965).

Once uniqueness of momentary equilibrium is assured it is not hard to show that the sequence of momentary equilibria approach the steady state (see Hahn and Matthews, 1964, for an intuitive account). For instance, for a classical saving postulate, \( k(0) \) must be inversely related to \( \phi(k(0)) \), the wage rental ratio. So if \( k^* \) is the steady state capital labour ratio, \( \rho(k(0)) < \rho(k^*) \) whenever \( k(0) > k^* \). But \( \rho(k(0)) = \frac{K}{K} \) while \( \rho(k^*) = \lambda \) hence

\[
\frac{\dot{k}}{k} = \rho(k(0)) - \rho(k^*) < 0
\]
and \( k(0) \) in declining at \( t = 0 \). In fact the reader can check that \( [k(t) - k^*]^2 \) is always declining with \( t \) as long as \( k(t) \neq k^* \) which suffices here to establish convergence to the steady state value \( k^* \).

On the other hand, it should be noted that this argument is very much at risk when there is a variety of capital goods (see Hagemann, 1987).

2.3 Technical progress

With two sectors the nature of technological change in the economy as a whole will clearly depend on what kind of progress occurs in each of the sectors and on the composition of output. For instance, if by Harrod neutrality we mean that the capital/output ratio in value terms is constant when the rate of profit is constant we need to know how the capital/output ratio in each of the sectors is changing as well as what is happening to the relative outputs of the two sectors.

The case of disembodied technical progress is fully analysed in Diamond (1965) while there seems to be no literature on two-sector embodied technical progress.

As an example consider steady state with a proportional savings function. The value share of investment in output must remain constant. Technical progress in the investment sector will have to be Harrod-neutral because the rate of profit equality with the marginal product of capital is there independent of relative prices (input and output are the same). So in steady state the marginal product of capital should remain constant. If the capital labour ratio in both sectors remains constant then technical progress in the consumption goods sector must also be Harrod-neutral. Differences in the rate of technical progress in the two sectors will be reflected in a changing price of consumption good in terms of investment good. However, there could be steady state equilibrium with the labour allocation between the two sectors changing. In that case in general technical progress in the consumption good sector will not be Harrod-neutral.

It is not profitable to go into greater detail.

3 Many sectors

As long as one is only concerned with steady state equilibrium there is no difficulty for neoclassical theory when there are many sectors. Although it was somewhat special the foundations for the study of this case were laid by von Neumann (1945). (He assumed labour to be in infinitely elastic supply (in fact producible) at a given vector input of consumption goods. He also considered a 'spectrum' of techniques.) More recent formulations are best studied in Morishima (1964). For a survey see Hahn and Matthews (1964).

The essentials of this case can be illustrated for a classical savings function with only intermediate goods used in production (i.e. no long lived inputs) and no joint production.

Suppose there are \( N \) produced goods and one non-produced good (e.g. labour). Production takes time. Let \( q \) be the price vector of the \( N \) produced goods in terms of the non-produced good. Let all inputs be paid for when purchased and let \( c(q) \) be the minimum unit cost function in terms of labour. That is \( c(q) \) is the unit cost of production when inputs have been chosen to minimise costs. We can write it in this way because constant returns prevail everywhere. If that were not so there would be no hope of finding a
steady state equilibrium.
In such an equilibrium if all goods are produced and relative prices are constant it must be that

\[ q = (1 + \rho) c(q). \]

(3.1)

If the economy is productive and indecomposable and every good needs labour in its production then one can solve (3.1) uniquely for \( q(\rho) \gg 0 \) provided \( \rho \) lies in some bounded interval. The function \( q(\rho) \) is the factor-price frontier.
It is easy to prove that

\[ \frac{\partial q_j}{\partial \rho} > 0. \]

(3.2)

Provided that the ratio in which wage earners consume goods depends only on \( q \) and not on their level of income one can now complete the story. The solution \( q(\rho) \) is plainly independent of the scale or composition of output. So one can always make demand equal to supply in each sector provided there is enough labour in the economy. Suppose that labour is inelastically supplied. Then the scale of output can be anything. But if the ratio of employed to unemployed is to remain constant then output must grow at the rate \( \lambda \) hence so must investment and we get \( \rho = \lambda \) as a further equilibrium condition. Relative prices will then be given by \( q(\lambda) \). In equilibrium the present value of an input's marginal product will equal its price. Moreover \( \rho \) can be shown to measure the increase, at constant prices, in consumption made possible tomorrow if there is a little less consumption today and resources saved thereby are allocated efficiently.
An alternative scenario is to suppose that labour can always be had at a constant real wage \( w^* \) where the real wage is written as some function of \( q \), say, \( w(q) \). Then \( w^* = w(q) \) together with (3.1) determine both \( q^* \) and \( \rho^* \) for steady state equilibrium. Given that there are classical savings the economy will grow at the rate \( \rho^* \) which will in fact be the highest (balanced) rate of growth the economy is capable of.
Perhaps a more general insight into these models can be gained as follows. Let \( Y \) and \( X \) be two \( n \)-vectors where the latter is the input of goods at one date and \( Y \) the output resulting at the subsequent date. Let \( L \) be the labour input. Then

\[ T(Y, X, L) \geq 0 \]

(3.3)
is the economy's transformation locus which is homogeneous of degree one in its argument. Now a perfectly competitive economy is production efficient. So if all goods are produced in the steady state \((Y^*/L^*, X^*/L^*)\) there must be prices \(q^*\) and profit rate \(p^*\) such that

\[
q^* Y^* - (1 + p^*) [q^* X^* + L^*] = 0
\]

(3.4)

is a supporting hyperplane of the set of \((Y, X, L)\) satisfying (3.3) at \((\lambda^*, X^*, L^*)\) Net output is \(q^* (Y^* - X^*)\). If there are proportional savings at the rate \(s\) then one requires

\[
sq^* (Y^* - X^*) = \lambda(q^* X^*)
\]

(3.5)

if employment is to grow at the rate \(\lambda\) and \(Y/L\) and \(X/L\) are constant. But that is just the Harrod equation. Now

\[
q^* Y^* - (1 + p^*) [q^* X^* + L^*] \geq q^* Y - (1 + p^*) [q^* X + L]
\]

(3.6)

for all \((Y, X, L)\) satisfying (3.3). Hence (3.4) is the maximum value of the r.h.s. of (3.6) subject to (3.3). Hence if \(T\) is differentiable:

\[
q_i^* = \frac{T X_i}{T L} = -(1 + p^*) \frac{T Y_i}{T L}
\]

(3.7)

as can be verified by carrying out the maximization. Write (3.3) as
\[ T(Y, kX, L) \geq 0 \]  
\[(3.8)\]

take \( k = 1 \) and differentiate with respect to \( k \) at \((Y^*, X^*, L^*)\) to get

\[
\left[ \sum T Y_i \frac{dY_i}{dk} + \sum T X_i X_i \right] d k = 0.
\]
\[(3.9)\]

Substitute from (3.7) into (3.9) writing

\[
\Delta Y_i = \frac{dY_i}{dk} d k, \Delta X_i = X d k,
\]

to obtain

\[
\sum q_i^* \Delta Y_i = (1 + \rho^*) \sum q_i^* \Delta X_i
\]

or

\[
\frac{\sum q_i^* \Delta Y_i - \sum q_i^* \Delta X_i}{\sum q_i^* \Delta X_i} = \rho^*
\]
\[(3.10)\]

Hence the equilibrium rate of profit measures the increase in the value of net output at equilibrium prices as a fraction of the increase in the value of inputs at equilibrium prices. Or the rate of substitution between present and future consumption bundles of constant composition, evaluated at \( q^* \). Of course,
there is no sense to the claim that (3.10) ‘determines’ $\rho^*$. The literature on growth theory is vast and this essay can usefully be supplemented by other accounts such as Meade (1962), Hahn and Matthews (1964) and Solow (1970).

Article
The term ‘neoclassical synthesis’ appears to have been coined by Paul Samuelson to denote the consensus view of macroeconomics which emerged in the mid-1950s in the United States. In the third edition of Economics (1955, p. 212), he wrote:
In recent years 90 per cent of American Economists have stopped being ‘Keynesian economists’ or ‘anti-Keynesian economists’. Instead they have worked toward a synthesis of whatever is valuable in older economics and in modern theories of income determination. The result might be called neo-classical economics and is accepted in its broad outlines by all but about 5 per cent of extreme left wing and right wing writers.

Unlike the old neoclassical economics, the new synthesis did not expect full employment to occur under laissez-faire; it believed, however, that, by proper use of monetary and fiscal policy, the old classical truths would come back into relevance.

This synthesis was to remain the dominant paradigm for another 20 years, in which most of the important contributions, by Hicks, Modigliani, Solow, Tobin and others, were to fit quite naturally. Its apotheosis was probably the large econometric models, in particular the MPS model developed by Modigliani and his collaborators, which incorporated most of these contributions in an empirically based and mathematically coherent model of the US economy. The synthesis had, however, suffered from the start from schizophrenia in its relation to microeconomics. This schizophrenia was eventually to lead to a serious crisis from which it is only now re-emerging. I describe in turn the initial synthesis, the mature synthesis, the crisis and the new emerging synthesis.

The initial synthesis

The post-war consensus was a consensus about two main beliefs. The first was that the decisions of firms and of individuals were largely rational, and as such amenable to study using standard methods from microeconomics. Modigliani, in the introduction to his collected papers, stated it strongly:

[One of the] basic themes that has dominated my scientific concern [has been to integrate] the main building blocks of the General Theory with the more established methodology of economics, which rests on the basic postulate of rational maximizing behavior on the part of economic agents…’ (1980, p. xi)

The faith in rationality was far from blind: animal spirits were perceived as the main source of movements in aggregate demand through investment. For example, the possibility that corporate saving was too high and not offset by personal saving was considered a serious issue, and discussed on empirical rather than theoretical grounds.

This faith in rationality did not, however, extend to a belief in the efficient functioning of markets. The second main belief was indeed that prices and wages did not adjust very quickly to clear markets. There was broad agreement that markets could not be seen as competitive. But, somewhat surprisingly given the popularity of imperfect competition theories at the time, there was no attempt to think in terms of theories of price and wage setting, with explicit agents setting prices and wages. Instead, the prevailing mode of thinking was in terms of tâtonnement, with prices adjusting to excess supply or demand, along the lines of the dynamic processes of adjustment studied by Samuelson in his Foundations of Economic Analysis (1947). The Phillips curve, imported to the United States by Samuelson and Solow in 1960, was in that context both a blessing and a curse. It gave strong empirical support to a tâtonnement-like
relation between the rate of change of nominal wages and the level of unemployment, but it also made less urgent the need for better microeconomic underpinnings of market adjustment. Given the existence of a reliable empirical relation and the perceived difficulty of the theoretical task, it made good sense to work on other and more urgent topics, where the marginal return was higher.

These twin beliefs had strong implications for the research agenda as well as for policy. Because prices and wages eventually adjusted to clear markets, and because policy could avoid prolonged disequilibrium anyway, macroeconomic research could progress along two separate lines. One could study long-run movements in output, employment and capital, ignoring business cycle fluctuations as epiphenomena along the path and using the standard tools of equilibrium analysis: ‘Solving the vital problems of monetary and fiscal policy by the tools of income analysis will validate and bring back into relevance the classical verities’ (Samuelson, 1955, p. 360). Or one could instead study short-run fluctuations around that trend, ignoring the trend itself. This is indeed where most of the breakthroughs had been made by the mid-1950s. Work by Hicks (1937) and Hansen (1949), attempting to formalize the major elements of Keynes’s informal model, had led to the IS–LM model. Modigliani (1944) had made clear the role played by nominal wage rigidity in the Keynesian model. Metzler (1951) had shown the importance of wealth effects, and the role of government debt. Patinkin (1956) had clarified the structure of the macroeconomic model, and the relation between the demands for goods, money and bonds, in the case of flexible prices and wages. There was general agreement that, except in unlikely and exotic cases, the IS curve was downward sloping and the LM curve upward sloping. Post-war interest rates were high enough – compared with pre-war rates – to make the liquidity trap less of an issue. There was still, however, considerable uncertainty about the effect of interest rates on investment, and thus about the slope of the IS relation. The assumption of fixed nominal wages made by Keynes and early Keynesian models had been relaxed in favour of slow adjustment of prices and wages to market conditions. This was not seen, however, as modifying substantially earlier conclusions. The ‘Pigou effect’ (so dubbed by Patinkin in 1948), according to which low enough prices would increase real money and wealth, was not considered to be of much practical significance. Only activist policy could avoid large fluctuations in economic activity.

Refinements of the model were not taken as implying that the case for policy activism was any less strong than Keynes had suggested. Because prices and wages did not adjust fast enough, active countercyclical policy was needed to keep the economy close to full employment. Because prices and wages, or policies themselves, eventually got the economy to remain not far from its growth path, standard microeconomic principles of fiscal policy should be used to choose the exact mix of fiscal measures at any point in time. The potential conflict between their relative efficacy in terms of demand management, and their effect on the efficiency of economic allocation, were considered an issue but not a major problem. Nor was the fact that the market failure which led to short-run fluctuations in the first place was not fully understood or even identified.

The ground rules for cyclical fiscal policy were laid in particular by Samuelson in a series of contributions (1951, for example). Countercyclical fiscal policy was to use both taxes and spending; in a depression, the best way to increase demand was to increase both public investment and private investment through tax breaks, so as to equalize social marginal rates of return on both. Where the synthesis stood on monetary policy is less clear. While the potential of monetary policy to smooth fluctuations was generally acknowledged, one feels that fiscal policy was still the instrument of
predilection, that policy was thought of as fiscal policy in the lead with accommodating monetary policy in tow.

**The mature synthesis**

For the next 20 years the initial synthesis was to supply a framework in which most macroeconomists felt at home and in which contributions fitted naturally. As Lucas remarks in his critique of the synthesis, ‘those economists, like Milton Friedman, who made no use of the framework, were treated with some impatience by its proponents’ (1980, p. 702). The research programme was largely implied by the initial synthesis, the emphasis on the behavioural components of IS–LM and its agnostic approach to price and wage adjustment; to quote Modigliani, ‘the Keynesian system rests on four basic blocks: the consumption function, the investment function, the demand and the supply of money, and the mechanisms determining prices and wages’ (1980, p. xii). Progress on many of these fronts was extraordinary; I summarize it briefly as these developments are reviewed in more depth elsewhere in this dictionary.

The failure of the widely predicted post-war over-saving to materialize had led to a reassessment of consumption theory. The theory of intertemporal utility maximization progressively emerged as the main contender. It was developed independently by Friedman (1957) as the ‘permanent income hypothesis’ and Modigliani and collaborators (1954 in particular) as the ‘life cycle hypothesis’. The life-cycle formulation, modified to allow for imperfect financial markets and liquidity constraints, was, however, to dominate most of empirical research. Part of the reason was that it emphasized more explicitly the role of wealth in consumption, and, through wealth, the role of interest rates. Neither wealth effects nor interest rate effects on consumption had figured prominently in the initial synthesis. Research on the investment function was less successful. Part of the difficulty arose from the complexity of the empirical task, the heterogeneity of capital, and the possibility of substituting factors ex ante but not ex post. Many of the conceptual issues were clarified by work on growth, but empirical implementation was harder. Part of the difficulty, however, came from the ambiguity of neoclassical theory about price behaviour, about whether firms could be thought of as setting prices or whether the slow adjustment of prices implied that firms were in fact output constrained. The ‘neoclassical theory of investment’ developed by Jorgenson and collaborators (for example, Hall and Jorgenson, 1967) was ambiguous in this respect, assuming implicitly that price is equal to marginal cost, but estimating empirical functions with output rather than real wages.

Research on the demand for and supply of money was extended to include all assets. Solid foundations for the demand for money were given by Tobin (1956) and Baumol (1952), and the theory of finance provided a theory of the demand for all assets (Tobin, 1958). The expectations hypothesis, which alleviated the need to estimate full demand and supply models of financial markets, was thoroughly tested and widely accepted as an approximation to reality.

In keeping with the initial synthesis, work on prices and wages was much less grounded in theory than work on the other components of the Keynesian model. While research on the microeconomic foundations of wage and price behaviour was proceeding (Phelps, 1972 in particular), it was poorly integrated in empirical wage and price equations. To a large extent, this block of the Keynesian synthesis remained throughout the period the ad hoc but empirically successful Phillips curve,
respecified through time to allow for a progressively larger effect of past inflation on current wage inflation. All these blocks, together with work on growth theory, were largely developed in relation with and then combined in macroeconometric models, starting with the models estimated by Klein (for example, Goldberger and Klein, 1955). The most important model was probably the MPS–FMP model developed by Modigliani and collaborators. This model, while maintaining the initial IS–LM Phillips curve structure of its ancestors, showed the richness of the channels through which shocks and policy could affect the economy. It could be used to derive optimal policy, show the effects of structural changes in financial markets, and so on. By the early 1970s the synthesis appeared to have been highly successful and the research programme laid down after the war to have been mostly completed. Only a few years later, however, the synthesis was in crisis and fighting for survival.

The crisis and the reconstruction

The initial trigger for the crisis was the failure of the synthesis to explain events. The scientific success of the synthesis had been largely due to its empirical success, especially during the Kennedy and the first phase of the Johnson administrations in the United States. As inflation increased in the late 1960s, the empirical success and, in turn, the theoretical foundations of the synthesis were more and more widely questioned. The more serious blow was, however, the stagflation of the mid-1970s in response to the increases in the price of oil: it was clear that policy was not able to maintain steady growth and low inflation. In a clarion call against the neoclassical synthesis, Lucas and Sargent (1978) judged its predictions to have been an ‘econometric failure on a grand scale’.

One cannot, however, condemn a theory for failing to anticipate the shape and the effects of shocks which have not been observed before; few theories would pass such a test and, as long as the events can be explained after the fact, there is no particular cause for concern. In fact, soon thereafter models were expanded to allow for supply shocks such as changes in the price of oil. It became clear, however, that while the models could indeed be adjusted ex post, there was a more serious problem behind the failure to predict the events of the 1970s. To quote again from the polemical article by Lucas and Sargent, ‘That the doctrine on which [these predictions] were made is fundamentally flawed is simply a matter of fact’ (1978, p. 49). The ‘fundamental flaw’ was the asymmetric treatment of agents as being highly rational and of markets as being inefficient in adjusting wages and prices to their appropriate levels. The tension between the treatment of rational agents and that of myopic impersonal markets had been made more obvious by the developments of the 1960s, and the representation of consumers and firms as highly rational intertemporal decision makers. It was further highlighted by the research on fixed price equilibria, which went to the extreme of taking prices as unexplained and solving for macroeconomic equilibrium under non-market clearing. That research made clear, in a negative way, that progress could be made only if one understood why markets did not clear, why prices and wages did not adjust.

The solution proposed by Lucas and others in the ‘new classical synthesis’ was thoroughly unappealing to economists trained in the neoclassical synthesis. It was to formalize the economy as if markets were competitive and clearing instantaneously. The ‘as if’ assumption seemed objectionable on a priori grounds, in that direct evidence on labour and goods markets suggested important departure from competition; it also appeared to many to be an unpromising approach if the goal was to explain
economic fluctuations and unemployment. Soon papers by Fischer (1977) and Taylor (1980) showed that one could replace the Phillips curve by a model of explicit nominal price and wage setting and still retain most of the traditional results of the neoclassical synthesis. These papers led the way to a major overhaul and reconstruction, and by the mid-1990s a new synthesis had emerged, a synthesis now dubbed the ‘new neoclassical synthesis’ (Goodfriend and King, 1997) or the ‘new Keynesian synthesis’ (for example, Clarida, Gali and Gertler, 1999). This new synthesis is described in more detail elsewhere in this dictionary, and I shall limit myself to a few remarks and comparisons between the old and the new. Like the old synthesis, the new synthesis has two major features: on the one hand, optimizing behaviour by firms, consumers and workers; on the other, the presence of distortions, most importantly nominal rigidities. In contrast to the old synthesis, however, the distortions are introduced explicitly, and price and wage behaviour is derived from optimizing behaviour by price and wage setters. These distortions imply that, as in the old synthesis, monetary policy and fiscal policy have a major role to play.

Like the old synthesis, the new synthesis is derived from microfoundations, utility maximization by consumers, and profit maximization by firms. But, while models in the old synthesis used theory as a loose guide to empirical specifications and allowed the data to determine the ultimate specification, models in the new synthesis remain much closer to their microfoundations. Dynamics are derived from the model itself, and the implied behavioural equations, rather than being estimated, are typically derived from assumptions about underlying technological and utility parameters. These more explicit microfoundations allow for a more careful welfare analysis of the implications of policy than was possible with the old models.

The models in the new synthesis are referred to as ‘dynamic stochastic general equilibrium’, or DSGE, models. Because they are typically difficult to solve, even the larger models are smaller than the models of the old synthesis, and their formalization of markets such as those for goods and labour remains primitive compared with the spirit of the formalizations in the old models. Improvements both in the formalization of these markets and in numerical techniques are, however, allowing for steadily richer and larger models.

To parallel the quotation from Samuelson given at the beginning, it is fair to say that the new neoclassical synthesis is attracting wide support, although less so than the old one. Some researchers, particularly those in the ‘real business cycle’ tradition, are sceptical about the importance of nominal rigidities in fluctuations. Others find the rationality assumptions embodied in the new synthesis to be too strong, and the methodology too constraining to capture the complexity present in the data. Nevertheless, DSGE models are increasingly used to guide policy. Many challenges remain, for example in capturing the relevant distortions in goods, labour, financial, and credit markets, or in using econometrics to assess the fit of both the specific components and the overall model to reality. Progress is rapid, however. When I wrote the first version of this contribution in 1991, the emergence of a new synthesis appeared uncertain, and at best far in the future. In updating this contribution, I am struck by the progress that has taken place since then, and by the speed at which progress continues to be made today.

Article

The term ‘neoclassical’ was first used by Veblen (1900, pp. 242, 260–2, 265–8), in order to characterize Marshall and Marshallian economics. Veblen did not appeal to any similarity in theoretical structure between the economics of Marshall and classical economics in order to defend this novel designation. Rather, he perceived Marshall's Cambridge School to have a continuity with classical economics on the alleged basis of a common utilitarian approach and the common assumption of a hedonistic psychology. Derivative from Veblen's use, this meaning of the term subsequently gained some currency, particularly in the 1920s and 1930s; for example, in the writings of Wesley Mitchell, J.A. Hobson, Maurice Dobb and Eric Roll. It is evident that the emergence of this notion of Marshallian economics as a ‘neoclassical’ project also involved, at least in part, an acquiescence to Marshall's portrayal of his own economics as a continuation of the classical tradition, though Marshall's sense of the continuity is not really that perceived by Veblen. Keynes (1936, pp. 177–8) also employed the term, though in an idiosyncratic matter, derivative from his equally idiosyncratic notion of classical economics.

The use of the term with the meaning which became the accepted convention after the Second World War, extending it to embrace marginalist theory in general, can be traced to Hicks (1932, p. 84) and Stigler (1941, pp. 8, 13, 297). From what source they derived the term is not certain. It is highly unlikely that either of them coined it independently. Perhaps the likeliest source of Hicks's use is Dobb's article, published as it was in the London School of Economics' ‘house journal’, Economica. Following Hamilton (1923), Dobb (1924, p. 68) writes that ‘neo-classical’ is not an entirely inappropriate term to describe Marshallian economics, ‘for what the Cambridge School has done is to divest Classical
Political Economy of its more obvious crudities, to sever its connection with the philosophy of natural
law, and to restate it in terms of the differential calculus. The line of descent is fairly direct from Smith,
Malthus, and Ricardo’. Hicks’s article, or Veblen, is the most likely source of Stigler’s use. He refers to
both of them. Hicks and Stigler were certainly more correct than Veblen in perceiving the unifying core
of the marginalist theories to be, on the one hand, methodological individualism and on the other, the
marginal productivity theory of distribution developed in connection with the subjective theory of value.
However, neither of them offered any significant defence for their (then) implicit view that the writings
of the classical economists also can be characterized in terms of this theoretical approach. Subsequently
this characterization – and the nomenclature for marginalism associated with it – has given way to a
recognition of the sharp theoretical disjuncture between classical and marginalist economics. Stigler's
use, albeit hesitant, was probably as influential as his book. The term first gained wide currency in the
debates on capital and growth in the 1950s and 1960s. It was no doubt also popularized by the extensive
use made of it in Samuelson's textbook. From the third edition, Samuelson (1955, p. vi) presents the
book as setting forth a ‘grand neoclassical synthesis’. (For a fuller account, see Aspromourgos, 1986.)
The question may be raised whether the depiction of ‘neoclassical economics’ in the mid-20th century,
understood as a characterization of the mainstream of the discipline, continues to represent an accurate
picture of dominant beliefs within economics. Colander (2000), for example, has questioned this. But,
even though the term was never sensible, the majority of the profession remains committed to the
fundamental convictions which were at issue in those earlier capital and growth debates – in particular,
the notion that competition brings about a tendency to full employment of resources (especially labour)
and the marginal productivity theory of functional income distribution.

‘neoclassical’ The New Palgrave Dictionary of Economics

How to cite this article

The term ‘neo-Ricardian economics’, as it is understood today, can mean several things. It was coined in the aftermath of the publication of The Works and Correspondence of David Ricardo, edited by Piero Sraffa with the collaboration of Maurice H. Dobb (Ricardo, 1951–73), and the publication of Sraffa’s Production of Commodities by Means of Commodities (Sraffa, 1960). One meaning of the term simply refers to these facts and interprets Sraffa's work in the way Sraffa himself saw it: as a return to the
‘standpoint of the old classical economists from Adam Smith to Ricardo, [which] has been submerged and forgotten since the advent of the “marginal” method’ (Sraffa, 1960, p. v; see Smith, 1776, and Ricardo, 1951–73). However, the term was first used by Marxist economists to distinguish Sraffa's approach to the theory of value and distribution, which explained relative prices and income distribution strictly in material terms (that is, quantities of commodities and labour), from the Marxist one, which starts from labour values (see Rowthorn, 1974). In some contributions Sraffa's analysis is described in a derogatory manner as a ‘peanut theory of profits’ and rejected together with marginalist (or ‘neoclassical’) theory as a variant of ‘vulgar economics’, dealing with ‘appearances’ only, whereas Marxist theory is taken to investigate ‘the real relations of production in bourgeois society’ (Marx, 1867, p. 85n). Neoclassical economists in turn occasionally (see, for example, Hahn, 1982) applied the term to the analysis of those critics who, in the so-called Cambridge controversies on the theory of capital, had attacked marginalism, especially its long-period version, showing it to be logically flawed (see Kurz and Salvadori, 1995, ch. 14). Because of the nationalities of the critics – especially Joan Robinson, Nicholas Kaldor, Piero Sraffa, Pierangelo Garegnani and Luigi Pasinetti – they also spoke of an ‘Anglo-Italian school’.

Such an unfortunate diversity of meanings may reflect a misunderstanding both of Sraffa's achievement and of the relation of his analysis to that of Marxist and marginalist economics respectively. What Sraffa in fact provides is a reformulation of the classical approach to the problem of value and distribution that sheds the weaknesses of its earlier formulations and builds upon their strengths. Put briefly, profits and all property incomes (such as interest and land rents) are explained in terms of the social surplus left over after the necessary means of production and the wages in the support of workers have been deducted from the gross outputs produced during a year. As Ricardo had stressed: ‘Profits come out of the surplus produce’ (Works, vol. 2, pp. 130–1; cf. vol. 1, p. 95). Therefore, instead of ‘neo-Ricardian economics’ it would be more appropriate to speak of that part of classical economics that deals with value and distribution. As is well known, this part was designed to constitute the foundation of all other economic analysis, including the investigation of capital accumulation and technical progress, of development and growth, of social transformation and structural change, and of taxation and public debt. The pivotal role of the theory of value and distribution in the classical authors can be inferred from the fact that it is typically developed at the beginning of their major works. By rectifying this part, Sraffa revived interest in classical economics. In addition to this constructive task Sraffa also pursued a critical task: the propositions of his book were explicitly ‘designed to serve as the basis for a critique of [the marginal theory of value and distribution]’ (1960, p. vi).

In the following we first summarize the achievements of Sraffa and his followers with respect to the constructive task. We then turn to the criticism of marginalist theory. In conclusion, we point out some of the problems that are currently being tackled by scholars working in the classical tradition.

Reformulating the classical theory of value and distribution

The concern of the classical economists, especially Smith and Ricardo, was the laws governing the emerging capitalist economy, characterized by the stratification of society into three classes: workers, landowners, and the rising class of capitalists; wage labour as the dominant form of the appropriation of other people's capacity to work; an increasingly sophisticated division of labour within and between
firms; the coordination of economic activity through a system of interdependent markets in which transactions were mediated through money; and significant technical, organizational and institutional change. In short, they were concerned with an economic system incessantly in motion. How to analyse such a system? The ingenious device of the classical authors to see through the complexities of the modern economy consisted in distinguishing between the ‘actual’ values of the relevant variables – the distributive rates and prices – and their ‘normal’ values. The former were taken to reflect all kinds of influences, many of an accidental or temporary nature, about which no general propositions were possible, whereas the latter were conceived of as expressing the persistent, non-accidental and non-temporary factors governing the economic system, which could be systematically studied.

The method of analysis adopted by the classical economists is known as the method of ‘long-period positions’ of the economy. Any such position is the situation towards which the system is taken to gravitate as the result of the self-seeking actions of agents, thereby putting into sharp relief the fundamental forces at work. In conditions of free competition the resulting long-period position is characterized by a uniform rate of profits (subject perhaps to persistent inter-industry differentials reflecting different levels of risk and of agreeableness of the business; see Kurz and Salvadori, 1995, ch. 11) and uniform rates of remuneration for each particular kind of primary input. Competitive conditions were taken to engender cost-minimizing behaviour of profit-seeking producers.

Alfred Marshall (1920) had interpreted the classical economists as essentially early and somewhat crude demand and supply theorists, with the demand side in its infancy. It was this interpretation and the underlying continuity thesis in economics that Sraffa challenged. As he showed, the classical economists' approach to the theory of value and distribution was fundamentally different from the later marginalist one, and explained profits in terms of basically two data: (a) the system of production in use and (b) a given real wage rate (or, alternatively, a given share of wages). Profits (and rents) were thus conceived of as a residual income. Whereas in marginalist theory wages and profits are treated symmetrically, in classical theory they are treated asymmetrically. On a still deeper methodological level the divide between the classical and the later marginalist authors could hardly be more pronounced. While the classical authors took the economic system to exist independently of the single agent and actually exert a considerable influence upon the latter depending upon the role ascribed to him as worker, capitalist or landowner, the marginalist authors advocated one version or another of ‘methodological individualism’, which takes a set of assumedly optimizing agents who exist independently of the system as a whole and who shape the system rather than the other way round.

Let us now examine more closely the scope, content and analytical structure of classical theory. The classical economists proceeded essentially in two steps. In the first step they isolated the kinds of factors that were seen to determine income distribution and the prices supporting that distribution in specified conditions, that is, in a given place and time. The theory of value and distribution was designed to identify in abstracto the dominant factors at work and to analyse their interaction. In the second step they turned to an investigation of the causes which over time affected systematically the factors at work from within the economic system. This was the realm of the classical analysis of capital accumulation, technical change, economic growth and socio-economic development.

It is another characteristic feature of the classical approach to profits, rents and relative prices that these are explained essentially in terms of magnitudes that can, in principle, be observed, measured or calculated. The objectivist orientation of classical economics has received its perhaps strongest expression in a famous proclamation by William Petty, who was arguably its founding father. Keen to
neo-Ricardian economics: The New Palgrave Dictionary of Economics

assume what he called the “physician's” outlook’, Petty in his *Political Arithmetick*, published in 1690, stressed that he was to express himself exclusively ‘in Terms of Number, Weight or Measure’ (Petty, 1986, p. 244). And James Mill noted significantly that ‘The agents of production are the commodities themselves … They are the food of the labourer, the tools and the machinery with which he works, and the raw materials which he works upon’ (Mill, 1826, p. 165, emphasis added). According to Sraffa the classical authors advocated essentially a concept of physical real cost. Man cannot create matter, man can only change its form and move it. Production involves destruction, and the real cost of a commodity consists in the commodities destroyed in the course of its production. This concept differs markedly from the later marginalist concepts, with their emphasis on ‘psychic cost’, reflected in such notions as ‘utility’ and ‘disutility’.

In line with what may be called their ‘thermodynamic’ view, the classical authors saw production as a circular flow. This idea can be traced back to William Petty and Richard Cantillon, and was most effectively expressed by François Quesnay (1759) in the *Tableau économique*: commodities are produced by means of commodities. This is in stark contrast with the view of production as a one-way avenue leading from the services of original factors of production via some intermediate products to consumption goods, as was entertained by the ‘Austrian’ economists.

Why then did the classical economists fail to elaborate a consistent theory of value and distribution on the basis of the twin concepts of (a) physical real costs and (b) a circular flow of production? According to Sraffa (see Kurz and Salvadori, 2005) a main, if not the main, reason consisted in a mismatch between highly sophisticated analytical concepts on the one hand and inadequate tools available to the classical authors to deal with them on the other. More specifically, the tool needed in order to bring to fruition an analysis based on these twin concepts was simultaneous equations: knowledge of how to solve them and how to discover what their properties are. This indispensable tool (alas!) was not at their disposal. They therefore tried to solve the problems they encountered in a roundabout way, typically by first identifying an ‘ultimate standard of value’ by means of which heterogeneous commodities could be rendered homogeneous. Several authors, including Smith, Ricardo and Marx, had then reached the conclusion that ‘labour’ was the standard they sought and had therefore arrived in one way or another at some version of the labour theory of value. This preserved the objectivist character of the theory by taking as data, or known quantities, only measurable things, such as amounts of commodities actually produced and amounts actually used up, including the means of subsistence in the support of workers. This was understandable in view of the unresolved tension between concepts and tools. However, with production as a circular flow, even labour values cannot be known independently of solving a system of simultaneous equations. Hence the route via labour values was not really a way out of the impasse in which the classical authors found themselves: it rather landed them right in that impasse again.

Commodities were produced by means of commodities and there was no way to circumnavigate the simultaneous equations approach.

What made it so difficult, if not impossible, for the classical authors to see that the theory of value and distribution could be firmly grounded in the concept of physical real cost? Given their primitive tools of analysis, they did not see that the information about the system of production in use and the quantities of the means of subsistence in support of workers was all that was needed in order to determine directly the system of necessary prices and the rate of profits. Sraffa understood this as early as November 1927, as we can see from his hitherto unpublished papers kept at Trinity College Library, Cambridge (UK), with
respect to what he called his ‘first’ (without a surplus) and ‘second’ (with a surplus) ‘equations’.
We may start with James Mill’s aforementioned case with three kinds of commodities, tools ($t$), raw
materials ($m$), and the food of the labourer ($f$). Production in the three industries may then be depicted
by the following system of quantities

\[
\begin{align*}
T_t &\rightarrow T \\
T_m &\rightarrow M \\
T_f &\rightarrow F
\end{align*}
\]

(1)

where $T_i$, $M_i$ and $F_i$ designate the inputs of the three commodities (employed as means of production
and means of subsistence) in industry $i$ ($i = t, m, f$), and $T$, $M$ and $F$ total outputs in the three industries;
the symbol $\oplus$ indicates that all inputs on the LHS of $\rightarrow$, representing production are required to
generate the output on its RHS. Invoking classical concepts, Sraffa called these relations ‘the methods of
production and productive consumption’ (1960, p. 3). In the hypothetical case in which the economy is
just viable, that is, able to reproduce itself without any surplus (or deficiency), we have $T = \Sigma_i T_i$, $M = \Sigma_i M_i$, and $F = \Sigma_i F_i$.

From this schema of reproduction and reproductive consumption we may directly derive the
comparing system of ‘absolute’ or ‘natural’ values, which expresses the idea of physical real cost-
based values in an unadulterated way. Denoting the value of one unit of commodity $i$ by $p_i$ ($i = t, m, f$),
we have

\[
\begin{align*}
T_t p_t + M_t p_m + F_t p_f &= T p_t \\
T_m p_t + M_m p_m + F_m p_f &= M p_m \\
T_f p_t + M_f p_m + F_f p_f &= F p_f
\end{align*}
\]

(2)

These linear equations are homogeneous and therefore only relative prices can be determined. Further,
only two of the three equations are independent of one another. This is enough to determine the two
relative prices. Alternatively, it is possible to fix a standard of value whose price is *ex definitione* equal
to unity. This provides an additional (non-homogeneous) equation without adding a further unknown,
and allows one to solve for the remaining dependent variables.
A numerical example illustrates the important finding that the given socio-technical relations rigidly fix
relative values:
These values depend exclusively on necessities of production. They are the only ones that allow the initial distribution of resources to be restored. Apparently, the value of one commodity may be ‘reduced’ to a certain amount of another commodity needed directly or indirectly in the production of the former. For example, one might reduce one unit of commodity $t$ to an amount needed of commodity $m$. Hence one might say that each of the three commodities could serve as a ‘common measure’ and that, for example, commodities $t$ and $f$ exchange for one another in the proportion 1:2 because commodity $t$ ‘contains’ or ‘embodies’ twice as much of commodity $m$ as commodity $f$.

There is no need even to talk about labour values at this stage of the argument. The same applies to the next stage, which refers to a system with a surplus and given commodity (or real) wages advanced at the beginning of the production period. In conditions of free competition the surplus will be distributed in terms of a uniform rate of profits on the ‘capitals’ advanced in the different industries.

We start again from the system of quantities consumed productively and produced (1), but now we assume that $T = \sum_i T_i$, $M = \sum_i M_i$, and $F = \sum_i F_i$, where at least with regard to one commodity the strict inequality sign holds. In conditions of free competition ‘normal’ prices, or ‘prices of production’, have to satisfy the following system of price equations:

\[
(T_t p_t + M_t p_m + F_t p_f)(1 + r) = T p_t
\]

\[
(T_m p_t + M_m p_m + F_m p_f)(1 + r) = M p_m
\]

\[
(T_f p_t + M_f p_m + F_f p_f)(1 + r) = F p_f
\]

The case of a uniform rate of physical surplus across all commodities contemplated by David Ricardo and Robert Torrens

\[
\frac{T - \sum_i T_i}{\sum_i T_i} = \frac{M - \sum_i M_i}{\sum_i M_i} = \frac{F - \sum_i F_i}{\sum_i F_i} = r
\]

\[
(3)
\]
denotes a very special constellation: in it the general rate of profits, \( r \), equals the uniform material rate of produce. Here we see the rate of profits in the commodities themselves, as having nothing to do with their values. In this case only two of the eqs. (3) are linearly independent so that eq. (4) determines the rate of profits, and eqs. (3), following the same procedure used for eqs. (2), determine relative prices. In general, the rates of physical surplus will be different for different commodities. Unequal rates of commodity surplus do not, however, by themselves imply unequal rates of profit across industries. In this case there are three numbers, each of which substituted for \( r \) in eqs. (3) makes them linearly dependent on one another with respect to prices. It is possible to show that, when the highest real number among such numbers is substituted for \( r \), the corresponding relative prices are positive, whereas when any of the other numbers is substituted for \( r \) some relative prices are negative. Since a negative relative price has no economic meaning in the present context, we can assert that there is a single solution which is relevant from an economic point of view. Fixing a standard of value provides a fourth equation and no extra unknown, so that the system of equations can be solved.

The important point to note here is the following. With the real wage rate given and paid at the beginning of the periodical production cycle, the problem of the determination of the rate of profits consists in distributing the surplus product in proportion to the capital advanced in each industry. Obviously, such a proportion between two aggregates of heterogeneous goods (in other words, the rate of profits) cannot be determined before we know the prices of the goods. On the other hand, we cannot defer the allotment of the surplus till after the prices are known, for … the prices cannot be determined before knowing the rate of profits. The result is that the distribution of the surplus must be determined through the same mechanism and at the same time as are the prices of commodities. (Sraffa, 1960, p. 6; emphasis added)

This passage shows that the idea which underlies Marx's so-called ‘transformation’ of labour values into prices of production (see Marx, 1894, part 2) cannot generally be sustained. Marx had proceeded in two steps; Ladislaus von Bortkiewicz (1906–7, essay 2, p. 38) aptly dubbed his approach ‘successivist’ (as opposed to ‘simultaneous’). In a first step Marx had assumed that the general rate of profits is determined independently of, and prior to, the determination of prices as the ratio between the labour value of the social surplus and that of social capital, consisting of ‘constant capital’ (means of production) and ‘variable capital’ (wages or means of subsistence). In a second step he had then used this rate to calculate prices.

So far we have assumed that real wages are given in kind at some level of subsistence. The classical economists, however, saw clearly that wages may rise above mere sustenance of labourers, which makes necessary a new wage concept. This case had made Ricardo adopt a \textit{share} concept of wages and establish the inverse relationship between the share of wages in the product and the rate of profits: ‘The greater the \textit{portion of the result of labour} that is given to the labourer, the smaller must be the \textit{rate of profits}, and vice versa’ (\textit{Works}, vol. 8, p. 194; emphasis added). The concept of ‘proportional wages’, as Sraffa called it, was then adopted by Marx in terms of a given rate of surplus value. Sraffa also adopted the concept, albeit with two important changes. First, when workers participate in the sharing out of the
surplus product, the original classical idea of wages being entirely paid out of social capital can no longer be sustained. After some deliberation Sraffa decided to treat wages as a whole as paid out of the product. Second, he did not express the share of wages in terms of labour but as the ratio of total wages to the net product expressed in terms of normal prices, \( w \). These changes necessitated reformulating the price equations by taking explicitly into account the amounts of labour expended in the different industries, \( L_i (i = t, m, f) \), because wages are taken to be paid in proportion to these amounts, and by defining these amounts as fractions of the total annual labour of society, that is, \( L_t + L_m + L_f = 1 \). In addition, it is assumed, following the classical economists, that differences in the quality of labour have been previously reduced to equivalent differences in quantity, so that each unit of labour receives the same wage rate (see Kurz and Salvadori, 1995, ch. 11). We may now formulate the corresponding system of production equations again for the case of the three kinds of commodities mentioned by Mill, where now the quantities represented by \( T_i, M_i \) and \( F_i \) refer exclusively to the inputs of the three commodities employed as means of production. We get (on the assumption that wages are paid post factum)

\[
\begin{align*}
(T_t p_t + M_t p_m + F_t p_f)(1 + r) + L_t w &= T p_t \\
(T_m p_t + M_m p_m + F_m p_f)(1 + r) + L_m w &= M p_m \\
(T_f p_t + M_f p_m + F_f p_f)(1 + r) + L_f w &= F p_f
\end{align*}
\]

(5.1)

With the net product taken as standard of value, we have in addition that

\[
(T - \Sigma_i T_i) p_t + (M - \Sigma M_i) p_m + (F - \Sigma F_i) p_f = 1.
\]

Taking one of the distributive variables, the share of wages \( w \) (or the rate of profits \( r \)) as given, allows one to determine the remaining variables: \( r \) (or \( w \)) and the prices of commodities. Using this approach, Sraffa was able to show that, whereas the wage rate as a function of the rate of profits is necessarily decreasing (but does not need to be so if commodities are produced jointly), any relative price as a function of the rate of profits typically does not follow a simple rule: the function can alternately be increasing or decreasing, and can pass through unity a number of times (but such a number is constrained by the overall number of commodities involved). This fact is important also because the problem of the choice of technique from among several alternatives can be studied by following substantially the same argument. Suppose, for instance, that commodity \( t \) can be produced also with process
Then we can add to system (5.1) the equation

\[(T'_t p_t + M'_t p_m + F'_t p_f)(1 + r) + L'_t w = T' p'_t\]

(5.2)

with the further unknown \(p'_t\). The study of the ratio \(p'_t / p_t\) allows one to say when it is profitable to use the old process and when the new one: if \(p'_t / p_t\) is smaller than 1, the new process will be chosen by cost-minimizing producers; if it is larger than 1, the old process will be retained, whereas the two processes can coexist in case \(p'_t / p_t = 1\). Obviously, if the new process is chosen and has replaced the old one, and if it is assumed that the rate of profits is unchanged, then eqs. (5.1) give way to the following equations, serving as the new system

\[
\begin{align*}
(T'_t p_t + M'_t p_m + F'_t p_f)(1 + r) + L'_t w' &= T' p'_t \\
(T_m p'_t + M_m p'_m + F_m p'_f)(1 + r) + L_m w' &= M p'_m \\
(T_f p'_t + M_f p'_m + F_f p'_f)(1 + r) + L_f w' &= F p'_f
\end{align*}
\]

(6.1)

In this new system prices and the wage are different (\(p'_j \neq p_j\) and \(w' \neq w\)), but they are not so when \(p'_j / p_t = 1\) in system (5). If we now evaluate the old process in terms of the prices and wage of the new system by combining system (6.1) and the equation

\[
(T_t p'_t + M_t p'_m + F_t p'_f)(1 + r) + L_t w' = T p_t
\]

(6.2)
we can calculate again the ratio $\frac{p'_t}{p_t}$, and the property that prices and the wage in the two systems coincide when $\frac{p'_t}{p_t} = 1$ is enough to prove that $\frac{p'_t}{p_t}$ is larger (lower) than 1 for a given $r$ in system (6) if and only if it is so in system (5). Hence the comparison between the new process and the old one can be indifferently done at the prices of either the old system or the new system.

In the following a system involving a number of processes equal to the number of commodities involved, each producing a different commodity, is called a *technique*, and a technique which is chosen at a given income distribution is called a *cost-minimizing technique* at that income distribution. The fact that a relative price can pass through unity at several income distributions implies that a technique can be cost-minimizing at different values of the rate of profits, with other techniques being cost minimizing in the interval in between. This fact has been called *reswitching*; it played an important role in the criticism of neoclassical theory.

In the above it has for simplicity been assumed that there is only single production, that is, only circulating capital. While the circulating part of the capital goods advanced in production contributes entirely and exclusively to the output generated, that is, ‘disappears’ from the scene, so to speak, the fixed part of it contributes to a sequence of outputs over time, that is, after a single round of production its items are still there – older but still useful. For a discussion of joint production, fixed capital and scarce natural resources, see Kurz and Salvadori (1995).

**Critique of marginalist theory**

The passage quoted above from Sraffa (1960, p. 6) contains the key to his critique of the long-period marginalist concept of capital. This concept hinges crucially on the possibility of defining the ‘quantity of capital’, whose relative scarcity and thus marginal productivity was taken to determine the rate of profits, independently of the rate of profits. However, according to the logic of Sraffa’s above argument the rate of profits and the quantity (that is, value) of social capital $(\Sigma_i \bar{T}_i p_t + \Sigma_i M_i p_m + \Sigma_i F_i p_f)$ can only be determined simultaneously.

We may approach the issues under consideration by first discussing what are known as ‘Wicksell effects’. The term was introduced by Joan Robinson (1953, p. 95) during a debate in the theory of capital (see Kurz and Salvadori, 1995, ch. 14). We distinguish between *price Wicksell effects* and *real Wicksell effects* (henceforth PWE and RWE). A PWE relates to a change in relative prices corresponding to a change in income distribution, given the system of production in use. A RWE relates to a change in technique, with the fact taken into account that at the income distribution at which two techniques are both cost-minimizing (one being so at higher, the other at lower levels of the rate of profits) both techniques have the same prices. The ‘changes’ under consideration refer to comparisons of long-period equilibria.

Marginalist theory contends that both effects are invariably positive. A *positive* PWE means that with a rise (fall) in the rate of interest prices of consumption goods will tend to rise (fall) relative to those of capital goods. The reason given is that consumption goods are said to be produced more capital intensively than capital goods: consumption goods emerge at the end of the production process, whereas capital goods are intermediate products that gradually ‘mature’ towards the final product. The higher (lower) is the rate of interest the less (more) expensive are the intermediate products in terms of a...
standard consisting of a (basket of) consumption good(s). At the macro level of a stationary economy (in which the net product contains only consumption goods) this implies that with a rise in the rate of interest the value of the net social product rises relatively to the value of the aggregate of capital goods employed. Clearly, seen from the marginalist perspective, a positive PWE with regard to the relative price of the two aggregates under consideration involves a negative relationship between the aggregate capital-to-net output ratio on the one hand and the interest rate on the other. Let \( \frac{K}{Y} = xP(r) / yP(r) \) (\( x \) is the row vector of capital goods, \( y \) the row vector of net outputs, and \( p(r) \) the column vector of prices (in terms of the consumption vector) which depends on \( r \)) designate the capital-output ratio, then the marginalist message is:

\[
\frac{\partial (K/Y)}{\partial r} \leq 0
\]

Since for a given system of production the amount of labour is constant irrespective of the level of the rate of interest, also the ratio of the value of the capital goods and the amount of labour employed, or capital–labour ratio, \( K/L \), would tend to fall (rise) with a rise (fall) in the rate of interest,

\[
\frac{\partial (K/L)}{\partial r} \leq 0 \tag{7}
\]

This is the first claim marginalist authors put forward. The second is that RWEs are also positive. A positive RWE means that with a rise (fall) in the rate of interest cost-minimizing producers switch to methods of production that generally exhibit higher (lower) labour intensities, ‘substituting’ for the ‘factor of production’ that has become more expensive – ‘capital’ (labour) – the one that has become less expensive – labour (‘capital’). Hence (7) is said to apply also in this case. The assumed positivity of the RWE underlies the marginalist concept of a demand function for labour (capital) that is inversely related to the real wage rate (rate of interest).

Careful scrutiny of the marginalist argument has shown that it cannot generally be sustained: there is no presumption that PWEs and RWEs are invariably positive. In fact there is no presumption that techniques can be ordered monotonically with the rate of interest (Sraffa, 1960). Reswitching implies that, even if PWEs happen to be positive, RWEs cannot always be positive. As Mas-Colell (1989) stressed, the relationship between \( K/L \) and \( r \) can have almost any shape whatsoever. In the intervals in which \( K/L \) is an increasing function of \( r \) we say that there is capital reversal. It implies that, if the neoclassical approach to value and distribution is followed, the ‘demand for capital’ is not decreasing, and therefore the resulting equilibrium, provided there is one, is not stable. Hence the finding that PWEs and RWEs need not be positive challenges the received doctrine of the working of the economic system, as it is portrayed by conventional economic theory with its reference to the ‘forces’ of demand and
Current work in the classical tradition

In more recent times authors working in the classical tradition, as it was revived by Sraffa, have focused attention on a large number of problems. First, there has been a lively interest in generalizing the results provided by Sraffa on joint production, fixed capital, and land. Then the approach was extended to cover renewable and exhaustible resources and to allow for the more realistic case of costly disposal, which leads to the concept of negative prices of products that have to be disposed of. There is also a renewed interest in the problem of economic growth and development. Freed from the straightjacket of Say’s Law, which can be said to be an implication of the finding that conventional equilibrium analysis cannot be sustained, there is no presumption that the economy will consistently follow a full-capacity path of economic expansion. Hence the problem of different degrees and modes of utilization of productive capacity and the role of effectual demand (Adam Smith) have to be analysed. This avenue has opened up avenues for cross-fertilization between classical economics on the one hand, and Keynesian economics, based on the principle of effective demand, and evolutionary economics, concerned with complex dynamics, on the other (see Coase, 1976; Nelson, 2005). This fact is also highlighted in comparisons with the so-called new growth theory, and allows one to better understand the latter’s merits and demerits (see Kurz and Salvadori, 1998a, ch. 4; 1999).

In the 1960s and 1970s the long-period versions of marginalist theory revolving around the concept of a uniform rate of return on capital were called into question on logical grounds. While many marginalist authors accepted this criticism, some of them contended that intertemporal equilibrium theory, the ‘highbrow version’ of neoclassicism, was not affected by it (see especially Bliss, 1975; Hahn, 1982). This claim has more recently been subjected to close scrutiny (see Garegnani, 2000, Schefold, 2000, and the special issue of *Metroeconomica*, vol. 56(4), 2006). While the criticism of the long-period versions of marginalist theory is irrefutable, as authors from Paul Samuelson to Andreu Mas-Colell have admitted, surprisingly this has not prevented the economics profession at large from still using this theory. This is perhaps so because in more recent years the way of theorizing in large parts of mainstream economics has fundamentally changed. Whether this change is a response to the criticism need not concern us here. It suffices to draw the reader’s attention to a statement by Paul Romer in one of his papers on endogenous growth in which he self-critically pointed out a slip in his earlier argument. The error he had committed, he wrote, ‘may seem a trifling matter in an area of theory that depends on so many other short cuts. After all, if one is going to do violence to the complexity of economic activity by assuming that there is an aggregate production function, how much more harm can it do to be sloppy about the difference between rival and nonrival goods?’ (Romer, 1994, pp. 15–16) Once economic theory has taken the road indicated, criticism becomes a barren instrument. Indeed, why should someone who seeks to provide ‘microfoundations’ in terms of a representative agent with an infinite time horizon find fault with the counter-factual but attractive assumption that there is only a single (capital) good?

network formation

Matthew O. Jackson
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

A brief introduction and overview of models of the formation of networks is given, with a focus on two types of model. The first views networks as arising stochastically, and uses random graph theory, while the second views the links in a network as social or economic relationships chosen by the involved parties, and uses game theoretic reasoning.

Keywords

clustering; degree distributions; graph theory; Myerson value; network formation; pairwise stability; random graphs; small worlds

Article

A growing literature in economics examines the formation of networks and complements a rich literature in sociology and recently emerging literatures in computer science and statistical physics. Research on network formation is generally motivated by the observation that social structure is important in a wide range of interactions, including the buying and selling of many goods and services, the transmission of job information, decisions on whether to undertake criminal activity, and informal insurance networks.

Networks are often modelled using tools and terminology from graph theory. Most models of networks view a network as either a non-directed or a directed graph; which type of graph is more appropriate depends on the context. For instance, if a network is a social network of people and links represent friendships or acquaintances, then it would tend to be non-directed. Here the people would be modelled as the nodes of the network and the relationships would be the links. (In terms of a graph, the people would be vertices and the relationships would be edges.) If, instead, the network represents citations from one article to another, then each article would be a node and the links would be directed, as one article could cite another. While many social and economic relationships are reciprocal or require the consent of both parties, there are also enough applications that take a directed form, so that both non-
directed and directed graphs are useful as modelling tools. Models of how networks form can be roughly divided into two classes. One derives from random graph theory, and views an economic or social relationship as a random variable. The other views the people (or firms or other actors involved) as exercising discretion in forming their relationships, and uses game theoretic tools to model formation. Each of these techniques is discussed in turn.

Models of random networks

Bernoulli random graphs

Some of the earliest formal models used to understand the formation of networks are random graphs: the canonical example is that of a pure Bernoulli process of link formation (for example, see the seminal study of Erdös and Rényi, 1960). For instance, consider a network where the (non-directed) link between any two nodes is formed with some probability $p$ (where $1>p>0$), and this process occurs independently across pairs of nodes. While such a random method of forming links allows any network to potentially emerge, some networks are much more likely to do so than others. Moreover, as the number of nodes becomes large, there is much that can be deduced about the structure the network is likely to take, as a function of $p$. For instance, one can examine the probability that the resulting network will be connected in the sense that one can find a path (sequence of links) leading from any given node to any other node. We can also ask what the average distance will be in terms of path length between different nodes, among other things. As Erdös and Rényi showed, such a random graph exhibits a number of ‘phase’ transitions as the probability of forming links, $p$, is varied in relation to the number of nodes, $n$; that is, resulting networks exhibit different characteristics depending on the relative sizes of $p$ and $n$.

Whether or not such a uniformly random graph model is a good fit as a model of network formation, it is of interest because it indicates that networks with different densities of links might tend to have very different structures and also provides some comparisons for network formation processes more generally. Some of the basic properties that such a random graph exhibits can be summarized as follows. When $p$ is small in relation to $n$, so that $p<1/n$ (that is, the average number of links per node is less than one), then with a probability approaching 1 as $n$ grows the resulting graph consists of a number of disjointed and relatively small components, each of which has a tree-like structure. (A component of a network is a subgraph, so that each node in the subgraph can be reached from any other node in the subgraph via a path that lies entirely in the subgraph, and there are no links between any nodes in the subgraph and any nodes outside the subgraph.) Once $p$ is large enough in relation to $n$, so that $p>1/n$, then a single ‘giant component’ emerges; that is, with a probability approaching 1 the graph consists of one large component, which contains a nontrivial fraction of the nodes, and all other components are vanishingly small in comparison. Why there is just one giant component and all other components are of a much smaller order is fairly intuitive. In order to have two ‘large’ components each having a nontrivial fraction of $n$ nodes, there would have to be no links between any node in one of the components and any node in the other. For large $n$, it becomes increasingly unlikely to have two large components with absolutely no links between them. Thus, nontrivial components mesh into a giant component, and any other components must be of a much smaller order. As $p$ is increased further, there is another phase transition when $p$ is proportional to $log(n)/n$. This is the threshold at which the network becomes
network formation: The New Palgrave Dictionary of Economics

‘connected’ so that all nodes are path-connected to each other and the network consists of a single component. Once we hit the threshold at which the network becomes connected, we also see further changes in the diameter of the network as we continue to increase \( p \) relative to \( n \). (The diameter is the maximal distance between two nodes, where distance is the minimal number of links that are needed to pass from one node to another.) Below the threshold, the diameter of a giant component is of the order of \( \log(n) \), then at the threshold of connectedness it hits \( \log(n)/\log\log(n) \), and it continues to shrink as \( p \) increases.

Similar properties and phase transitions have been studied in the context of other models of random graphs. For example, Molloy and Reed (1995), among others (see Newman, 2003), have studied component size and connectedness in a ‘configuration model’. There, a set of nodes is given together with the number of links that each node should have, and then links are randomly formed to leave each node with the pre-specified number of links.

Clustering and Markov graphs

Although the random graphs of Erdös and Rényi are a useful starting point for modelling network formation, they lack many characteristics observed in most social and economic networks. This has led to a series of richer random graph-based models of networks. The most basic property that is absent from such random networks is that the presence of links tends to be correlated. For instance, social networks tend to exhibit significant clustering. Clustering refers to the following property of a network. If we examine triples of nodes so that two of them are each connected to the third, what is the frequency with which those two nodes are linked to each other? This tends to be much larger in real social networks than one would see in a Bernoulli random graph. On an intuitive level, models of network formation where links are formed independently tend to look too much like ‘trees’, while observed social and economic networks tend to exhibit substantial clustering, with many more cycles than would be generated at random (see Watts, 1999, for discussion and evidence).

Frank and Strauss (1986) identified a class of random graphs that generalize Bernoulli random graphs, which they called ‘Markov graphs’ (also referred to as \( p^* \) networks). Their idea was to allow the chance that a given link forms to be dependent on whether or not neighbouring links are formed. Specific interdependencies require special structures, because, for instance, making one link dependent on a second, and the second on the third, can imply some interdependencies between the first and third. These sorts of dependencies are difficult to analyse in a tractable manner, but nevertheless some special versions of such models have been useful in statistical estimation of networks.

Small worlds

Another variation on a Bernoulli network was explored by Watts and Strogatz (1998) in order to generate networks that exhibit both relatively low distances (in terms of minimum path length) between nodes and relatively high clustering – two features that are present in many observed networks but not in the Bernoulli random graphs unless the number of links per node \( (p(n-1)) \) is extremely high. They started with a very structured network that exhibits a high degree of clustering. Then, by randomly rewiring enough (but not too many) links, one ends up with a network that has a small average distance
between links but still has substantial clustering. While such a rewiring process results in networks that exhibit some of the features of social networks, it leads to networks that miss out on other basic characteristics that are present in many social networks. For example, the nodes of such a network tend to be too similar in terms of the number of links that they each have.

**Degree distributions**

One fundamental characteristic of a social network is a network’s degree distribution. The degree of a node is the number of links it has, and the degree distribution keeps track of how varied the degree is across the nodes of the network. That is, the degree distribution is simply the frequency distribution of degrees across nodes. For instance, in a friendship network some individuals might have only a few friends while other individuals might have many, and then the degree distribution quantifies this information.

Price (1965) examined a network of citations (between scientific articles), and found that the degree distribution exhibited ‘fat tails’ compared with what one would observe in a Bernoulli random graph; that is, there was a higher frequency of articles that had many citations and a higher frequency of articles that had no citations than should be observed if citations were generated independently. In fact, many social networks exhibit such fat tails, and some have even been thought to exhibit what is known as a ‘scale-free’ degree distribution or said to ‘follow a power law’. A scale-free distribution is one where the frequency of degrees can be written in the form $f(d) = ad^{-b}$, for some parameters $a$ and $b$, where $d$ is the degree and $f(d)$ is the relative frequency of nodes with degree $d$. Such distributions date to Pareto (1896), and have been observed in a variety of other contexts ranging from the distribution of wealth in a society to the relative use of words in a language. Price (1976) adapted ideas from Simon (1955) to develop a random link formation process that produces networks with such degree distributions. A similar model was later studied by Barabási and Albert (2001), who called the process of link formation ‘preferential attachment’. The idea is that nodes gain new links with probabilities that are proportional to the number of links they already have (which is closely related to a lognormal growth process). In a system where new nodes are born over time, this process generates scale-free degree distributions.

A simple preferential attachment model also has its limitations. One is that most social networks do not in fact have degree distributions that are scale-free. Observed degree distributions tend to lie somewhere between the extremes of a scale-free distribution and that corresponding to an independent Bernoulli random graph (sometimes known as a Poisson random graph for its approximate degree distribution). Second, the preferential attachment model fails to produce the type of clustering observed in many social networks, just as Bernoulli random graphs do. This has led to the construction of hybrid models that allow for richer sets of degree distributions, as well as clustering and correlation in degrees, and allows for the structural fitting of random graph based network formation models to data (for example, see Jackson and Rogers, 2007, and the discussion there).

**Strategic models of network formation**

Strategic models of network formation have emerged from the economics literature, and offer a very different perspective from that seen in random graph models, and a complementary set of insights (see...
network formation: The New Palgrave Dictionary of Economics

Jackson, 2006, for comparison and discussion). The starting point for a game theoretic approach is to assume that the nodes are active discretionary agents or players who get payoffs that depend on the social network that emerges. For example, if nodes are countries and links are political alliances, or nodes are firms and links are trading or collaboration agreements, then the relationships are entered into with some care and thought. Even in modelling something like a friendship network, while individuals might not be directly calculating costs and benefits from the relationship, they do react to how enjoyable or worthwhile the relationship is and might tend to spend more effort or time in relationships that are more beneficial and avoid ones that are less so. Different social networks lead to different outcomes for the involved agents (for example, different trades, different access to information or favours, and so on). Links are then formed at the discretion of the agents, and various equilibrium notions are used to predict which networks will form. This differs from the random models not only in that links result as a function of decisions rather than at random, but also in that there are natural costs and benefits associated with networks which then allow a welfare analysis.

Some of the first models to bring explicit utilities and choice to the formation of social links were in the context of modelling the trade-offs between ‘strong’ and ‘weak’ ties (links) in labour contact networks. Such models by Boorman (1975) and Montgomery (1991) explored a theory, due to Granovetter (1973), about different strengths of social relationships and their role in finding employment. Granovetter observed that when individuals obtained jobs through their social contacts, while they sometimes did so through strong ties (people whom they knew well and interacted with on a frequent basis), they also quite often obtained jobs through weak ties (acquaintances whom they knew less well and/or interacted with relatively infrequently). This led Granovetter to coin the phrase ‘the strength of weak ties’.

Boorman's article and Montgomery's articles provided explicit models where costs and benefits could be assigned to strong and weak ties, and trade-offs between them could be explored.

In a very different setting, another use of utility functions involving networks emerged in the work of Myerson (1977). Myerson analysed a class of cooperative games that were augmented with a graph structure. In these games the only coalitions that could produce value are those that are pathwise connected by the graph, and so such graphs indicate the possible cooperation or communication structures. This approach led Myerson to characterize a variation on the Shapley value, now called the Myerson value, which was a cooperative game solution concept for the class of cooperative games where constraints on coalitions were imposed by a graph structure. Although the graphs in Myerson's analysis are tools to define a special class of cooperative games, they allow the graph structure to influence the allocation of societal value among a set of players. Aumann and Myerson (1988), recognizing that different graph structures led to different allocations of value, used this to study a game where the graph structure was endogenous. They studied an extensive form game where links are considered one by one according to some exogenous order, and formed if both agents involved agree. While that game turns out to be hard to analyse even in three-person examples, it was an important precursor to the more recent economic literature on network formation.

In contrast to the cooperative game setting, Jackson and Wolinsky (1996) explicitly considered networks, rather than coalitions, as the primitive. Thus, rather than deducing utilities indirectly through a cooperative game on a graph, they posited that networks were the primitive structure and agents derived utilities based on the network structure in place. So, once a social network structure is in place, one can then deduce what the agent's payoffs will be. Using such a formulation where players' payoffs are determined as a function of the social network in place, it is easy to model network formation using...
game theoretic techniques.

**Pairwise stability**

In modelling network formation from a game theoretic perspective, one needs to have some notion of equilibrium or stable networks. Since it is natural to require mutual consent in many applications, standard Nash equilibrium based ideas are not very useful. For instance, consider a game where each agent simultaneously announces which other agents he or she is willing to link to. It is always a Nash equilibrium for each agent to say that he or she does not want to form any links, anticipating that the others will do the same. Generally, this allows for a multiplicity of equilibria, many of which make little sense from a social network perspective. Even equilibrium refinements (such as undominated Nash or perfect equilibrium) do not avoid this problem. Given that it is natural in a network setting for the agents prospectively forming a link to be able to communicate with each other, they should also be able to coordinate with each other on the forming of a link. An approach taken by Jackson and Wolinsky (1996) is to define a stability notion that directly incorporates the mutual consent needed to form links. Jackson and Wolinsky (1996) defined the following notion of ‘pairwise stability’: a network is pairwise stable if (i) no player would be better off if he or she severed one of his or her links, and (ii) no pair of players would both benefit (with at least one of the pair seeing a strict benefit) from adding a link that is not in the network. The requirement that no player wishes to delete a link that he or she is involved in implies that a player has the discretion to unilaterally terminate relationships that he or she is involved in. The second part of the definition captures the idea that if we are at a network where the creation of a new link would benefit both players involved, then the network is not stable, as it will be in the players' interests to add the link.

Pairwise stability is a fairly permissive stability concept – for instance, it does not consider deviations where players delete some links and add others at the same time. While pairwise stability is easy to work with and often makes fairly pointed predictions, the consideration of further refinements can make a difference. A variety of refinements and alternative notions have been introduced, including allowing agents to form and sever links at the same time, allowing coalitions of agents to add and sever links in a coordinated fashion, or behaviour where agents anticipate how the formation of one link might influence others to form further links (see Jackson, 2004, for discussion and references). There are also dynamic models (for example, Watts, 2001) in which the possibility of forming links arises (repeatedly) over time, and agents might ‘tremble’ when they form links (see Jackson, 2004, for references). These various equilibrium/stability concepts have different properties and are appropriate in different contexts. With pairwise stability, or some other solution in hand, one can address a series of questions. One fundamental question is whether, from society's point of view, efficient or optimal networks will be stable when agents form links with their selfish interests in mind. Given that transfers are being considered here, one natural definition of an ‘efficient’ or ‘optimal’ network is one that maximizes the total value or the sum of utilities of all agents in the society. Another basic question is to ask whether in situations where no efficient network is pairwise stable, is it possible for some sort of intervention (for example, in the form of taxing or subsidizing links), to lead efficient networks to form.

A connections model of social networks
One stylized example from Jackson and Wolinsky (1996) gives some feeling for the issues involved in the above questions and is useful for illustrating the relationship between efficient and pairwise stable networks. Jackson and Wolinsky called this example the ‘symmetric connections model’, in which the links represent social relationships between players such as friendships. These relationships offer benefits in terms of favours, information, and so on, and also involve some costs. Moreover, players benefit from having indirect relationships. A ‘friend of a friend’ produces benefits or utility for a player, although of a lesser value than the direct benefits that come from a ‘friend’. The same is true of ‘friends of a friend of a friend’, and so forth. Benefit deteriorates in the ‘distance’ of the relationship, as represented by a factor $\delta$ between 0 and 1, which indicates the benefit from a direct relationship between two agents and is raised to higher powers for more distant relationships. For instance, in the network where player 1 is linked to 2, 2 is linked to 3, and 3 is linked to 4; player 1 gets a benefit of $\delta$ from the direct connection with player 2, an indirect benefit of $\delta^2$ from the indirect connection with player 3, and an indirect benefit of $\delta^3$ from the indirect connection with player 4. For $\delta <1$ this leads to a lower benefit from an indirect connection than a direct one. Players also pay some cost $c$ for maintaining each of their direct relationships (but not for indirect ones). Once the benefit parameter, $\delta$, and the cost parameter, $c>0$ are specified, it is possible to determine each agent's payoff from every possible network, allowing a characterization of the pairwise stable networks as well as the efficient networks. The efficient network structures are the complete network if $c<\delta -\delta^2$, a ‘star’ (a network where one agent is connected to each other agent and there are no other connections) encompassing all nodes if $\delta -\delta^2 < c < \delta + \frac{(n-2)}{2}\delta^2$, and the empty network if $\delta + \frac{(n-2)}{2}\delta^2 < c$. The idea is that if costs are very low it will be efficient to include all links in the network, because shortening any path leads to higher payoffs. When the link cost is at an intermediate level, then the unique efficient network structure is to have all players arranged in a star network, since such a structure has the minimal number of links $(n-1)$ needed to connect all individuals, and yet still has all nodes within at most two links from one another. Once links become so costly that a star results in more cost than benefit, then the empty network is efficient. One can also examine a directed version of such a model, as in Bala and Goyal (2000), who find related results, but with some differences that depend on whether both agents or just one of the agents enjoys the benefits from a directed link.

Inefficiency of stable networks

The set of pairwise stable networks does not always coincide with the efficient ones, and sometimes do not even intersect with the set of efficient networks. For instance, if the cost of a link is greater than the direct benefit ($c>\delta$), then relationships are only valuable to a given agent if they generate indirect benefits as well as direct ones. In such a situation a star is not pairwise stable since the centre player gets benefit of the direct value from each of his or her links, which is less than the cost of each of those links. This model of social networks makes it obvious that there will be situations where individual incentives are not aligned with overall societal benefits.

As it will generally be the case that in economic and social networks there are some sort of externalities present, since two agents' decisions of whether or not to form a relationship can affect the well-being of other agents, one should expect that there will be situations where the networks formed through the
selfish decisions of the agents do not coincide with those that are efficient from society's perspective. In such situations, it is natural to ask whether intervention in the form of transfers among agents might help align individual and overall societal incentives to form the right network. For instance, in the connections model, it would make sense to have the peripheral agents in a star pay the centre of the star in order to maintain their links. The peripheral agents benefit much more from the relationship with the centre agent than vice versa, as the centre agent provides access to many indirect agents. Although a simple set of transfers can align individual and overall incentives in the connections model, it is impossible to always correct this tension between individual incentives and overall efficiency by taxing and subsidizing agents for the links they form (even in a complete information setting). The fact that there are very simple, natural network settings where no ‘reasonable’ set of transfers can help rectify the disparity stability and efficiency was shown in Jackson and Wolinsky (1996). Without providing details, the impossibility of reconciling stability and efficiency stems from the following considerations: from any given network, there are many other networks that can be reached. In fact, if there are \( n \) nodes, then there are \( n(n-1)/2 \) possible links that can be added to or deleted from any given network. In order to ensure that a given efficient network is pairwise stable, payoffs to all neighbouring networks have to be configured so that no agent finds it in his or her interest to delete a link and no two agents find it in their interests to add a link. It is impossible to assign all the necessary taxes and subsidies in such a way that (i) the transfers are feasible (and are not given to unattached agents), (ii) identical agents are treated identically, and (iii) it is always the case that at least one efficient network is pairwise stable.

Much more has been learned about the relationship between stable and efficient networks and possible transfers to ensure that efficient networks form. For instance, one can characterize some classes of settings where the efficient networks and the stable ones coincide (see Jackson and Wolinsky, 1996). One can also design transfers that ensure that some efficient network is stable by treating agents unequally (for example, taxing or subsidizing them differently even though the agents are identical in the problem as shown by Dutta and Mutuswami, 1997). Another important point was made by Curra\-rini and Morelli (2000), who showed that if agents bargain over the division of payoffs generated by network relationships at the time when they form link, then in a nontrivial class of settings equilibrium networks are efficient. While the conclusions hinge on the structure of the link-formation-bargaining game, and in particular on an asymmetry in bargaining power across the agents, such a result tells us that it can be important to model the formation of the links of a network together with any potential bargaining over payoffs or transfers. Further study in this area shows how the types of transfers needed to reach efficient networks relate to the types of network externalities that are present in the setting.

**Small worlds and strategic network formation**

Beyond understanding the relationship between stable and efficient networks, strategic models of network formation have also shed light on some empirical regularities and helped predict which networks will arise in settings of particular interest. For instance, strategic models of network formation provide substantial insight into the ‘small-worlds’ properties of social networks: the simultaneous presence of high clustering (a high density of links on a local level) and short average path length between nodes (see Jackson, 2006, for references). The reasoning is based on a premise that different nodes have different distances from each other, either geographically or according to some other
characteristic, such as profession, tastes, and so on. The low cost of forming links to other nodes that are nearby then naturally explains high clustering. High benefits from forming links that bridge disparate parts of the network, due to the access and indirect connections that they bring, naturally explain low average path length.

Networks and markets

There is a rich set of studies of markets and networks from an economics perspective, including models that explicitly examine whether or not buyers and sellers have incentives to form an efficient network of relationships (for example, Kranton and Minehart, 2001). The incentives to form efficient networks depend on the setting and which agents bear the cost of forming relationships. In some settings competitive forces lead to the right configuration of links, and in others buyers and sellers over-connect in order to improve their relative bargaining positions. Other studies focus on the context of specific markets, such as labour markets, where people benefit from connections with neighbours who provide information about job opportunities (see Ioannides and Loury, 2004, for an overview and references). In addition to studies of networks of relationships between buyers and sellers, firms also form relationships amongst themselves that affect their costs and the sets of products they offer. Such oligopoly settings where network formation is important (see Bloch, 2004, for a recent survey), again provide a rich set of results regarding the structure of networks that emerge, and contrasts between settings where efficient networks naturally emerge and others where only inefficient networks are formed.

Network formation has also been studied in the context of many other applications, including risk-sharing in developing countries, social mobility, criminal activity, international trade and banking deposits.

Finally, there have been a number of experiments on network formation, using human subjects. These examine a variety of questions, ranging from how forward-looking agents are when they form social ties, to whether or not agents overcome coordination problems when forming links, to whether there are pronounced differences between network formation when links can be formed unilaterally as opposed to when they require mutual consent, to whether efficient networks will tend to result and how that depends on symmetries or asymmetries in the efficient network structure (see Falk and Kosfeld, 2003, for some discussion and references).

Abstract

A network effect exists if the consumption benefits of a good or service increase with the total number of consumers who purchase compatible products. A growing empirical literature examines technological adoption of products with network effects. The early literature mainly addressed the question of whether network effects are indeed significant; this work typically employed reduced form models. Later literature employed structural methodology, which can address aspects of firm strategy, such as incentives to provide compatible products. Key issues in the empirical work on network industries are examined.

Keywords

hedonic prices; logit models of individual choice; network effect (empirical studies); product differentiation

Article

A network effect exists if the consumption benefits of a good or service increase with the total number of consumers who purchase compatible products. The literature distinguishes between direct and indirect network effects. In the case of a direct (or physical) network effect, an increase in the number of consumers on the same network raises the consumption benefits for everyone on the network. Communication networks such as telephone and e-mail networks are examples of goods with direct network effects. A network effect can also arise in a setting with a ‘hardware/software’ system. Here, the benefits of the hardware good increase when the variety of compatible software increases. An indirect (or virtual) network effect arises endogenously in this case because an increase in the number of users of compatible hardware increases the demand for compatible software. Since software goods are typically characterized by economies of scale, the increase in demand leads to increases in the supply of software varieties. Examples of settings where virtual network effects arise include consumer electronics such as...
CD players and compact discs, computer operating systems and applications programs, and television sets and programming.

Given the dramatic growth of the internet and information technology industries, and the importance of interconnection in these networks, it is not surprising that there is a large theoretical literature on competition in industries with network goods. Important questions in this literature include

- the examination of the private and social incentives to attain compatibility;
- the trade-off between standardization and variety;
- modelling the dynamics of competition between competing networks; and
- how the private and social choice among competing incompatible networks differs when there are both early and late adopters.

See Farrell and Klemperer (2007) for further discussion.

Although relatively small, a growing empirical literature has developed to examine technological adoption of products with network effects. In this short article, I briefly discuss this literature. The empirical work can be organized by the issues addressed and the methodology employed. The primary issue addressed by the early literature is whether network effects are indeed significant; this work typically employed reduced form models. The article first surveys early work in this genre, then examines papers that employed structural methodology. The main advantage of this methodology is that it can address aspects of firm strategy, such as incentives to provide compatible products. The article closes by examining key issues in empirical work on network industries.

Early work: indirect evidence of network effects

Greenstein (1993), Gandal (1994; 1995), and Saloner and Shepard (1995) provide early evidence that the value of the ‘hardware’ good depends on the variety of compatible complementary software. (Shy, 2001, surveys many of the empirical papers discussed in this article in greater detail than space permits here.)

Software for the IBM 1400 mainframe could not run on succeeding generations of IBM mainframes while software for the IBM 360 could run on succeeding models. Greenstein (1993) finds that, other things being equal, a firm with an IBM 1400 was no more likely than any other firm to purchase an IBM mainframe when making a future purchase. On the other hand, a firm with an IBM 360 was more likely to purchase an IBM mainframe than a firm that did not own an IBM 360. This result can be interpreted as a demand for compatible software.

Gandal (1994) estimates hedonic (quality-adjusted) price equations for spreadsheets to examine whether spreadsheet programs that were compatible with Lotus – the de facto standard – command a premium. The results – that consumers place a positive value on compatibility – suggest (a) direct network effects because people want to share files and (b) indirect network effects because compatible software enables the transfer of data among a variety of software programs. Gandal (1995) extends the analysis to database management software (DMS) and multiple standards and finds that only the Lotus file compatibility standard is significant in explaining price variations, suggesting that indirect network effects are important in the DMS market.
Saloner and Shepard (1995) test for network effects in the automated teller machine (ATM) industry. In particular, they test whether banks with a larger expected number of ATM locations will adopt the ATM technology sooner. Since expected network size is not an observable variable, they use the number of branches as a proxy. The results suggest that banks with more branches will adopt earlier, which is consistent with virtual network effects.

**Structural models: explicitly modelling the complementary goods market**

Because hedonic price equations are a reduced form, rather than a structural model, parameter estimates associated with compatibility in Gandal (1994; 1995) may be capturing demand effects or supply effects or some combination of both. In other words, are consumers really willing to pay a premium for compatibility or is the marginal cost of compatibility relatively high? In the case of software, fixed costs of providing characteristics are quite significant, while marginal production costs associated with the characteristics are typically very small; they primarily include duplication of digital material. Hence, in these papers the estimated hedonic price coefficients on compatibility indeed measure consumer willingness to pay for compatibility.

Nevertheless, reduced form models are not suitable for examining business strategies or conducting counterfactuals. Gandal, Kende and Rob (2000) develop a dynamic structural model of consumer adoption and software entry, and use the model to estimate the feedback from hardware to software and vice versa in the CD industry. The advantage of the structural methodology is that it enables researchers to assess business strategies as well as examine conduct counterfactuals. In the case of business strategies, Gandal, Kende and Rob (2000) show that a five per cent reduction in price would have had the same effect as a ten per cent increase in CD variety in terms of increasing sales of CD players. They also show that, if it had been possible to make CD players compatible with LPs, compatibility could have accelerated the adoption process by more than a year. This is just a ‘thought experiment’ for CD players, but it has policy relevance for other systems like HDTV.

Rysman (2004) develops a structural model to examine the importance of network effects in the market for Yellow Pages. The model includes a consumer adoption equation, advertiser demand for space, and a firm's profit maximizing behaviour. He finds that consumers value advertising and advertisers value consumer adoption, suggesting virtual network effects.

In several recent papers, advances in the estimation of discrete choice models of product differentiation – see Berry (1994) and Berry, Levinsohn and Pakes (1995) – have also been employed when testing for indirect network effects in differentiated product markets. Ohashi and Clements (2005), for example, use a logit model to test for indirect network effects in the US video game market.

**Key issues in empirical work**

As in most fields, empirical work is typically limited by the available data. A key problem exists when one tries to estimate network effects in homogeneous product industries using time series data. For many network industries, technological progress drives down prices and costs. Hence an increase in the number of users on a network might be due to a network effect or to falling prices.
network goods (empirical studies) : The New Palgrave Dictionary of Economics

and Stavins, 2004, for further discussion). In order to estimate these effects, one must have additional data. Gandal, Kende and Rob (2000), for example, have data on the number of available compact disc titles at each point in time. Hence, in their model the two main effects that lead to greater adoption of CD players – lower prices of the hardware good and network effects due to increases in the number of titles – are measured separately. Nevertheless, that is only a start, since both of these variables are typically endogenous. Identification in Gandal, Kende, and Rob (2000) was possible only because there were data on the fixed costs of entering the CD production industry over time. These data were used as an instrument for CD (title) availability. Additionally, case studies indicated that the CD player industry was quite competitive, leading the authors to assume that the price of CD players was exogenous. Without both of these assumptions, it would not have been possible to identify the model.

Additionally, there is the thorny issue of pricing in dynamic models of competition in network industries. Since hardware firms may want to subsidize early adopters in order to build up a network advantage and then (perhaps) charge a higher price when the installed base grows, pricing issues are dynamic; firms will take into account (current and expected future) network size when choosing their prices. Park (2004) develops a dynamic structural model of competition in an oligopolistic market with network effects that addresses the dynamic pricing issues; he then estimates the model for VCRs. To the best of my knowledge, this is the only empirical paper that deals explicitly with dynamic pricing issues. A similar issue arises in dynamic models of competition in network industries when firms make investment in quality over time. Markovich (2001) examines the trade-off between standardization and variety in a dynamic setting using numerical methods. With suitable data one might be able to use her framework to empirically examine investment incentives and pricing decisions in a dynamic setting with network effects.

Finally, there is a budding empirical literature on standardization via committees. Papers include Simcoe (2006), who examines the standardization process in various committees of the Internet Engineering Task Force, and Gandal, Gantman and Genesove (2006), who examine firms' incentives to participate in Telecommunication Industry Association standardization meetings.

Abstract

Network effects arise where current users of a good gain when additional users adopt it (classic examples are telephones and faxes). The effects create multiple equilibria and fierce competition between incompatible networks; users' expectations are crucial in determining which network succeeds. Early choices, such as the QWERTY typewriter keyboard, lock in the market; new entry, especially against established networks with proprietary technology, is often nearly impossible. Incompatible networks can induce efficient ‘competition for the market’, but more often create biases and inefficiencies. Policymakers should scrutinize markets where firms deliberately choose incompatibility.

Article

Direct network effects arise if each user's payoff from the adoption of a good, and his incentive to adopt it, increase as more others adopt it; that is, if adoption by different users is complementary. For example, telecommunications users gain directly from more widespread adoption, and telecommunications networks with more users are also more attractive to non-users contemplating adoption. Indirect network effects arise if adoption is complementary because of its effect on a related market. For example, users of hardware may gain when other users join them, not because of any direct benefit, but because it encourages the provision of more and better software.

Extensive case studies and more formal econometric evidence document significant network effects in
network goods (theory): The New Palgrave Dictionary of Economics

many areas including, for example, telecommunications, radio and television, computer hardware and software, applications software and operating systems (including Microsoft's), securities markets and exchanges (including Ebay), and credit cards (see, for example, Gabel, 1991; Rohlfs, 2001; Shy, 2001; and the article on network goods (empirical studies) in this dictionary).

Usually adoption prices do not fully internalize the network effects, so there is a positive externality from adoption. A single network product therefore tends to be under-adopted at the margin – this issue was the main focus of the early literature (see, for example, Leibenstein, 1950; Rohlfs, 1974). However, if two networks compete, then adopting one network means not adopting the other, which dilutes or reverses the externality.

More interestingly – and what is the starting point for the more recent literature – network effects create incentives to ‘herd’ with others. In a static (simultaneous-adoption) game there are often multiple equilibria, so expectations are crucial, and self-fulfilling. Likewise, a dynamic (sequential-adoption) game exhibits positive feedback or ‘tipping’ – a network that looks like succeeding will as a result do so (see, for example, David, 1985; Arthur, 1989; Arthur and Rusczyk, 1992).

How well competition among incompatible networks works depends dramatically on how adopters form expectations and coordinate their choices. If adopters smoothly coordinate on the best deals, vendors face strong pressure to offer them. Competition may then be unusually fierce because all-or-nothing competition neutralizes horizontal differentiation – since adopters focus not on matching a product to their own tastes but on joining the expected winner.

However, coordination is not easy. With simultaneous adoption, adopters may fail to coordinate at all and ‘splinter’ among different networks, or may coordinate on a different equilibrium from the one that is best for them – for example, each adopter may expect others to choose a low-quality product because it is produced by a firm that was successful in the past. Furthermore, consensus standard-setting (informally or through standards organizations) can be painfully slow when different adopters prefer different coordinated outcomes (see Bulow and Klemperer, 1999). Coordination through contingent contracts is possible in theory (see, for example, Dybvig and Spatt, 1983; Segal, 1999), but seems uncommon in practice.

When adoption is sequential, we see early instability and later lock-in (see, for example, Arthur, 1989) – this corresponds to the multiple equilibria that arise with simultaneous adoption. Because early adoptions influence later ones, long-term behaviour is determined largely by early events, whether accidental or strategic. In theory, at least, fully sequential adoption achieves the efficient outcome if it is best for all adopters, but more generally early adopters' preferences count for more than later adopters': this is ‘excess early power’. Note that ‘excess early power’ does not depend on ‘excess inertia’, that is, on incompatible transitions being too hard given ex post incompatibility. (Both ‘excess inertia’, and its opposite, ‘excess momentum’, are theoretically possible; see Farrell and Saloner, 1985.)

Firms promoting incompatible networks compete to win the pivotal early adopters, and so achieve ex post dominance and monopoly rents. Strategies such as penetration pricing and pre-announcements (see, for example, Farrell and Saloner, 1986) are common. History, and especially market share, matter because an installed base both directly means a firm offers more network benefits and boosts expectations about its future sales. Such ‘Schumpeterian’ competition ‘for the market’ can neutralize (or even overturn) excess early power if promoters of networks that will be more efficient later on set low penetration prices in anticipation of this (see Katz and Shapiro, 1986a). More commonly, though, late
developers struggle while networks that are preferred by early pivotal customers thrive. So early preferences and early information are likely to be excessively important in determining long-term outcomes. For example, whether or not the Dvorak typewriter keyboard is really much better than QWERTY (as David, 1985, contends), there clearly was a chance in the 1800s that a keyboard superior to QWERTY would later be developed, and it is not clear what could have persuaded early generations of typists to wait, or to adopt diverse keyboards, if that was socially desirable. So it seems unlikely that the market gave a very good test of whether or not waiting was efficient. (Liebowitz and Margolis, 1990, and Liebowitz, 2002, contest both the details of the QWERTY example and the claim that network effects are significant more generally, but at least the second view is probably a minority one.)

Despite the possibility of competition for the market passing *ex post* rents through to earlier buyers, incompatibility often reduces efficiency and harms consumers in several ways. Incompatibility means that consumers are faced with either a segmented market with low network benefits, or – if the market does ‘tip’ all the way to one network – with reduced product variety and without the option value from the possibility that a currently inferior technology might later become superior. Product variety is more sustainable if niche products are compatible with the mainstream, and so don’t force users to sacrifice network effects. These direct costs of poor coordination by adopters may be exacerbated by weaker incentives for vendors to offer good deals. For example, if a firm like Microsoft is widely believed to have the ability to offer the highest quality, it may never bother to do so: the fact that everyone expects Microsoft to recapture the market if it ever lost any one cohort of customers (or lost any one cohort of providers of complementary products) means everyone rationally chooses Microsoft even if it never actually produces high quality or offers a low price (see Katz and Shapiro, 1992).

*Ex post* rents are often not fully dissipated by *ex ante* competition, especially if expectations fail to track relative surplus. Worse, the rent dissipation that does occur may be wasteful, such as socially inefficient marketing. At best, *ex ante* competition induces ‘bargain-then-rip-off’ pricing (low to attract business, high to extract surplus) but this distorts buyers’ quantity choices and gives them artificial incentives to be or appear pivotal.

Furthermore, outcomes are biased in favour of a proprietary technology (for example, Microsoft's) whose single owner has the incentive to market it strategically over ‘open’ unsponsored alternatives (for example, Linux) – see, for example, Katz and Shapiro (1986b). As discussed above, outcomes are also often biased in favour of networks that are more efficient early on, and are generally biased in favour of established firms on whom expectations focus. The last bias implies entry with proprietary network effects is often nearly impossible (and frequently much too hard from the social viewpoint even *given* incompatibility). And this in turn makes it easier to recoup profits after predatory behaviour that eliminates a rival, and so encourages such predation.

So while incompatibility does not necessarily damage competition, it often does, and firms may therefore also dissipate further resources creating and defending incompatibility.

If firms offer compatible products, then consumers don't need to buy from the same firm to enjoy full network benefits, and (differentiated) products will be better matched with customers. Consumers will be willing to pay more for these benefits, and this may encourage firms to choose compatibility. But compatibility often intensifies competition and nullifies the competitive advantage of a large installed base, whereas proprietary networks tend to make competition all-or-nothing, with the advantage going to large firms, and may completely shut out weaker firms. So large firms and those who are good at
steering adopters' expectations may prefer their products to be incompatible with rivals' (see, for example, Katz and Shapiro, 1985; Bresnahan, 2001), and may be able to use their intellectual property to enforce this.

Competition with incompatible network effects is closely related to other forms of competition when market share is important, especially competition when consumers have switching costs (see, for example, Klemperer, 1995; Farrell and Klemperer, 2007; and the companion-piece to this article, switching costs), and has similar broader implications (for example, for international trade, see Froot and Klemperer, 1989).

Because competition ‘for the market’ differs greatly from conventional competition ‘in the market’, and especially because capturing consumers' and complementors' expectations can be so profitable, competition policy needs to be vigilant against predatory or exclusionary tactics by advantaged firms, including deliberately creating incompatibility by misusing intellectual property protection. Thus, for example, the network effect by which more popular operating systems attract more applications software took centre stage in both the US and European Microsoft cases (see, for example, Bresnahan, 2001).

And because coordination is often important and difficult, institutions such as standards organizations matter, and government procurement policy takes on more significance than usual.

In summary, network effects can involve efficient competition for larger units of business – ‘competition for the market’ – but very often make competition, especially entry, less effective. So I, and others, recommend that public policymakers should have a cautious presumption in favour of compatibility, and should look particularly carefully at markets where incompatibility is strategically chosen rather than inevitable.

Farrell and Klemperer (2007) contains a recent and comprehensive survey of network effects.

Abstract

Neuroeconomics aims at improving the science of major economic phenomena such as the formation of prices and the design and performance of institutions. A revised model of choice is expected, based on the behavior of the neuronal structures of the brain. Researchers are tackling issues such as determining how fundamental constructs like probabilities and payoffs are reflected in neuronal activity; disentangling the processing of inputs to choice from the act of choice; isolating learning, impulsive and analytic components of neuronal behavior; and distinguishing how context affects the processing of the brain and subsequent levels of trust and cooperation in exchange.

Article

The fundamental unit of activity of the brain is the neuron. It ingests nutrients, receives chemical signals from other neurons, and fires (produces electro-chemical action potentials), which results in sending chemical signals (that is, neurotransmitters) to other neurons. Human brains are estimated to have as many as 100 billion neurons. A first task of neuroeconomics is to accumulate information about the behavior of collections of neurons and how they interact to produce economic choices.

Research methods

Research methods employed include single neuron recordings of non-human primates, often macaque monkeys, brain scans (such as functional magnetic resonance imaging, fMRI) of humans and comparative studies of lesioned and normal patients.

Single cell recording

Only in rare instances is it possible to target specific neurons of living human beings (for example, when someone is having open brain surgery). Because many brain structures of non-humans correspond to human brain structures, it is possible to use results from non-human studies to postulate neuronal structures that function in human brains making economic choices. The method for making observations of a neuron’s behavior using monkeys is single cell recording. In this approach specific groups of neurons are targeted. Electrodes are implanted in individual neurons in the group. When a neuron fires, an electrical impulse is sent to a recording device. Figure 1 shows a typical result for a specific neuron in a targeted group of neurons. The distance along the horizontal axis represents the number of seconds into the experimental trial. In this picture an experimental event such as the receipt of reward occurred roughly one fifth of the way through the experimental trial. The vertical axis represents the sum of activations for this neuron at each particular time over a set of experimental trials; here there is much activation immediately after the experimental event when looking across trials.
In studying the human brain researchers employ scanning, for example, functional magnetic resonance imaging (fMRI). fMRI surrounds the economic agent with a strong magnetic field. When specific neurons are engaged in a task, capillaries near those neurons carry more oxygenated blood than capillaries surrounding neurons not engaged in the task. fMRI assesses where such oxygenated blood is. These assessments can be represented in an image indicating areas of the brain that activate differentially. A typical scan produces an image like that in Figure 2. The image shows the implicit activation in the superior parietal lobe (upper-left darkened spot of image) when a subject performs certain numerical operations. The whitened area surrounding the darkened spot suggests the increasing activation around the location.

**Figure 2**

*Source:* Dehaene et al. (2003).
An fMRI captures brain activity at a much coarser level than single unit recording; it cannot isolate some brain structures in humans to the same degree as single unit recording can isolate neuronal activation in monkeys. fMRI allows investigators time resolution in milliseconds.

A related type of scanning is positron emission tomography (PET). In PET studies subjects are injected with radioactive isotopes. Activated neurons in the brain recruit more blood than other neurons and thus brain areas with more positron emissions indicate where more blood is flowing. These areas are then highlighted to produce an image similar to that in

2009-1-2 20:50:28
Using lesioned and normal subjects

Another type of study involves using lesioned (subjects with damaged brain areas) and normal subjects. When normal subjects perform differently on tasks from lesioned subjects, it is evidence consistent with the hypothesis that the area in question is responsible for the differential performance.

Skin conductance

Skin conductance (SCR) measures the ability of skin to conduct electricity (conductance increases with sweat secretion). Generally measures such as SCR and heart rate (HR) have been used to proxy behaviour in the emotional part of the brain. Brain structures associated with emotion send signals to both the heart and the sweat glands.

Figure 3 is intended to assist the reader in identifying brain areas mentioned in the discussion. The image depicts a cross-section (a sagittal view) of the brain taken at the midline of the brain. Approximate locations of brain structures are provided. Where the word ‘To’ appears in the figure it means the brain part is behind the cross-section at that location. Figure 3
A critical question about such research concerns what we have learned so far about the economic behaviours of humans (in relation to monkeys) using these methods. The remainder of this article suggests several answers to this question.

Results related to games against nature

1. The monkey brain has mechanisms that are sensitive to environmental differences in probabilities (relative frequencies) and payoffs. Typically, neuroeconomists with neuroscience backgrounds use a reinforcement perspective. For example, no representation of a probabilistic process is made. Rather, a subject learns probabilities through repeated exposure to outcome feedback. One important set of findings using this paradigm reveals a collection of neurons responsible for detecting differences in economic information in the environment. Tremblay and Schultz (1999) used single cell recording to demonstrate that a region of the brain, the ventromedial prefrontal cortex (VPC), has some very specialized neurons. These VPC neurons are differentially activated for different reward expectations in macaque monkeys. The experimenters established that monkeys reveal a preference for different food and liquid items. For example, they were able to establish that a raisin was stochastically preferred to a piece of apple, which was stochastically preferred to cereal. Then they established that, when the raisin and pieces of apple were alternated as rewards, the VPC neurons activated more for raisins than for apples; on the other hand when apples and cereal were the rewards, the same neurons activated more for the pieces of apple.

2. Fiorillo, Tobler and Schultz (2003) showed monkeys were differentially sensitive to differences in probabilities of stimuli. The researchers employed five different visual cues, each of which yielded a reward with different probabilities, 0, .25, .5, .75 and 1.00. Neurons in the ventral tegmental area (VTA) showed higher activation immediately after cues the more likely the cue was to yield a reward. At the actual time of reward the same neurons activated more the less likely it was that the reward would follow.

3. Researchers have begun to incorporate results in experiments with feedback into a testable dynamic theory of choice. The diagnostic role of VTA neurons in relating expectation to outcome serves as a basis for a particular dynamic model of choice, the actor–critic model (Schultz, Dayan and Montague, 1997). In the model the critic assesses the difference between expectation and outcome, the difference forms the basis for evaluating the stimuli in the experiment and for revising the probability for the next choice. Berns et al. (2001) showed that parts of this model are appropriate to human behaviour when they looked specifically at how predictable sequences of squirts of water and juice activate brains of human subjects as compared with unpredictable ones. Areas more activated for unpredicted areas than predicted areas included the NA and the orbital frontal cortex (OFC), clusters of neurons also downstream from the VTA. O’Doherty et al. (2004) pinpointed differential activation associated with the actor, dorsal striatum (DS), and the critic, ventral striatum (VS).

4. Emotions can play a beneficial role in choice. Bechara and Damasio (2005) invented the Iowa gambling task (IGT) to assess the role of emotions in choice. In earlier studies, emotions had been shown to be associated with activation in the OFC and the amygdala (A). In the IGT subjects sampled 100 times from four decks of cards and subjects received the reward that showed up on the face of the card drawn. Two of the decks were bad decks, resulting in occasional high losses as well as a low long-run payoff. Two were good decks, which produced moderate gains and an occasional moderate loss, but yielded long-run gains. To show that emotions aided choice, Bechara and Damasio report using three sets of subjects – subjects with damage to the VTA area of the brain, subjects with damage to the A, and normal subjects. None of the subjects knew the composition of the decks, but as they performed the task they received feedback; hence the potential for learning the composition of the decks. Neuronal firing was implicitly detected using skin conductance and heart
Normal and VPC damaged subjects showed SCR and HR increases when the card was observed, but A damaged subjects showed no response. Furthermore, while learning the task normal subjects developed ‘anticipatory’ SCRs, that is, their SCR measurement increased as their hand neared the choice of a bad deck even though supplemental evidence showed no awareness of the bad deck. This anticipatory response was not detected in either of the groups with brain damage. The final piece of evidence corroborating that emotions play a positive role in choice is that subjects with brain damage made poorer choices in the task.

5. A decision itself consists of more than just a choice. There is a neuronal modification of sensory inputs, a choice, and various neuronal communications to muscular structures that reveal the choice. Shadlen and Newsome (2001) used a task in which a monkey sees moving dots presented on a screen. A portion of the dots had direction determined randomly and a portion had a fixed direction right or left. The monkey’s choice involved making an eye movement, a saccade, to the right or left signifying the net direction of movements in the dots. The monkey was rewarded if correct.

Suppose there is a small net movement of dots to the right. When the monkey first sees the dots, they are registered on the retinas of the monkey’s eyes. These signals are transferred through the optic chiasm back to the occipital lobe and then to secondary areas of the visual cortex (MT). This process takes place encoding and partially preserving various aspects of the stimuli, including colour, size and background, but most importantly the direction of movement of the dots on the screen. MT enervates (sends signals to) the lateral interior parietal cortex (LIP); however the LIP does not just preserve the signals in MT but summarizes the net activation between groups of neurons in the MT, in particular the difference in activation in neurons representing movement of dots from right to left. The LIP then sends signals which direct the muscle movements of the eye.

Such a structure seems somewhat removed from probability and value as they might be expected to be seen in economic choice. Platt and Glimcher (1999) provided the work that helps make the linkage clear. Using single unit recording, they placed electrodes in the LIP. A monkey indicated choices by making eye movements to the left or right. When appropriate a movement to the left yielded a juice squirt of .01•ml while a movement to the right yielded .03•ml. The monkey was signalled the appropriate direction of eye movement by different coloured fixation points in the middle of the monkey’s computer screen. The fixation point signalled left and right with .5 probability. This set-up allowed the investigators to compute the expected payoff at different levels of information (before and after showing the fixation point) to the monkeys. Results revealed a collection of neurons in the LIP that responded monotonically to increases in expected payoff. Thus, in a task with computable expected payoffs, the LIP registers how differences in expected payoff enter into the decision process.

6. The implicit processes of traditional choice theory tend to be evoked when subjects deal with numerical representations of outcomes. In results 1–5 a reinforcement paradigm is involved, and many findings are the result of repeated trials with subjects bringing no knowledge of the stimuli to the task. For example, in Fiorillo, Tobler and Schultz (2003), monkeys experienced one signal at a time and seconds later learned whether a reward occurred. On the other hand economic theory often assumes there can be a structured and often numerical representation of the choice problem. In experiments conducted by economists, physical objects such as dice, urns filled with different-coloured marbles, and wheels of fortune with different-coloured segments have been used to convey probabilistic information. At times subjects have been simply told numbers that represent probabilities that the experimenters would like them to believe were the true probabilities.

Furthermore, because decision theory describes the relationship between choices that are available to the decision maker given no changes in subject's endowments, studies done by experimental economists have often provided no feedback after every choice; but rather, a randomly selected choice is played only after a set of choices have been made. In this sense experimental economics has traditionally been concerned with choice, while experiments conducted by neuroscientists are often concerned with learning. Such traditional types of experimental economics studies have unearthed a large number of regularities including the Allais and Ellsberg paradoxes and preference reversals, and in some studies expected utility is supported.

Dickhaut et al. (2003) had subjects make binary choices between gambles. For example, the subject could choose between a certainty gamble and a risky gamble (or two risky gambles). Probabilities were represented to subjects as the number of balls of particular colours that could be drawn from an urn, and after a set of choices was made one or more of the subject's designated choices was played. In the study the balls were drawn from a real urn. The study showed that context plays a role in how the brain functions during choice. For risky gambles comparison brain areas such as the frontal lobe (FL) and parietal (P) are relatively more activated than the OFC and nearby areas. Thus, context alters how parts of the brain come into play in choice and simultaneously how analytical functions of the brain are recruited.

Employing this paradigm, Rustichini et al. (2005) added ambiguous and partially ambiguous gambles. They uncovered key aspects of the choice process that are involved when subjects work with explicit probabilistic representations and payoffs. Subjects behaved as if they were employing cut-offs to distinguish between numerical magnitudes; it was also shown that the closer the gamble evaluated was to the cut-off the more difficult the judgment (that is, the longer was the reaction time.) Areas of major activation found by Rustichini et al. included P, precuneus (Pr) and Brodmann area 6. Rustichini et al. raised the possibility that such cut-off rules operate as approximate calculations like those found by Dehaine et al. when subjects compare numbers to a criterion. In monkeys Dehaine et al. isolated the horizontal inferior parietal (HIP) area as an area capable of making relational comparisons. Within the classical paradigm Hsu et al. (2005) studied ways in which the brain processed information differently under ambiguity and risk. Using three different approaches to approximating ambiguous and risky tasks, they identified the A and OFC as areas in which ambiguity and risk are differentially processed. In supplemental materials the authors reported inferior parietal activation, which is consistent with giving the subjects both verbal and numerical representations of the choice.

Leland and Grafman (2005) also studied the traditional type of economic tasks. Their study was constructed along the lines of the Bechara and Damasio (2005) studies since they...
neuroeconomics: The New Palgrave Dictionary of Economics

used normal subjects and subjects with brain damage to the VPC. There was no difference between the performance of these groups on these traditional types of tasks, which is consistent with the proposition that people recruit areas other than orbital frontal cortex in performing these tasks.

Another study that examined economic behaviour in a more traditional choice context is McClure et al. (2004), who studied whether agents have a propensity to discount hyperbolically. They found that the evaluation of immediate payoffs produced relatively more VPC activation, but for all decisions (those involving immediate and non-immediate payoffs) a broader set of areas including the Pr and the P areas was activated.

Camille et al. (2004) examined the degree to which normal and subjects with VPC lesions incorporate regret into their choices. In this study regret is the maximum difference in payoffs that exists between two choices. Camille et al. reported that normal subjects are much more likely to incorporate regret into their choices. The authors found that normal and lesioned subjects both incorporated expected value into their choices. In this study subjects saw gambles represented explicitly in terms of payoffs and probabilities. Feedback was provided after every choice. The results of this study and Hsu et al.'s results imply that some of the more analytic processes implied by Dickhaut et al. and Rustichini et al. can be at work in these studies, but that there is emerging a potentially delicate interplay between the reward areas and the analytical areas of the brain.

Results related to game theory

7. Monkeys' neuronal activity encodes mixed strategies. Dorris and Glimcher (2004) extended the examination of the behaviour of monkeys to consider how a monkey plays against different strategies of the computer in a game with a mixed strategy equilibrium. Results reveal that monkeys are capable of adjusting their mixed strategies approximately optimally to the mixed strategies played by the computer. Dorris and Glimcher examined the behaviour of LIP neurons and found that they reflected the mixed strategy of the monkeys.

8. Games with other agents are consistent with a theory of mind. In typical game theory experiments it is customary to attempt to give players a complete description of the game, from which strategic behaviour ensues. Then it is assumed that individual players generate beliefs contingent on their beliefs about others' strategies. Given this perspective of how choice proceeds, technically it becomes useful to have an experimental design that attempts to ensure that every player has the chance to fully anticipate the other players' actions prior to any moves made by any of the players. Often this common knowledge approach is approximated by representation of a game matrix in a simultaneous-play game or a game tree in a sequential game.

Neuroscientists have isolated the paracingulate cortex (ParC) as a location associated with the ability to understand another person's deception. Utilizing this perspective, McCabe et al. (2001) investigated whether this area was implicated in cooperative games such as the trust game. They uncovered increased ParC activity when subjects knew they were playing against a person as opposed to a computer, and also found increased ParC activity for cooperative as opposed to non-cooperative players. Sanfey et al. (2003) further examined the McCabe results by employing the ultimatum game and Prisoner's Dilemma games. They preprogrammed a set of outcomes for the subjects to play against. The experimenters attempted to lead subjects to believe they were playing against computers for one set of outcomes and against real people for the other set. These differences in procedure yielded some differences in the brain areas activated. McCabe et al. (2001) found P activation that is not reported by Sanfey et al. However, Sanfey et al. found temporal (T), FL and Pr activation in addition to ParC activation.

9. Economic reputation building is identifiable at a neuronal level. King-Casas et al. (2005) used fMRI to scan pairs of subjects in a trust game repeated ten periods. The researchers were able to show that activations in the middle cingulate cortex (MCC) of a sender (when an amount is invested) were coterminous with activations of the anterior cingulate cortex (ACC) of the receiver in the game when the receiver saw the money sent. The receiver's intent to reciprocate was reflected in activation of the receiver's caudate nucleus (CN). Initially this activation lagged the receipt of the investment by approximately eight seconds, but with repeated play the activation precedes receiver's knowledge of the investment by approximately eight seconds. In this way the authors implicitly measured the way economic reputation is built by the sender in the receiver's brain in the trust game.

10. The brain has mechanisms that reveal individuals enjoy punishing norm violators. De Quervain et al. (2003) examined the neuronal basis of costly punishment. They allowed the sender to penalize the receiver when the receiver did not reciprocate, but at a cost to the sender. They found evidence consistent with the assumption that the sender was comparing the costs of punishment with a derived benefit (satisfaction) from punishing. The locus of the derived benefit from punishing was reflected in behaviour of the CN and the VPC, the area in which the authors argued the evaluations take place.

Conclusion

Neuroeconomics has moved the economics from the discussion of useful fictions regarding choice to the direct examination of the structures in the human brain that are making the choices. Evidence to date suggests that the underpinnings of modern-day homo economicus are reflected in brain structures that exist in both monkeys and humans and in both Robinson Crusoe and multi-agent settings, and findings are emerging on which a more informed model of choice and exchange can be formulated using brain function as the underpinning.

neutral taxation

Arnold C. Harberger
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Formally, neutral taxation is taxation falling on something that is in completely inelastic supply, with the tax being so designed as not to affect resource allocation either within or among the affected categories or between them and the other activities not subject to the tax. To minimize deadweight loss, the Ramsey rule says that, the more demand-elastic a good is, the less it should be taxed. But in practice, given ignorance about demand elasticities, uniform low-rate, broad-based taxation reliably reduces deadweight loss and implies neutrality on the part of the state between citizens' preferred actions within the rule of law.

Keywords

deadweight loss; efficiency vs. equity; elasticity; Harberger, A. C.; land tax; neutral taxation; optimal taxation; Ramsey rule taxation; uniform taxation; value-added tax

Article

One can detect in the literature of economics two important lines of thinking on the subject of neutral taxation. One emphasizes economic efficiency (i.e. the elimination of deadweight loss) as the objective in terms of which the neutrality of taxation is defined. The other emphasizes the generality of a tax as itself imparting the quality of neutrality. Two examples, each with a long history in economic thinking, illustrate the main lines of the distinction.

On the one hand we have the taxation of land rents or land values. It builds on the notion (not precisely true in fact) that each piece or plot of land is totally fixed in supply, with the consequence that any tax levied upon it will ultimately be paid out of its pure economic rent. On the other hand we have the relatively modern idea of a general tax on value added, the tax being applied at a uniform rate on all activities in the economy. Here there is no thought that the underlying resources are fixed in each activity; quite to the contrary, mobility among the various taxed activities is taken for granted for most of the resources on whose product the tax will fall.
It is easy enough by making artful assumptions to bring these two notions very close together. For example we can assume that no manmade improvements to the soil are possible, or alternatively that the tax assessors can always distinguish between ‘the intrinsic and immutable qualities of the soil’, on which tax is then duly assessed, and the manmade improvements thereon or accretions thereto, on which (under our convenient assumption) no tax is either assessed or paid. Similarly, we can assume for the value added tax that there are just three basic resources in the economy – land, labour and capital – and that each of them is fixed in supply. Therefore a uniform tax on the marginal product of any one of them will be neutral, striking the factor equally regardless of the end use to which it is applied, and leaving the factor (because of the assumed zero-elasticity of its supply) no untaxed haven (not even leisure) to which it might choose to escape.

The above assumptions make it easy to define neutral taxation for a Dictionary. (Neutral taxation is taxation falling on something that is in completely inelastic supply, with the tax being so designed as not to affect resource allocation either within or among the affected categories or between them and the other activities not subject to the tax.) But it would probably not add much to the usefulness of the Dictionary.

To be truly useful, I believe, a definition of neutral taxation should be able to throw away such artificial crutches as the two assumptions presented above. It should be able to live in the real world, where we know that the relevant supply elasticities are rarely zero, but where we do not feel at all sure about their magnitudes nor how they vary as between the short, middle and long run. It should be able to cope with reality that, for tax policy at least, the objects of tax do not have an independent essence as commodities; rather, a commodity subject to tax is whatever the tax law (including the regulations and practices followed in enforcing that law) defines it to be. And finally it should come to grips with the serious claims that can be made for considering equality (among the affected activities) in the applicable tax rate to be an attribute whose presence connotes neutrality and whose absence creates a presumption of non-neutrality.

Economics has come the farthest in responding to the first of the desiderata expressed above. Deadweight loss is a concept completely familiar to the discipline, as is the idea of minimizing the deadweight loss of raising a certain amount of tax revenue subject to given constraints. A clear line of thinking runs from Ramsey in the 1920s through Hotelling in the 1930s, Meade in the 1940s, Corlett and Hague and Lipsey and Lancaster in the 1950s, Harberger in the 1960s, to the modern writers on optimal taxation of whom Atkinson, Diamond, Dixit, Mirrlees, and Stiglitz are a representative few. Flowing through this strand of thought are the related ideas (a) that uniform taxation is not always neutral; (b) that the special condition under which uniform taxation of a subset of commodities or activities minimizes the deadweight loss of raising a given amount of revenue from that subset is met when the equilibrium quantity (or activity level) of each member of the taxed subset would respond in the same proportion to a (hypothetical) uniform tax on all goods or activities that are not in the taxed subset; and (c) that whenever the condition stated in (b) is not met then instead of uniform taxation the minimization of deadweight loss requires higher-than-average taxation on goods whose quantities would fall as a result of a (hypothetical) uniform tax on the uncovered group and lower-than-average taxation on those whose equilibrium quantities would rise most sharply.

The analysis underlying the above statements is straightforward, and one can even call economic intuition into play to explain the conclusion. If the tax authorities are denied the possibility of taxing certain goods or activities, then it can to some degree ‘get around’ the ban by putting higher taxes on
those items within the taxable subset which are complements of those that cannot be taxed. In a similar
vein, since one way of thinking of the resource misallocation that occurs when only a subset of activities
is allowed to be taxed is that resources are ‘artificially’ shunted from the taxed to the untaxed subset, it
seems quite plausible that the optimal patterning of tax rates within the taxed subset should entail taxing
at somewhat lower-than-average rates those particular activities in which a percentage point increment
of tax would lead to notably greater-than-average ‘shunting’ of resources to untaxed activities.
The line of reasoning just presented is persuasive – sufficiently so that some economists have been
tempted to write off uniformity altogether as a plausible objective of tax policy. There remain many,
however, who adhere to uniformity as a goal. Given the ease with which propositions (a) through (c)
above can be derived, one should hope that most of those who hold to uniformity base their adherence
on considerations extraneous to the derivation, say, of the Ramsey rule and other similar propositions in
the literature on optimal taxation. The discussion that follows assumes so.
To build a case for uniformity in taxation in the face of the foregoing logic, one should (appropriately, I
think) postulate that one is not dealing with two quite arbitrary categories of goods and/or activities, viz.,
the taxed subset and the untaxed subset. Instead, one should assume that the taxed subset, rather than
being ‘any arbitrary bundle’, is so selected as to contain all the goods and activities that can plausibly
and without unusual administrative or regulatory effort be brought into the tax net. One then proceeds to
view the problem not as a simple analytical puzzle but as one of guiding or governing the interaction
between the society's fiscal authorities and its members.
With this objective in mind, an advocate of uniform taxation might set up a quite different problem from
that posed earlier. He might consider the ‘disturbance’ with which he is dealing to be a consumer
changing his mind about how to spend his money or a worker changing his preference about where or
for whom to work. A uniform-tax advocate would likely place a considerable value on the authorities'
simply not caring about these various changes of mind.
When one solves the Ramsey problem one takes as given the tastes and preferences of economic agents
and maximizes government revenue for a given aggregate level of the agents' welfare. Under the
differentiated set of tax rates that emerges from this exercise, the maximizer is not indifferent to changes
in tastes of the agents. The maximizer likes it when agents shift their tastes from low-taxed to high-taxed
activities, and is disappointed by shifts in the other direction.
Something of the same thing occurs when uniform taxation is implemented. Here the ‘good’ event
would be a shift in tastes that caused untaxed activities to contract and taxed activities to expand; the
‘bad’ event would be the opposite. But there would be a wide range of changes of tastes that would be
neutral – these would cover shifts among commodities or activities within the sector subject to the
uniform tax, and also shifts among activities in the untaxed sector. To the degree that the authorities are
successful in extending the tax net over quite a wide range, it may turn out to be true that most changes
in tastes simply lead to shifts in the composition of goods within the taxed group. This is the sort of
scenario that would best fit the vision of an advocate of broad-based, uniform taxation and at the same
time would (at least if changes in tastes within the taxed sector were frequent and important) create
problems for proponents of Ramsey rule taxation.
Subtle overtones of a less technical nature also arise when Ramsey-rule taxation is compared to a broad-
based, uniform levy. In Ramsey-rule taxation individuals are genuinely presented with incentives to shift
their demand from high-taxed to low-taxed products, and workers are likewise motivated to shift their
labour efforts from high-taxed to low-taxed activities. Both these incentives are counterproductive from

the social point of view. Subtly hidden in the way the problem is framed is the assumption that people's tastes are given. The reality of the world is that tax laws change only rarely; once enacted, they stay in effect for long periods of time, over which economists can be certain that there will be important changes in the parameters of tastes and technology. The goal of having a tax system that is robust against these unknown future shifts in demand and supply is not capricious; it deserves to be taken seriously.

In a quite different vein, there arises the question of to what degree we want our choice of tax patterns to depend on parameters like elasticities of supply and demand about which our knowledge is very spotty and imperfect. Proponents of uniform taxation can fairly argue that their choice of such a form does not depend seriously on knowledge about the parameters of demand and supply. Economic theory assures us that the dominant force is substitution (in the sense that a tax on an activity will, other things equal, cause that activity to contract). There is thus a very strong presumption that broadening the coverage and lowering the rate of a uniform tax will reduce the deadweight loss associated with it (for given revenue yield). One can build policy on this basis without having any detailed knowledge of the parameters of supply and demand, without any particular hope of gaining anything more than a very patchy knowledge about them in the future, and indeed with an almost absolute assurance that whatever the relevant parameters might be now, they will undergo substantial changes in the future. If one believes that these conditions come close to describing our present and likely future state of knowledge about the relevant parameters, he will likely be predisposed toward uniform as against Ramsey-rule taxation.

The last line of argument favouring uniform taxation has to do with the interplay between equity and efficiency considerations in governing tax policy. The motivations that fall under the umbrella of 'equity' are too numerous and too varied to try to recount here. But nowhere among them can one find that it is fairer to tax more heavily factors of production that cannot flee to other activities or that it is more just to tax heavily those items whose demand happens to be less elastic. To tax salt more heavily than sugar simply and solely because it has a lower elasticity of demand is at least as capricious (from the standpoint of equity) as taxing people differently according to the colour of their eyes.

Ultimately, I believe, the issue of uniform versus Ramsey-rule taxation may turn out to be just one facet of much broader philosophical differences. Consider the philosophy of government that assigns to government the role of creating a framework of laws and regulations within which the private sector then is encouraged to operate freely. Under this philosophy a positive value is placed on the authorities’ not caring about what private agents do (so long as they abide by the rules). It is a position desideratum to create a tax system that is robust against changes in tastes and technology.

On the other side of the coin we have a philosophy of social engineering, in which the detailed tastes and technology of the society enter as data into a process by which the policy makers choose parameters such as tax rates and coverages so as to maximize some measure of social net benefit.

Each of these philosophies has had its own long trajectory within the profession of economics. Each has its representatives today. Each will surely be reflected in the literature of future decades. In my opinion, the future debate as to how the concept of neutrality in taxation should be reflected in real-world policy decisions will swirl around the subtle differences between the ways in which holders of these two philosophies view the world, between the roles they envision for government, and between the ways they see the science of economics interacting with government in the formation of policy.

Article

‘Neutrality of money’ is a shorthand expression for the basic quantity-theory proposition that it is only the level of prices in an economy, and not the level of its real outputs, that is affected by the quantity of money which circulates in it. Thus the notion – though not the term – goes back to early statements of the quantity theory, such as the classic one by David Hume in his 1752 essays ‘Of Money’, ‘Of Interest’ and ‘Of the Balance of Trade’. At that time the notion also served as one of the arguments against the mercantilist doctrine that the wealth of a nation was to be measured by the quantity of gold (which in 18th-century England constituted a – if not the – major form of metallic money: Feaveryear, 1963, p. 158) that it possessed. The term itself is much more recent. Though attributed by Hayek (1935, pp. 129–31) to Wicksell, it is actually due to continental economists in the late 1920s and early 1930s to whom Hayek also refers (see 1935, pp. 129–31; see also Patinkin and Steiger, 1988).

1. The rigorous demonstration of, the neutrality of money is based on the critical assumption that individuals are free of ‘money illusion’. An individual is said to suffer from such an illusion if he changes his economic behaviour when a currency conversion takes place: when, for example (as in Israel in 1985), a new monetary unit – the ‘new shekel’ – is introduced in circulation and declared to be equivalent to 1,000 old shekels.

It can be shown (Patinkin, 1965) that an illusion-free individual in an economy with borrowing who maximizes utility subject to his budget constraint will have demand functions which depend on relative prices, the rate of interest, and the real value of his initial wealth – which consists of physical capital, bond holdings, and money balances. That is, the demand of this representative individual for the jth good, \( d_j \), is described by the function

\[
d_j = f_j(p_1 / p, ..., p_{n-2} / p, r, K_0 + B_0 / p + M_0 / p)(j = 1, ..., n - 2),
\]

where the \( p_j \) are the respective money (or absolute) prices of the \( n - 2 \) goods; \( p \) is the average price level as defined by \( \bar{p} = \sum w_j p_j \) where the \( w_j \) are fixed weights; \( r \) is the rate of interest; \( K_0 \) is physical capital, \( B_0 \) is the initial nominal value of bond holdings (which, for a debtor, is negative), and \( M_0 \) is the initial quantity of money. Thus when the new shekel is introduced in circulation, the price of each good in terms of this shekel (and hence the general price level), the terms of indebtedness, and the nominal quantity of initial money holdings are respectively reduced to 1/1,000th of what they were before; hence relative prices and the real value of initial wealth are unaffected; hence so are the amounts demanded of each good.

Mathematically, the foregoing property of the demand functions is described by the statement that these functions are homogeneous of degree zero in the money prices and in the
initial quantity of financial assets, including money. Accordingly, the absence of money illusion is sometimes referred to as the homogeneity property of the demand functions. (For the necessary and sufficient conditions that must be satisfied by the utility function in order to generate such illusion-free demand functions, see Howitt and Patinkin, 1980.) This homogeneity property is to be sharply distinguished from what the earlier literature denoted as the ‘homogeneity postulate’, by which it meant the invariance of demand functions with respect to an equiproportionate change in money prices alone, and which invariance it erroneously regarded as the condition for the absence of money illusion and hence for the neutrality of money (Leontief, 1936, p. 192; Modigliani, 1944, pp. 214–15): for even in the case of an individual who is neither debtor nor creditor, such a change affects the real value of his initial money balances, hence is not analogous to a change in the monetary unit, and hence – by virtue of the real-balance effect – will generally lead him to change the amounts he demands of the various goods.

For a closed economy, the aggregate value of $B_0$ is obviously zero, for to each creditor there corresponds a debtor. For simplicity, we can also consider the amount of physical capital, $K_0$, to remain constant. Disregarding distribution effects, the demand functions of the economy as a whole for the $n$–2 goods can then be represented by

$$D_j = \bar{f}_j(p_1 / p, \ldots, p_{n-2} / p, r, M_0 / p) (j = 1, \ldots, n - 2)$$

and the corresponding supply functions by

$$S_j = G_j(p_1 / p, \ldots, p_{n-2} / p, r).$$

The general-equilibrium system of the economy is then

$$
\begin{align*}
F_1(p_1 / p, \ldots, p_{n-2} / p, r, M_0 / p) &= G_1(p_1 / p, \ldots, p_{n-2} / p, r) \\
&\vdots \\
F_{n-2}(p_1 / p, \ldots, p_{n-2} / p, r, M_0 / p) &= G_{n-2}(p_1 / p, \ldots, p_{n-2} / p, r) \\
F_{n-1}(p_1 / p, \ldots, p_{n-2} / p, r, M_0 / p) &= 0 \\
F_n(p_1 / p, \ldots, p_{n-2} / p, r, M_0 / p) &= M_0 / p.
\end{align*}
$$

The $(n - 1)$st equation is for real bond holdings, whose aggregate net value is (as already noted) zero; and the $n$th equation is for real money balances. Assume that this system has a unique equilibrium solution with money prices $p_1^0, \ldots, p_{n-2}^0, p_n^0$ and the rate of interest $r^0$, and that the economy is initially at this position. Let the quantity of money now be changed to $kM_0$, where $k$ is some positive constant. From the preceding system of equations we can immediately see that (on the further assumption that the system is stable) the economy will reach a new equilibrium position with money prices $k p_1^0, \ldots, k p_{n-2}^0, k p_n^0$ and an unchanged rate of interest $r^0$. (Clearly, this conclusion would continue to hold if the supply functions $G_j$ were also dependent on $M_0/p$.). Thus the increased quantity of money does not affect any of the real variables of the system, namely, relative prices, the rate of interest, the real value of money balances, and hence the respective outputs of the $n$–2 goods. In brief, money is neutral: or in the picturesque phrase which Robertson (1922, p. 1) apparently coined, money is a veil. (For empirical studies, see Lucas, 1980, and Lothian, 1985.)

Furthermore, Archibald and Lipsey (1958) have shown that if the initial equilibrium exists not only with respect to the economy as a whole, but also with respect to each and every individual in it (which, inter alia, means that each individual was initially holding his optimum quantity of money), then this neutrality will obtain in the long run even if one does take account of distribution effects. That is, even if one takes account of differences in tastes, endowments, and hence individual demand functions, an increase in the quantity of money,
neutrality of money: The New Palgrave Dictionary of Economics

no matter how distributed among individuals, will in the long run cause an equiproportionate increase in prices and leave the rate of interest invariant. This conclusion in turn follows from the fact that the sequence of short-run equilibria generated by the increase in the quantity of money will in the long run redistribute this quantity in a way that results in an equiproportionate increase in the money holdings of each individual, relative to his holdings in the initial equilibrium position (see also Patinkin, 1965, pp. 50–9).

It should also be noted that the preceding analysis has implicitly assumed a unitary elasticity of expectations with respect to future prices, so that neutrality is not disturbed by substitution between present and future commodities.

2. The conclusions of the foregoing analysis are clearly those of long-run comparative-statics analysis. It was this fact that led Keynes – even in his quantity-theory period as represented by his *Tract on Monetary Reform* (1923) – to disparage their policy implications with the famous remark that 'in the long run we are all dead' (1923, p. 80, italics in original). It should therefore be emphasized that at the same time they demonstrated the long-run neutrality of money, quantity theorists (including Keynes of the *Tract*) also emphasized its non-neutrality in the short run (Patinkin, 1972a). Thus Hume emphasized that prices do not immediately rise proportionately to the increased quantity of money and that in the intervening period this stimulates production. In Hume's words:

> it is of no manner of consequence, with regard to the domestic happiness of a state, whether money be in a greater or less quantity. The good policy of the magistrate consists only in keeping it, if possible, still increasing; because, by that means, he keeps alive a spirit of industry in the nation … (1752, pp. 39–40)

Hume's emphasis on the irrelevance of the absolute level of the money supply (and hence of money prices) in contrast with the significance of the rate of change of this level was also made by later quantity-theorists. Some of them stressed the stimulating effects of rising prices on 'business confidence' and hence economic activity. A more frequent explanation of the short-run non-neutrality of money was in terms of the shift in the distribution of real income as between creditors and debtors generated by a changing price level. Of particular importance was the danger that a sharply declining price level would increase the number of bankruptcies among debtors, with all its adverse repercussions on the economy. Another source of non-neutrality was the fact that individual prices do not change at the same rate in response to a monetary change. Thus if after a monetary decrease, wage rigidities cause the decline in wages to lag behind that of product prices, the resulting increase in the real wage rate would generate unemployment; conversely, the lag of wages in the case of an inflation would increase profits and hence stimulate production. This consideration led some quantity-theorists to deny even the long-run neutrality of money on the grounds that profit-recipients had a higher tendency to save than wage-earners, so that the shift in income in favour of profits would increase savings, and that these would lead to an increase in the real stock of physical capital in the economy, and hence to a decline in the long-run rate of interest.

For Irving Fisher, the important lag was that of the nominal rate of interest behind the rate of (say) inflation generated by a monetary increase. In particular, because of the lack of perfect foresight on the part of savers (who are the lenders), the nominal rate does not rise sufficiently to offset this inflation; and the resulting decline in the real rate of interest causes entrepreneurs to increase their borrowings, hence investments and economic activity in general. Conversely, when prices decline, corresponding misperceptions cause an increase in the real rate of interest and hence a decline in economic activity. Indeed, Fisher (1913, ch. 4) based his whole theory of the business cycle on this process: the cycle was for him 'the dance of the dollar' (Fisher, 1923).

The greatly increased importance of income and capital-gains taxation since Fisher's time is the background of the present-day view – much stressed by Feldstein (1982, and references there cited) – that inflation would have real effects on the economy even if there were perfect foresight, so that the nominal rate fully adjusted itself to the rate of inflation, leaving the real rate of interest unchanged. This is particularly true for the taxation of income from capital, with the simplest example being the increased tax burden on corporations generated by the calculation of depreciation expenses on the basis of historical (as distinct from replacement) costs in an inflationary economy (see also Birati and Cukierman, 1979).

This is a specific instance of the short-run non-neutrality of money generated by the existence of a tax structure formulated in nominal terms (as is the case with, for example, specific taxes and income-tax brackets) which are generally adjusted to the rate of inflation only after a lag.

Short-run non-neutrality is a basic feature of Keynesian monetary theory and stems from the contention that in a situation of unemployment, prices will not rise proportionately to the increased quantity of money, and that the resulting increase in the real quantity of money will cause a decline in the rate of interest and hence an increase in the volume of investment and the level of national income. The short-run non-neutrality of money is, however, also a basic tenet of today's monetarists, who contend that though the long-run effect of a change in the quantity of money is primarily on prices, its short-run effect is primarily on output. In Friedman's words: 'In the short run, which may be as much as five or ten years, monetary changes affect primarily output. Over decades, on the other hand, the rate of monetary growth affects primarily prices' (Friedman, 1970, pp. 23–4).

This non-neutrality has been rationalized by Lucas (1972) in terms of the individual's inability to determine whether a change in the price of a good with which he is particularly concerned (for example labour, in the case of a wage-earner) is a change only in the price of that good (in which case it represents a change in its relative price, which calls for a quantity adjustment) or is part of a general change in prices which does not affect relative prices. In accordance with this approach, and under the assumption that markets always clear, it has also been claimed that only an anticipated change in the quantity of money will have real effects; for an anticipated one will be expected by the individual to affect all prices proportionately (Lucas, 1975; Barro, 1976). A far-reaching corollary of this claim is that if, in accordance with the assumption of rational expectations, the public anticipates the changes that government will carry out within the framework of its proclaimed monetary policy, then this policy too will be neutral: that is, the systematic component of monetary
policy will not affect any of the real variables of the system (cf. McCallum, 1980 and references there cited). Thus under these circumstances even the short-run Phillips curve is – from the viewpoint of systematic monetary policy – vertical.

Empirical support for the claim that only unanticipated monetary changes will have real effects was at first provided by Sargent (1976) and Barro (1978). Contrary conclusions were, however, reached in subsequent empirical studies by Fischer (1980), Boschen and Grossman (1982), Gordon (1982), Mishkin (1982; 1983) and Cecchetti (1986). These differing conclusions stem from different views about the respective ways to estimate (1) that part of a monetary change that is anticipated and/or (2) the extent of the time lags that must be taken account of in measuring the effects of a monetary change on output. In any event, the weight of opinion today is that both anticipated and unanticipated changes in the money supply have short-term real effects. To the extent that anticipated changes have such effects, this can be interpreted either as reflecting the influence of nominally formulated elements (for example the aforementioned tax structure, or long-term wage contracts – Fischer, 1977) in an economy functioning in accordance with the hypothesis of rational expectations cum market-clearing; or, alternatively, it can be interpreted as a refutation of this hypothesis in part or in whole. Thus once again we are confronted with la condition scientifique of our discipline: its inability in all too many cases to reach definitive conclusions about theoretical questions on the basis of empirical studies, an inability which increases directly with the political significance of the question at issue.

3. Neoclassical quantity-theorists contended that a shift in the demand curve for money would also have a long-run neutral effect on the economy. Thus consider the Cambridge cash-balance equation, $M = KPY$, where $Y$ is the real volume of expenditures and $K$ is that proportion of his planned money expenditures, $PY$, which the individual wishes to hold in the form of money. Assume that the economy is in equilibrium with a fixed quantity of money $M_0$ and price level $P_0$. Let there now take place a positive shift in the demand for money – that is, an increase in $K$. Because of the budget constraint, this must be accompanied by a negative shift in the demand for goods. Consequently, the price level $P$ will decline until equilibrium is reestablished with the same nominal quantity of money, $M_0$, but at a lower price level, $P_1 < P_0$. Thus the automatic functioning of the market will in the long run generate the additional quantity of real balances that individuals wish to hold, without affecting the output of goods.

This neutrality can also be demonstrated in terms of the general-equilibrium system presented above. In particular, if we assume that the increased demand for money is accompanied by a symmetric decrease in the demand for all other goods and for bonds, then a new equilibrium will be established with all money prices reduced in the same proportion, and with an unchanged rate of interest; correspondingly, the respective outputs of goods are also unchanged. In Keynesian monetary theory, however, the increased demand for money is assumed to be solely at the expense of bond holdings: this, after all, is an implication of Keynes's theory of liquidity preference. Such a shift in liquidity preference will accordingly not be neutral in its effects; instead, it will cause an increase in the rate of interest with consequent effects on investment and other real variables of the system (Patinkin, 1965, chs VIII:5 and X:4).

In an analogous manner, a change in the proportions between inside and outside money generated by a change in the currency/deposit ratio and/or the bank-reserve/deposit ratio will not be neutral in its effects (Gurley and Shaw, 1960, pp. 231–6). It should, however, be emphasized that if the demand and supply functions of the financial sector are also characterized by absence of money illusion, then an increase in outside money will leave these ratios unchanged and hence be neutral (Patinkin, 1965, ch. XII: 5–6).

So far, our concern has implicitly been an increase in the quantity of money generated by a one-time government deficit, after which the government returns to a balanced budget. This results in an initial net increase in the total of financial assets in the economy and is thus the real-world analytical counterpart of an increase in the quantity of money generated by the proverbial helicopter dropping down money from the skies. If, however, the monetary increase is generated by an open-market purchase of government bonds (so that initially there is no change in total financial assets), and if there is a real-balance effect in the commodity market, then, as Metzler (1951) showed in a classic article, the equilibrium rate of interest will decline, so that money will not be neutral in its effects. If, however, individuals fully anticipate and discount the future stream of tax payments needed to service the government bonds (in which case these bonds are not part of net wealth), neutrality will obtain in this case too (Patinkin, 1965, ch. XII:4).

4. The discussion until this point has dealt almost entirely with the neutrality of a once-and-for-all increase in the quantity of money in a stationary economy. An analogous question arises with reference to the long-run neutrality of a change in the rate of growth of the money supply in a growing economy – in which context the notion is referred to as ‘superneutrality’. Thus consider an economy in steady-state equilibrium whose population is growing at the rate $n$. Assume that the nominal quantity of money is growing at a faster rate, $\mu = M / M_0$ so that (in order to maintain the constant level of per-capita real money balances that is one of the characteristics of such a steady state) prices rise at the constant rate $\pi = u - n$. Money is said to be superneutral if (say) an increase in the steady-state rate of its expansion, and hence in the corresponding rate of inflation, will not affect any of the steady-state real variables in the system, with the exception of per-capita real-balances: that is, per-capita capital, $k$; per-capita output, $y$; and the real rate of interest, $r$, equal to the marginal productivity of capital. On the other hand, because of the higher costs of holding real balances – in terms of loss of purchasing power, or, alternatively, in terms of the forgone higher nominal rate of interest, $i$, generated by the increased rate of inflation – the steady-state per capita real value of these balances, $m$, should generally be expected to decrease.

As already indicated, for Irving Fisher (1907, ch. 5; 1913, pp. 59–60; 1930, pp. 43–4) it was only the absence of perfect foresight which prevented such superneutrality from obtaining: for were such foresight to exist, the nominal rate of interest would simply increase so as to compensate for the inflation and thus leave the real rate of interest (which, under the assumption of continuous compounding, equals $i - \pi$) unchanged. Fisher, however, did not take account of the possible effects of the way the increased amount of money is injected into the economy and/or the possible effects of the resulting decrease in real balances on other markets. Thus by assuming the government increases the quantity of
money in the economy by distributing it to households and thereby increasing their disposable income, Tobin (1965; 1967) – in a generalization of the Solow (1956) growth model to a money economy – showed that a higher rate of inflation will generally cause individuals to change the composition of their asset portfolios by shifting out of real money balances and into physical capital, thus increasing the steady-state values of $k$ and $y$ – and hence (by the law of diminishing returns) decreasing that of $r$ – so that superneutrality does not obtain.

Tobin’s analysis assumes a constant savings ratio. In a critique of this analysis, Levhari and Patinkin (1968) showed inter alia that if instead this ratio is assumed to depend positively on the respective rates of return on capital and on real money balances – that is, on the real rate of interest and on the rate of deflation – then an increase in the rate of inflation might decrease steady-state savings and hence $k$, thus causing an increase in the real rate of interest. Similarly, if real money balances were explicitly introduced into the production function, an increase in the rate of inflation might so decrease these balances as to decrease steady-state per-capita output and hence savings sufficiently to offset the positive substitution effect on $k$, thus generating a decrease in the latter.

Patinkin (1972b) analysed superneutrality by means of an IS–LM model generalized to a full employment economy with a real-balance effect in the commodity market (the following largely reproduces the relevant material in this reference). As in Solow (1956), the economy is assumed to have a linearly homogeneous production function, $Y=F(K, L)$, where $Y$ is output, $K$ capital, and $L$ labour, with the labour force assumed to be growing at the exogenous rate $n$. The intensive form of this function is then $y=f(k)$ and its derivative, $f’(k)$ is accordingly the marginal productivity of capital, so that the equilibrium real rate of interest is $r = f’(k)$. Following Mundell (1963; 1965), the crucial assumption of this model is that whereas investment and saving (and hence consumption) decisions depend upon the real rate of interest, $r = i – \pi$, the decision with respect to the amount of real money balances to hold depends on the nominal rate of interest, $i$ – for the alternative cost of holding money instead of a bond is precisely this rate. The same is true if we measure this cost in terms of the alternative of holding physical capital: for the total yield on this capital is its marginal product (equal in equilibrium to the real rate of interest) plus the capital gain generated by the price change ($\pi$): that is, it is $r + \pi = i$. Alternatively, if we measure rates of return in real terms, the rate of return on money balances is $-\pi$ and that on physical capital $r$; hence the alternative cost of holding money is the difference between these two rates, or $r – (–\pi) = i$.

Consider now the commodity market. Let $E$ represent the aggregate real demand for consumption and investment commodities combined. For simplicity, assume that this demand is a certain proportion, $\alpha$, of total real income, $Y$. Assume further that this proportion depends inversely on the real rate of interest and directly on the ratio of real money balances, $M/\pi$, to physical capital, $K$. The second dependence is a type of real-balance effect, reflecting the assumption that the greater the ratio of real money balances to physical capital in the portfolios of individuals, the more they will tend (for any given level of income) to shift out of money and into commodities. The equilibrium condition in the commodity market is then represented by

$$\alpha(i – \pi, (M/\pi)/K) \cdot Y = Y.$$ (1)

By assumption, $\alpha_1(\cdot)$ is negative and $\alpha_2(\cdot)$ positive, where $\alpha_1(\alpha_2)$ is the partial derivative of $\alpha(\cdot)$ with respect to its first (second) argument.

Consider now the money market. Following Tobin (1965, p. 679), assume that the demand in this market depends on the volume of physical capital and the nominal rate of interest. More specifically, assume that the demand for money is a certain proportion, $\lambda$, of physical capital. Thus the larger $K$, the greater (other things equal) the total portfolio of the individuals, hence the greater the demand for money: this can be designated as the scale or wealth effect of the portfolio. Assume further that the proportion $\lambda$ depends inversely on the nominal rate of interest. That is, the higher this rate, the smaller the proportion of money relative to physical capital which individuals wish to hold in their portfolios: this can be designated as the composition or substitution effect. The equilibrium condition in the money market is then

$$\lambda(i) \cdot K = M/\pi.$$ (2)

where by assumption the derivative $\lambda’(\cdot)$ is negative.

Dividing equations (1) and (2) through by $Y$ and $K$, respectively – and transforming them into per capita form – we then obtain the equations...
In the steady state,

\[ \mu = \pi + n. \]  
(5)

Since \( \mu \) and \( n \) are both assumed to be exogenously determined, the same can be said for the steady-state value of \( \pi \). Thus in steady states, equations (3) and (4) can be considered as a system of two equations in the two endogenous variables \( i \) and \( m/k \), and in the exogenous variable \( \pi \). On the assumption of the solubility of these equations, the specific value of \( k \) (and hence \( m \)) can then be determined by making use of the additional equilibrium condition that the marginal productivity of capital equals the real rate of interest, or,

\[ f'(k) = i - \pi. \]  
(6)

In accordance with the usual assumption of diminishing marginal productivity, we also have

\[ f''(k) < 0. \]  
(7)

The solution of system (3)–(4) can be presented diagrammatically in terms of Figure 1. The curve \( CC \) represents the locus of points of equilibrium in the commodity market for a given value of \( \pi \). Its positive slope reflects the assumption made above about the respective influences of the real rate of interest \( (i-\pi) \) and of the real-balance effect (as represented by \( m/k \)) on \( \alpha \). Namely, a (say) increase in \( i \) increases the real rate of interest and thus tends to decrease \( \alpha \): hence the ratio \( m/k \) must increase in order to generate a compensating increase in \( \alpha \) and thus restore equilibrium to the commodity market. On the other hand, \( LL \) – the locus of points of equilibriums in the money market – must be negatively sloped: an increase in the supply of money and hence in \( m/k \) must be offset by a corresponding increase in the demand for money, which means that \( i \) must decline. The intersection of the two curves at \( W \) thus determines the steady-state position of the economy.
neutrality of money: The New Palgrave Dictionary of Economics
Assume for simplicity that the given value of $\pi$ for which $CC$ and $LL$ are drawn is $\pi = \pi_2 > 0$, corresponding to the rate of monetary expansion $\mu_2$. Assume now that this rate is exogenously increased to $\mu = \mu_3$ so that (by (5)) the steady-state value of $\pi$ is increased accordingly to $\pi_3 = \mu_3 - \pi > \pi_2$. From the fact that $\pi$ does not appear in (4), it is clear that $LL$ remains invariant under this change. On the other hand, the curve $CC$ must shift upwards in a parallel fashion by the distance $\pi_3 - \pi_2$; for at (say) the point $Z'$ on the curve $C'C$ so constructed, the money/capital ratio $m/k$ and the real rate of interest $i - \pi$ are the same as they were at point $Z$ on the original curve $CC$; hence $Z'$ too must be a position of equilibrium in the commodity market.

We can therefore conclude from Figure 1 that the increase in the rate of monetary expansion (and hence rate of inflation) shifts the steady-state position of the economy from $W$ to $Y'$. From the construction of $C'C$ it is also clear that the real rate of interest at $Y'$ is $r_3 = i_3 - \pi_3$ which is less than the real rate at $W$, namely, $r_0 = i_0 - \pi_2$. Thus the policy of increasing the rate of inflation decreases the steady-state value of the real rate of interest, and also the money/capital ratio.

Because of the diminishing marginal productivity of capital, the decline in $r$ implies that $k$ has increased. Thus the fact that $m/k$ has declined does not necessarily imply that $m$ has declined. This indeterminacy reflects the two opposing influences operating on $m$ reflected in eq. (2), rewritten here in the per capita form as

$$\lambda(i) \cdot k = m.$$ (8)

To use the terminology indicated above, the increased inflation increases the steady-state stock of physical capital, and thus exerts a positive wealth effect on the quantity of real-money balances demanded. At the same time, the increased inflation means that the alternative cost of holding money balances (for a given level of $k$ and hence $r$) has increased, and this exerts a negative substitution effect on the demand for these balances; that is, individuals will tend to shift out of money and into capital. Thus the final effect on $m$ depends on the relative strength of these two forces. As is, however, generally assumed in economic theory, we shall assume that the substitution effect dominates, so that an increase in $\pi$ decreases $m$.

We now note that the only exogenous variable which appears in system (3)–(5) is the rate of change of the money supply, as represented by its steady-state surrogate, $\pi = \mu - r$. In contrast, the absolute quantity of money, $M$, does not appear. It follows that once-and-for-all changes in $M$ (after which the money supply continues to grow at the same rate) will not affect the steady-state values of $m$, $k$, and $i$ as determined by the foregoing system for a given value of $\pi$. In brief, system (3)–(5) continues to reflect the neutrality of money. On the other hand, because of the Keynesian-like interdependence between the commodity and money markets, the system is not superneutral.

Note that in the absence of this interdependence, the system would also be superneutral. This would be the case either if the demand for commodities depended only on the real rate of interest, and not on $m/k$ (that is if there were no real-balance effect); or if the demand for money depended only on $k$, and not on the nominal rate of interest – an unrealistic assumption, particularly in inflationary situations which cause this rate to increase greatly.

The first of these cases is analogous to the dichotomized case of stationary macroeconomic models (cf. Patinkin, 1965, pp. 242, 251 (n.19), and 297–8). It would be represented in Figure 1 by a $CC$ curve which was horizontal to the abscissa. Correspondingly, the upward shift generated by the rate of inflation would cause the new $CC$ curve to intersect the unchanged $LL$ curve at a money rate of interest which was $\pi_3 - \pi_2$ greater than the original one, and hence at a real rate of interest (and hence value of $k$) which was unchanged; the value of $m$, however, would unequivocally decline. The second of these cases would be represented by a vertical $LL$ curve. Hence the upward parallel shift in the $CC$ curve generated
by inflation would once again shift the intersection point to one which represented an unchanged real rate of interest. In this case (which, as already noted, is an unrealistic one) the value of $m$ also remains unchanged.

5. A common characteristic of the foregoing money-and-growth models is that their respective savings functions are postulated and not derived from utility maximization. An analysis which does derive consumption (and hence savings) behaviour from such maximization was presented by Sidrauski (1967) in an influential article. As before, consider an economy growing at the constant rate $n$ with a linearly homogeneous production function having the intensive form $y = f(k)$. Assume now that the representative individual of this economy is infinitely lived with a utility function which depends on consumption and real balances, and that he maximizes the discounted value of this function over infinite time, using the constant subjective rate of time preference, $q$. Under these assumptions, Sidrauski shows that money is superneutral.

As Sidrauski is fully aware, this conclusion follows from the form of his production function together with his assumption of a constant rate of time preference; for this fixes the steady-state real rate of interest at $r = q + n = f'(k)$, which determines the steady-state value of $k$ and hence of $r$. If, however, the production function depends also on real balances – say, $y = g(k, m)$ – then this superneutrality no longer obtains. For the necessary equality between the marginal productivity of capital and $q+n$ in this case is expressed by the equation $g_k (k, m) = q+n$ (where $g_k (k, m)$ is the partial derivative with respect to $k$), which no longer fixes the value of $k$ (Levhari and Patinkin, 1968, p. 234). In an analogous argument, Brock (1974) showed that if the individual's utility function depends also on leisure, then an increase in the rate of inflation will affect his demand for leisure, which means that it will affect his supply of leisure (that is, leisure per capita). Hence even though (in accordance with Sidrauski's argument) the increased rate of inflation will not affect the steady-state values of $r$, $k$ (that is, capital per labour-input), and $y$ (that is output per labour-input), it will affect the respective amounts of labour and capital per capita and hence output per capita – so that it will not be superneutral. Needless to say, Sidrauski's results will also not obtain if the rate of time preference is not constant.

6. The conclusion that can be drawn from this discussion is that whereas there is a firm theoretical basis for attributing long-run neutrality to money (but see Gale, 1982, pp. 7–58, and Grandmont, 1983, pp. 38–45, 91–5), there is no such basis for long-run superneutrality: for changes in the rate of growth of the nominal money supply and hence in the rate of inflation generally cause changes in the long-run equilibrium level of real balances; and if there are enough avenues of substitution between these balances and other real variables in the system (viz., commodities, physical capital, leisure), then the long-run equilibrium levels of these variables will also be affected. An exception to this generalization would obtain if money were to earn a rate of interest which varied one-to-one with the rate of inflation, so that the alternative cost of holding money balances would not be affected by changes in the latter rate; but though it is generally true that interest (though not necessarily at the foregoing rate) will eventually be paid on the inside money (that is bank deposits) of economies characterized by significant long-run inflation, this is not the case for the outside money which is a necessary (though in modern times quantitatively relatively small) component of any monetary system.

The discussion to this point has treated the economy's output as a single homogeneous quantity. A more detailed analysis which considers the sectoral composition of this output yields another manifestation of the absence of superneutrality. In particular, it is a commonplace that the higher the rate of inflation, the higher the so-called 'shoe-leather costs' of running to and from the banks and other financial institutions in order to carry out economic activity with smaller real money balances. In the case of households, the resulting loss of leisure is denoted as the 'welfare costs of inflation' as measured by the loss of consumers' surplus: that is, by the reduction in the triangular area under the demand curve for real money balances (cf. Bailey, 1956). In the case of businesses, the costs of inflation take the concrete form of the costs of the additional time and efforts devoted to managing the cash flow. What must now be emphasized is that the obverse side of the additional efforts of both households and businesses is the additional resources that must be diverted to the financial sector of the economy in order to enable it to meet the increased demand for its services. Thus the higher the rate of inflation, the higher (say) the proportion of the labour force of an economy employed in its financial sector as opposed to its 'real' sectors, and hence the smaller its 'real' output. This is a phenomenon that has been observed in economies with two- and especially three-digit inflation (cf. Kleiman, 1984 on the Israeli experience). Viewing the phenomenon in this way implicitly assumes that the services of the financial sector are not final products (which are a component of net national product) but 'intermediate products', whose function it is 'to eliminate friction in the productive system' and which accordingly are 'not net contributions to ultimate consumption' (Kuznets, 1951, p. 162; see also Kuznets, 1941, pp. 34–45).

new classical macroeconomics

Stanley Fischer
Edited by Steven N. Durlauf and Lawrence E. Blume

Article

The new classical macroeconomics (NCM) attempts to build macroeconomics entirely on the foundations of market clearing and optimization by economic agents. It is also known as the rational expectations–equilibrium approach to macroeconomics. The leading figures are Robert Lucas of the University of Chicago and Thomas Sargent of the University of Minnesota, whose 1981 volume contains many of the formative contributions. Lucas (1977) and Sargent (1982) provide non-technical accounts of the approach. Other leading figures include Edward Prescott and Neil Wallace of the University of Minnesota and Robert Barro of the University of Rochester.

The monetary approach: the Lucas supply function

The new classical macroeconomics can be dated from work by Robert Lucas in the early 1970s. The article with greatest popular impact is Lucas's (1973) ‘Some International Evidence on Output–Inflation Tradeoffs’. This is a market-clearing model from which the Phillips curve emerges as a result of imperfect information about the aggregate price level. (Lucas (1972) is a more difficult article that produces a similar result.) The nature of the approach is clarified by outlining the Lucas model and by contrasting it with other models of the Phillips curve.

Markets are physically separated. There are two types of disturbance in the economy, aggregate disturbances that move the aggregate price level and relative disturbances that affect price in each market, but by definition average zero across all markets. Knowledge about past events and the probability distributions of disturbances is complete, but suppliers and demanders within each market observe only the nominal price in that market in the current period in which they have to make their output and purchase decisions.

In a full information set-up, supply and demand in an individual market would depend on relative price. Participants in the market know the price in that market, but cannot calculate relative price without an estimate of the aggregate price level. The optimal estimate of the aggregate price level, conditioned on the observed price in the market, is a weighted average of the expected aggregate price level and the absolute price observed in the market.
Estimated relative price in each market thus increases with the absolute price in that market relative to the expected aggregate price level. Aggregating across all markets, aggregate output is an increasing function of the absolute price level relative to the expected price level. This is the famous Lucas supply function

\[ Y_t = \alpha(P_t - \hat{P}_{t-1}) \]

where \( Y \) is aggregate output or its logarithm, \( P \) is the logarithm of the aggregate price level, and \( \hat{P}_{t-1} \) is the expectation of \( P_t \) based on information available at the end of period \((t - 1)\). The model is closed by assuming that aggregate demand is determined by the quantity equation. The Lucas model contains a Phillips curve in the sense that output and the price level (relative to the expected price level) are positively correlated. If the price level followed a random walk, the standard Phillips curve relationship between output and the inflation rate would be observed in the data.

**What NCM is not**

The Lucas supply function illustrates the difference between NCM and alternative approaches. The original Phillips–Lipsey approach views the Phillips curve as a reflection of disequilibrium in the labour market, with the wage adjusting to the excess demand for labour according to ‘the law of supply and demand’. Such an assumption is regarded as unsatisfactory by NCM because the existence of labour market disequilibrium (or disequilibrium anywhere) implies a failure to exploit mutually beneficial trades. NCM would rule out models with that feature – such as Keynesian models with unemployment – unless the failure to trade is explained within the model. Despite many shared policy positions, the new approach also differs radically from monetarism. While the Lucas supply function is closely related to the Phillips curve model in Friedman's Presidential Address (1968), Friedman assumed that expectations were adaptive and that the monetary authority by accelerating inflation could keep the unemployment rate below the natural rate. The rational expectations assumption distinguishes NCM from monetarism. It is clear from a reading of Friedman and Schwartz (1963) that monetarists are more willing than the NCM to entertain the possibility of disequilibrium and slow adjustment of expectations. Indeed, from the perspective of NCM, monetarism and Keynesianism are of a piece – and equally unsatisfactory – in their willingness to use rules of thumb and crude empirical relationships to model economic behaviour, and in their willingness to proceed on macroeconomic issues in models without firm microfoundations. Rational expectations is necessary but not sufficient for NCM. Many economists who do not assume that markets clear do assume that expectations are rational.

**Policy ineffectiveness**

The Lucas supply function has two important implications that are central to the new classical
The policy ineffectiveness result is that any anticipated monetary policy action will not affect output. Rather, such actions are reflected in both the expected and the actual price levels, leading to no effect on output. The result, contained in Lucas (1973) but made most explicit in Sargent and Wallace (1975), is that monetary policy actions affect output only if they are unanticipated – meaning not reflected in pricing decisions. The result has been misinterpreted as applying to all macroeconomic policy, but would not apply to any real policy action: for instance an anticipated increase in the investment tax credit would certainly affect investment and typically also aggregate output. The ineffectiveness result relates only to monetary policy, in a model in which money is neutral except for its Phillips curve effects. That is, the Lucas supply curve produces a tradeoff between inflation and unemployment that is not systematically exploitable by policy makers.

The monetary policy ineffectiveness result has been the subject of much controversy. Models in which the monetary policy makers can respond to events after prices have been set leave open the possibility that systematic monetary policy can have real effects. Long-term labour contracts (as in Fischer, 1977, or Taylor, 1980) may be a source of effective monetary policy. Barro (1977) pointed out that the assumed form of contracts in Fischer was not optimal in that output decisions were left to the firm rather than being set as part of the contract. In practice, output decisions are made by firms; subsequent microeconomic research has shown that asymmetric information may generate that feature of contracts (Hart and Holmstrom, 1987) though it remains difficult to account for the failure of contracts to index for nominal disturbances.

Much of the controversy over the effectiveness of monetary policy derives from an implicit view that the aims of the government and the private sector differ. Stabilizing monetary policy may have a useful role to play if contracts cannot fully describe future contingencies, and if there are costs of frequent renegotiation. By creating a stable macro-economic environment, active monetary policy can encourage long-term contracting even when not all states of nature can be described – but it thereby also increases the damage that can be done by inappropriate policy (Fischer, 1980).

**Early success**

The NCM derived early success from empirical work by Barro (1978) that appeared to support the implication of the Lucas supply function that only unanticipated changes in the money stock had real effects. However, this implication of the NCM approach is shared by sticky wage theories, such as Fischer (1977), and turns out not to distinguish the NCM from other approaches. Further, empirical work by Mishkin (1983) shows that the result that only unanticipated money matters is not robust to lag length.

Within the NCM school, three sets of empirical results led to a loss of confidence in the Lucas supply function approach and the view that monetary shocks affect output. First, Barro (1978) found that although output was closely related to unanticipated changes in the money stock, the aggregate price level was not. This raised doubts about the Lucas supply function, in which prices are the transmission mechanism through which unanticipated money induces suppliers to increase output. Second, Barro and Hercowitz (1980) and Boschen and Grossman (1982) find that currently perceived changes in the money
stock, as reflected in preliminary money stock data, do affect output. Since the theory is built on the assumption that money has real effects only because it is not known, this result was a serious blow to the view that the Phillips curve is a result of imperfect information about current nominal variables. Third, Sims (1980) found in a vector autoregressive system including output, money and interest rates that interest rate shocks accounted for a far larger share of variations in output than money shocks.

## Econometric implications

The rational expectations assumption used by NCM has led to the development of major new econometric methods for the treatment of expectations. Much of the econometric development is contained in Lucas and Sargent (1981). One focus has been on methods of testing the typical rational expectations cross equation constraints. These are restrictions on relations between parameters in different equations that follow from the assumption that expectations are optimal predictors of variables accounted for elsewhere in the model. A second focus is the econometric policy evaluation critique.

### Econometric policy evaluation

In deriving the supply function, Lucas shows that the parameter $\alpha$, the slope of the Phillips curve, is a decreasing function of the variance of the absolute price level. That is because it is a mixture of the structural supply elasticity in an individual market and the signal extraction problem solved by the supplier in deciding how much to respond to any observed nominal price in her market. The implication is that parameters of macroeconomic models that appear structural, such as $\alpha$, the slope of the Phillips curve, may not be invariant to changes in policy. In this case a reduction in the variance of the money supply, which is a policy parameter, will make the Phillips curve steeper.

The implication that parameters may not be invariant to changes in policy is the central point of Lucas’s influential econometric policy evaluation critique, which has had a profound effect on both policy modelling and econometric practice in general (Lucas, 1976). On policy modelling, the argument is that existing econometric models, almost all of which are large-scale versions of textbook IS–LM models with an aggregate supply sector appended, cannot be used for analysing changes in policy, since the parameters in those models would likely change as policy changes. Lucas (1976) concedes that existing econometric models, some of which are commercially successful, may do a good job of forecasting. Nor does he argue that econometric models cannot ever be used for policy evaluation, since the true structural parameters (in the Phillips curve example the micro supply elasticity in an individual market) could in principle sometimes be identified. However in practice identification would be almost impossible for many parameters unless there had been frequent changes in policy ‘regimes’, or policy rules, that would produce variation in parameters such as the variance of the aggregate price level that affect responses to price signals.

The effect of the Lucas critique on econometric practice arises from a pervasive fear that parameters that had previously been thought structural and that were routinely estimated in empirical macroeconomics, such as the propensity to consume out of wealth, or the interest elasticity of money demand, are not invariant to economic policy. Few practising macroeconomists estimate a demand function for money or consumption function without making a pro forma bow in the direction of the Lucas critique — and those
who do not are reminded of the protocol by their discussants.

The influence of the Lucas critique is remarkable in that parameter instability induced by policy changes has not been shown to have been empirically important in whatever failures macroeconomic models have suffered. Nonetheless, the critique has led to a new empirical research agenda in macroeconomics.

**Deep structural parameters**

The argument is that the only truly structural parameters in the economy are tastes and technology, utility and production functions. Technology is to be widely interpreted as including the transactions technology and mechanisms for intertemporal trade. Once these primitives are known, it becomes possible to deduce how consumers and producers will respond to policy actions, whose only significance is in how they modify the constraints facing economic agents. Sargent (1982) presents an eloquent account of the research agenda.

The new approach has been to estimate parameters of utility and production functions from first order conditions rather than to attempt to estimate structural relations. In intertemporal optimization first order conditions are Euler equations. For instance in the life cycle consumption model with one consumption good and contemporaneously separable utility function, the discrete time Euler equation is:

$$U'(c_t) = \beta E_t[(1 + r_{t+1})U'(c_{t+1})]$$

where $\beta < 1$ is the discount factor, $r$ is the (perhaps stochastic) rate of return on any asset, and $E_t$ is the expectation conditional on information available in period $t$.

Aggregate and cross section data can be used to estimate such equations. Hall and Mishkin (1982) on panel data and Hansen and Singleton (1983) are examples. The purpose may be both to estimate utility function parameters and to test restrictions imposed by the underlying model of consumer optimization. Hall and Mishkin for instance conclude that 20 per cent of consumption is accounted for by consumers who are not satisfying the first order condition with equality, and that such consumers may be liquidity constrained. Mankiw, Rotemberg and Summers (1985) attempt using aggregate time series data to estimate parameters of utility functions defined over consumption and leisure. Examples of estimates of technological relations include Sargent (1978) on the demand for labour and Blanchard (1983) on inventory demand. Garber and King (1983) have severely criticized the Euler equation approach on the grounds that the identification problem has not been faced squarely.

**III Real business cycles**

The apparent failure of the Lucas supply function to account for the correlation between inflation and output as a result of imperfect information has led to the alternative real business cycle approach. In this
view, business cycles are equilibrium real phenomena, driven largely by productivity shocks. Endogeneity of the money stock accounts for the inflation- or money-output link. The most fully worked out real business cycle model is that of Kydland and Prescott (1982). There is a representative agent, an infinite horizon intertemporal maximizer. Production inputs are labour, capital and inventories. The economy is hit by imperfectly observed productivity shocks, which are a mixture of permanent and transitory components. Slow acquisition of information about past shocks is one source of lags in the economy; another is lags in the process by which investment turns into capital. Kydland and Prescott can find parameter values, including the variance of the productivity shocks, that enable them to broadly match the stochastic processes that characterize United States business cycles. The Kydland–Prescott paper has to deal with a basic problem in the NCM approach, that of the cyclical patterns of wages and leisure.

**Intertemporal substitution of leisure**

All theories of the business cycle have to account for relatively large movements in labour input accompanied by only small changes in real wages. If disequilibrium is disallowed, then the problem is to explain labour's willingness to supply, say, five per cent more labour in booms than in slumps for real wages that may be only one per cent higher. The obvious explanation, if the real wage is in fact procyclical, is that labour supply is very responsive to the wage. If this hypothesis explains business cycle correlations, it remains to reconcile short- and long-run labour supply behaviour, for in the long run labour supply curves may be backward bending. The theoretical explanation comes from the distinction between responses to transitory and permanent increases in the real wage (Lucas, 1977). Workers may respond significantly to a transitory increase in the real wage, choosing to work harder now and substitute future for current leisure when the cost of leisure returns to normal. The intertemporal substitution of leisure mechanism plays an extremely significant role in NCM, for at a deeper level it is the rationale for the Lucas supply function. Direct evidence in support of this hypothesis has been difficult to find (Altonji, 1982). Indeed there is some evidence that the real wage follows a random walk, which means that real wage changes are permanent. Unless transitory wage changes are identifiable at a local level, this result rules out the intertemporal substitution of leisure explanation of large movements of labour input over the cycle. Alternative explanations may be available in which the observed wage does not measure the marginal utility of leisure because long-term arrangements between firms produce efficient allocations of resources without using the wage for short-term allocative purposes. Hart and Holmstrom (1987) present several models of contracts in which the wage is not equal to the marginal utility of leisure.

**Leisure and consumption over the cycle**

It is well known that an intertemporally separable utility function in which both consumption and leisure are normal goods implies that consumption and leisure should be positively correlated unless their relative price (the real wage) changes. In fact, measured consumption and leisure move in opposite directions over the cycle. The correlation cannot be explained in the typical model without significant movements in the real wage, which do not occur. Mankiw, Rotemberg and Summers' (1985) empirical
work documents this difficulty.

Kydland and Prescott account for cyclical patterns of leisure and goods consumption by, first, making productivity shocks the driving force in the cycle, and second, by assuming that past levels of leisure affect the current marginal utility of leisure.

**Endogenous money**

The real business cycle approach accounts for the Phillips curve by assuming that the money stock accommodates itself to the level of economic activity (King and Plosser, 1984). This view derives some support from the fact that the correlation with output is closer for inside than for outside money. Ironically the real business cycle and early Keynesian views of the unimportance of money are close, despite the dissimilarities of the analytic approaches.

**IV Policy analysis**

The game-theoretic view of the operation of economic policy implicit in the policy ineffectiveness result has become extremely influential in the wake of the important paper on dynamic inconsistency by Kydland and Prescott (1977). Dynamic inconsistency occurs when a future policy decision that forms part of an optimal plan formulated at an initial date is no longer optimal from the viewpoint of a later date, even though no new information has appeared in the meantime. The problem is likely to arise when expectations of future policy affect current decisions. For instance, to produce low rates of wage change, policymakers would like it believed that future policy will not accommodate wage increases. However, if wage increases occur, policy may well accommodate them rather than cause unemployment.

Kydland and Prescott view dynamic inconsistency as a major argument for the use of policy rules rather than discretion. Dynamic inconsistency will not occur if policy rules are set out and adhered to. Subsequent developments have analysed the tradeoff between the gains from flexibility produced by discretion and the losses due to dynamic inconsistency (e.g. Rogoff, 1985). It is also possible that a rational concern for reputation by policy makers will produce consistent behaviour (Barro and Gordon, 1983).

The game theory approach implies a stress on the credibility of policy makers, leading for instance to the view that a credible change in monetary policy could lead to a costless disinflation. This view was expressed in the United States before the disinflation of the early Eighties; the subsequent recessionary disinflation helped reduce support for the NCM. Although the game theory approach is not inherently related to NCM, in that expectations of future policy may matter in models without market clearing, it has in practice been pursued largely in an NCM context.

**V Summary**

The promise of the original Lucas NCM model that an imperfect information market clearing approach to macroeconomics could satisfactorily account for most business cycle phenomena including the Phillips curve has not been fulfilled. Beyond its difficulty in accounting for the apparent real effects of
monetary policy, the theory is not good at explaining unemployment in a market-clearing context. The NCM approach builds on the joint assumptions of market-clearing and optimizing behaviour. The market-clearing hypothesis is unlikely to persist as an analytic axiom, unless it is redefined to the point of being meaningless. But the assumption of maximizing behaviour within a specified environment is the microeconomic ideal to which economists aspire. That component of NCM will surely remain as a major impulse in macroeconomics. So too will the rational expectations assumption and the econometrics associated with that approach.

**New Deal**

Price V. Fishback

Edited by Steven N. Durlauf and Lawrence E. Blume

**Abstract**

US President Franklin Roosevelt's New Deal created the most dramatic peacetime expansion of government in American economic history. It established the basic structures for modern federal/state social welfare programmes, farm programmes, labour policies, regulations of many industries, and government insurance of deposits and mortgages. Roosevelt experimented with a cartel-like industrial policy that was declared unconstitutional by the Supreme Court. The emergency public works and relief programmes built a large number of roads, dams, and other public works, and employed millions of labourers. Recent studies suggest that the impact of the New Deal varied greatly by programme.

**Article**

Franklin Roosevelt's New Deal created the most dramatic peacetime expansion of government in American economic history.

When Franklin D. Roosevelt became president in March 1933, real output had fallen 30 per cent from its 1929 peak and the unemployment rate exceeded 25 per cent. Within his first hundred days in office Roosevelt and the Democratic Congress established an incredible array of programmes, a virtual ‘alphabet soup’ of acronyms. More programmes were added under the First New Deal until 1935, when
the Supreme Court declared the National Recovery Administration's (NRA) codes of ‘fair’ competition for industry and the Agricultural Adjustment Administration (AAA) farm programme unconstitutional. A Second New Deal re-established the farm programme in the name of soil conservation, strengthened the role of unions in collective bargaining, and established the basic structure of most of America's current social insurance and public assistance programmes.

After Roosevelt took office, the federal government, often in conjunction with state and local governments, built a huge number of roads, dams, sanitation facilities, schools, public housing projects, and other public works. The federal government expanded regulation of banking, finance, labour, and a host of other markets, insured and refinanced housing loans, and made extensive loans to numerous private and public entities. In the decades following the 1930s, several waves of historians have provided narratives and interpretations of the New Deal and introductions to their work can be found in collections edited by Dubofksy (1992), Braeeman, Bremner and Brody (1975), and Hamby (1969). The recent trends in New Deal studies include a series of studies by economists and economic historians (Fishback et al., 2007; Bordo, Goldin and White, 1998).

Searching for an overarching theme for the programmes is a daunting task. The doubling of annual federal spending between the Hoover (1929–32) and Roosevelt years tempts many to describe the New Deal as Keynesian expansionary policy. But the Roosevelt administration ran relatively small budget deficits, as federal tax collections also more than doubled. In a brief meeting and a letter to the New York Times Keynes had encouraged Roosevelt to follow an expansionary policy, but the levels of government spending and the small budget deficits pale in comparison with the fall in output to be counteracted (Barber, 1996; Brown, 1956; Peppers, 1973; Romer, 1992).

One goal appeared to have been to raise prices and wages, as the establishment of the NRA allowed each industry to establish cartel-like codes that stifled price and quality competition, labour policies promoted unionization and high wages, and farm policies offered price guarantees while cutting output. Ultimately, Roosevelt and his advisors were pragmatists faced with terrible economic problems of nearly every kind. They established agencies and programmes meant to try to solve nearly each and every one. At times the programmes operated at cross-purposes. Higher farm and industry prices worsened the plight of the unemployed and other consumers. The pressure to raise wages exacerbated the unemployment problem, and the NRA codes limited output growth. The administration made constant adjustments in policies, creating a climate of uncertainty about the regulatory environment that left businesses wary of making new investments (Higgs, 1997).

New Deal monetary, banking, and international policy

Building on the seminal work by Friedman and Schwartz (1963), many economists argue that monetary policy contributed significantly to the harsh decline in the economy between 1929 and 1933. The Federal Reserve took seriously its international responsibilities in maintaining the gold standard and thus failed to respond sufficiently to three major waves of bank failures in a timely fashion. Many states had begun declaring ‘holidays’ that closed state banks to stave off bank runs. Roosevelt took office in the midst of the third wave of failures and declared a Bank Holiday that closed all national banks. Two-thirds of the banks were declared sound and reopened within the week. The troubled banks were reorganized and the Reconstruction Finance Corporation (RFC) subscribed to their new stock issues,
reassuring the public about the solvency of the banking system (Smiley, 2002; Mason, 2001).

In 1933 Roosevelt also announced that the United States was leaving the gold standard, prohibited gold exports, and devalued the dollar to $35 per ounce of gold. In response, the United States received a substantial flow of gold that stimulated the money supply, and economic growth resumed. Japan, Britain, France and several other leading nations experienced similar resumptions of economic growth when they broke free of their ‘golden fetters’ (Eichengreen, 1992; Temin, 1989; Temin and Wigmore, 1990). Gold inflows continued for the rest of the 1930s as Europe moved towards war. By choosing not to offset the gold inflows, Roosevelt and the Federal Reserve allowed the money supply to expand (Romer, 1992). The Federal Reserve took a misstep, however, when it used its newly awarded control over reserve requirements to double them in three steps between 1935 and 1937. The goal was to prevent a potentially inflationary rise in lending by soaking up the substantial excess reserves that banks were holding at the time. The banks responded by increasing their reserves and keeping the same cushion because they did not trust the Federal Reserve to provide adequate liquidity if a bank run occurred. The money supply fell and contributed to a sharp rise in unemployment and drop in real GDP in 1937–8 (Friedman and Schwartz, 1963; Romer, 1992). There is some disagreement about the impact of the monetary policies. Real business cycle economists argue that monetary and investment changes played much smaller roles than productivity shocks and high-wage labour policies in accounting for the fluctuations during the 1930s (Chari, Kehoe and McGratton, 2005).

The decision to leave the gold standard was accompanied by efforts to expand world trade beginning in 1934 with the Reciprocal Trade Agreement Act (RTA). The Smoot–Hawley Tariff Act of 1930 had helped touch off a series of protectionist responses by other countries that had caused total imports for a group of 75 countries to fall to one-third of their 1929 level. The RTA freed the Roosevelt administration to sign a series of tariff reduction agreements with Canada, several South American countries, Britain and key European trading partners. Consequently, American imports rose from a 20-year low in 1932–3 to an all-time high by 1940 (Irwin, 1998; Kindleberger, 1986).

Meanwhile, the Banking (Glass–Steagall) Act of June 1933 enacted an additional set of banking policies. Despite the checkered history experienced by state deposit insurance programmes (Calomiris and White, 2000), the act created the Federal Deposit Insurance Corporation (FDIC) to insure commercial bank deposits of up to $10,000. Insurance for savings and loans followed within the year. The Banking Act also established regulations, eliminated in the late 1970s, that prevented commercial banks from investing more than ten per cent of their assets in stocks and paying interest on deposits (Regulation Q). To increase the capital available for housing loans, the Home Owners’ Loan Corporation (HOLC) provided funds to refinance troubled mortgages between 1933 and 1936, and the Federal Housing Administration (FHA) began offering insurance of mortgages and home improvement loans. Both agencies aided in the spread of the modern long-term, amortized mortgage loan that replaced short-term loans in which repayment of only interest over the course of the loan was followed by a balloon payment of the principal when it fell due.

The Reconstruction Finance Corporation (RFC): New Deal lender

Established by President Herbert Hoover in 1932, the RFC was an off-budget government corporation that maintained control of the funds repaid on its earlier loans. The RFC offered the Roosevelt
administration flexibility because they could start funding programmes without constantly seeking new appropriations from Congress. In consequence, the RFC became the lender during the starting phase of nearly every major New Deal grant and lending programme. In addition, the RFC provided loans to large numbers of financial institutions of all types, railroads, farmers and local governments (Olson, 1998). The RFC loans to private business met with mixed success. The liquidity loans to failing banks in 1932 had not prevented many bankruptcies because the RFC loans were given first priority over depositors and other lenders in case of failure; therefore, banks were prevented from selling their most liquid assets to meet depositor demands for cash. The RFC's purchases of preferred stock in banks reorganized after the Bank Holiday of 1933 exposed the RFC funds to more risk but led to more success at preventing failures (Mason, 2001). RFC lending to railroads succeeded in preventing several railroad bankruptcies. However, the spared railroads continued to underinvest in maintenance and capital improvements. In contrast, railroads forced into bankruptcy had to make such investments to attract enough capital to reopen for business (Mason and Schiffman, 2004).

Emergency relief and public works programmes

Unprecedented unemployment rates ranging from 10 to 25 per cent through the 1930s were the New Deal's greatest challenge. Prior to the New Deal, aid to the poor and labour policies had been the purview of state and local governments. Claiming unemployment to be a national emergency, Roosevelt and Congress raised the federal share of relief spending as high as 79 per cent while nearly quadrupling relief spending even as unemployment rates fell by the mid-1930s. The Federal Emergency Relief Administration (FERA, 1933–5), the Civil Works Administration (CWA, winter of 1933–4), and the Works Progress Administration (WPA, 1935–42) offered work relief jobs to households whose incomes fell below a target budget for necessities. The Civilian Conservation Corps (CCC) offered conservation jobs in the nation's hinterlands to youths whose earnings were shared with their parents. The FERA also handed out direct relief until 1935, when the responsibility for 'unemployables' was returned to state and local governments, and the federal government began offering matching grants for public assistance for children, the blind, and the elderly.

Harry Hopkins, who headed the FERA, CWA and the WPA, preferred work relief because it 'provided a man with something to do, put money in his pocket, and kept his self-respect' (Adams, 1977, p. 53). To give people incentive to leave work relief for private jobs, WPA monthly earnings averaged 40 to 50 per cent of full-time private earnings, and the WPA assured people that they would be reaccepted should the private job end. Even so, a significant percentage of workers stayed on work relief jobs for periods as long as a year and in some cases several years (Margo, 1993).

Roughly one-fourth of New Deal grant spending went to the Public Works Administration (PWA), Public Buildings Administration (PBA), the Public Roads Administration (PRA), and the Tennessee Valley Authority (TVA). The planning stages on these large-scale projects were longer, the wages were higher, and there was more freedom to hire already employed workers. The relief and public works programmes grants were designed to provide employment, build public projects, and stimulate the economy.

At one level the relief and public works programmes were very successful. Millions of Americans obtained work relief jobs to tide them over, and most of the original public works, many renovated
since, are still in place today. To understand the true impact of the New Deal, areas with different amounts of spending need to be compared to get a sense of how their economies would have performed without the New Deal. Since the mid-1990s economists have been using the substantial variation in spending across local areas to make such comparisons while working to control for the feedbacks caused by administrators using New Deal programmes to respond to economic problems. At the local level the benefits of the projects were likely to be stronger when the general share of goods produced in the area for local consumption was higher, the projects hired the unemployed without crowding out private or state and local government employment, and expansions did not raise incomes enough to generate federal income tax payments.

Although cross-sectional studies show little effect of relief jobs on private employment, analysis of panel data can control for unmeasured factors using the information across time for a cross section of areas. The panel studies suggest that an additional relief job reduced private employment by up to half a job (Wallis and Benjamin, 1981; 1989; Fleck, 1999a). A new relief job also raised ‘measured’ unemployment by one person because many discouraged workers, who had been out of the labour force and thus not counted as unemployed, were defined as re-entering the labour force as unemployed workers when they accepted relief jobs (Darby, 1976; Fleck 1999a).

The impact of public works and relief programmes had more clearly beneficial effects on other measures of socio-economic welfare. Cross-sectional studies of US counties suggest that an added dollar of public works and relief spending per person raised per capita income by roughly 85 cents and stimulated in-migration (Fishback, Horrace and Kantor, 2005; 2006). Panel studies of more than 100 major cities between 1929 and 1940 show that increased relief spending stimulated birth rates, reduced property crime, and reduced infant deaths and deaths from suicide and several diseases. The relief costs per death prevented in today's dollars are within the range of modern market values of life, and the costs are lower than the costs per death prevented of many modern safety programmes (Fishback, Haines and Kantor, 2007; Johnson, Kantor and Fishback, 2006).

Farm programmes

To raise the incomes of farmers, who had struggled through over a decade of hard times, the New Deal established the structure of the modern US farm programmes. The Agricultural Adjustment Administration (AAA) paid farmers to take land out of production. In 1935 in United States v. Butler the Supreme Court struck down the output processing tax that had originally funded the payments. The AAA payments were quickly reinstituted (minus the processing tax) under the Soil Conservation and Domestic Allotment Act (1935). The Commodity Credit Corporation (CCC) insured that farmers were paid higher prices by making loans that could be repaid with the crop itself if market prices fell below a target price. The Farm Credit Administration (FCA) reorganized and expanded farm lending, ultimately becoming involved in more than half of all farm mortgages and a large share of production loans. Meanwhile, the Rural Electrification Administration (REA) provided subsidized loans to give farmers access to electricity, while the Farm Security Administration (FSA) developed programmes to aid low-income farmers.

Efforts to determine the AAA’s impact on limiting farm output have been confounded because a series of major climatic disasters in the 1930s served to cut output anyway. There is evidence that farmers
stopped planting their least productive land and raised the inputs used on the remaining land. The AAA clearly aided large farmers but possibly at the expense of farm workers and tenants (Alston and Ferrie, 1999; Whatley, 1983). Cross-county studies show that increases in AAA payments in counties led to no increases in retail sales, were associated with higher infant mortality in the South, and stimulated net outmigration (Fishback, Horrace and Kantor, 2005; 2006; Fishback, Haines and Kantor, 2001; Alston and Ferrie, 1999; Whatley, 1983). On the positive side, the AAA soil conservation programmes encouraged a move to larger farms and practices that cut soil erosion, so that the Great Plains avoided a recurrence of the Dust Bowl when the same drought and wind conditions arose later (Hansen and Libecap, 2004).

The political economic geography of New Deal spending

New Deal grant spending across states and counties varied enormously, as some western states received several times more per head than some southern states. Roosevelt in a radio ‘fireside chat’ vowed that the New Deal would promote ‘Relief, Recovery, and Reform’. Critics argued that Roosevelt used the monies primarily to aid his re-election efforts. The distribution process for many programmes was opaque, so New Deal scholars have turned to econometric analysis that simultaneously tests the importance of the stated motives and presidential politicking. Politicking was clearly part of the process in the distribution of total funds and at the programme level. Nearly every study finds that more grants went to swing states and areas with higher political turnout, while some find rewards for loyal Democratic areas as well as districts represented by powerful congressmen. The Roosevelt administration was innovative in targeting radio owners in their push to win elections (Wright, 1974; Wallis, 1998; Fleck, 1999b; Stromberg, 2004; Couch and Shughart, 1998).

Winning elections required more than just manipulation of spending to hit specific political targets. The Roosevelt administration also enhanced its future re-election prospects by following its stated aims. Many studies find evidence that the Roosevelt administration promoted recovery and relief by spending more in areas with higher unemployment and larger declines in income from 1929 to 1933. Few find signs that the total spending was reform-oriented, but specific relief programmes did target areas with long-term poverty. State governments influenced the distribution by the intensity of their lobbying and their spending in matching grant programmes, while the presence of federal land in a state also drew substantial public works grants. Specific programmes typically followed stated goals. There were so many programmes that nearly everybody could find one that benefited them, ranging from relief for the unemployed and poor to loans and AAA grants for large farmers. The HOLC and FHA housing programmes benefited carefully vetted home owners who were perceived as having lower risk of default (Fishback, Wallis and Kantor, 2003). There were constant charges of corruption, but the WPA actively battled corruption at the state and local levels by establishing an internal investigative agency. When the federal government increased its control of the distribution of funds within states in the switch from the FERA to the WPA, the distribution of funds within states more closely mirrored the relief, recovery and reform goals (Wallis, Fishback and Kantor, 2006).

Industrial and labour policies
To combat ‘destructive competition’, low prices and low wages, the National Recovery Administration (NRA) was created to allow industries to establish their own codes for minimum prices, quality standards, trade practices, and labour relations (Bellush, 1975). The NRA appeared to be sponsoring a series of industry cartels, as large firms tended to dominate the code-writing process in most industries. Wholesale prices jumped 23 per cent in two years, although consumer prices were much slower to rise. Simulations of the economy with and without the NRA imply that it served to slow economic recovery (Cole and Ohanian, 2004). The internal problems of cartels were also present, as industries with diverse firms had trouble coming to agreement and a number of firms routinely violated the codes (Alexander and Libecap, 2000). The NRA ended in 1935 when the Supreme Court declared it unconstitutional in the Schechter Poultry case, and few mourned its passing.

The National Labor Relations (Wagner) Act of 1935 expanded the right of workers to collective bargaining through their own representatives beyond the protections originally offered in the 1933 act that created the NRA. Employers were required to bargain with unions when a majority of workers voted for union representation, and employer-sponsored unions were banned. The National Labor Relations Board (NLRB) was established to oversee union elections and the collective bargaining process. As a result, unionization expanded rapidly through a mixture of strikes and elections. In the long run the NLRB policies regularized the union recognition and bargaining process, and the incidence of violent strikes has diminished sharply since (Freeman, 1998).

The emphasis on raising wages continued when the Fair Labor Standards Act (FSLA) of 1938 set a national minimum wage, overtime requirements, and child labour restrictions. Workers in agriculture or not employed in interstate commerce were exempted. Congressional support for the act was centred in states outside the South with high-wage industries, more unionization, and more advocates for teenage workers. As a result, the first minimum wage was binding only for low-wage industries in the South, where employers in some southern industries responded by reducing employment, and others switched to labour-saving technologies or limited their business to intra-state commerce to avoid federal regulation (Seltzer, 1995, 1997; Fleck, 2004).

The Social Security Act of 1935

The legislative centerpiece of the Second New Deal was the Social Security Act (SSA) of 1935, which established the modern structure of public assistance and social insurance programmes. The public assistance grants set some federal guidelines and offered matching grants that gave the states latitude in setting benefits. The new Aid to Dependent Children (ADC), Aid to the Blind (AB), and Old-Age Assistance (OAA) programmes replaced similar state programmes in more than half of the states, and provided coverage for the first time in the remaining states.

State unemployment insurance programmes funded by employer contributions with administrative costs paid by the federal government were established as a long-term alternative to providing emergency work relief. The states retained control over benefits offered. Each designed its own experience-rating system that required employers who laid off more workers to pay higher premiums, a feature not commonly found in other countries' unemployment insurance systems. The experience rating helped reduce seasonal unemployment fluctuations (Baicker, Goldin and Katz, 1998).

Social security is most associated with the federal old-age retirement system. In the debates over social
security, Roosevelt pressed for an actuarially sound system where the individual's retirement benefits were based purely on his and his employer's own contributions. He was not convinced the old-age pensions were necessary and sought to ensure that future generations would not be saddled with the costs. Others pressed for a subsidized system that provided adequate payments to all who contributed. The plan adopted in 1935 was a hybrid, but the inadequacies of the hybrid system had become apparent by 1939, and the current pay-as-you-go structure was created. A worker and his employer pay taxes into an administrative trust fund that pays benefits to current retirees and serves as a commitment by the federal government to collect enough taxes to pay the worker his own social security pension when he reaches retirement age. The initial taxes were one per cent of wages each for workers and employers, and the initial benefits paid in 1940 were roughly 25 per cent of the average earnings of workers contributing to the system. Average pension payments are now roughly 40 per cent of the contributing workers' average earnings, and the increase in average lifespans has caused rapid increases in the ratio of retirees to workers. In consequence, the tax rates had risen to over 5.3 per cent each for worker and employer by 2000, with expectations that relative benefits will have to be cut or taxes raised in the future to sustain the system (Schieber and Shoven, 1999).

Conclusion

The New Deal was a response to the Great Depression, a major peacetime crisis sandwiched between two world wars. All three crises contributed to short-run rapid expansions of the federal government. When each ended, the government's role retracted somewhat but never to the level that would likely have occurred without the crisis (Higgs, 1987). In the span of six years the Roosevelt administration built an incredible array of public works and established a series of regulations, government insurance, and public assistance programmes that are still in place today. The New Deal arguably did more to expand the role of government in the United States than the more evolutionary changes that have occurred since the end of the Second World War.

new economic geography

Anthony J. Venables
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

New economic geography provides an integrated and micro-founded approach to spatial economics. It emphasizes the role of clustering forces in generating an uneven distribution of economic activity and income across space. The approach has been applied to the economics of cities, the emergence of regional disparities, and the origins of international inequalities.

Keywords

clustering; comparative advantage; congestion; core–periphery mode; dispersion; factor price equalization; foreign direct investment; gravity modelling; imperfect markets; increasing returns to scale; industrial organization; international portfolio investment; international trade (theory); knowledge spillovers; labour mobility; linkages; location of economic activity; market access; Marshall, A.; monopolistic competition; new economic geography; productivity; regional development; spatial economics; urban agglomeration; urban economics

Article

Why is economic activity distributed unevenly across space, with centres of concentrated activity surrounded by ‘peripheral’ regions of lower density? What economic interactions are there between different geographical areas, and how do these shape income levels in the areas? How does the spatial organization of economic activity respond to exogenous shocks, such as technological change or policy measures? The contribution of ‘new economic geography’ (NEG) is to address these questions in a manner that is based on rigorous microeconomic foundations. It shows how the spatial structure of an economy is determined by the interplay between costs of transactions across space and various types of increasing returns to scale. The questions posed above can be addressed at different spatial levels – international, regional and urban. NEG provides a unified framework for analysis at these different levels.

Clustering versus dispersion

The NEG approach has several key analytical ingredients. The first is the recognition that spatial interactions are costly. These costs are shaped by geography and depend on the nature of the interaction. Thus, trade in goods incurs shipping costs and costs of time in transit, depending on distance shipped, on transport infrastructure and on geography. Communications and coordination costs mean that workers may be less effective if they are not in close proximity with co-workers. Factor mobility may be impeded by distance and geography. This approach contrasts with that of international trade theory, in which spatial units are identified solely with countries – jurisdictions rather than geography – and where goods and factors are typically assumed to either be traded freely or to be completely non-tradable. The NEG approach shows how outcomes depend on the extent to which different goods and activities are mobile between locations.

The second key ingredient is the possibility that there are clustering forces, inducing activity to concentrate in space. Clustering arises because of spatially concentrated increasing returns to scale which can derive from a number of different underlying forces. (The classic discussion is Marshall, 1890; for a recent survey see Duranton and Puga, 2004.) One
One way to derive clustering forces is through thick market effects, particularly in the labour market. Dense labour markets may allow for better matching of the skills of workers and the requirements of firms (Helsley and Strange, 1990). Incentives to acquire skills may be greater where workers face more prospective employers (Matouschek and Robert-Nicoud, 2005). Another way in which to derive clustering is to use industrial organization models of imperfect competition. The route followed in much of the NEG literature is to suppose that an industry (we will call it ‘manufacturing’) contains a number of firms, each of which has increasing returns to scale. The presence of internal economies of scale means that firms are faced with a location choice (if they had constant or diminishing returns then, given transport costs and dispersed consumers, they would choose to produce a very small amount in all locations – ‘backyard capitalism’, Starrett, 1978). The questions are, then, where do firms choose to locate, and under what circumstances will they cluster together?

The model often used to analyse the choice is the Dixit and Stiglitz (1977) model of monopolistic competition and its international trade extensions (Krugman, 1980). In this model each firm has a distinct variety of product which it produces in a single location and exports to other locations, and entry and exit occur until profits are bid down to zero. It turns out that, as firms take location decisions in order to maximize profits, so their location pattern tends to amplify any underlying differences between locations, and from this it is possible to generate an outcome in which clustering occurs.

To understand the argument, suppose that there are two regions A and B, and that A has demand $k > 1$ times larger than B (we ignore factor supply considerations for the moment). Could there be an equilibrium in which firms are located in proportion to the size of the regions, so A has $k$ times more manufacturing firms than B? If trade costs are prohibitively high the answer is ‘yes’: only local firms supply each market, and the number of firms is proportional to the size of the market. (Notice that this argument uses the Dixit–Stiglitz property that all firms are the same size in equilibrium.) But as trade costs are reduced and firms start to export, two things happen. First, the region B market comes to be supplied by $k$ times as many importing firms as does the country A market, thus reducing the profitability of producers in B. Second, each firm in B will pay transport costs on a large part of their output (sales to the large country A market) while firms in A will pay transport costs only on a smaller fraction of their output (sales to the smaller region B market). Both arguments suggest that firms in A become relatively more profitable, implying that in equilibrium with free entry the number of firms in A must exceed the number in B by a factor greater than $k$. The large region therefore has a disproportionately large share of manufacturing production, and is a net exporter of manufactures and importer of agriculture. More generally, a region with good ‘market access’ will attract a high share of firms.

This argument holds only if transport costs lie strictly between zero and a prohibitive level. If transport costs are prohibitive no firms ship any exports; each region is self-sufficient, and the location of industry is in proportion to the size of the regions. Conversely, if transport costs are zero, then the argument collapses, as firms in all regions have equally good access to all markets. The argument shows that it is at intermediate levels of transport costs that market access matters, and manufacturing is pulled disproportionately into the large region.

While this argument creates an incentive for clustering of firms, it is balanced by dispersion forces. These could be due to negative externalities, such as congestion, or arise as a consequence of immobility of some factors of production. Which factors are immobile depend on context, but typically include land (as in the tradition of urban economic modelling) and some or all types of labour. Thus, if labour were immobile, any benefit that firms derived from locating in one region rather than another would create a regional wage differential, until profits (more generally, the return to mobile activities) were equalized across regions.

Labour mobility is central to the Krugman (1991) ‘core–periphery’ model. This analyses two regions and two sectors, a constant returns to scale agriculture and manufacturing modelled as outlined above. Each sector uses a sector-specific type of labour (‘peasants’ and manufacturing workers respectively), and the regions’ endowments of these factors are, ex ante, identical. Crucially, manufacturing workers are mobile between the locations, whereas peasants are immobile. What is the division of manufacturing workers and firms between the two locations? Outcomes, as a function of trade costs, are illustrated on Figure 1. When trade costs are high manufacturing is equally divided between regions. However, when trade costs are low enough, manufacturing (and all manufacturing workers) concentrate entirely in one region or the other. There are two mutually reinforcing arguments supporting this clustering. The concentration of manufacturing workers creates a large market, so making the location profitable for firms. And the entry of firms bids up wages, so making the location attractive for workers (this effect reinforced by the fact that workers also benefit from not having to pay trade costs on their consumption of manufactures). It is not profitable for any single firm to leave the cluster, because the benefit of lower wages is outweighed by the loss of market access. As Figure 1 makes clear, the switch from dispersed manufacturing to agglomeration arises discontinuously. There is a critical value of trade costs, $t^*$, above which dispersed production is the stable equilibrium, and below which dispersed activity is unstable, while clustering of activity, in either of the regions, is a stable equilibrium.
Krugman’s ‘core–periphery’ model is perhaps the seminal paper, and brings the insight that agglomeration forces can be derived from a standard model of trade and monopolistic competition (see Fujita, Krugman and Venables, 1999, for further development these ideas). These micro-foundations mean that outcomes (clustering or dispersion) can be linked to
parameters such as trade costs, as in Figure 1. The model also makes it clear that ex ante identical locations can be different ex post, and that there are multiple equilibria – we have to look outside the model, or rely on chance, to determine which of the regions has the manufacturing cluster.

The model was constructed with just two locations. How do these insights extend when there are many locations? With many locations the number of equilibria increases dramatically, and there is a danger that little can be said about outcomes. There are several ways through this problem. One is to investigate how the size and number of manufacturing centres on a given geographical space depends on underlying parameters such as trade costs and population levels. The approach of Fujita, Krugman and Venables (1999) is to hypothesize a circular economy (with population on the circumference) and to show that an initial random allocation of manufacturing grows into a determinate number of centres, the size of which is greater (and number of which is smaller) the lower trade costs are. Given some number of centres, reducing trade costs will have no effect until some critical point is reached, at which the economy will reorganize itself to a new economic geography with fewer and larger centres. The approach of Fujita and Mori (1997) is to suppose that initially there is a small populated region. Population growth causes this to expand, at first with the spread of agricultural production into the hinterland. However, these agriculture workers demand manufactures, and this will cause new manufacturing centres to develop. The expanding economy therefore grows its urban structure, and cities will tend to be larger (and further apart) the greater increasing returns to scale are and the lower trade costs are. Both of these approaches work with underlying geographies that are undifferentiated. Adding structure to these underlying geographies simplifies the problem in fairly natural ways. A transport node – such as a port or river crossing – will attract manufacturing, as firms in such a location have better access to a larger number of consumers.

Intermediate goods and industrial clusters

The clustering mechanisms described in the preceding section turn on the mobility of labour. Clustering occurs because, as firms and workers move, so do both supply and demand for manufactures. What if labour is immobile? An analogous mechanism can work between firms when we take into account intermediate goods, that is, goods that are both supplied and demanded by the manufacturing sector. This mechanism is similar to the idea of ‘linkages’ common in the development economics literature of the 1950s and 1960s. This studied the roles of backward linkages (demands from downstream firms to their suppliers) and of forward linkages (supply from intermediate producers to downstream activities) in developing industrial activity. However, as we saw above, rigorous treatment requires that the concepts are placed in an environment with increasing returns to scale, in order to force firms to make a location choice. This can be done in a model isomorphic to that outlined above, but in which firms in the manufacturing sector produce and use intermediate as well as final goods. Clustering can occur as it is profitable for firms producing intermediate and final goods to co-locate. Depending on the strength of linkages within and between industrial sectors, clustering might occur through a wide part of the economy or within narrowly defined sectors.

In this model clustering arises purely from the mobility of firms, even if there is little or no labour mobility. It is applicable to a number of different situations. For example, within a country there might be inelastic supply of land or housing in each city which places a limit on labour mobility. Clustering of particular sectors can nevertheless occur, and might be associated with different levels of employment and different house prices across cities.

The model has also been applied in the international context, with labour immobile across national boundaries. Manufacturing may then concentrate in a single country or group of countries, and this clustering may lead to international wage differences. This idea is developed by Krugman and Venables (1995) in a model with two countries, N and S, assumed to be ex ante identical. Firms produce final and intermediate goods, and use labour and intermediates as inputs. Equilibrium outcomes are summarized in Figure 2, which has trade costs on the horizontal axis and real wages on the vertical axis. At very high trade costs there is no clustering, so the two economies are identical; this is because firms operate in each country to supply local consumers. As trade costs fall (moving left on the figure) so the possibility of supplying consumers through trade rather than local production develops, and clustering forces become relatively more important. Below some level of trade costs, *t*, clustering forces come to dominate, and one of the countries (N) gains most of manufacturing, and consequently has a high real wage. This clustering ‘deindustrializes’ the other country (S), which experiences a fall in its real wage. For the case illustrated in Figure 2, there is a range of trade costs in which the world necessarily has a dichotomous structure. Wages are lower in S than in N, but it does not pay any firm to move to S as to do so would be to forgo the clustering benefits of large markets and proximity to suppliers that are found in N. However, as trade costs fall it becomes cheaper to ship intermediate goods, so the location of manufacturing becomes more sensitive to factor price differences. This is the era of globalization, in which manufacturing starts to move to S and the equilibrium wage gap narrows. In this model factor price equalization is attained when trade is perfectly free – the ‘death of distance’.

**Figure 2**

Real wages in a two-country model
This model offers quite a general theory of location, in which four forces are at work, two of which are dispersion forces, and two favour clustering. The dispersion forces are factor supply and product market competition: moving a firm from S to N reduces the profitability of firms in N both by bidding up wages and by driving down product prices. Against this there are two agglomeration forces, demand linkages and cost linkages: moving a firm from S to N raises the profitability of firms in N by increasing the size of the market and by increasing the supply of intermediate goods. The balance between these four forces depends on parameters, including trade costs, giving the outcomes illustrated on Figure 2. It is worth comparing the four forces present in this model with the conventional model of free international trade, in which factor supply alone determines the location of economic activities.

Extensions of this approach provide a number of further insights concerning international inequalities. It suggests that the world may tend to organize into a rich club of countries and...
a poor club. Economic development takes the form of countries growing from the poor club to the rich club in sequence rather than in parallel. Parallel growth is unstable because of the tendency of developing manufacturing sectors to cluster in a few countries.

**Empirical findings**

The new economic geography literature offers explanations of a number of phenomena that are empirically well documented – even obvious – such as the existence of cities and the presence of regional and international inequalities. Its insights range across different spatial scales, from the urban to the international. Empirical work is correspondingly diverse, and we refer to just four elements of it.

First, there is strong evidence of the importance of geography in shaping economic interactions. Trade costs are high (Anderson and van Wincoop, 2004), and ‘gravity modelling’ points to the fact that bilateral trade flows approximately halve with each doubling of distance between country pairs. Similar results hold for other cross-border interactions such as foreign direct investment flows, telephone calls, and international portfolio investments.

To turn to outcomes, a number of researchers have investigated the extent to which individual sectors are prone to clustering. There is a long business school tradition of work in this area, for example Porter (1990), who studies a number of industrial clusters. Econometric work has established that sectors are more prone to cluster than would be explained by chance or by comparative advantage (Ellison and Glaeser, 1997). A further prediction of NEG is that prices of immobile factors will be high in locations with good market access. As we have seen, in the national context this will show up in the price of land and housing and hence nominal wages differences, a prediction confirmed for US counties by Hanson (2005). In the international context this may show up as real wage differences. Gallup and Sachs (1999) find that 70 per cent of cross-country variation in per capita income can be accounted for by just four measures of physical and economic geography (malaria, hydrocarbon endowment, coastal access and transport costs). A structural approach to identifying the importance of market access in explaining cross-country income differentials is adopted by Redding and Venables (2004), who use gravity modelling to calculate measures of market access for each country. With other factors (such as institutional quality) controlled for, these measures of market access are important determinants of international wage gaps. Finally, there is considerable evidence of the productivity benefits derived from being located in dense centres of economic activity. A recent survey of the literature on cities (Rosenthal and Strange, 2004) reports a consensus view that doubling city size is associated with a productivity increase of some three to eight per cent. However, a good deal of uncertainty surrounds the extent to which this is driven by the different clustering mechanisms – knowledge spillovers, thick labour markets, market access benefits, or inter-firm linkages – that we described above. Identifying the importance of each of these underlying mechanisms remains an active area of current research.

new institutional economics

L.J. Alston
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The new institutional economics (NIE) consists of a set of analytical tools or concepts from a variety of disciplines in the social sciences, business and law. The NIE addresses two overarching issues: what are the determinants of institutions – the formal and informal rules shaping social, economic and political behaviour? And what impact do institutions have on economic performance? It is the impact of institutions via property rights and transaction costs that ultimately affect the ability of individuals and societies (at a macro level) to extract the gains from trade which in turn can lead to enhanced economic well-being.

Article

What is the new institutional economics (NIE)? The NIE adds to the neoclassical framework insights and concepts from a variety of social sciences as well as business organization, history and law. Unlike past interdisciplinary forays by economists into other disciplines, proponents of the NIE have been less imperialist and instead have been importers of various concepts. This does not mean that the NIE is internally inconsistent. Indeed, the NIE is a set of analytical spokes that when put together properly form a wheel of analysis capable of addressing a broad variety of issues. The NIE consists of analytical spokes from a variety of disciplines: anthropology, business organization, economics, history, law, political science, psychology, and sociology. My purpose in this article is to identify the spokes and try to form the wheel in order to give a better understanding of the NIE.

A framework for understanding the new institutional economics

The alpha and the omega of the NIE are institutions and economic performance (Alston and Ferrie, 1999; Eggertsson, 1996; North, 1990). Institutions determine economic performance and economic performance determines institutions. This is nothing new. What is new are the conceptual spokes such as transaction costs, property rights, credible commitment, and agenda control that determine the simultaneous causal links between institutions and economic performance. It is important to emphasize that the NIE does not abandon neoclassical theory. As Figure 1 illustrates, the conceptual arrows beginning with technology to transformation costs (production isoquants, along with relative prices) are still the backbone of the theory of the firm that determine the costs of production and in the neoclassical world led to discussions of how far inside and/or where on the production possibilities frontier a country would be. Because of the limited ability of this stark depiction of the theory of the firm to transformation costs many of the ‘big’ questions facing economists – for example, the lack of convergence in standards of living across countries – many economists added various concepts. Let us begin with the role of institutions.

Figure 1

Institutions and economic performance
Institutions are the informal norms and formal laws of societies that constrain and shape decision-making or, as North (1990) defined them, 'the rules of the game'. For a good
treatment of the interaction of norms and laws see Greig (2006). For the importance of social capital or norms see Keefer and Knack (2005). Informal norms do not rely on the coercive power of the state for enforcement whereas formal laws do, in part. The enforcement of formal laws does not rely entirely on the coercive power of the state because some of their force is derived from the beliefs of its citizens. For example, if more people believe that littering is morally wrong, the costs that governments incur to police littering are lower. Similarly, if more people believe that recycling is morally right then they will incur their own costs to recycle even though to do so would not be in their self-interest strictly speaking. The existence of certain laws may simply be the codification of the norms of the majority. But, at times, and particularly during crises, some political leaders can influence the norms of citizens (Higgs, 1987). To the extent that political leaders can sway public opinion, the passage of laws may affect the beliefs of the constituents.

As Figure 1 shows, the norms and laws of society determine the property rights that individuals possess. Here I am concerned with rights that individuals have in regard to goods and services: (1) the right to sell an asset; (2) the right to use and derive income from an asset; and (3) the right to bequeath an asset. Property rights are enforced in three ways. Individuals themselves enforce their assigned rights; for example, we put locks on our doors to protect our property. Societal sanctions such as ostracism can deter individuals from violating the assigned rights of others. And the coercive power of the state can be used to enforce property rights; for example, the police will evict trespassers.

Technology, which the standard neoclassical model took as exogenous, is shaped by the property rights, and the norms and endowments of citizens. Property rights along with technology determine the transaction costs and transformation costs associated with exchange and production. Robertson and Alston (1992) present a schematic framework for analysing the impact of technology on the transaction costs of production. Technology costs are the physical costs (in an engineering sense but based also on relative prices) of combining inputs to produce output. The transformation costs of production depend on the technology in society. The transaction costs of production are the invisible costs of production and initially discussed by Coase (1937) in his seminal article for the NIE, ‘The Nature of the Firm’. Transaction costs include: (1) search and negotiation costs; (2) monitoring labour effort; (3) coordinating the physical factors of production; (4) monitoring the use of the physical and financial capital employed in the production process; and (5) enforcing the terms of the contract. It is the transaction costs within a firm – along with transformation costs – relative to the transaction costs of using the market that Coase first identified as being decisive in determining the firm/market boundary. Others within the tradition of the NIE have extended this considerably, most notably Yoram Barzel (1989) and Oliver Williamson (1985). The extensions have provided answers to issues associated with long-term contracting, for example, Goldberg and Erickson (1987); Joskow (1985); hybrid contracts of various sorts (Menard, 2005) and various forms of business organization, for example, franchises (Lafontaine, 1992).

Both technology and property rights can affect the transaction costs of production in a variety of ways. Technology generally reduces both the direct costs of monitoring, through better surveillance, and reduces the need to monitor, that is, capital standardizes the marginal productivity of labour, holding constant monitoring. As an historical example, in agriculture, when workers cut down weeds by hand, monitoring costs were higher than when workers drove through the fields with a mechanical cultivator that cut down the weeds. Whether on the farm or in the factory, machines by their very nature reduce the discretion of labour. They standardize the production process and thereby reduce the variation in the marginal product of labour. In addition, technology influences the transaction costs of coordinating production; for example the computer is partially responsible for the observed increase in horizontal integration in commercial banking in the United States in the 1990s. The huge merger wave in the banking industry in the 1990s was partially the result of legal changes that in turn could have been prompted by the lobbying efforts from the financial industry in recognition of the cost savings associated with the advent of computer technology. Norms and property rights can also affect the transaction costs of production. For example, if people believe in working hard in some cultures (perhaps because of past incentives), providing ‘an honest day’s work for an honest day’s pay’, then the monitoring costs borne by the residual claimant are lower. Similarly, if the property rights in a society make it easy to dismiss workers for shirking, then monitoring costs would also decrease.

The transaction costs of exchange include the costs associated with negotiating and enforcing contracts. For some exchanges, the transaction costs of exchange are low because informal norms suffice to uphold bargains. Most local communities have well-established customs that limit opportunistic behaviour. Similarly, repeat transactions often give a sufficient incentive to deal fairly. Though local or repeat exchanges may have low transaction costs, the gains from such trade are limited because the extent of the market limits the number of individuals with whom one can deal locally or repeatedly. Formal institutions are necessary if the full gains from specialization in an extended market are to be captured. I use the term ‘full gains’ because some trade can be accomplished through self-generated reputation and the prospect of repeat business without relying on outside formal government institutions (Telser, 1981). This is particularly evident in the case of international transactions where the participants do not share a common body of law. For example, the extension of the market may require that more trades occur among anonymous parties or that more trades occur where payment and delivery are not simultaneous. Institutions can reduce the potential for unscrupulous behaviour inherent in such arrangements.

The presence of ‘honest’ courts and a body of law that upholds contracts and safeguards exchanges is a formal institution that determines the property rights of individuals which in turn affect the transaction costs of exchange. The shorthand concept used to describe this system is ‘the rule of law’ (Arrunada and Adonova, 2005; Beck and Levine, 2005; Hadfield, 2005). This does not imply that the courts are used frequently, only that they form a backdrop for exchange. The availability of recourse to law and the courts provides a safeguard for market participants engaged in anonymous or non-simultaneous exchanges. In the absence of honest courts, negotiation and enforcement costs will be higher. As a consequence, contracts will be written in ways that will safeguard the exchange should one party desire to act opportunistically. Williamson (1985) describes how contractors shield themselves from the potential opportunistic behaviour of others. Levy and Spiller (1994) illustrate the role of institutions in providing commitment in the context of safeguarding investments in the regulation of telecommunications. Firms (and legislative and executive bodies) also use the courts strategically but here I treat firms as responding exogenously to their
new institutional economics: The New Palgrave Dictionary of Economics

At times there may be insufficient safeguards so that the result is not an exchange. For example, large investments are generally required to reap economies of scale. A part of that investment may not be readily transferable to other uses (that is the investments are asset specific – see Williamson, 1985, for an expansive treatment of specific assets). Before the investment is made, if there is a fear that some of the value of the investment will be expropriated, either through nationalization, taxes, regulations, or opportunistic behaviour by one of the contractors, firms will not invest as much as they would in the absence of such fears (Spiller and Tommasi, 2005). Expropriation could occur either through actions taken by the state (such as regulation or nationalization) or through actions taken by one of the parties (such as refusing to execute the exchange without a renegotiation of terms).

Given the set of institutions in a society, residual claimants will construct contracts with the suppliers of inputs to minimize the sum of transformation and transaction costs within a firm, and between firms and firms and consumers. The results are a variety of contracts with differing transaction cost and production cost components, and different total costs of production. The varying contracts in turn influence economic performance. As an example there is a voluminous literature associated with principal agent problems ranging from tenancy in agriculture (Alston, 2003) to corporate governance (Fama, 1980).

The conceptual framework presented in Figure 1 and discussed thus far is basically static; it illustrates the ultimate importance of institutions for economic performance but it does not address the determinants of institutions and institutional change (Alston, 1996; North, 2005). To understand the process of institutional change, it is useful to think about economic performance or economic growth as a process of creative destruction (Schumpeter, 1942). Creative destruction means that there are winners and losers associated with economic performance (see Figure 2). The losers have an incentive to lobby government for institutional change to protect them from the ravages of the market, while the winners have an incentive to lobby for the status quo or an even better outcome. Consumers have an interest in the outcome, but given the existence of rational ignorance and free-rider problems consumers tend not to be as effective as special interests in the political marketplace. By rational ignorance, we mean that it does not pay the consumer to be as informed about legislation as special interest groups (Olson, 1965; Buchanan and Tullock, 1962). The free-rider problem arises because of the large numbers of consumers have difficulties in organizing collectively to prevent policy changes. Political entrepreneurs may attenuate both these problems because the interests of consumers are represented somewhat through competition amongst politicians who bring issues to the attention of consumers, and thus limit the power of special interests (Denzau and Munger, 1986).
We can think of those who lobby for changes in institutions or for the status quo as the demand side of legislation. But special interest groups do not enact legislation. Their demands get filtered through a political process of government institutions – what I call the supply side of legislation. By using the terms ‘demand’ and ‘supply’ I do not mean that there is necessarily a unique outcome; the term ‘bargaining’ may be more appropriate. Curiously, until recently, economists have paid little attention to the supply side of government, leaving the modelling of the political process to political scientists; ‘curiously’ because the concepts of demand and supply are the two most important components of neoclassical economics. The supply of legislation can be initially decomposed into the executive, legislative and judicial branches. In parliamentary systems, the executive, prime minister, and the legislature...
are more interconnected than in presidential systems, so that the same demands may end up with a different result depending on whether a country has a presidential or parliamentary system (Carey, 2005). Within legislatures there are a myriad of coordinating devices; historically, in the United States, political parties and the committee structure in legislatures have played major roles in shaping political outcomes (Cox and McCubbins, 1993; 2005; Shepsle, 1978; Shepsle and Weingast, 1984). Political parties and committees have a certain amount of agenda control. For example, the party leadership makes appointments to committees, and committees in turn have the power to veto bills simply by refusing to report the bill out of committee. In addition they can amend bills to better suit their preferences. In parliamentary systems, particularly two-party dominant parliamentary systems, the majority power has significant agenda control. In other countries, most notably those with strong executive powers, such as in Brazil or Chile, the demand for legislation is filtered through the preferences of the president who negotiates with members of Congress using his powers to sway votes (Alston and Mueller, 2006). Changes in either demand or supply side forces will result in institutional change. Legislation can be either specific or vague in content (Spiller, 1996). In either case the law is administered through bureaucracies, giving rise to another set of principal–agent problems between the legislature and the agency to which the law is delegated (Ferejohn and Shipan, 1990; Weingast and Moran, 1983; McCubbins, Noll and Weingast, 1987). In the United States, the Environmental Protection Agency (EPA) is frequently cited as an example of a bureaucracy with large discretion because of the vagueness of its mandate from Congress.

The outcomes of this demand and supply side bargaining are the formal laws and regulations of a society, subject to the explicit or implicit sanction of the courts. It matters a great deal whether the courts that interpret the constitutionality of legislation are independent of the executive and legislative branches. If the courts are truly independent the executive and legislative branches will enact legislation ‘in the shadow of the court’, knowing that the court could overturn legislation. The dismal political and economic history of Argentina since 1945 is a good example of the impact on economic performance from a Supreme Court that has not been independent (Alston and Gallo, 2007; Iaryczower, Spiller and Tommasi, 2002).

Where do we go from here?

Before discussing institutional lock-in, the topic to which I believe we should devote more of our intellectual resources, it is worth considering which parts of the framework of the new institutional economics we know best. The hands-down winner is the area of contracting. We have much empirical evidence on how contracts change in response to different transaction costs, which in turn result from the formal laws and informal norms in societies. We also know a good deal about why governments pass the laws and regulations that they do. Here there has been an outpouring by both economists and political scientists, with economists tending to specialize in demand-side explanations – for example, the role of special interests – and political scientists specializing in supply-side explanations – for example, the role of committees and the importance of agenda control. So if we know why we get the laws, and we know how laws affect contracting, what is missing? What is missing is a better understanding of the transaction costs associated with getting laws and regulations that are more conducive to better economic performance, especially when it becomes obvious that the existing laws and regulations are not fostering economic growth (Shirley, 2005). In many scenarios special interests are in a position to either enact legislation or block legislation so that they reap the gains. Yet society is worse off by such activity. The question is: why cannot ‘we’, the citizens or consumers, buy out the special interests? For many societies, poor economic performance is explained by corrupt governments, who are more or less stealing from their own citizens. Here we focus on issues beyond corruption, though corruption is clearly in the domain of the NIE. There are several possible explanations for institutional lock-in:

1. Informational problems abound such that citizens are unaware of possible policy moves that would improve on the status quo (North, 2005 and citations therein).
2. Though citizens do not like the outcome, they approve of the process that produced the outcome.
3. Even when aware, there are serious collective action problems.
4. Insecurity in political property rights prevents transactions from occurring, that is, you cannot buy what someone else does not own.

Let us explore each of these in turn.

Given rational ignorance it may be that many citizens are simply unaware of property rights arrangements that would improve societal welfare. For example, under the Homestead Act in the United States settlers could acquire property rights to 160 acres of unoccupied federal land by residing and ‘improving’ the land. These homestead plots turned out to be economically too small and promoted externalities associated with wind erosion. Even after the great dust bowl of the 1930s, plots remained small because subsidies by the federal government enabled farmers to remain on the land. Why did the federal government not move to reallocate land or at least not interfere with consolidation through markets? It appears that the answer rests with the information available to citizens and their beliefs in the virtues of small landholdings. This is coupled with the efforts of local politicians to maintain a population base (Hansen and Libecap, 2004a; 2004b). Ironically, in the latter part of the 19th century Major John Wesley Powell recognized the potential problems of settlements in the arid or sub-humid regions of the country, but his reports to Congress were ignored in favour of boosterism (Stegner, 1954).

Another example concerns consumers who may simply be unaware of policy moves that would improve their welfare. For example, the United States and many other countries have
allowed their ocean shippers to participate in cartels that set prices on ocean routes around the globe (Sicotte, 1997). When I mention this to scholars, most are unaware of this price fixing. What needs to be done is to determine how many redistributive programmes exist where a policy move would be wealth-enhancing yet does not occur either because of insufficient information or an inability of citizens to process the cause and effects of potential policy moves in the face of risk aversion, that is, we know the effect of the status and do not fully comprehend a counterfactual policy world. Many institutions are bundled in ways that makes decoupling difficult. It is partially a coordination problem and it is partially a case of risk aversion – once you open Pandora’s Box you are uncertain as to the final outcome.

Another reason for institutional path dependence is circumstances where citizens have a deep belief in the process that produces laws and regulations even though they may disapprove of some legislative outcomes. The majority may opt to support the status quo legislation because changing the law would entail changing a higher order institution concerning overall institutional development. From US history an example of public disapproval of changing the system of checks and balances was the attempt by President Roosevelt to add Justices to the Supreme Court. Roosevelt wanted to stack the Court because the Court was ruling that some major legislative acts were unconstitutional, for example, the Agricultural Adjustment Act and the National Industrial Recovery Act. By adding Justices, Roosevelt believed that his New Deal legislation would pass the constitutional test. Even though most people supported the New Deal legislation, there was a public outcry against Roosevelt’s attempt to change the rules affecting checks and balances so as to achieve his legislative goals.

Alternatively, people may be aware of the dissipation associated with the status quo arrangement of property rights, but it is in no one’s self-interest to mount an organizational campaign to change the existing regulations. This is the classic collective action problem developed independently but almost simultaneously by Buchanan and Tullock (1962) and Olson (1965) – one could also model this as a multi-player Prisoner’s Dilemma game. The collective action problems are particularly acute in situations entailing multiple governments across international boundaries, for example, overfishing in international waters or global warming. The difficulties for international property rights are twofold: specification and enforcement. Specification is difficult because of knowledge or beliefs about the state of the world differ (for example, global warming) but even if beliefs are the same, preferences can vary across countries because of incomes (for example, the United States versus Mexico) or simply preferences (for example, the United States versus Germany on green issues). Collective action problems occur in representative democracies as well as dictatorial regimes. We have instances of both types of regimes not specifying and enforcing property rights at what would appear to be optimal times. For example, the United States squandered considerable oil reserves in the early 20th century and Indonesia mowed through a large stock of their tropical hardwoods in the latter part of the 20th century.

A fourth possibility for the lack of policy reform is insecure political property rights. It may be that individuals are aware and willing to organize but there is no ‘market’ for the emergence of property rights. Suppose that the winners from a status quo policy have the political power to veto or allow policy changes. Given their power, they would be foolish to acquiesce to policy moves that made them worse off, even if they were wealth enhancing. But, they would allow such a policy move if they were compensated. The actions of the landless peasants’ movement (MST) in Brazil are consistent with this argument. The MST is very effective at swaying public opinion and thereby prompting politicians to expropriate land and transfer it to peasants; but they do not support deeding the land to peasants. The MST prefers to keep the peasants dependent on the MST as a collective because it is easier for them to extract payments from the group than individual farmers (Alston, Libecap and Mueller, 2005).

Why is it that we generally do not allow such side payments? One answer is that transparent side payments would undermine the legitimacy of the organization, whether the organization is the MST, a union or a government. If the current property rights arrangement is viewed as inferior to an alternative, people ‘believe’ that they should not pay to move to a better property rights arrangement. The result is institutional lock-in. Yet there have been examples of improving the status quo for all parties involved. A case involving the sale of water in the 1990s illustrates the difficulties in changing the status quo. The Imperial Valley Irrigation District, a governmental unit that has jurisdiction over water, entered into a contract to sell some of its water to the city of San Diego. The Imperial Valley Water District has property rights to water that are subsidized by US taxpayers. As such it can sell water at prices higher than it pays. Interestingly, members of the Imperial Water District decided that they would only sell water that they have conserved through better irrigation technologies. The interesting question is: why didn’t they follow all their land and sell their entire water allocation? I speculate that they were concerned about the political fallout that could have resulted in the district losing its current subsidy. In short, it appears as if they have secure property rights to the rental stream of water but not the clear ‘political’ property right to the stock. The establishment of ‘water banks’ throughout the West – whereby farmers could sell their flow of water to urban users or resort users – have failed primarily because farmers are afraid of losing their property right when it becomes transparent that farming is not the highest-valued use of water in the West.

Another factor promoting the insecurity of political property rights falls under the rubric of credible commitment (North and Weingast, 1989). In representative democracies politicians face the demands of constituents who may be harmed or obtain benefits from a rearrangement of property rights. The demands of the majority of voters may not coincide with the optimal arrangements of property rights, and politicians cannot commit to making side payments over time to compensate the losers. Authoritarian regimes are subject to similar problems associated with catering to populist demands. A good example of this was the infringement in property rights by Peron in Argentina in the late 1940s. Peron imposed rent and price controls in the Pampas, the most fertile and productive agricultural producing area in Argentina. The punitive arrangement in property rights lead to a decline in investment which, along with political instability, affected growth in the long run (Alston and Gallo, 2007; Spiller and Tommasi, 2003; 2007).

A more cynical view of political behaviour suggests that we do not want to encourage paying for changes in property rights because to do so would promote the creation and maintenance of non-optimal property rights in order to be paid to move to a more optimal situation. Campaign finance and corruption around the globe may be testimony to special interests trying to ‘bribe’ politicians to maintain or change property rights. In some instances politicians may use part of the contributions to make side payments (Norlin, 2003).
Explaining institutional rigidities in the face of poor economic performance is a difficult research agenda. To understand the lock-in requires insights from the disciplines that comprise the NIE – anthropology, business organization, economics, history, law, political science, psychology and sociology. Yet the potential reward from an understanding of the forces that account for poor economic performance is huge. The research agenda includes both international cross-sectional studies and case studies of successful and unsuccessful institutional change. The international cross-sections allow us to quickly determine the correlates of successful economic performance, for example secure property rights, while the case studies allow us to stack the building blocks that will ultimately allow us to produce a more general framework for the determinants of institutional change (Alston, 2007).

new Keynesian macroeconomics

Huw David Dixon
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The term ‘new Keynesian economics’ refers to a body of work done by macroeconomists in the late 1970s and 1980s in which the notion of imperfect competition was introduced into macroeconomics in order to provide a micro-foundation for nominal rigidities and also to provide an alternative to supply-equals-demand equilibrium. This led in the 1990s to the new-neoclassical-synthesis approach to monetary economics in which dynamic pricing models have become central to our understanding how monetary policy influences output and inflation. Other themes in the new Keynesian approach include the effect of imperfect competition on the fiscal multiplier, and coordination failures.

Article

The term ‘new Keynesian economics’ came into popular usage in the 1980s. The origins of the term are
fairly easy to understand in broad historical terms. In the classical approach of the pre-Keynes world (prior to 1936), wages and prices were seen as perfectly flexible and markets competitive (or at least ideally so). The Keynesian Revolution argued that prices, and more importantly wages, were rigid, and in order to understand phenomena like prolonged mass unemployment it was necessary to see how the economy operated when not in competitive equilibrium. In the post-Second World War period there emerged the neoclassical synthesis model that dominated macroeconomics from the 1950s to the mid-1970s. The essence was that in the long run all prices are perfectly flexible and the competitive or ‘Walrasian’ equilibrium will hold. However, in the short run prices and/or wages were treated as given. Thus there were the IS–LM and aggregate supply and demand (AS–AD) models, which were the workhorses of macroeconomic research until the mid-1970s and have remained established in many textbooks to the present day.

This approach was in the process of being overtaken at the level of research by the ‘new classical’ or rational expectations revolution of the 1970s. One aspect of the neoclassical synthesis was that not only prices but also expectations were treated as fixed in the short run, or subject to ad hoc adjustment, as under the adaptive expectations hypothesis. The new classical approach was based on the idea that wages and prices are perfectly flexible, but that agents did not have full information: even though agents used the information they had optimally (rational expectations), markets could deviate from the full information equilibrium. For example, agents might not know about the values of certain current variables such as aggregate price or the money supply when deciding how much output to produce or labour to supply.

The new Keynesian economics was to incorporate the rational expectations framework. However, it was to focus on the key issue of nominal rigidity: how do we understand the short-term rigidity of wages and/or prices in terms of providing a microfoundation that will explain why prices might not be perfectly flexible? Now, this required a ‘revolution’ of the order of magnitude of the rational expectations revolution. That revolution consisted in one idea: in order to understand nominal rigidity, it was necessary to abandon the approach of perfect competition with price-taking agents, and replace it with an approach where there are wage and price-setting agents. This is self-evident in hindsight: if you want to understand why wages and prices are rigid in the short run, you have to have agents who set the price, so that you can understand the microeconomics of price adjustment. If all agents (firms, households) are price-takers, prices can only be explained by some notion of ‘demand equals supply’ and a shadowy Walrasian auctioneer acting like an invisible puppet master-cum-market maker, adjusting prices gradually in response to excess demand or supply. This is hardly the basis for a rigorous theory of why prices and wages are not always at their market clearing levels: maybe the auctioneer called in sick or went on holiday!

Just to complete the historical setting, alongside the new Keynesian ideas there was the real business cycle (RBC) research programme which put forward the radical idea that nominal wage and price behaviour were irrelevant for understanding macroeconomic dynamics. Changes in output and employment were seen to be driven by real things such as productivity shocks, and the savings and investment decisions of agents as inherently dynamic. This was a radical agenda, which also pushed macroeconomics into trying to provide a quantitative explanation of economic fluctuations based on a competitive equilibrium model. However, despite many successes, the methodological idea of ignoring nominal things was an unsustainable self-limitation. For one thing, governments and central bankers are interested in the nominal side of the economy – inflation, the transmission mechanism of monetary
policy, to name a few.

So, in the mid-1990s there emerged the ‘new’ neoclassical synthesis (NNS). This combined the dynamic framework of the RBC approach with dynamic pricing models developed by the new Keynesian approach. The key idea is that in the long run money is neutral, but in the short run there is some nominal rigidity resulting from the price-setting behaviour of firms (and wage-setting behaviour of unions). This approach to modelling has certainly become the dominant school of thought, at least in central banks of Europe and the United States. It differs from the old neoclassical synthesis in that the model is fully dynamic and microfounded and the equilibrium imperfectly competitive.

The microfoundations of wage and price rigidity

So the problem in the late 1970s and early 1980s was clear. Most of economics was based on models of perfect competition, where all agents are price-takers. An agent is a ‘price-taker’ if it believes that it can trade any quantity at the market price which it treats as given, or exogenous. Price-taking makes sense only when markets clear, and supply equals demand. If supply does not equal demand, then something has got to give because the chosen trades do not add up to zero. An alternative was needed. Up until then, various ad hoc assumptions had been made: the simplest was that wages and/or prices were simply assumed to be fixed (this was justified by the notion that the model was a short-run model). Another ad hoc fix was that the market was competitive but that the price cleared the market *ex ante*: the invisible auctioneer sets the price which he or she expects to clear the market before it opens. The basic and fundamental new Keynesian insight was that the assumption of price-taking behaviour had to be abandoned. Real agents such as firms, households or unions needed to be price-makers. But this meant that the notion of perfectly competitive equilibrium had to be abandoned: the alternative was going to be an imperfectly competitive equilibrium where (some) agents have market power. The classic imperfectly competitive equilibrium is pure monopoly: a monopolist can set any price he pleases, and will maximize profits. The monopolist equates marginal revenue with marginal cost: if he faces a downward sloping demand curve, this means that the monopolist will set a price above the competitive price and output will be lower than in the competitive equilibrium. While the firm increases its profits there is also a decline in consumer surplus and the total surplus (consumer plus producer) declines.

In the absence of market failure, the perfectly competitive equilibrium is Pareto optimal. If we are adopting a representative agent framework (as has most often been the case in macroeconomics since the neoclassical synthesis), Pareto optimality means that the equilibrium outcome maximizes the utility of the representative agent. Hence, if we look at small deviations from equilibrium (in terms of output, employment and so on), they will not have a first-order effect on welfare. This is an envelope theorem: the first-order conditions for optimality state that the first-order effect is zero at the optimum. With imperfect competition, by contrast, we start away from the optimum. Hence there are first-order effects of changes in output and employment: since the monopolist restricts output, an increase is good and a decrease bad. To many macroeconomists, this seems more plausible and common sense than the implication of the first welfare theorem that holds that, if one starts from the competitive equilibrium, increases and decreases in output and employment are both (slightly) bad.

The introduction of imperfect competition into a tractable general equilibrium framework (albeit a static one) was achieved by Oliver Hart (1982), who stressed the ‘Keynesian features’ of the model. However, Hart's was a real model without money: what was needed was to link this idea to nominal rigidity. It was
a few years later that the concept was taken up simultaneously in three papers: Akerlof and Yellen (1985), Mankiw (1985) and Parkin (1986). The new idea was that of ‘menu costs’, whereby there might be ‘costs’ to changing a price, which might be interpreted broadly as decision and implementation costs (the line taken by Akerlof and Yellen and interpreted as a sort of bounded rationality) or as literally the cost of implementing a price change (having new menus printed). This idea was not new: it was used by the (S,s) models of pricing with inflation developed in the 1970s by Sheshinski and Weiss (1977), and in some other papers in the non-macroeconomic literature.

The insight is that if a monopolist sets its price optimally, a small deviation from the optimum will have no first-order effect on profits. If there is a small but lump-sum cost of changing a price, then the effect of a price-setting monopolist to an increase in demand (or cost) might be to leave the price where it is, not to change it. Thus, even small menu costs can give rise to some nominal rigidity: because at the optimum there is no first-order effect on profits, the menu costs only have to overcome the smaller higher order effects. Thus began a theory of nominal rigidity based on monopolistic competition and menu costs. The nice feature of the model was that, although the menu costs could be small, the nominal rigidity they created would give rise to first-order welfare effects (since we start from a level of output and employment below equilibrium). Whilst the idea is very simple and powerful, it did alas run into a problem. In static models it is easy to use the menu-cost approach. However, macroeconomists in the 1980s were interested in dynamic models, and menu-cost models have proven very difficult to solve except under very special cases. For example, Caplin and Spulber (1987) looked at steady-state inflation and found that although the menu costs caused individual firms to have prices that remained fixed for a time, in aggregate prices they drifted up, with the aggregate money supply yielding the same aggregate output and inflation as with flexible prices. It has only been much later, since the late 1990s, that these models are beginning to be solved for interesting dynamic cases (under the new name ‘state-dependent pricing’ models).

However, the menu-cost idea spawned a large literature that looked into how certain features of the economy might allow even smaller menu costs to give rise to nominal rigidity. For example, Ball and Romer (1990) argued that if there were some real rigidity in the economy, it would interact with the nominal rigidity of prices, reducing the size of menu costs required to induce nominal rigidity. The real rigidity might take the form of an efficiency wage model, for example, where the equilibrium determined the real wage which was not sensitive to the level of economic activity. On the empirical level, Ball, Mankiw and Romer (1988) argued that the menu-cost theory had a clear prediction for the relation between inflation and the inflation–output trade-off. If steady-state inflation was higher, this would mean that for a given level of menu costs, firms would change prices more frequently (there is less nominal rigidity). This in turn would mean that changes in nominal demand would have less effect on output when inflation is higher. Thus the non-neutrality of money in the short run was higher in low-inflation economies than in high-inflation economies, which was confirmed in the data.

Whilst there has been until recently quite some difficulty in making state-dependent or menu-cost models tractable enough to model wage and price dynamics out of steady state, another class of models proved well suited to a dynamic setting. These were the time-dependent models of pricing, which focused on the notion of staggered wage- and price-setting: Taylor (1979) and Calvo (1983). Indeed, these two models have become the workhorses of the NNS framework. John B. Taylor's model focused on wage-setting: the empirical evidence suggests that many wage contracts take the form of a nominal
wage being set for a period of four quarters. However, wages in different sectors are negotiated at different times. It is usually assumed that there are four equally sized cohorts, one cohort resetting the wage each quarter. Whilst this framework does not explain why wage contracts last for a particular period, it does start out from firm empirical observation and works out the implications of this for the resultant process. What we find is that wages gradually adjust to their new steady state values. The reason for this is that when setting wages the current cohort is facing an aggregate price level partly determined by cohorts that have moved previously. At any one time, with four cohorts, three cohorts will not reset the wage: they reset their wages in the previous three quarters. When the union sets its wage, it looks at what the aggregate price level and demand will be over the period of the contract: in this sense the wage-setting rule is dynamic and forward looking. However, it is also looking back at the previous wages insofar as they are reflected in the current price. This results in a gradual adjustment of wages and prices in response to a nominal shock. Taylor (1999) provides a good survey of this approach.

Calvo's model of nominal rigidity is based on a constant hazard rate model: each period, the firm or union faces a given probability of resetting its price or wage. The expected duration of the price or wage when it is set is the reciprocal of the reset probability. When the firm sets its price it looks into the infinite horizon, and takes into account the future price with the probability that the current price being set will still be in force. Thus, if the reset probability is 0.25 per quarter, we will observe 25 per cent of firms resetting price in any one quarter. In setting the price, each firm expects that the price will last for four quarters, but there is an ever diminishing probability that it might last ever longer. If we look across all firms, the average contract length will be about twice the life expectation at birth (twice the life expectation at birth minus 1). Thus a reset probability of 0.25 implies an average lifetime of prices set by all firms across the economy of seven quarters (see Dixon and Kara, 2006). The firms choose an optimal price in a dynamic setting, but the setting itself leaves the fundamental probability of resetting the price unexplained. However, the model is highly tractable and has since become very popular.

Other new Keynesian themes

Whilst the theoretical microfoundation of nominal rigidity was the main theme of the new Keynesian economics, other themes aimed to establish the implications of imperfect competition and other market imperfections as an alternative equilibrium concept to perfect competition.

One theme that ran through the new Keynesian literature that did not involve nominal rigidity was the effect of imperfect competition on the government expenditure multiplier. Papers by Dixon (1987) and Mankiw (1988) found that in simple general equilibrium models an increase in the degree of imperfect competition reflected in a bigger markup of price over marginal cost meant that the balanced budget government multiplier was bigger. The intuition behind this result was that there was a profit feedback effect: as output increased, so did firms' profits, which were paid back to households in dividends, part of which were spent again, and so on. This feedback effect was bigger than the markup. In a constant returns to scale world, there were no profits in a perfectly competitive equilibrium, so the effect was completely absent. In a follow-up paper, Startz (1989) argued that whilst the Dixon–Mankiw result held in the short run with a fixed number of firms, in the long run free entry would eliminate profits and the relationship between profits and the multiplier would disappear. This argument turned out to be true in general only in the case of constant returns to scale. The point is that when you allow for a concave
production function with diminishing marginal product of labour, a second mechanism comes into effect: as employment rises, the real wage falls, which tends to reduce consumption. In the Walrasian case of perfect competition, the real wage effect always dominates the profit effect: the long-run multiplier with free entry is always greater than the short-run multiplier. It follows that if there is only a little imperfect competition, this will still be true, as shown in Dixon and Lawler (1996). Startz's result holds because with a constant marginal product of labour the real wage mechanism is absent and only the profit feedback is present.

It should be noted that the fiscal multiplier is still always less than unity. What is happening is that in equilibrium imperfect competition leads to lower real wages (the markup in the product market leads to real wages being below the marginal product). Households react to this by choosing more leisure and less consumption for any given utility level (the level of economic activity is below the perfectly competitive level). Now, an increase in government expenditure financed by a lump-sum tax makes the household worse off; so the household reacts by reducing its consumption and leisure (less leisure means working harder). The reason the short-run multiplier tends to be larger when there is more imperfect competition is that the equilibrium ratio of leisure to consumption is larger, so the effect of the tax on labour supply is larger, resulting in a bigger overall increase in labour supply and hence less crowding out of consumption. The mechanism underlying this is essentially a supply side effect, which is not exactly what some people might think of as ‘Keynesian’.

The notion of ‘coordination failure’ was also important in the new Keynesian thought. The idea arose out of the concept of strategic complementarity. Strategic complementarity occurs when the marginal benefit from the action of one agent is increasing in the level of activity chosen by other agents. Effectively, the reaction functions are upward sloping. Cooper and John (1988) applied this idea to several macroeconomic applications, including search models and demand spillovers in multi-sector economies, and the subsequent literature has applied this concept to almost any model with positive externalities. One interesting feature of the coordination failure approach is that there may be multiple equilibria: if this is so and the equilibria are symmetric the equilibria will be Pareto ranked. With positive externalities the high activity equilibria will Pareto dominate the low-level equilibria. The existence of multiple equilibria is not easy to establish: it requires as a necessary condition that the slope of the reaction function must be greater than 1 for some values in between the two symmetric equilibria.

In the labour market, there were several developments in the new Keynesian literature. Perhaps the most important was the development of efficiency wage models. Whilst the model of efficiency wages had a long pedigree, it was seen as a way of modelling how firms might set wages at a level different from the competitive level. In Shapiro and Stiglitz (1984), the internal monitoring problem faced by the firm is influenced by the level of unemployment, since the higher the level of unemployment the costlier it is for an employee to lose his or her job. Unemployment can therefore act as a disciplining device. This model predicts that firms will be forced to pay workers a higher wage when unemployment is lower, leading to a theoretical explanation of pro-cyclical wages.

The new neoclassical synthesis (NNS)

In the 1990s, the new Keynesian ideas become part of the NNS approach, which is a combination of the dynamic structures developed by the RBC theory with a nominal side to the economy, which is based on imperfect competition and nominal rigidity. One of the main contributions has been the new Keynesian
Phillips curve: this can be derived from both the Calvo and Taylor models of dynamic pricing (see Roberts, 1995). The equation relates current inflation to current output and expected inflation next period

\[ \pi_t = \beta E_t \pi_{t+1} + \kappa y_t. \]

where inflation is \( \pi_t \), the discount rate is \( \beta \) and output (deviation from capacity) is \( y_t \). This differs from the traditional Phillips curve in which the expectation of current inflation appears on the right-hand side. The coefficient on the output gap is related to the probability the firm can reset its price, the discount rate and a parameter capturing the sensitivity of marginal cost to output. Empirically, the new Keynesian Phillips curve has not done very well. The evidence seems to support the idea that lagged inflation needs to be included as well (resulting in the so-called ‘hybrid Phillips curve’). This has led to the idea that indexation might be important: in the periods when firms cannot set prices or wages explicitly, they are updated by a ‘rule of thumb’ using last periods inflation rate (see Christiano, Eichenbaum and Evans, 2005) which results in a hybrid Phillips curve.

The Keynesian notion of demand management is very much at the centre of the analysis of monetary policy: the central bank is seen as using interest rate policy to stabilize the economy in two senses. The overall policy design should be to stabilize expectations and rule out explosive or indeterminate solutions: the possibility of economic turbulence caused by sunspot equilibria is seen as welfare reducing and is to be avoided (this is called extrinsic uncertainty). Thus policy should give rise to a unique rational expectations equilibrium path. In most models, a necessary condition for a unique equilibrium path is that the interest rate policy satisfies the Taylor principle, which states that if nominal inflation rises the central bank should raise the nominal interest rate by more, so that the real interest rate rises. Monetary policy should also be designed to stabilize the economy in response to real shocks, the intrinsic uncertainty facing the economy. This has been dubbed by some the ‘science of monetary policy’ (see Clarida, Gali and Gertler, 1999). Of course, the new Keynesian science is different from the old Keynesian art in that the interest rate is the only instrument and fiscal policy is reduced to providing a prudent and sustainable regime of expenditure and taxation. But the view is still Keynesian in that the economy needs and benefits from having an active monetary policy.

An evaluation

The most lasting legacy of the new Keynesian economics was to put imperfect competition and non-competitive models at the heart of macroeconomics. For a long time many economists had been impatient with the assumption of market clearing/demand equals supply as a basis for macroeconomics. However, a quest for a rigorous and consistent alternative was in place since Keynes's *General Theory* in 1936 raised more questions than it had answered. Whilst the book had given rise to the notion of using fiscal and monetary policy to stabilize the economy, this remained a practical art without a proper theoretical framework to underpin it. The macroeconomic theory developed was not consistent with standard microeconomics and was in this sense unsatisfactory. The real achievement of the new
Keynesian literature was to provide the theoretical alternative to demand and supply economics that was rigorous and microfounded. Economics has always been ideological as well as scientific. There are those free market ideologues who believe that the free market is almost always the best and that the state should intervene as little as possible in the market. There are also those who believe that although markets are pretty good at many things, they can also malfunction and so maybe there is a role for some sort of public policy. In macroeconomics this polarity was at its most obvious in the 1980s and 1990s. The real business cycle theorists used models with perfect markets and were largely of the ‘free-market’ variety of economists. The new Keynesian economics provided a rigorous alternative to the free-market perspective and as such has left a lasting legacy which we can see is firmly embedded in the way nominal rigidity is understood and monetary policy is practiced.

Further reading

Insofar as there is a defining book of the new Keynesian macroeconomics, it is Mankiw and Romer’s two-volume collection (1991). Some good surveys were made in the early 1990s: Gordon (1990) is one; Silvestre (1993) focuses on the issue of imperfect competition; Dixon and Rankin (1994) focused more on the implications for macroeconomic policy issues. There was also a Journal of Economic Perspectives symposium on ‘Keynesian Economics Today’ in 1993 (volume 7, number 1) which takes a broader view of new and old Keynesian macroeconomics. On the NNS approach, the monetary policy aspects are well surveyed by Clarida, Gali and Gertler (1999), and for text book treatment of the modelling foundations turn to Walsh (2003, ch. 5) and Woodford (2003, ch. 3). There is also an excellent survey of several NNS models of nominal rigidity in Ascari (2003).

new open economy macroeconomics

Giancarlo Corsetti
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

‘New open economy macroeconomics’ (NOEM) refers to a body of literature embracing a new theoretical framework for policy analysis in open economy, aiming to overcome the limitations of the Mundell–Fleming model while preserving the empirical wisdom and policy friendliness of traditional analysis. NOEM contributions have developed general equilibrium models with imperfect competition and nominal rigidities, to reconsider conventional views on the transmission of monetary and exchange rate shocks; they have contributed to the design of optimal stabilization policies, identifying international dimensions of optimal monetary policy; and they have raised issues about the desirability of international policy coordination.

Article

The new open economy macroeconomics (NOEM) is a leading development in international economics that began in the early 1990s. Its objective is to provide a new theoretical framework for open economy analysis and policy design, overcoming the limitations of the Mundell–Fleming model, while preserving the empirical wisdom and the close connection to policy debates of the traditional literature. The new framework consists of choice-theoretic, general-equilibrium models featuring nominal rigidities and imperfect competition in the markets for goods or labour. In this respect, the NOEM has close links with related agendas pursued in closed-economy macro, such as the ‘new neoclassical synthesis’ and the ‘neo-Wicksellian’ monetary economics. The assumption of imperfect competition is logically consistent with the maintained hypothesis that firms and workers optimally choose prices and wages subject to nominal frictions, as well as with the idea that output is demand-determined over some range in which firms (workers) can meet demand at non-negative profits (surplus).

NOEM models differ from the Mundell–Fleming approach in at least two notable dimensions. First, all agents are optimizing, that is, households maximize expected utility and managers maximize firms' value. The expected utility of the national representative consumer thus provides a natural welfare criterion for policy evaluation and design. Second, general-equilibrium analysis paves the way towards further integration of international economics as a unified field, bridging the traditional gap between open macroeconomic and trade theory.

From a historical perspective, NOEM was launched by Obstfeld and Rogoff (1995), although Svensson and van Wijnbergen (1989) had also worked out a model with NOEM features as an open economy development of Blanchard and Kiyotaki (1987).

A specific goal of the NOEM agenda is to achieve the standards of tractability which made traditional models so popular and long-lived among academics and policymakers. For instance, many contributions have adopted the model specification by Corsetti and Pesenti (2001), which admits a closed-form solution by virtue of some educated restrictions on
preferences (Tille, 2001, explains the relation of this model to Obstfeld and Rogoff, 1995). At the same time, the NOEM literature has promoted the construction of a new generation of large, multi-country quantitative models by international institutions and national monetary authorities. A leading example is the Global Economic Model (GEM) of the International Monetary Fund (see, for example, Laxton and Pesenti, 2003).

This article first introduces a stylized NOEM model. Based on this model, it then provides a short selective survey of the NOEM literature, and its main advances in the analysis of the international transmission mechanism and policy design in open economies.

1A stylized NOEM model

To illustrate the basic features of NOEM models, highlighting similarities and differences with the Mundell–Fleming model, it is useful to refer to the model by Corsetti and Pesenti (2001; 2005a; 2005b) and Obstfeld and Rogoff (2000) (henceforth CP–OR). The economy consists of two countries, Home and Foreign, specialized in the production of one type of tradable goods, denoted H and F, respectively. Home consumption falls on both local goods and imports, that is, \( C = C(CH, CF) \); the price level \( P \) includes both local goods and imports prices in Home currency, that is, \( P = P(P_H, P_F) \). Preferences over local and imported goods are Cobb–Douglas with identical weights across countries: as the elasticity of substitution is equal to 1, any increase in domestic output is matched by a proportional fall in its price, so that terms-of-trade movements ensure efficient risk sharing. Furthermore, utility from consumption is assumed to be logarithmic, while disutility from labour \( \ell \) is linear.

Let \( \mu \) index the Home monetary stance. Specifically, \( \mu \) is the nominal value of the inverse of consumption marginal utility – for example, with log utility, \( \mu = PC \). Whatever the instruments used by monetary authorities, \( \mu \) indexes its ultimate effect on current spending. With competitive labour markets, the Households' optimality conditions imply that the nominal wage moves proportionally to \( \mu \), that is, \( W = \mu \). Furthermore, abstracting from investment and government spending, \( \mu \) indexes nominal aggregate demand. Similar definitions and conditions hold for the Foreign country, whose variables are denoted with a star, that is, \( \mu^* = W^* \).

Let \( \varepsilon \) denote the nominal exchange rate, measured in units of Home currency per unit of Foreign currency. With perfect risk sharing, it is well known that the real exchange rate \( \varepsilon P/P^* \) is equal to the ratio between the two countries’ consumption marginal utilities (see Backus and Smith, 1993). Rearranging this condition, the nominal exchange rate is equal to the ratio of Home to Foreign monetary stance, that is, \( \varepsilon = \mu / \mu^* \). A Home expansion depreciates \( \varepsilon \).

Goods are supplied by a continuum of firms, each being the only producer of a differentiated variety of the national good. For simplicity, production is linear in labour. With nominal rigidities, managers optimally set prices as to maximize the market value of the firm. (Since households are assumed to own firms, the discount factor used in calculating the present value is the growth in the marginal utility of consumption.) In the CP–OR model, prices are preset for one period and marginal costs coincide with unit labour costs \( W/Z = \mu / Z \). In this model, optimal pricing actually takes a form that is very similar to textbook monopoly pricing: Home firms selling in the domestic market set \( P_H \) by charging the optimal markup over expected marginal costs, that is:

\[
P_H = \text{markup} \cdot \varepsilon \left( \frac{\mu}{Z} \right)
\]

where \( E \) denotes conditional expectations. If prices were flexible, the above would hold with current instead of expected costs.

When modelling nominal rigidities in the exports market, however, the following issue arises: are export prices sticky in the currency of the producers or in the currency of the destination market? In the NOEM literature, this issue has fed an extensive debate on the international transmission mechanism and the design of optimal stabilization policies, discussed in detail in the next sections.

The equilibrium allocation can be characterized in terms of three equilibrium relationships, labelled AD, TT and NR. In Figure 1, these are drawn in the space ‘consumption’ vs. ‘labour’, \( C \) vs. \( \ell \). The horizontal AD locus represents the Home aggregate demand in real terms, given by the ratio of the monetary stance to the price level: \( C = \mu / P \). The upward-sloping TT locus shows the level of consumption that Home agents obtain (at market prices) for \( \varepsilon \) units of labour. The slope of the TT locus depends on the (exogenous) productivity level \( Z \), and the (endogenous) price of domestic GDP \( (Y=Z\varepsilon) \), in terms of domestic consumption \( \tau \), that is, \( C = \tau \cdot Z \cdot \varepsilon \). Since agents consume both local goods and imports, \( \tau \) rises with an improvement in the terms of trade of the Home country, conventionally defined as the price of imports in terms of exports. The vertical NR locus marks the equilibrium employment in the flexible prices (or natural rate) allocation, \( \varepsilon^{\text{flex}} \). Because of firms’ monopoly power, \( \varepsilon^{\text{flex}} \) is inefficiently low. To stress this point, Figure 1 includes the indifference curve passing through the equilibrium point E, where it crosses the TT locus from above: with monopolistic distortions, the marginal rate of substitution between labour...
and consumption differs from the marginal rate of transformation.

Figure 1

With flexible prices, the macroeconomic equilibrium is determined by the NR locus and the TT locus. For a given $\mu$, nominal prices adjustment ensures that demand is in equilibrium. With nominal rigidities, the equilibrium is instead determined by the AD locus and the TT locus. Depending on the level of demand, employment may fall short of or exceed the natural rate, opening employment and output gaps proportional to $(\ell^{\text{flex}} - \ell)$.

2 The international transmission mechanism and the allocative properties of the exchange rate

According to traditional open macroeconomic models, exchange rate movements play the stabilizing role of adjusting international relative prices in response to shocks, when frictions prevent or slow down price adjustment in the local currency. At the heart of this view is the idea that nominal depreciation transpires into real depreciation, making domestic goods cheaper in the world markets, hence redirecting world demand towards them: exchange rate movements therefore have ‘expenditure switching effects’.
Consistent with this view, NOEM contributions after Obstfeld and Rogoff (1995) draws on the Mundell–Fleming and Keynesian tradition, and posits that export prices are sticky in the currency of the producers. Thus the nominal import prices in local currency move one-to-one with the exchange rate. This hypothesis is commonly dubbed ‘producer currency pricing’ (PCP).

Under PCP firms preset \( P_H \) and \( P_F^* \), so the Home country's terms of trade \( \varepsilon P_F^*/P_H \) deteriorate with unexpected depreciation. Moreover, as long as demand elasticities are identical in all markets, firms have no incentive to price discriminate: the price of exports obeys the law of one price, that is, \( P_H^* = P_H/\varepsilon \) and \( P_F^* = \varepsilon P_F^* \).

Monetary shocks have two distinct effects on the Home allocation and welfare. Expansions raise demand and output: because of monopolistic distortions in production, positive nominal shocks benefit domestic consumers by raising output towards its efficient (competitive) level. However, currency depreciation also raises the relative price of Foreign goods, reducing the real income of domestic consumers. In terms of Figure 1, monetary expansions shift the AD locus upward and, due to currency depreciation, cause the TT locus to rotate clockwise. The new equilibrium may lie either above or below the indifference curve passing through \( E \), the initial equilibrium. In other words, Home welfare may rise or fall, depending on the relative magnitude of monopoly power in production, vis-à-vis the terms-of-trade externality, in turn related to openness and the degree of substitutability between Home and Foreign tradables. (The size of the monetary shock also matters: by the same argument, by the theory of optimal tariffs a country never gains from monetary shocks which are large enough to raise output up to its competitive – Pareto-efficient – level.)

A noteworthy implication for policy analysis is that, in relatively open economies where terms-of-trade distortions are strong, benevolent policymakers may derive short-run benefits by implementing surprise monetary contractions, which appreciate the Home currency and boost the purchasing power of Home consumers. In these economies, monetary policy can have a deflationary bias.

In the Foreign country, welfare spillovers of a Home monetary expansion are unambiguously positive. Foreign consumers benefit from the terms-of-trade movement, which raises their income in real terms: the Foreign TT rotates counterclockwise. In addition, cheaper imports reduce inflation, raising aggregate demand for a given monetary stance \( \mu^* \): the Foreign AD shifts upward.

The high elasticity of import prices to the exchange rate underlying the above analysis is, however, at odds with a large body of empirical studies showing that the exchange rate pass-through on import prices is far from complete in the short run, and deviations from the law of one price are large and persistent (see, for example, Engel and Rogers, 1996; Goldberg and Knetter, 1997; Campa and Goldberg, 2005). This evidence has motivated a thorough critique of the received wisdom on the expenditure switching effects of the exchange rate. Specifically, Betts and Devereux (2000) and Devereux and Engel (2003), among others, posit that firms preset prices in the currency of the markets where they sell their goods. This assumption, commonly dubbed ‘local currency pricing’ (LCP), attributes local currency price stability of imports mainly to nominal frictions, with far-reaching implications for the role of the exchange rate in the international transmission mechanism (see Engel, 2003).

To the extent that import prices are sticky in the local currency, a Home depreciation does not affect the price of Home goods in the world markets; hence, it has no expenditure switching effects. Instead, it raises \textit{ex post} markups on Home exports: at given marginal costs, revenues in domestic currency from selling goods abroad rise. In contrast with the received wisdom, nominal depreciation strengthens a country’s terms of trade: if \( P_F^* \) and \( P_H^* \) are preset during the period, the Home terms of trade \( P_F^*/\varepsilon P_H^* \) improve when the Home currency weakens. In Figure 1, with LCP, a Home monetary expansion shifts aggregate demand AD upward and rotates the TT counterclockwise. It follows that monetary authorities cannot derive short-run welfare benefits from surprise contraction. As currency depreciation improves the terms of trade, the inflationary bias in policymaking is even stronger than in a closed economy.

International spillovers from Home monetary expansions are detrimental to Foreign welfare. If prices in local currency remain constant, a Home expansion does not at all affect the aggregate demand in the Foreign country. Yet the adverse terms-of-trade movement forces Foreign agents to work more to sustain an unchanged level of consumption: for a given AD, the TT locus rotates clockwise.

An interesting case with asymmetric transmission is one in which the prices of exports are all preset in one currency, so that Home firms adopt PCP while Foreign firms adopt LCP (see, for example, Devereux, Engel and Tille, 2003).

While the NOEM literature has encompassed additional real and financial aspects in the analysis of the transmission mechanism, the PCP versus LCP debate identifies essential building blocks of optimal stabilization policy.

### 3 International dimensions of optimal monetary policies

A defining question of open economy macroeconomics is whether monetary and fiscal policy should react to international variables, such as the exchange rate or the terms of trade, beyond the influence that these variables have on the domestic output gap (for example, via external demand) and domestic inflation (for example, via import prices). This is a research area where choice-theoretic NOEM models have comparative advantages over the traditional literature. Indeed early NOEM contributions have established a set of original and provocative results, setting benchmarks for further analytical and quantitative studies.
To account for these results, consider the stabilization problem in a CP–OR economy with country-specific productivity uncertainty. In a flexible price environment (corresponding to the long run of the CP–OR model), a positive productivity shock in the Home country causes the world price of Home goods to fall. This raises both domestic and foreign demand for Home output, and worsens the Home terms of trade. With sticky prices, by contrast, unexpected gains in productivity simply translate into lower employment: given \( \mu \) and \( \mu^* \) (hence given the exchange rate), current demand is satisfied with a lower labour input. (In Figure 1, a higher \( \Gamma \) rotates the TT locus counterclockwise. With the AD and the TT loci held fixed, the equilibrium employment is below the natural rate. A fall in domestic prices would shift the AD locus up, while offsetting part of the rotation of the TT locus. The flexible price equilibrium always lies on the NR locus.)

However, under the hypothesis of PCP, it is easy to see that monetary policy in a sticky-price environment can support the flexible price allocation. Posit that monetary rules satisfy \( \mu = \Gamma Z \), where \( \Gamma \) denotes a (possibly time-varying) variable indexing the level of nominal variables in the Home country. When such rules are implemented, any gain in productivity is matched by a proportional expansion of the monetary stance, which raises Home demand and depreciates the Home currency. Marginal costs remain constant in nominal terms (since \( \mu / Z = \Gamma \) ): hence product prices in domestic currency would remain fixed even if there were no nominal rigidities. At the same time, however, exchange rate movements adjust international relative prices, as monetary policy moves \( \epsilon \) in proportion to productivity changes.

A first benchmark result is that, in economies with the CP–OR features, monetary policy rules supporting the flexible price allocation are optimal: no rule welfare-dominates complete marginal cost and output gap stabilization. This is true under different assumptions regarding nominal rigidities, including staggered price setting and partial adjustment (see, for example, Clarida, Galí and Gertler, 2002). Optimal monetary rules are completely ‘inward-looking’: welfare-maximizing central banks stabilize the GDP deflator while letting the consumer price index (CPI) fluctuate with movements in the relative price of imports. There is no need for monetary policies to react to international variables.

The result that monetary rules supporting a flexible price allocation are optimal, however, does not hold in general. In the presence of multiple distortions monetary authorities are generally able to exploit nominal rigidities and improve welfare relative to such allocation (Benigno and Benigno, 2003; Corsetti and Dedola, 2005). Yet, holding PCP, it is unclear whether and under which conditions deviating from full domestic stabilization could yield significant welfare gains.

A second result concerns the costs of inefficient stabilization. The New Keynesian theory has emphasized welfare costs from relative price dispersion when private pricing decisions are not synchronized (see, for example, Galí and Monacelli, 2003). Early NOEM contributions have instead pioneered the analysis of the effect of uncertainty on the level of prices and economic activity. A simple example illustrates this point. Suppose that monetary policy responds to productivity shocks according to rule: \( \mu = \Gamma Y \). When \( \gamma < 1 \), marginal cost uncertainty due to insufficient stabilization implies \( \mathbb{E}(\mu / Z) = \Gamma \mathbb{E}(1/Z^{1-\gamma}) > \Gamma \) : by a straightforward application of Jensen's inequality, expected marginal costs are higher than under complete stabilization. Higher costs transpire into higher prices both in nominal terms and relative to wages, reducing the average supply of domestic goods, thus exacerbating monopolistic distortions in the economy (see, for example, Sutherland, 2005, and Kollmann, 2002, for a quantitative assessment).

Similar effects, with potentially stronger welfare implications, are caused by a noisy conduct of monetary policy and exchange rate variability (Obstfeld and Rogoff, 1998). Notably, Broda (2006) provides evidence consistent with the (NOEM) prediction that incomplete stabilization and monetary/exchange rate noise transpire into higher price levels and real appreciation.

A third result, derived on the assumption of LCP, defines a clear-cut argument in favour of policies with an international dimension. To the extent that exporters' revenues and markups are exposed to exchange rate uncertainty, firms' optimal pricing strategies internalize the monetary policy of the importing country. In the CP–OR model, for instance, Foreign firms optimally preset the price of their goods in the Home market \( P_F \) by charging the equilibrium markup over expected marginal costs evaluated in Home currency, that is,

\[
P_F = \text{markup} \cdot \mathbb{E}\left(\frac{\mu^*}{Z}\right) = \text{markup} \cdot \mathbb{E}\left(\frac{\mu}{Z}\right).
\]

Clearly, the price of Home imports depends on the joint distribution of Home monetary policy and Foreign productivity shocks.

Suppose that Home monetary authorities ignore the influence of their decisions on the price of Home imports. For the reason discussed above, import prices will tend to be inefficiently high. On the other hand, if Home monetary authorities want to stabilize Foreign firms' marginal costs, they can only do so at the cost of raising costs and markup uncertainty for Home producers, resulting in higher Home good prices. It follows that, to maximize Home welfare, Home policymakers should optimally trade off the stabilization of marginal costs of all producers (domestic and foreign) selling in the Home markets.

When foreign firms' profits are exposed to exchange rate uncertainty, optimal monetary rules are no longer inward-looking. The importance of Foreign shocks in the conduct of monetary policy depends on the degree of openness of the economy, measured by the overall share of imports in the CPI (see Corsetti and Pesenti, 2005a, and Sutherland, 2005, for a discussion of intermediate degrees of pass-through, and Smets and Wouters, 2002, and Monacelli, 2005, for models with staggered price setting).
Notably, the case for an international dimension in monetary policy described above transpires into limited exchange rate variability. Since with LCP optimal monetary policies respond to both domestic and foreign shocks, national monetary stances tend to be more correlated than in the case of inward-looking stabilization of output gaps. This implies lower exchange rate volatility. In the baseline CP–OR model, the optimal policy rules actually prevent any short-run fluctuations of the exchange rate, a point stressed by Devereux and Engel (2003). But this exact result holds only when the weights of Home and Foreign goods in final expenditure are assumed to be identical across countries: Home and Foreign monetary authorities de facto stabilize the same weighted average of marginal costs. The presence of non-traded goods or some Home bias in consumption would obviously imply asymmetries in the optimal monetary stances, which would be incompatible with a fixed exchange rate (Duarte and Obstfeld, 2007; Corsetti, 2006). Even if, with LCP, exchange rate variability does not perform any role in adjusting international prices, a fixed rate regime would impose unwarranted constraints on the efficient conduct of monetary policy.

A fourth result concerns the desirability of international policy coordination. Leading NOEM contributions have fed considerable scepticism on this issue. At the core of this scepticism is the disappointing quantitative assessment of welfare gains from coordination. By using the CP–OR model, for instance, it is possible to build economies with either PCP or LCP behaviour, where optimal monetary rules are identical whether national policymakers act independently or cooperatively (maximizing an equally weighted sum of national welfare functions). When this exact result breaks down (depending on the elasticity of substitution between Home and Foreign tradables, and/or sector-specific shocks in the presence of non-tradables), gains from coordination usually remain quite small (see, for example, Pappa, 2004; Benigno and Benigno, 2006).

The lesson from the NOEM literature, stressed by Obstfeld and Rogoff (2002), is a new welfare-based argument against coordination: once policymakers independently pursue efficient stabilization policies in their own country (that is, they ‘keep their house in order’), the room for improving welfare through cooperation is quite limited (see Canzoneri, Cumby and Diba, 2005, for a discussion).

The results reviewed above were first derived in highly stylized economies. A critical question directing current NOEM research is whether they would still hold in richer models with good quantitative performance.

4 Challenges to the NOEM literature

The above debate on the role of exchange rate in the international transmission has motivated further empirical and theoretical work on market segmentation along national borders and on its implications for international macroeconomic adjustment. As stressed by Obstfeld and Rogoff (2001), despite the ongoing process of real and financial globalization, frictions and imperfections appear to keep national economies ‘insular’.

An important issue is the extent to which the evidence of local currency price stability of imports can be explained by nominal rigidities. It is well understood that the low elasticity of import prices with respect to the exchange rate is in large part due to the incidence of distribution (Burstein, Eichenbaum and Rebelo, 2007). Several macro and micro contributions have emphasized the role of optimal destination-specific markup adjustment by monopolistic firms depending on market structure (Dornbusch, 1987; Goldberg and Verboven, 2001), or vertical interactions between producers and retailers (Corsetti and Dedola, 2005).

The main point is that low pass-through is not necessarily incompatible with expenditure switching effects (see, for example, Obstfeld, 2002). In this respect, Obstfeld and Rogoff (2000) emphasizes that, in the data (and consistent with the received wisdom), nominal depreciation does tend to be associated with deteriorating terms of trade. This piece of evidence clearly sets an empirical hurdle for LCP models, if we assume a high degree of price stickiness in local currency (see Corsetti, Dedola and Leduc, 2005, for a quantitative assessment). Interestingly, estimates of LCP models downplaying price discrimination, distribution and other real determinants of incomplete pass-through predict that the degree of price stickiness is implausibly higher for imports than for domestic goods, a result suggesting model misspecification (see, for example, Lubik and Schorfheide, 2006).

Moreover, the currency denomination of exports prices should be treated as an endogenous choice by profit maximizing firms (see, for example, Bacchetta and Van Wincoop, 2005; Devereux, Engel and Storgaard, 2004). To appreciate the contribution by the NOEM literature on this issue, recall that, in the CP–OR model above, expansionary monetary shocks unrelated to productivity raise nominal wages and marginal costs while depreciating the currency. For a firm located in a country with noisy monetary policy, pricing its exports in foreign currency (that is, choosing LCP) is therefore quite attractive: it ensures that revenues from exports in domestic currency will tend to rise in parallel with nominal marginal costs, with stabilizing effects on the markup. This may help explain why exporters from emerging markets with relatively unstable domestic monetary policies prefer to price their exports to advanced countries in the importers’ currency. The same argument, however, suggests that LCP is not necessarily optimal for exporters producing in countries where monetary policy systematically stabilizes marginal costs (see Goldberg and Tille, 2005, for empirical evidence).

New waves of studies are building models with trade costs where goods tradability is endogenous, and/or new varieties are created at business cycle frequencies. Trade and transaction costs are also at the heart of recent attempts to integrate current account and macroeconomic dynamics with international portfolio diversification in a unified analytical framework (see, for example, Devereux and Sutherland, 2007).

The discussion above is far from exhausting the range of topics and issues analysed by the NOEM literature, which has marked a radical change of paradigm in international macroeconomics. Many authors have undertaken a systematic reconsideration of classical themes in the new framework. A partial list of themes includes overshooting (for example,
Yet most NOEM contributions so far specify models which predict a counterfactually high degree of consumption risk sharing: even when financial markets are incomplete, intertemporal trade and terms-of-trade spillovers ensure that the consumption risk of productivity shocks is contained, and the market allocation is not too distant from the efficient one (see, for example, Chari, Kehoe and McGrattan, 2002). Not only this is inconsistent with a large body of evidence (see Backus and Smith, 1993); most crucially, a counterfactually high degree of risk sharing built in NOEM models may limit their capacity to comprehend significant cross-border spillovers and policy trade-offs. Similarly, in most models the exchange rate is tightly related to fundamentals, at odds with a large body of evidence showing that the relation between the exchange rate and virtually any macroeconomic aggregate is exceedingly weak – the so-called disconnect puzzle.

Further progress in these areas is crucial towards the fulfilment of the NOEM research agenda.

Bibliography

Newcomb, Simon (1835–1909)

Milton Friedman

Edited by Steven N. Durlauf and Lawrence E. Blume

Article

Newcomb entitled his autobiography Reminiscences of an Astronomer (1903), devoted only 10 pages out of 416 to his activities in economics, and remarked: ‘Being sometimes looked upon as an economist, I deem it not improper to disclaim any part in the economic research of today’ (p. 408). The 1913 Encyclopaedia Britannica in a lengthy article describes him as ‘one of the most distinguished astronomers of his time’ and includes one sentence, ‘He also wrote on questions of finance and economics.’ The 1970 edition of the Encyclopaedia describes him as ‘the greatest American astronomer of the 19th century’ and repeats the remark that ‘he wrote on finance and economics’. Those may well be correct evaluations of the relative importance of Newcomb’s work in astronomy and economics. Yet they give a wholly misleading impression of the absolute importance of his contribution to economics. He wrote two classics of economic science: A Critical Examination of Our Financial Policy during the Southern Rebellion (1865) and Principles of Political Economy (1885). The first ‘contains the most sophisticated, original, and profound analysis of the theoretical issues involved in Civil War finance that we have encountered, regardless of date of publication’ (Friedman and Schwartz, 1963, p. 18). The second contains what Irving Fisher, in his obituary note on Newcomb, regarded as ‘his chief and most fruitful contribution to economic science’, namely,

the distinction he applied in particular to what he called ‘societary circulation’, or the equation of exchange between money and goods. So far as I am aware, he was the first definitely to enunciate this equation, expressing the fact that the quantity of money multiplied by its velocity of circulation is equal to price-level multiplied by volume of business transactions. This equation, with due amplifications, represents the so-called ‘quantity theory of money’ in its highest form. He also employed this same distinction … to expose the fallacy of ‘the wage-fund’. (Fisher, 1909, p. 642)
Another notable item in the *Principles* is its final chapter, ‘Of Charitable Effort’, an economic analysis of charity that is highly relevant to modern problems of the welfare state, in part because Newcomb writes about currently sensitive issues with a frankness and plainness that is absent from contemporary literature.

In addition to these two books, Newcomb published well over 50 popular magazine articles on economic issues, some of which formed the basis for two popular books: *The ABC of Finance* (1877) and *A Plain Man's Talk on the Labor Question* (1886). The latter, which was still in print in the 1980s, remains today an extraordinarily persuasive and effective exposition of the basic principles of a market economy and the effects of labour union activity on the interests of the worker.

Had these items constituted the whole of Newcomb's canon, instead of only a surprising few out of a total of well over 500 items, including not only major works in astronomy but also textbooks in mathematics, important contributions to statistics, and even a science fiction novel, he would have come to be regarded as one of the leading American economists of the 19th century. Irving Fisher noted that one reason ‘his economic writings did not attract the attention among economists which they deserved … is that … once a man's name becomes associated with a particular department of knowledge like astronomy, any attempts to contribute to other departments encounter a prejudice which it is difficult to overcome’ (Fisher, 1909, p. 641). Perhaps also it was not irrelevant that he was completely self-taught in economics, as in much else.

Newcomb was born on 12 March 1835 in a small town in Nova Scotia, son of an impecunious country school teacher. He died on 11 July 1909, and was buried with all the military pomp due to his congressionally conferred rank of Rear Admiral, a remarkable transition due entirely to Newcomb's own talents, character and persistence. Though his only formal schooling consisted of occasional attendance at his father's schools, he early displayed unusual intellectual interests and capacities. As what seemed in that remote region and time the only avenue of further instruction, he was apprenticed at the age of 16 to a herb doctor for a five-year period. The doctor turned out to be a quack who treated Simon as a slave, and provided no training whatsoever.

After two years, Simon finally summoned up the courage to run away, hiding in the woods as his erstwhile master sought to track him down. He joined his father, who had gone to New England after the death of Simon's mother, and father and son made their way to the Eastern Shore of Maryland, where both found employment as country teachers. Despite being entirely self-taught, Simon started to write articles on mathematical and astronomical subjects, one of which he sent to Professor Henry, Secretary of the Smithsonian Institute. This led to Professor Henry's becoming interested in Newcomb and ultimately recommending him for a job as a 'computer' at the Nautical Almanac in Cambridge, Massachusetts – an event which Newcomb described as ‘an epoch – an entrance into a new world’.

Employment at the Nautical Almanac enabled him to take courses at the Lowell Scientific School of Harvard University, where he received a degree in 1857. In 1861 he received a commission as professor of mathematics at the US Naval Observatory; in 1877 he was appointed superintendent of the Nautical Almanac, and in 1884 professor of mathematics and astronomy at the Johns Hopkins University, a position he held concurrently with his posts at the Naval Observatory and the Nautical Almanac.

In addition to his prodigious written output, Newcomb served for many years as editor of the *American Journal of Mathematics* and was active in the National Academy of Sciences, and the American Association for the Advancement of Science, of which he was president in 1877. Truly a Renaissance

Newmarch, William (1820–1882)

D.P. O'Brien

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

monetary theory; prices; Newmarch, William; Tooke, Thomas

Article

Newmarch was born in Thirsk, Yorkshire, and died in Torquay. He had little formal education, but rose from the position of bank clerk to be a force in the City of London, being manager of Glyn Mills from 1862 to 1881. An excitable but effective speaker, he was a member of the Political Economy Club from 1852 (Treasurer 1855–82), and a considerable force in the (Royal) Statistical Society of which he was Secretary 1854–62 and President 1869–71. He was also elected a Fellow of the Royal Society and wrote for the *Morning Chronicle* and the *Economist*.

Newmarch was important as the principal author of the last two volumes of Tooke's monumental *History of Prices* (though, oddly, this publication, unlike Newmarch's own work in the *Economist*, did not employ index numbers), and as an economist in his own right for exploring the effects of the gold discoveries, public debt, and questions of monetary control. He was one of the leading opponents of the Currency School and the Bank Act of 1844, arguing that causality ran from prices to note issue, so long as the notes were convertible. He believed that monetary base control, as embodied in the 1844 Act, was not only ineffective – following the work of William Leatham he showed that the actual number of bills of exchange increased in times of monetary contraction – but that it produced, at times, both unnecessary stringency and harmful fluctuations in the rate of interest. Though his position was analytically underdeveloped his work is still of considerable interest.

Hukukane Nikaido graduated from the Department of Mathematics, University of Tokyo, in 1949. While he was a university student he became interested in economics and studied Marx's *Das Kapital*, Hicks's *Value and Capital* and Samuelson's *Foundations of Economic Analysis*. After graduating from the University of Tokyo and becoming an Associate Professor of Mathematics at the Tokyo College of Science, he wrote papers concerning the von Neumann growth model and the minimax theorem (1954a; 1954b; 1955). He also worked on the existence of equilibria in the general equilibrium model with many firms and many consumers. His paper had been completed independently of Arrow and Debreu (1954) and McKenzie (1954), and was published in *Metroeconomica* (1956a). One of his results in the existence proof is now known as Gale–Nikaido lemma. These achievements led him to visit Stanford in 1955–6 at the invitation of Kenneth Arrow. At Stanford, Nikaido started to work on the existence of general equilibria for an economy with infinitely many commodities (1956b; 1957), and then published in the *Journal of the Mathematical Society of Japan* (1959a). His contributions on the existence of general equilibria in the infinite dimensional space had long remained unknown.

After he returned from Stanford he was invited by Michio Morishima to join the Institute of Socioeconomic Research at Osaka University. There he began to work on the stability of general equilibria (1959b; 1960; 1964a). Osaka was very active in research in those days, and many well-known economists from abroad visited Osaka University. One was John Hicks, who in those days was interested in the turnpike theorem of multi-sector economic growth. Turnpike theorems had been proved by Morishima (1961) and Radner (1961). Radner’s result was improved by Nikaido (1964b). David Gale also visited Osaka in 1961. He and Nikaido wrote a joint paper (1965) on the uniqueness of solutions of
nonlinear simultaneous equations; the condition used in the paper has been called the Gale–Nikaido condition. In 1969 Nikaido moved from Osaka University to Hitotsubashi University in Tokyo. His previous research was published in a book, *Convex Structures and Economic Theory* (1968), which has been read by many graduate students and researchers worldwide.

After moving to Hitotsubashi University, he began to work on general equilibrium combined with monopolistic competition. Nikaido recognized, however, that the demand function, a partial equilibrium theoretic construction, involves inconsistencies in a general equilibrium situation. By introducing the concept of ‘objective demand functions’ Nikaido explored the existence of monopolistically competitive equilibria (1974). His research was published in *Monopolistic Competition and Effective Demand* (1975). Thereafter Nikaido developed his previous work on imperfect competition into a dynamic model (1978; 1979; 1980a). His main concern was in the theory of out-of-equilibrium adjustments. Nikaido also re-examined the knife-edge property in the Harrod–Domar model and the stability property in Solow's neoclassical growth model. He showed that the stability of Solow's model depends on the assumption that an investment is equal to a saving, rather than the smooth factor substitution as had been generally believed, and that, if an intended investment is not the same as a realized investment, the steady state solution is not necessarily stable and the imbalance is not solved even with flexible factor substitution (1975; 1980b).

In 1983 Nikaido joined Tsukuba University and later Tokyo International University. From then on he spent most of his time working on Marxian economics and then Keynesian models, using dynamic analysis developed in his earlier research. They were problems that he had been concerned with when he was a young university student.

Abstract

Noise traders are agents whose theoretical existence has been hypothesized as a way of solving certain fundamental problems in financial economics. We briefly review the literature on noise traders.

Keywords

‘no trade’ theorem; arbitrage; Grossman, S.; hedging; imperfect information revelation; information aggregation and prices; information costs; insurance motive; liquidity traders; market microstructure; market selection hypothesis; noise; noise traders; private information; rational expectations equilibrium

Article

‘Noise traders’ are economic agents who trade in security markets for non-information-based reasons. The existence of noise traders was theoretically posited as a solution to the ‘no trade’ or ‘no speculation’ results of Grossman and Stiglitz (1980) and Milgrom and Stokey (1982). These authors showed that it is impossible under most circumstances for an agent with superior information to profit from that information by trading. The intuition for the ‘no trade’ result is as follows. A buyer of an asset is prepared to pay a seller a price \( p \) only if the buyer believes that, conditional on the seller agreeing to sell the asset, the value of the asset exceeds \( p \). But then the seller, knowing this, is at least as well off keeping the asset. So no one trades.

But we do observe trade in the world. Moreover, no trade is difficult to reconcile with the notion of asset market efficiency, in which prices allegedly contain all available information. If some agents produce costly private information and then trade on their private information, security prices will reflect some or all of the information and hence become more informationally efficient. To explain how informed traders can cover the costs of information production when they trade in securities markets, someone in the market must lose money trading against them. ‘Noise traders’ or ‘liquidity traders’ are the names given to the traders who lose money, on average, when they trade. Their trade then provides the subsidy
to cover the informed traders' cost of information production.
The idea that there are traders who systematically lose money trading securities leads to obvious questions. Do noise traders really exist? Who exactly are noise traders in reality? How do noise traders survive and persist when they are losing money trading?

Rational expectations and efficient security markets

In security markets, prices are alleged to reflect ‘all available information’. But how does this come about? What is the information, and how is it aggregated into the price? The concept of a rational expectations equilibrium (REE) gave formal content to the notion of ‘market efficiency’, which has been a central concept in financial economics since the 1960s. The idea is that, if agents understand the economy and understand how markets work, they know that current prices reflect the information which is known to some agents but maybe not to others. The uninformed agents understand the link between current prices and the information of the informed agents, and so can infer something about the information in prices. When the prices that prevail in equilibrium coincide with what the uninformed agents can learn from the prices and with the actions taken by the informed agents, who trade on their information knowing that the uninformed agents will infer (some or all) of the information, then the equilibrium is said to be a rational expectations equilibrium. The idea that prices can convey information, in the sense of REE, is due to Lucas (1972). (See also Green, 1977, and Radner, 1979. Grossman, 1981, provides a brief intellectual history of REE; see also Allen and Jordan, 1998.)

But, when all the information of the informed agents is revealed in a fully revealing REE, there is a problem if information acquisition is costly. Grossman (1976) considers a model of the stock market in which there are two types of traders: ‘informed’ and ‘uninformed’. Informed traders take positions in the market based on their information. Uninformed traders have no information but know that prices will reflect the information of the informed traders. Grossman shows that the equilibrium prices aggregate and reveal the information perfectly, ‘but in doing this the price system eliminates the private incentive for collecting the information’ (1976, p. 574). Grossman is quite clear in identifying the paradox, but he also proposes a solution:

> When a price system is a perfect aggregator of information it removes private incentives to collect information. If information is costly, there must be noise in the price system so that traders can earn a return on information gathering. If there is no noise and information collection is costly, then a perfect competitive market will break down because no equilibrium exists where one collects information. (1976, p. 574; emphasis added)

Beja (1976) also argues that REE and costly endogenous information acquisition are not compatible when agents are strategic and that consequently asset prices cannot be efficient. So ‘noise’ is required if agents are to acquire and trade on their costly information. But what is this ‘noise’? The example of ‘noise’ that Grossman points to is ‘an uncertain total stock of the risky asset’ (1976, p. 574). He describes ‘noise’ simply as ‘many other factors’ (1977, p. 431). The device of adding a random noise term to the aggregate supply of the asset is used in Grossman and Stiglitz (1980). They show that, when information production is costly and there is noise in the asset supply, then some
traders will acquire information and trade, but rational expectations prices will not be fully revealing. If there is uncertainty about the supply of the asset in the market, or about the level of demand, or about the risk aversion of other traders, then uninformed traders cannot be sure that prices reflect the information of the informed traders. The basic idea is that the uninformed traders confuse the private information with uncertainty about the other unknown variables. It is this additional uncertainty, or noise, which makes it possible for the informed traders to trade without perfectly revealing their information, and hence profit from its production.

The device of adding a noise term to aggregate supply does result in REE that are only partially revealing. Unfortunately, there were two problems with this approach as a general matter. First, the partially revealing REE models require somewhat special assumptions. Second, it was not clear what the proposed noise shock to aggregate supply really corresponds to in reality. (There are other problems as well. Hellwig, 1980, pointed out that REE requires traders to act rationally with respect to information, yet they ignore the effect of their transactions on the price. This was deemed the ‘Schizophrenia problem’: ‘…Grossman's agents are slightly schizophrenic: (Hellwig', 1980, p. 478’. The model in Kyle, 1985, avoided this problem.) On the first point, Green's (1977) non-existence example uses a noise term on the traders' endowments, and suggests that this will not be a suitable basis for a general approach. The general equilibrium literature did develop a number of generalizations, including, for example, the difference between the dimensions of the signals and the dimension of the prices (see, for example, Jordan, 1983, and Ausubel, 1990). Others have provided slightly different models that have partially revealing equilibria, but still there seems to be no general approach (see, for example, Allen, 1981, and see Allen and Jordan, 1998, for a discussion).

**Noise traders**

REE models assume that traders maximize expected utility with rational beliefs, where rational beliefs are defined to be consistent with the model itself. There may be ‘noise’, but this was not viewed as emanating from incorrect beliefs. (There is the issue of how traders come to understand the model, that is, how they learn. On that question see, for example, Blume, Bray and Easley, 1982, and Blume and Easley, 2004.) In general, the notion of ‘noise’ in the REE literature was somewhat vague and corresponded to a random error term added to the aggregate excess demand function. Understanding the role of ‘noise’ appeared to require leaving the REE world and explicitly detailing the origin of noise. This was done by Kyle (1985).

Kyle posited the existence of ‘uninformed noise traders who trade randomly’ (1985, p. 1315). (In private correspondence, Kyle said that he did not coin the term ‘noise trading’ but attributes it to Sanford Grossman.) Kyle identified certain people as trading in a way which made noise in the sense that their trade was not based on information. That is, he explicitly posited the existence of a class of agents – people – who traded in a certain way so as to fulfil the role of ‘noise’. By explicitly introducing noise traders, Kyle focused attention on the details of the trading process. This became the foundation for the study of market microstructure. (Garman, 1976, appears to have been the first to use the term ‘market microstructure’. See Easley and O'Hara, 2003, for a survey of the microstructure literature.) Around the same time Kyle, Glosten and Milgrom introduced a similar class of agents: ‘…we assume that there are

In REE models agents do not act strategically; the process of learning from prices occurs in equilibrium (as opposed to happening in real time), and the details of trading are treated in reduced form (agents submit demand functions to an auctioneer). Kyle and Glosten and Milgrom changed this by specifying the trading process in a way that was not possible in REE models. In both papers there is a competitive market-maker who receives orders from traders, at least one of whom has superior information. The market-maker must infer the information of the informed trader from the order flow. The market-maker knows that some traders are privately informed, and that others are not trading based on any superior information (the noise traders). Inference about information occurs as the market-maker learns by watching the order flow. Gradually, the market-maker changes his price to reflect the information.

Still, the noise traders in this new type of model were not well-motivated. In fact, their motives are not explained. They earn a lower-than-average return than the informed agents, who earn an above-average return. If the uninformed noise traders could at least buy the market portfolio, then they could earn the average return on the market. But in fact they are not allowed to buy the market portfolio. That is their root problem (see Dow and Gorton, 1995).

Diamond and Verrecchia (1981) suggest adding a noise term to agents' risk exposures (their endowments). Risk-averse agents will then have an insurance motive for trading. DeMarzo and Duffie (1999) propose a model where different traders have different discount rates. Shocks to their discount rates provide an incentive to trade that other traders cannot distinguish from speculative trading intended to profit from information about the liquidation value of the asset. These papers solve the theoretical problem of finding a logically consistent model that can be used as a basis for economic analysis, including welfare statements, of markets with imperfect information revelation. Papers that have applied these models in various settings include Biais and Mariotti (2005) (for the DeMarzo and Duffie model) and Dow and Rahi (2000; 2003) (for the Diamond and Verrecchia approach).

But is it really plausible to believe that there is a significant demand for individual stocks or bonds based on an insurance motive? Stock indexes, exposure to the yield curve, or foreign currency could experience demand variations due to insurance motives, but there are close substitutes for individual stocks and bonds from a risk point of view. Also, if investors do start off with different discount factors, one would expect them to trade these differences away.

In other words, plausibly the demand curve for an individual asset should be almost perfectly elastic. The price at which it becomes elastic (given the prices of all other assets) should be almost identical for all agents. Hence, we revert to the situation where the asset has a unique fundamental value that all agents will agree on if they have the same information about the asset's cash flows. So the question of who noise traders actually are remains open.

**Who are the noise traders?**

The details of the identity of noise traders or liquidity traders were initially left vague. For example, Glosten and Milgrom write of exogenous events motivating their trade, like ‘job promotions or unemployment, deaths or disabilities…’ (1985, p. 77). These shocks were not well identified. Notably, noise traders were modelled as equally likely to be buying or selling securities, which, while making
Noise traders: The New Palgrave Dictionary of Economics

models technically tractable, is counter-intuitive. Exogenous reasons for needing money and hence having to sell securities seems more natural than exogenous reasons for having to buy securities. The details of the identity of noise traders are important, because if noise traders are simply irrational there is clearly an incentive for ‘smart money’ to take advantage of them, and eventually eliminate them from the market. The ‘market selection hypothesis’ holds that irrational traders will eventually be driven out of the market. Noise traders should not survive, and so cannot play the role envisioned for them. In fact, it has long been argued that rational traders will eliminate irrational traders from the market by taking their money when they trade at incorrect prices. This process is what causes prices to be driven to (or close to) fundamental values (see, for example, Friedman, 1953).

Noise traders can survive only if there are some frictions or barriers preventing them from being eliminated by the smart money. That is, there must be some limits to arbitrage. One possibility is that the smart money has a limited horizon over which trade can occur. With a limited horizon, the noise traders could cause losses to the smart money by moving prices further away from fundamentals. This is the idea in DeLong et al. (1990), Dow and Gorton (1994), and Shleifer and Vishny (1997). These papers argue that there are ‘limits to arbitrage’, providing an explanation for the persistence of noise trade. Still, the question remains: who are the noise traders? On one view, noise traders are simply individuals who are less than rational; they are subject to behavioural biases and fads. For example, Shiller (1984) argued that some investors rely on ‘popular models’ which are wrong, and also that they can be subject to fads. Along the same lines, Shleifer and Summers (1990, p. 19) wrote: ‘their demand for assets is affected by their beliefs or sentiments that are not fully justified by fundamental news.’ A large literature argues that individual investor trading is subject to a myriad of psychological biases, and that such individuals may use various heuristics, ‘popular models’, as the basis for their investment decisions. This literature is surveyed in Barberis and Thaler (2003).

A second rationale for noise trading focuses not on individual investors but on professional traders and money managers (‘funds’) hired by principals/investors. Funds do not invest and trade their own money; they work for others. This creates a potential conflict of interest or agency problem. This notion is developed by Dow and Gorton (1997). They argue that churning by funds, which occurs when they do not become informed and want to pretend that they have, is ‘noise’ in a setting where all market participants are rational. Among the other agents in the market are hedgers. Noise trading, being a manifestation of agency problems, reduces the profitability of traders to the employers of the traders and money managers. But it benefits hedgers who earn more when they hedge. Consequently, they hedge more, which in turn can support more informed fund trading. Dow and Gorton (1997) show that a ‘small’ amount of hedging demand can result in a ‘large’ noise. Irrationality is not needed to explain significant amounts of noise.

Summary

Noise traders play an essential role in modern finance theory, but their identities, motivations, and ability to persist remain topics of research. We thank Pete Kyle for comments.

nominal exchange rates

Richard T. Baillie
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The nominal exchange rate is the rate at which the currency of one country can be exchanged for that of another. The overall value of a currency can be summarized through the ‘effective nominal exchange rate’, which is a weighted average of a country's nominal bilateral exchange rates. Following the advent of freely floating exchange rates in 1973 there has been intense research on understanding the mechanisms of nominal exchange rate determination and the search for an adequate model, but no model has so far withstood rigorous empirical tests.

Keywords

Article

The nominal exchange rate is the price at which the money of one country can be exchanged for another. Usually, nominal exchange rates are bilateral, which means they denote the number of units of one country in terms of one unit of another; for example, two US dollars to one UK pound; or 0.50 UK pounds to one US dollar. Bilateral exchange rates can be expressed either in terms of spot rates, which are prices for immediate delivery, or in terms of forward contracts for delivery in the future. Some foreign exchange (FX) markets also trade currency options and futures. The worldwide FX market
nominal exchange rates: The New Palgrave Dictionary of Economics

transacted approximately $1,700bn a day in 2006, making it by far the largest financial market. On most weeks it operates for 156 of the 168 hours available, with New York, London and Tokyo being considered as the most important and heavily traded markets. Surveys of FX market participants generally suggests that 98 per cent or more of currency transactions are motivated by speculation, arbitrage and international capital movements, rather than for the purposes of importing or exporting goods.

The overall value of a particular currency can be summarized through the ‘effective nominal exchange rate’, which is a weighted average of a country's nominal bilateral exchange rates. A number of international financial institutions regularly report these effective rates, with different weights being used dependent on which criteria – for example, the patterns of trade – are being emphasized. A real exchange rate is the nominal bilateral exchange rate divided by the ratio of the price indices for the two countries. Usually consumer price indices (CPIs) are used for this purpose, although trade weighted price indices are also sometimes used.

**Historical perspective**

Following the end of the Second World War in 1945, a conference in Bretton Woods, New Hampshire established a system of fixed exchange rates based on the US dollar, with the US dollar in turn being convertible to gold at a fixed gold standard. However, continuing trade imbalances and apparent exchange rate misalignments led to a collapse of the Bretton Woods fixed exchange rate system in March 1973. Since then the international monetary system has generally followed what is best characterized as a managed or ‘dirty floating’ regime, with governments and/or central banks occasionally intervening to attempt to influence the value of the currencies and volatility of the market. Until the early 1990s the nominal rates between the three major regions of North America, Western Europe and Japan were formally freely floating. However, many bilateral rates were pegged under various arrangements. In particular, the European Monetary System (EMS) allowed individual countries currencies to move in a narrow band, named the ‘snake’ around par rates for each member country’s bilateral rate vis-à-vis the German Deutschmark. After several periods of apparent instability, such as the autumn of 1992 when the UK pound exited the EMS, and also the autumn of 1993 when the bands were widened to plus and minus 15 per cent of par rate; the new euro currency was introduced in 1999. Originally ten member countries of the EMS surrendered their sovereign currencies to form the euro area.

The other major development, converse to the formation of the euro, has been the collapse of communism in the late 1980s and the early 1990s, which has led many of the previously fixed exchange rates of eastern Europe and Asia to become floating rates.

As of 2007 the currencies of the US dollar, Japanese yen, euro, British pound, Swiss franc and Canadian dollar are the most actively traded, freely floating currencies.

**Empirical behaviour**

To a large extent nominal exchange values and returns behave in similar manner to other asset prices. On denoting the spot exchange rate at time $t$ as $S_t$, then $\Delta S_t = \Delta \ln(S_t)$ is the approximately continuously
compounded rate of return. Many empirical studies have found that the hypothesis of a unit root in $\ln(S_t)$ cannot be rejected, so that returns appear to be stationary. Furthermore, returns generally appear to be approximately serially uncorrelated, so that the returns appear to be close to a martingale difference sequence, which is consistent with the theory of weak form efficiency. This has led to the one of the most striking empirical properties of high frequency, daily, weekly, or even monthly nominal exchange rate returns, concerning their apparent lack of predictability in their conditional mean. Numerous studies such as Meese and Rogoff (1983), using forward rates, surveys of market participant's expectations, and nonlinear time series models have been unable in the MSE sense to improve on random walk predictions of the nominal exchange rate.

However, the unconditional distribution of short-term nominal spot exchange rate returns is non-Gaussian and has substantial excess kurtosis; that is, they are leptokurtic. Also, returns generally exhibit time-dependent volatility, which can be well represented by various types of generalized autoregressive conditionally heteroskedastic (GARCH) models. These models represent the autocorrelated nature of volatility, which is generally considered to be due to arrival of news and to the patterns of trading volume. See Baillie and Bollerslev (1989), who estimate and discuss these models for different levels of temporal aggregation. The degree of non-Gaussianity and the level of persistence of the volatility in GARCH models are particularly high for daily returns and decreases for lower frequencies of returns. Andersen and Bollerslev (1997a; 1997b) have used high-frequency data to examine returns and the volatility process of nominal spot exchange rate returns. They find particular stylized patterns of worldwide FX market volatility which characterizes the volatility process for each spot returns series. Andersen et al. (2003) consider the concept of realized volatility, which is an observable measure of (daily) volatility obtained from aggregating information on high-frequency returns within the day. For example, the sum of squared high-frequency returns is often used to measure daily realized volatility. The daily realized volatility is generally found to be almost pure fractional white noise, with the long-memory parameter generally being in the range of 0.30–0.40.

**Purchasing power parity**

The theory of purchasing power parity (PPP) is sometimes known as the law of one price and is to be found in the work of Ricardo in the 18th century and by Cassel in the 1920s. If $S_t$ denotes the spot exchange rate, measured in terms of the dollar–yen rate at time $t$, $P_t$ is the domestic US price level and $P_t^*$ is the foreign country (Japan's) price level, then continuous PPP requires $P_t = S_t P_t^*$. The real exchange rate is defined as $Q_t$, where $Q_t = (S_t P_t^*/P_t)$ and, if PPP held continuously, the real exchange rate would be constant over time. In general, empirical real exchange rates since 1973 have been found to exhibit highly persistent autocorrelation and may possibly be non-stationary (see Abauf and Jorion, 1990). An important area of research in international finance has been to understand the duration of the effect of shocks to the real exchange rate, and the evidence for whether the real exchange rate returns to equilibrium in ‘finite’ time and restores PPP. More empirical work has re-established PPP holding in the long run, but with significant deviations (see Frankel and Rose, 1996).
Uncovered interest rate parity

On denoting domestic interest rates as $i_t$ and foreign rates as $i_t^*$, it is known that covered interest rate parity holds exactly apart from very small transaction costs and brokerage fees so that

$$(1 + i_t)S_t = (1 + i_t^*)F_t,$$

where $F_t$ is the forward exchange rate. This relationship implies that the forward premium is equivalent to the interest rate differential. An important extension is the theory of uncovered interest rate parity (UIP), where

$$(1 + i_t) = (1 + i_t^*)E_t(S_{t+1}/S_t),$$

which implies that the interest rate differential is approximately the expected rate of appreciation (depreciation) of a currency. Hence,

$$E_t\Delta S_{t+1} \approx (i_t - i_t^*),$$

where $E_t$ represents the expectation operator conditioned on a sigma field of information available at time $t$. Hence the country with the higher rate of interest is expected to have the currency depreciation. The UIP hypothesis requires the joint assumptions of rational expectations, risk neutrality, free capital mobility and the absence of taxes on capital transfers. The theory can be derived from the solution of an Euler equation where expected real returns in the forward market are hypothesized to be zero.

Models of exchange rate determination

Following the advent of freely floating exchange rates in 1973 there has been intense research on understanding the mechanisms of nominal exchange rate determination and the search for an adequate model. Earlier work by Mundell (1963) and Fleming (1962) emphasized a Keynesian approach and considered the relative advantages of fixed versus floating nominal exchange rates. In particular, monetary policy was shown to be ineffective as a policy tool under a fixed exchange rate, while fiscal policy is effective. Conversely, monetary policy was shown to be effective under a flexible exchange rate, and fiscal policy to be ineffective under flexible exchange rates. The dominant modern paradigm is the asset market approach, which implies that the nominal exchange rate is the value of one country’s money supply against another. The simplest version of the monetary model assumes PPP to hold continuously and for the existence of stable and static demand for real balances for one and possibly both countries. If the demand for real balances in the United States is

$$m_t - p_t = \varphi y_t - \alpha i_t,$$

where the lower case letters $m_t$, $p_t$ and $y_t$ represent the natural logarithms of money, prices and income respectively, and where $i_t$ is the level of nominal interest rates; where $\varphi$ is the elasticity of the demand for real balances with respect to income and $\alpha$ is the semi-elasticity with respect to the nominal rate of interest. The combination of PPP, uncovered interest rate parity and the demand for real balances equation is sufficient to generate a first-order rational expectations equation of the form
\[ s_t = \left( \frac{1}{1 + \alpha} \right) z_t + \left( \frac{\alpha}{1 + \alpha} \right) E_t s_t + 1 \]

where \( z_t \) are the fundamentals, and in this case are \( z_t = (m_t - \varphi v_t - \rho_t^* + \alpha i_t^*) \), and asterisks denote foreign equivalents. On assuming the transversality condition which eliminates bubbles, the forward looking solution is

\[ s_t = \left( \frac{1}{1 + \alpha} \right) \sum_{j=0}^{\infty} \left( \frac{\alpha}{1 + \alpha} \right)^j E_t (m_{t+j} - \varphi v_{t+j} - \rho_{t+j}^* + \alpha i_{t+j}^*) . \]

A more intuitive solution is to further assume the same demand for real balances equation for the foreign country, in which case the solution is

\[ s_t = \left( \frac{1}{1 + \alpha} \right) \sum_{j=0}^{\infty} \left( \frac{\alpha}{1 + \alpha} \right)^j E_t [(m_{t+j} - m_{t+j}^*) - \varphi (v_{t+j} - v_{t+j}^*)] . \]

Similarly to the Keynesian approach, the monetary model implies an equivalent depreciation of the exchange rate with respect to an increase in US money supply and prices. However, the model also implies dollar appreciation following an increase in US incomes, and a dollar depreciation following an increase in US nominal interest rates; both implications are contrary to the Keynesian approach.

The empirical realization that nominal exchange rates did not move in perfect synchronization with relative prices and money supplies generated attempts to loosen the constraints of the model. Frankel (1979) introduced the real interest differential (RID) model, while the celebrated concept of overshooting was due to Dornbusch (1976). Under rational expectations, the overshooting model is very similar to an alternative model of Woo (1985), which assumes flexible prices but dynamic adjustments in the demand for real balances. The solution paths for both models are obtained from the forward solution of a second-order forward-looking rational expectations equation.

It has been hard to find rigorous empirical support for any of the models. While the log of the exchange rate and most of the macroeconomic fundamentals appear to be well approximated by integrated processes, there has been an absence of cointegration. This rejects the long-run properties of the basic monetary model as well as the Dornbusch overshooting formulation. In fact, the macro fundamentals are found to add little explanatory power to the model. This again is consistent with the findings of Meese.
and Rogoff (1983), who found that most models and forecasting methods were inferior, in the sense of *ex ante* MSE forecasting comparisons, to a simple random walk model. Mark (1995) and Mark and Choi (1997) have found some evidence that fundamentals have increased explanatory power when predicting exchange rates a year or more ahead. An alternative approach considering the possibility of nonlinear adjustment to equilibrium has been advocated by Engel and Hamilton (1990) and Taylor and Peel (2000), and is likely to remain an active area of research for the foreseeable future.

High-frequency analyses by Anderson and Bollerslev (1998) and Andersen et al. (2003) have examined the role of macro news announcements on exchange rate returns. Some explanatory power has been detected, but not as much as would be suggested by the macro models. These findings tend to support perceived wisdom in the FX market concerning the fact that traders react less to macroeconomic news than previously expected.

**Forward premium anomaly**

The forward premium or forward discount anomaly refers to the widespread result that the returns on freely floating exchange rates are invariably negatively correlated with the lagged forward premium. One of the most widespread tests of uncovered interest rate parity is based on the regression of future spot returns on the lagged forward premium, or equivalently the lagged interest rate differential,

\[ \Delta s_{t+1} = \alpha + \beta (f_t - s_t) + \epsilon_{t+1}, \]

where \( \epsilon_{t+1} \) is the regression disturbance. While the theory of uncovered interest rate parity would suggest that \( \alpha = 0, \beta = 1 \) and \( \epsilon_{t+1} \) uncorrelated, a substantial body of empirical work has found the estimate of the slope coefficient \( \beta \) to be negative. Interestingly, this result is found for different currencies, different numeraire currencies and over different sample periods, including the 1920s. As discussed by Baillie and Bollerslev (2000), the estimated \( \beta \) coefficient is time varying and can be as low as \(-13\) for periods within the 1980s. Possible explanations of the forward premium anomaly have included ‘peso problem’ effects, the role of learning and heterogeneous beliefs on the part of agents; while the most dominant explanation has been in terms of the presence of a time-dependent risk premium, \( \rho_{t+1} \) which is defined as

\[ E_t \Delta s_{t+1} = (f_t - s_t) - \rho_{t+1}. \]

Fama (1984) has shown that a \( \hat{\beta} < 0 \) implies that \( \text{Cov}(E_t \Delta s_{t+1}, \rho_{t+1}) < 0 \), so that the expected rate of appreciation is negatively correlated with the risk premium, and also \( \text{Var}(\rho_{t+1}) > \text{Var}(E_t \Delta s_{t+1}) \), so
that the variability of the risk premium must exceed that of the expected rate of appreciation. Models of the time-dependent risk premium are generally motivated by versions of the Lucas–Breeden asset pricing approach (see Lucas, 1978). Following Domowitz and Hakkio (1985) many parametric models for the risk premium have been formulated from micro theoretic models. See Hodrick (1989) for one of the most detailed formulations, which is discussed in detail by Engel (1996). These models generally represent the risk premium in terms of the second conditional moments of fundamentals, and there has been little definitive empirical support for these models. However, Baillie and Kilic (2006) have found evidence for nonlinear smooth transition regime adjustment to uncovered interest rate parity with threshold variables, such as the conditional variability of US money growth, and the interest rate differential, which are variables derived for risk premium from theoretical models.

Other authors have noted that the problem of econometric specification with uncorrelated returns being regressed on the forward premium or interest rate differential appears to have very persistent, or ‘long-memory’ autocorrelation. Baillie and Bollerslev (2000) and Maynard and Phillips (2001) discuss some of the specification issues that result.

Target regimes and intervention

There has been considerable research on the implementation of target zones for nominal exchange rates. In particular, Krugman (1991) has considered the differential equations behind monetary policy-style intervention at the bands of the target zone; while Neely (1999) documents some of the statistical properties of such returns. Complications due to intra-marginal intervention have also been considered, and the empirical success of the models is discussed by Bekaert and Gray (1998). Perhaps most work in this area has been done on trying to understand the transmission mechanism of sterilized intervention, where open market operations by a central bank are designed to maintain levels of money supply following their purchase (sale) of domestic currency. Such intervention is generally officially motivated as an attempt to either move a nominal exchange rate closer to a target level, and/or to reduce FX market volatility. The empirical results are controversial with relatively small effects being detected, although Baillie and Osterberg (1997) use an extension of Hodrick (1989) to motivate intervention affecting the risk premium, and find quite strong supportive econometric evidence. The reasons for currency crises and the possibility of early warning corrective actions that may be taken to avoid crises have also attracted attention (see Kaminsky, Lizondo and Reinhart, 1998; Kaminsky and Schumaker, 2000; Rose and Svensson, 1995).

non-clearing markets in general equilibrium

Jean-Pascal Bénassy
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

In this article we study models with non-clearing markets in a full general equilibrium framework. The theories we describe synthesize three major schools of thought, Walrasian, Keynesian and imperfect competition. This synthesis is notably achieved by introducing quantity signals in addition to price signals into the traditional general equilibrium model. This considerably enlarges the scope of traditional general equilibrium, allowing us not only to construct equilibria with various price rigidities but also to endogenize prices in a decentralized imperfect competition framework.

Keywords

active demand; budget constraint; dual decision method; fixprice equilibria; fixprice-fixwage macroeconomic model; frictions; general equilibrium; imperfect competition; Keynesianism; market efficiency; monopolistic competition; non-clearing markets in general equilibrium; non-tâtonnement processes; objective demand curve; overbidding; price making; price signals; price taking; quantity constraints; quantity signals; quasi-equilibrium; rational expectations; rationing; subjective demand curves; Walrasian equilibrium

Article

In this article we study how to model situations of non-clearing markets in a full general equilibrium framework. As we shall see from the historical discussion at the end, the theories we obtain synthesize three major schools of thought: (a) the Walrasian school, as Walras was the first to study a fully fledged general equilibrium system; (b) the Keynesian school, as Keynes emphasized the importance of quantity adjustments in reaching a macroeconomic equilibrium with at least one non-clearing market (that is, the labour market); and (c) the imperfect competition school, which endogenized prices through explicit price making by agents internal to the system.

This synthesis is notably achieved by introducing quantity signals into the traditional general equilibrium model. These quantity signals are quantity constraints which tell each agent the maximum quantity he can trade in each market. As we shall see, the introduction of these quantity signals in addition to price signals considerably enlarges the scope of traditional general equilibrium since they allow us not only to treat equilibria with various price rigidities, but also to endogenize prices in a decentralized imperfect competition framework.

The plan of the entry is the following. In the next three sections we describe the general concepts. The fourth section gives a brief historical outline of this line of thought.

Non-clearing markets and quantity signals

In this section and the next two we describe various concepts in the framework of a monetary exchange economy where one good, money, serves as numéraire, medium of exchange and reserve of value (similar concepts have been developed for barter economies – see Bénassy, 1975b; 1982 – but the formalization gets quite clumsy). There are • markets in the period considered, where non-monetary goods indexed by \( h \) = 1, \( 2, \ldots, t \) are exchanged against money at the price \( p_h \). We call \( p \) the vector of these prices.

Agents are indexed by \( i = 1, \ldots, n \). In market \( h \) agent \( i \) may make a purchase \( d_i h \geq 0 \) or a sale \( s_i h \geq 0 \). Define his net transaction of good \( h \), \( z_i h = d_i h - s_i h \), and \( z_i \) the \( n \)-dimensional vector of these net transactions.
At the beginning of the period agent \( i \) holds quantities \( \overline{m}_i \) of money, and \( \omega_{ih} \) of good \( h \). Call \( \omega_i \) the vector of the \( \omega_{ih} \). As a result of his trades \( z_i \), agent \( i \) ends up with final holdings of non-monetary goods and money, \( x_i \) and \( m_i \), given respectively by:

\[
x_i = \omega_i + z_i m_i = \overline{m}_i - p z_i
\]

We assume that agent \( i \) has a utility function on these final holdings \( U_i(x_i, m_i) = U_i(\omega_i + z_i, m_i) \), which we assume throughout strictly concave in its arguments.

**Walrasian equilibrium**

In order to contrast it with the non-Walrasian equilibrium concepts that will follow, let us describe briefly the Walrasian equilibrium of this economy (Arrow and Debreu, 1954; Debreu, 1959). Each agent \( i \) receives (from the implicit auctioneer) a price signal \( p \). As a response he expresses a Walrasian net demand given by the function \( z_i(p) \), solution in \( z_i \) of the following program:

\[
\text{Maximize } U_i(\omega_i + z_i, m_i) \text{ s.t.}
\]

\[
p z_i + m_i = \overline{m}_i
\]

A Walrasian equilibrium price vector \( p^* \) is defined by the condition that all markets clear, that is:

\[
\sum_{i=1}^{n} z_i(p^*) = 0
\]

The vector of transactions realized by each agent \( i \) is \( z_i(p^*) \).

**Demands and transactions**

As we will be studying non-clearing markets, we must now make an important distinction, that between demands and supplies on the one hand, and the resulting transactions on the other.

Transactions, that is, purchases or sales of goods, denoted \( d_{ih}^* \) and \( s_{ih}^* \), are exchanges actually made, and must thus identically balance on each market, that is:

\[
D_h^* = \sum_{i=1}^{n} d_{ih}^* = \sum_{i=1}^{n} s_{ih}^* = S_h^* \text{ for all } h
\]
On the other hand, demands and supplies, denoted $\tilde{d}_h$ and $\tilde{s}_h$, are signals transmitted to the market (that is, to the other agents) before exchange takes place. They represent as a first approximation the exchanges the agents wish to make on each market. So they do not necessarily match in a specific market, and no identity like (1) applies to them:

$$\tilde{D}_h = \sum_{i=1}^{n} \tilde{d}_i \neq \sum_{i=1}^{n} \tilde{s}_i = \tilde{S}_h$$

In order to shorten notation, we often work in what follows with net demands and net transactions defined respectively by:

$$\check{z}_h = \tilde{d}_h - \tilde{s}_h \quad \check{z}_h = \tilde{d}_h - \tilde{s}_h$$

The equality of aggregate purchases and sales (eq. (1)) is then rewritten:

$$\sum_{i=1}^{n} \check{z}_i = 0 \text{ for all } h \quad (2)$$

**Rationing schemes**

In each market $h$ the exchange process must generate consistent transactions (that is, transactions satisfying eqs. (1) or (2)) from any set of possibly inconsistent demands and supplies. Some rationing will necessarily occur, which may take various forms, such as uniform rationing, queuing, priority systems, proportional rationing, and so forth … depending on the particular organization of each market. We call *rationing scheme* the mathematical representation of each specific organization. To be more precise, the rationing scheme in market $h$ is defined by a set of $n$ functions:

$$\check{z}_h^n = F_h(\check{z}_1, \ldots, \check{z}_n) \quad i = 1, \ldots, n \quad (3)$$

such that:

$$\sum_{i=1}^{n} F_h(\check{z}_1, \ldots, \check{z}_n) = 0 \text{ for all } \check{z}_1, \ldots, \check{z}_n$$
We assume that $F_{ih}$ is continuous, non-decreasing in $\tilde{x}_{ih}$ and non-increasing in the other arguments. Before examining the possible properties of these rationing schemes, let us take a most simple example with two agents. Agent 1 emits a demand $\bar{d}_{1h}$, agent 2 a supply $\bar{s}_{2h}$. Then a natural rationing scheme, implicit in most macroeconomic models, is to take the level of transactions as equal to the minimum of demand and supply, that is:

$$d_{1h}^* = s_{2h}^* = \min (\bar{d}_{1h}, \bar{s}_{2h})$$

Properties of rationing schemes

We first study two possible properties that a rationing scheme may satisfy: voluntary exchange and market efficiency. The first property is actually an extremely natural one in a free market economy: We shall say that there is voluntary exchange in market $h$ if no agent can be forced to purchase more than he demands, or to sell more than he supplies, which is expressed by:

$$d_{1i}^* \leq \bar{d}_{1i} \leq s_{2i}^* \leq \bar{s}_{2i} \forall i$$

or equivalently in algebraic terms:

$$|\bar{z}_{ih}| < |\bar{z}_{ph}| \bar{z}_{ih} \bar{s}_{ph} \geq 0 \forall i.$$

Most markets in reality meet this condition, and we henceforth assume that it always holds. This allows us to classify agents in a market $h$ in two categories: unrationed agents for which $\bar{z}_{ih} = \bar{s}_{ih}$ and rationed agents who trade less than they wanted.

The second property we study here is that of market efficiency, or absence of frictions, which corresponds to the idea of exhaustion of all mutually advantageous exchanges: a rationing scheme on a market $h$ is efficient, or frictionless, if one cannot find simultaneously a rationed demander and a rationed supplier in market $h$. The intuitive idea behind this is that in an efficiently organized market a rationed buyer and a rationed seller would meet and exchange until one of the two is not rationed. Together with voluntary exchange, it implies the 'short-side rule', according to which agents on the 'short side' of the market can realize their desired transactions:

$$\bar{d}_{ih} \geq \bar{s}_{ih} \Rightarrow s_{ip}^* = \bar{s}_{ih} \forall p \bar{d}_{ih} \geq \bar{d}_{ih} \Rightarrow d_{ip}^* = \bar{d}_{ih} \forall i$$

This rule also implies that the global level of transactions on a market $h$ will be equal to the minimum of aggregate demand and supply:
We should note that the market efficiency assumption may not always hold, notably if one considers a fairly wide and decentralized market, because some demanders and suppliers might not meet pairwise. In particular, the market efficiency property is usually lost by aggregation of sub-markets, whereas the voluntary exchange property remains intact in the aggregation process. So we must keep in mind that it does not always hold. Fortunately, this hypothesis is not necessary for most of the microeconomic concepts presented in the next sections.

**Quantity signals**

Now it is clear that at least rationed agents must perceive a quantity constraint in addition to the price signal. As it turns out, these quantity signals appear quite naturally in the formulation of a number of rationing schemes called *non-manipulable*, which can be written under the form:

\[
D^*_h = \min \{ \bar{D}^*_h, \bar{\bar{D}}^*_h \} = \min \{ \bar{\bar{D}}^*_h, \bar{D}^*_h \}
\]

where the quantity signals \( \bar{D}^*_h \) and \( \bar{\bar{D}}^*_h \) are functions only of the demands and supplies of the other agents. As an example, we can note that the rationing scheme corresponding to eq. (4) above is of this type with:

\[
\bar{D}^*_h = \bar{\bar{D}}^*_h = \bar{\bar{D}}^*_1 = \bar{D}^*_2 = \bar{D}^*_3 = \bar{D}^*_4
\]

For non-manipulable schemes the relation between \( \bar{D}^*_h \) and \( \bar{\bar{D}}^*_h \) looks as in Figure 1, in which we see where the term 'non-manipulable' comes from: once rationed, the agent cannot increase, or 'manipulate', the level of his transactions by increasing his demand and supply.

Figure 1
To make things a little more precise, let us rewrite the rationing scheme in market $h$ (eq. (3)) under the form:
\[ z^*_{ih} = f_{ih}(\mathcal{Z}_{ih} - \mathcal{Z}_{-ih}) \] (6)

where \( \mathcal{Z}_{-ih} \) is the set of all net demands on market \( h \), except that of agent \( i \), that is, \( \mathcal{Z}_{-ih} = \{ \mathcal{Z}_{jh} | j \neq i \} \). The rationing scheme is non-manipulable if it can be rewritten as in eqs. (5), or algebraically:

\[
F_{ih}(\mathcal{Z}_{ih}, \mathcal{Z}_{-ih}) = \begin{cases} 
\min (\mathcal{Z}_{ih} - \mathcal{Z}_{ih}) \geq 0 \\
\max (\mathcal{Z}_{ih} - \mathcal{Z}_{ih}) \geq 0 
\end{cases}
\]

where \( \mathcal{Z}_{ih} \) and \( \mathcal{Z}_{ih} \) are functions of all demands and supplies in market \( h \), except that of agent \( i \), which we shall write as:

\[
\mathcal{Z}_{ih} = \mathcal{Z} - \mathcal{Z}_{ih} = \mathcal{Z} - \mathcal{Z}_{ih} \geq 0
\]

Note that the functions \( \mathcal{C}_{ih}^{d}(\mathcal{Z}_{-ih}) \) and \( \mathcal{C}_{ih}^{s}(\mathcal{Z}_{-ih}) \) are not arbitrary, but are related to the rationing scheme \( F_{ih} \) through:

\[
\mathcal{C}_{ih}^{d}(\mathcal{Z}_{-ih}) = \max \left\{ \mathcal{Z}_{ih} | F_{ih}(\mathcal{Z}_{ih}, \mathcal{Z}_{-ih}) = \mathcal{Z}_{ih} \right\}
\]

(8)

\[
\mathcal{C}_{ih}^{s}(\mathcal{Z}_{-ih}) = \min \left\{ \mathcal{Z}_{ih} | F_{ih}(\mathcal{Z}_{ih}, \mathcal{Z}_{-ih}) = \mathcal{Z}_{ih} \right\}
\]

(9)

where it appears clearly that these quantity constraints are indeed the maximum purchase and sale that agent \( i \) can make in market \( h \).

We may note that some rationing schemes, called manipulable, such as the proportional rationing scheme, cannot be written under this form. The phenomenon of manipulation through demand and supply leads then to a perverse phenomenon of overbidding, and to the non-existence of an equilibrium unless additional constraints are put on demands and supplies (Bénassy, 1977b; 1982).

Most rationing schemes in the real world are actually non-manipulable through demand and supply, and we thus from now on study only such rationing schemes as can be...
characterized by eqs. (5) or (7). The variables \( \tilde{d}_{hi} \) and \( \tilde{z}_{hi} \) in (5) and (7) are \textit{quantity constraints}. These are the quantity signals that each agent receives, and they play a fundamental role in both quantity and price determination, as we see in the next two sections. Before moving to the study of these problems and to the definition of non Walrasian equilibria, it is useful to rewrite eqs. (6) and (7) pertaining to an agent \( i \) under vector form:

\[
\tilde{z}_i^* = f_i(2_{-i}) \tilde{d}_i = C_i^d (2_{-i}) \tilde{z}_i = C_i^d (2_{-i})
\]

where \( \tilde{z}_i \) is the vector of \( \tilde{z}_{hi}, h = 1, \ldots, \ell \), and \( 2_{-i} \) is the set of all such vectors, except that of agent \( i \) himself, i.e. \( 2_{-i} = \{ \tilde{z}_j : j \neq i \} \).

### Fixprice equilibria

We now study a first concept of non-Walrasian equilibrium, that of fixprice equilibrium. This concept is of interest for several reasons. First, it gives us a very large class of consistent market allocations, since we shall find that under very standard conditions a fixprice equilibrium exists for every positive price system and every set of rationing schemes (we may note that Walrasian allocations are particular fixprice allocations, specifically those corresponding to a Walrasian price vector). Second, as we see in the next section, fixprice equilibria are a very important building block in constructing other non-Walrasian equilibrium concepts with flexible prices.

We thus assume that the price system \( p \) is given. As indicated, we assume that the rationing schemes in all markets are non-manipulable. Accordingly, transactions and quantity signals are generated in all markets according to the formulas seen above (eqs. (10)). We immediately see that all that remains to be done in order to obtain a fixprice equilibrium concept is to determine how demands themselves are formed, a task to which we now turn.

### Effective demands and supplies

Demands and supplies are signals that agents send to the ‘market’ (that is, to the other agents) in order to obtain the best transactions. Consider thus an agent \( i \) faced with a price vector \( p \) and vectors of quantity constraints, \( \tilde{d}_i \) and \( \tilde{z}_i \). He knows that his transactions will be related to his demands and supplies by formulas (5) seen above, namely,

\[
\tilde{d}_i^* = \min (\tilde{d}_{hi}, \tilde{d}_{hi}) \tilde{z}_i^* = \min (\tilde{z}_{hi}, \tilde{z}_{hi})
\]

Now the problem is to choose a vector of net effective demands \( \tilde{z}_i \) which will lead him to the best possible transactions. As it turns out, there exists a simple and workable definition which generalizes Clower’s (1965) original ‘dual decision’ method: the effective demand of agent \( i \) on market \( h \) is the trade which maximizes his utility subject to the budget constraints and to the quantity constraints on the \textit{other} markets. Formally the effective demand \( \tilde{z}_{hi} \) is solution in \( z_{hi} \) of the following programme:

Maximize \( U_i (\omega_i + z_i, m_i) \) s.t.
\[
\begin{align*}
& p z_i + m_i = \tilde{m}_i, \\
& -\tilde{z}_{hi} \leq z_{hi} \leq \tilde{z}_{hi} \quad (k \neq h)
\end{align*}
\]
Because of the strict concavity of $U_i$, we obtain a function, denoted $\xi_i(p, \bar{d}_i, \bar{s}_i)$. Repeating the operation for all markets $h = 1, \ldots, \epsilon$, we obtain a vector function of effective demands $\bar{\xi}_h(p, \bar{d}_i, \bar{s}_i)$. This vector of effective demands has two good properties. First, it leads to the best transactions that it is possible to attain given the price vector $p$ and the quantity constraints $\bar{d}_i$ and $\bar{s}_i$. Second, whenever a constraint is binding on a market $h$, the corresponding demand or supply is greater than the quantity constraint, which thus ‘signals’ to the market that the agent trades less than he would want. Such signals are useful to avoid trivial equilibria where no one would trade because nobody else signals that he wants to trade.

**Fixprice equilibrium**

With the above definition of effective demand, we are now ready to give a first definition of a fixprice equilibrium, found in Bénassy (1975a; 1982).

**Definition 1:** A fixprice equilibrium associated with a price system $p$ and rationing schemes represented by functions $F_i$, $i = 1, \ldots, \eta$, is a set of effective demands $\bar{z}_i$, transactions $\bar{z}_i^*$, and quantity constraints $\bar{d}_i$ and $\bar{s}_i$ such that:

1. $\bar{z}_i = \bar{\xi}_i(p, \bar{d}_i, \bar{s}_i), i = 1, \ldots, \eta$
2. $\bar{z}_i^* = F_i(\bar{z}_i, \bar{z}_i^*), i = 1, \ldots, \eta$
3. $\bar{d}_i = C_d(\bar{z}_i^*, \bar{s}_i), \bar{s}_i = C_s(\bar{z}_i^*, \bar{d}_i), i = 1, \ldots, \eta$

Equilibria defined in this way exist for all positive prices and all rationing schemes satisfying voluntary exchange and non-manipulability (Bénassy, 1975a; 1982). The ‘exogenous’ data are the price system $p$ and the rationing schemes $F_i, i = 1, \ldots, \eta$. One may wonder whether for given such exogenous data the equilibrium is likely to be unique. A positive answer has been given by Schulz (1983), who showed that the equilibrium is globally unique, provided the ‘spillover’ effects (there is a spillover effect when a binding constraint in one market modifies the effective demand in another market) are less than 100 per cent in value terms. For example in the simplest Keynesian model this would amount to a propensity to consume strictly smaller than 1.

In what follows we assume that the Schulz conditions hold, and denote by $\bar{z}_i(p), \bar{z}_i^*(p), \bar{d}_i(p)$ and $\bar{s}_i(p)$ the functions giving the values of $\bar{z}_i, \bar{z}_i^*, \bar{d}_i$ and $\bar{s}_i$ at a fixprice equilibrium corresponding to $p$ (the market organization, and thus the rationing schemes, being assumed invariant).

**An alternative concept**

We shall now present an alternative concept of fixprice equilibrium, due to Drèze (1975) (who actually dealt with the more general case of prices variable between fixed limits), and which we shall recast using our notations. That concept does not separate demands from transactions, and thus considers directly the vectors of transactions $\bar{z}_i^*$ and quantity constraints $\bar{d}_i$ and $\bar{s}_i$. The original concept actually assumed uniform rationing, so that the vectors $\bar{d}_i$ and $\bar{s}_i$ were the same for all agents.

**Definition 2:** A fixprice equilibrium for a given set of prices $p$ is defined as a set of transactions $\bar{z}_i^*$ and quantity constraints $\bar{d}_i$ and $\bar{s}_i$ such that:

1. $\sum_{i=1}^{\eta} \bar{z}_i^{*} = 0 \forall h$
2. The vector $\bar{z}_i^*$ is solution in $z_i$ of:

$$\begin{align*}
\text{Maximize:} & \quad U_i(u_i + z_i, m_i) \\
\text{Subject to:} & \quad \bar{d}_i + m_i, \bar{s}_i \quad \text{s.t.} \\
& \quad \bar{d}_i \leq z_i \leq \bar{s}_i \quad \forall h
\end{align*}$$
3. (c) $\forall h \sum_{i} z_{ih} = \bar{d}_{ih}$ for some $i$ implies $z_{jh} > -\bar{d}_{jh} \forall j$ for some $i$ implies $z_{jh} < -\bar{d}_{jh} \forall j$

Let us now interpret these conditions. Condition (a) is the natural requirement that transactions should balance in each market. Condition (b) says that transactions must be individually rational, that is, they must maximize utility subject to the budget constraint and the quantity constraints on all markets. We may note at this stage that using quantity constraints under the form of upper and lower bounds on trades implicitly assumes rationing schemes which exhibit voluntary exchange and non-manipulability, as we saw when studying rationing schemes. Condition (c) says that rationing may affect either supply or demand, but not both simultaneously. We recognize here with a different formalization the condition of market efficiency which is thus built into this definition of equilibrium, whereas it is not in the previous definition.

Drèze (1975) proved that an equilibrium according to def 2 exists for all positive price systems and for uniform rationing schemes under the standard concavity assumptions for the utility functions. The concept is easily extended to non-uniform bounds (Grandmont and Laroque, 1976; Greenberg and Muller, 1979), but in this last case it is not specified in the concept how shortages are allocated. Because of this there will be usually an infinity of equilibria corresponding to a given price vector, as soon as there are two rationed agents on one side of a market.

As we noted above, the two concepts of fixprice equilibrium we described in this section are based, implicitly or explicitly, on a representation of markets under the form of rationing schemes satisfying voluntary exchange and non-manipulability. This suggests that, if in the first definition we further assume that all rationing schemes are efficient or frictionless, the two definitions should yield similar sets of equilibrium allocations for a given price system. This was indeed proved by Silvestre (1982; 1983) for both exchange and production economies. The relation between the two concepts has been further explored by D’Autume (1985).

**Price making and equilibrium**

As this stage we still need a description of price making by agents internal to the system. We describe in this section a concept dealing with that problem and we shall see that, just as in demand and supply theory, quantity signals play a prominent role. It is indeed quite intuitive that quantity constraints must be a fundamental part of the competitive process in a decentralized economy; it is the inability to sell as much that they want which leads suppliers to propose, or accept from other agents, a lower price, and conversely it is the inability to purchase as much as they want that leads demanders to propose, or accept, a higher price.

Various modes of price making integrating these aspects can be envisioned. We deal here with a realistic organization of the pricing process where agents on one side of the market (most often the suppliers) quote prices and agents on the other side act as price takers. The general idea relating the concepts in this section to those of the previous one is that price makers change their prices so as to ‘manipulate’ the quantity constraints they face (that is, so as to increase or decrease their possible sales or purchases). As we shall see, this model of price making is quite reminiscent of the imperfect competition line (Chamberlin, 1933; Robinson, 1933; Triffin, 1940; Bushaw and Clower, 1957; Arrow, 1959), and more particularly of the theories of general equilibrium with monopolistic competition, as developed notably by Negishi (1961).

**The framework**

We thus now assume that agent $i$ controls the prices of a (possibly empty) subset $H_i$ of goods. Goods are distinguished both by their physical characteristics and by the agent who sets their price. We thus consider two goods sold by different sellers as different goods, a fairly natural assumption since these goods differ at least by location, quality, and so on, so that:

$$H_i \cap H_j = \{ \emptyset \} \neq j$$

We denote by $p_i$ the set of prices controlled by agent $i$ and $p_{-i}$ the rest of prices, that is:

$$p_i = \{ p_h | h \in H_i \} \quad p_{-i} = \{ p_h | h \notin H_i \}$$
Each agent chooses his price vector $p_i$ taking the other prices $p_{-i}$ as given. The equilibrium structure is thus that of a Nash equilibrium in prices, corresponding to an idea close to that of monopolistic competition. The basic idea behind the modelling of price making itself in such models is, as we indicated above, that each price maker uses the prices he controls to ‘manipulate’ the quantity constraints he faces. Consider the markets whose price are determined by agent $i$, and subdivide further $H_i$ into $H_i^d$ (goods demanded by $i$) and $H_i^s$ (goods supplied by $i$). We may note in passing that, although agent $i$ appears formally as a monopolist in markets $h \in H_i^d$ or a monopsonist in markets $h \in H_i^s$, his actual ‘monopoly power’ may be very low due to the fact that other agents sell or buy products which are extremely close substitutes to those he controls. Because the price makers are alone on their side of the markets where they set prices, their quantity constraints on these markets have the simple form:

$$\exists h \in H_i \ni \exists \tilde{\pi}_h \in \mathbb{R}^n \ni \sum_{j \neq i} \tilde{\pi}_j h = \sum_{j \neq i} \exists h \in H_i^d$$

that is, the maximum quantity that price setter $i$ can sell is the total demand of the others, and conversely if he is a buyer. All we need to know, in order to pose the problem of price setting as a standard decision problem, is the relation, as perceived by the price maker, between the quantity constraints he faces and the prices he sets. Several approaches allow us to treat this problem and to link it with the concepts seen previously. The first, based on Negishi’s (1961) subjective demand curve approach, was developed in Bénassy (1976; 1982). The second is an objective demand curve approach, developed in Bénassy (1987; 1988), and which we shall now briefly describe.

**Objective demand curves**

The implicit idea behind the objective demand curve approach (Gabszewicz and Vial, 1972; Marschak and Selten, 1976; Nikaido, 1975) is that each price maker knows the economy well enough to be able to compute under all circumstances the actual quantity constraints he will face. Since we are considering a Nash equilibrium, he must be able to perform this computation for any set $p_i$ of prices he chooses as well as for any set $p_{-i}$ of the other prices; that is, he must be able to compute his constraints for any vector of prices, once all feedback effects have been accounted for.

But we know from the previous section that, for a given organization of the economy (that is, notably for given rationing schemes), and for a given set of prices $p$, the quantity constraints agent $i$ faces are given by the functions $\overline{D}_i(p)$ and $\overline{F}_i(p)$. If the agent has full knowledge of the parameters of the economy (a strong assumption, of course, but which is embedded in the notion of an objective demand curve), then he knows this and the objective demand and supply curves will be respectively given by the functions $\overline{F}_i(p)$ and $\overline{D}_i(p)$.

We may note that the objective demand curve $\overline{F}_i(p)$ is denoted as a constraint on agent $i$’s supply, which is natural since the sum of all other agents’ demands acts as a constraint on the sales of agent $i$, and symmetrically with the objective supply curve $\overline{D}_i(p)$.

**Price making and equilibrium**

If agent $i$ knows the two vector functions $\overline{D}_i(p)$ and $\overline{F}_i(p)$, the programme giving his optimal price $p_i$ is the following:

Maximize $U_i(\omega_i + z_i, m_i)$ s.t.

$$\left\{ \begin{array}{l}
p z_i + m_i = m_i \\
-\overline{F}_i(p) \leq z_i \leq \overline{D}_i(p)
\end{array} \right.$$
which yields the optimum price $p_i$ chosen by agent $i$ as a function of the other prices $p_{-i}$:

$$p_i = \psi_i(p_{-i})$$

This naturally leads us to the definition of an equilibrium with price makers:

**Definition 3:** An equilibrium with price makers is characterized by a set of prices $p_i^*$, net demands $\bar{z}_i^*$, transactions $\bar{z}_i^*$ and quantity constraints $\bar{d}_i^*$ and $\bar{s}_i^*$ such that:

1. (a) $p_i^* = \psi_i(p_{-i}^*)$
2. (b) $\bar{z}_i^*, \bar{z}_i^*, \bar{d}_i^*, \bar{s}_i^*$ are equal respectively to $\bar{z}_i(p^*), \bar{z}_i(p^*), \bar{d}_i(p^*), \bar{s}_i(p^*)$.

Condition (a) indicates that we have a Nash equilibrium in prices, given each agent's optimal price responses. Condition (b) says that the various quantities form a fixprice equilibrium (according to def 1) for the price vector $p^*$. Further discussion and conditions for existence can be found in Bénassy (1988; 1990).

**Bibliographical references**

So far we have concentrated in this entry on the microeconomic concepts allowing us to deal with non-clearing markets at a general equilibrium level. We now indicate further bibliographical references both on the early history of the domain and on macroeconomic applications.

**History**

The field we described in this entry has a triple ancestry. On one hand Walras (1874) developed a model of general equilibrium with interdependent markets where adjustment was made through prices. This model, in its modern reformulation (Arrow and Debreu, 1954; Arrow, 1963; Debreu, 1959) has become the basic benchmark concept in microeconomics. On the other hand Keynes (1936) and Hicks (1937) built, at the macroeconomic level, a concept of equilibrium where adjustment was made by quantities (the level of national income) as well as by prices. Finally, following the contributions by Chamberlin (1933) and Robinson (1933), progress was made on the treatment of imperfect competition. Notably, Negishi (1961) formalized imperfect competition with subjective demand curves in a general equilibrium framework.

A few isolated contributions in the post-war period made some steps towards modern theories of non-clearing markets. Bent Hansen (1951) introduced the ideas of active demand, close in spirit to that of effective demand, and of quasi-equilibrium where persistent disequilibrium created steady inflation. Patinkin (1956, ch. 13) considered the situation where firms might not be able to sell all their Walrasian output. Hahn and Negishi (1962) studied non-tâtonnement processes where trade could take place before a general equilibrium price system was reached.

A stimulating impetus came from the contributions of Clower (1965) and Leijonhufvud (1968), who reinterpreted Keynesian analysis in terms of market rationing and quantity adjustments. These insights were included in the first fixprice-fixwage macroeconomic model by Barro and Grossman (1971; 1976).

The main subsequent development was the construction of rigorous microeconomic concepts allowing us to deal with non-clearing markets and imperfect competition in a full multi-market general equilibrium setting, as described above. Notably, Drèze (1975) and Bénassy (1975a; 1977b; 1982) bridged the gap between the Walrasian and Keynesian lines of thought by generalizing the Walrasian equilibrium concept to integrate non-clearing markets and quantity signals. The link between this new line of work and the imperfect competition equilibrium concepts in the Negishi (1961) line was made in Bénassy (1976; 1977a; 1988). These contributions led to the unified framework we set out in the previous sections. Of course, since one of the main goals of this line of research was to bridge the gap between microeconomics and macroeconomics, there were a number of macroeconomic applications of the above concepts, which we now briefly describe.

**Macroeconomic applications**
As indicated above, the first fully worked out fixprice-fixwage macroeconomic model embedding the notions set out above is that of Barro and Grossman (1971; 1976). Early attempts are found in Glustoff (1968) and Solow and Stiglitz (1968). Further developments of the model were made in Bénassy (1977a; 1982; 1986), Malinvaud (1977), Hildenbrand and Hildenbrand (1978), Muehlbauer and Portes (1978), Honkapohja (1979), Neary and Stiglitz (1983), and Persson and Svensson (1983). Most of these models concentrated on the problem of employment and policy. Other problems have been treated with this methodology, including notably foreign trade (Dixit, 1978; Neary, 1980; Cuddington, Johansson and Löfgren, 1984), growth (Ito, 1980; Picard, 1983; D’Autume, 1985), business cycles (Bénassy, 1984), as well as the specific problems of planned socialist economies (Portes, 1981).

Now the concepts described in this entry are full general equilibrium models in the tradition of, say, Arrow and Debreu (1954) and Debreu (1959). Contemporaneously to these developments, other authors developed, under the initial name of real business cycles, dynamic stochastic models based on the hypothesis of rational expectations. At some point these two lines of work were synthesized, and the result of this synthesis is described in the dictionary article ‘dynamic models with non-clearing markets’.

non-cooperative games (equilibrium existence)

Philip J. Reny
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article provides a brief overview of equilibrium existence results for continuous and discontinuous non-cooperative games.

Keywords

auctions; Bertrand price-competition models; convexity; Cournot oligopoly models; discontinuous games; endogenous sharing rules; equilibrium; equilibrium existence; finite-action games; fixed point theorems; infinite-action games; mixed strategy Nash equilibria; Nash equilibrium; non-cooperative games; pure strategy Nash equilibria; quasi-concavity; quasi-convexity; spatial economics; strategic form games

Article

1 Introduction

Nash equilibrium is the central notion of rational behaviour in non-cooperative game theory (see Osborne and Rubinstein, 1994, for a discussion of Nash equilibrium, including motivation and input). Our purpose here is to discuss various conditions under which a strategic form game possesses at least one Nash equilibrium.

Strategic settings arising in economics are often naturally modelled as games with infinite strategy spaces. For example, models of price and spatial competition (Bertrand, 1883; Hotelling, 1929), quantity competition (Cournot, 1838), auctions (Milgrom and Weber, 1982), patent races (Fudenberg et al., 1983), and so on, typically allow players to choose any one of a continuum of actions. The analytic convenience of the continuum from both an equilibrium characterization and a comparative statics point of view is perhaps the central reason for the prevalence and usefulness of infinite-action games. Because of this, our treatment will permit both finite-action and infinite-action games.
Games with possibly infinite strategy spaces can be divided into two categories: those with continuous payoffs and those with discontinuous payoffs. Cournot oligopoly models and Bertrand price-competition models with differentiated products, as well as all finite-action games, are important examples of continuous games, while Bertrand price-competition with homogeneous products, auctions, and Hotelling spatial competition are important examples in which payoffs are discontinuous. Equilibrium existence results for both continuous and discontinuous games will be reviewed here. We begin with some notation.

A strategic form game, \( G = (S_i, u_i) \), consists of a positive finite number, \( N \), of players, and for each player \( i \in \{1, \ldots, N\} \), a non-empty set of pure strategies, \( S_i \), and a payoff function \( u_i: S \to \mathbb{R} \), where \( S = \times_{i=1}^{N} S_i \). The notations \( s_{-i} \) and \( S_{-i} \) have their conventional meanings:

\[
S_{-i} = (s_1, \ldots, s_{i-1}, s_{i+1}, \ldots, s_N) \quad \text{and} \quad S_{-i} = \times_{j \neq i} S_j.
\]

Throughout, we assume that each \( S_i \) is a subset of some metric space and that, if any finite number of sets are each endowed with a topology, then the product of those sets is endowed with the product topology.

2 Continuous games

2.1 Pure strategy Nash equilibria

Pure strategy equilibria are more basic than their mixed strategy counterparts for at least two reasons. First, pure strategies do not require the players to possess preferences over lotteries. Second, mixed strategy equilibrium existence results often follow as corollaries of the pure strategy results. It is therefore natural to consider first the case of pure strategies.

**Definition**: \( s^* \in S \) is a pure strategy Nash equilibrium of \( G = (S_i, u_i) \) if for every player \( i \),

\[
u_i(s^*) \geq u_i(s^*_i, s_{-i}^*) \quad \text{for every } s_i \in S_i.
\]

An important and very useful result is the following.

**Theorem 1**: If each \( S_i \) is a non-empty, compact, convex subset of a metric space, and each \( u_i(s_1, \ldots, s_N) \) is continuous in \( (s_1, \ldots, s_N) \) and quasi-concave in \( s_i \), then \( G = (S_i, u_i) \) possesses at least one pure strategy Nash equilibrium.

**Proof**: For each player \( i \), and each \( s_{-i} \in S_{-i} \), let \( B_i(s_{-i}) \) denote the set of maximizers in \( S_i \) of \( u_i(\cdot, s_{-i}) \). The continuity of \( u_i \) and the compactness of \( S_i \) ensure that \( B_i(s_{-i}) \) is non-empty and also ensure, given the compactness of \( S_{-i} \), that the correspondence, \( B_i: S_{-i} \to S_i \), is upper hemicontinuous. The quasi-concavity of \( u_i \) in \( s_i \) implies that \( B_i(s_{-i}) \) is convex. Consequently, each \( B_i \) is upper hemicontinuous, non empty-valued and convex-valued. All three of these properties are therefore inherited by the correspondence \( B: S \to S \) defined by \( B(s) = \times_{i=1}^{N} B_i(s_{-i}) \) for each \( s \in S \). Consequently, we may apply Glicksberg's (1952) fixed point theorem to \( B \) and conclude that there exists \( s^* \in S \) such that \( s^* \in B(s^*) \). This \( s^* \) is therefore a pure strategy Nash equilibrium. Q.E.D.

**Remark**: Theorem 1 remains valid when ‘metric space’ is replaced by ‘locally convex Hausdorff topological vector space’. See Glicksberg (1952).
**Remark:** The convexity property of strategy sets and the quasi-concavity of payoffs in own action cannot be dispensed with. For example, strategy sets are not convex in matching pennies, and, even though the continuity and compactness assumptions hold there, no pure strategy equilibrium exists. On the other hand, in the two-person zero-sum game in which both players' compact convex pure strategy set is \([-1,1]\) and player 1's payoff function is \(u_1(s_1, s_2) = |s_1 + s_2|\), all of the assumptions of Theorem 1 hold except the quasi-concavity of \(u_1\) in \(s_1\). But this is enough to preclude the existence of a pure strategy equilibrium because in any such equilibrium player 2's payoff would have to be zero (given \(s_1, 2\) can choose \(s_2 = -s_1\)) and 1's payoff would have to be positive (given \(s_2\), 1 can choose \(s_1 \neq -s_2\)).

**Remark:** More general results for continuous games can be found in Debreu (1952) and Schafer and Sonnenschein (1975). Existence results for games with strategic complements on lattices can be found in Milgrom and Roberts (1990) and Vives (1990).

### 2.2 Mixed strategy Nash equilibria

A mixed strategy for player \(i\) is a probability measure, \(m_i\), over \(S_i\). If \(S_i\) is finite, then \(m_i(s_i)\) denotes the probability assigned to \(s_i \in S_i\) by the mixed strategy \(m_i\), and \(i\)'s set of mixed strategies is the compact convex subset of Euclidean space \(M_i = \{m_i \in [0, 1] \# S_i : \sum_{s_i \in S_i} m_i(s_i) = 1\}\). In general, we shall not require \(S_i\) to be finite. Rather, we shall suppose only that it is a subset of some metric space. In this more general case, a mixed strategy for player \(i\) is a (regular, countably additive) probability measure, \(m_i\), over the Borel subsets of \(S_i\); for any Borel subset \(A\) of \(S_i\), \(m_i(A)\) denotes the probability assigned to \(A\) by the mixed strategy \(m_i\). Player \(i\)'s set of such mixed strategies, \(M_i\), is then convex. Further, if \(S_i\) is compact, the convex set \(M_i\) is compact in the weak-* topology (see, for example, Billingsley, 1968).

Extend \(u_i: S \rightarrow \mathbb{R}\) to \(M = \times_{i=1}^N M_i\) by an expected utility calculation (hence, the \(u_i(s)\) are assumed to be von Neumann–Morgenstern utilities). That is, define

\[
u_i(m_1, ..., m_N) = \int_{S_1} \cdots \int_{S_N} u_i(s_1, ..., s_N) \, dm_1 \cdots dm_N
\]

for all \(m = (m_1, ..., m_N) \in M\). (This is an extension because we view \(S\) as a subset of \(M\); each \(s \in S\) is identified with the \(m \in M\) that assigns probability one to \(s\).) Finally, let \(\bar{G} = (M_i, u_i)_{i=1}^N\) denote the mixed extension of \(G = (S_i, u_i)_{i=1}^N\).

**Definition:** \(m^* \in M\) is a mixed strategy Nash equilibrium of \(\bar{G} = (S_i, u_i)_{i=1}^N\) if \(m^*\) is a pure strategy Nash equilibrium of the mixed extension, \(\bar{G}\), of \(G\). That is, if for every player \(i\), \(u_i(m^*) \geq u_i(m, m^*_{\neg i})\) for every \(m \in M_i\).

Because \(u_i(m^*_i, m^-_{\neg i})\) is linear and therefore quasi-concave, in \(m_i \in M_i\) for each \(m_{\neg i} \in M_{\neg i}\), and because continuity of \(u_i(\cdot)\) on \(S\) implies continuity of \(u_i(\cdot)\) on \(M\) (in the weak-* topology), Theorem 1 applied to the mixed extension of \(G\) yields the following basic mixed strategy Nash equilibrium existence result:

**Corollary 1:** If each \(S_i\) is a non-empty compact subset of a metric space, and each \(u_i(s)\) is continuous in \(s \in S\), then \(G = (S_i, u_i)_{i=1}^N\) possesses at least one mixed strategy Nash equilibrium, \(m^* \in M\).

**Remark:** Note that Corollary 1 does not require \(u_i(s_i, s_{\neg i})\) to be quasi-concave in \(S_i\), nor does it require
Remark: Corollary 1 yields von Neumann's (1928) classic result for two-person zero-sum games as well as Nash's (1950; 1951) seminal result for finite games as special cases. To obtain Nash's result, note that if each $S_i$ is finite, then each $u_i$ is continuous on $S$ in the discrete metric. Hence, the corollary applies and we conclude that every finite game possesses at least one mixed strategy Nash equilibrium.

Remark: To see how Theorem 1 can be applied to obtain the existence of mixed strategy equilibria in Bayesian games, see Milgrom and Weber (1985).

Remark: See Glicksberg (1952) for a generalization to non-metrizable strategy spaces.

3 Discontinuous games

The basic challenge one must overcome in extending equilibrium existence results from continuous games to discontinuous games is the failure of the best reply correspondence to satisfy the properties required for application of a fixed point theorem. For example, in auction or Bertrand price-competition settings, discontinuities in payoffs sometimes preclude the existence of best replies. The best reply correspondence then fails to be non-empty valued, and Glicksberg's theorem, for example, cannot be applied.

A natural technique for overcoming such difficulties is to approximate the infinite strategy spaces by a sequence of finer and finer finite approximations. Each of the approximating finite games is guaranteed to possess a mixed strategy equilibrium (by Corollary 1) and the resulting sequence of equilibria is guaranteed, by compactness, to possess at least one limit point. Under appropriate assumptions, the limit point is a Nash equilibrium of the original game. This technique has been cleverly employed in Dasgupta and Maskin's (1986) pioneering work, and also by Simon (1987). However, while this finite approximation technique can yield results on the existence of mixed strategy Nash equilibria, it is unable to produce equally general existence results for pure strategy Nash equilibria. The reason, of course, is that the approximating games, being finite, are guaranteed to possess mixed strategy, but not necessarily pure strategy, Nash equilibria. Consequently, the sequence of equilibria, and so also the limit point, cannot be guaranteed to be pure.

One might be tempted to conclude that, unlike the continuous game case where the mixed strategy result is a special case of the pure strategy result, discontinuous games require a separate treatment of pure and mixed strategy equilibria. But such a conclusion would be premature. A connection between pure and mixed strategy equilibrium existence results similar to that for continuous games can be obtained for discontinuous games by considering a different kind of approximation. Rather than approximating the infinite strategy spaces by a sequence of finite approximations, one can instead approximate the discontinuous payoff functions by a sequence of continuous payoff functions. This payoff-approximation technique is employed in Reny (1999), whose main result we now proceed to describe.

All of the definitions, notation, and conventions of the previous sections remain in effect. In particular, each $S_i$ is a subset of some metric space. (This is for simplicity of presentation only. The results to follow hold in non-metrizable settings as well. See Reny, 1999.)

3.1 Better-reply security
Definition: . Player $i$ can secure a payoff of $\alpha \in \mathbb{R}$ at $s \in S$ if there exists $\bar{s}_i \in S_i$, such that $u_i(\bar{s}_i, s_{-i}) \geq \alpha$ for all $s_{-i}$ close enough to $s$ - $i$.

Thus, a payoff can be secured by $i$ at $s$ if $i$ has a strategy that guarantees at least that payoff even if the other players deviate slightly from $s$.

A pair $(s, u) \in S \times \mathbb{R}^N$ is in the closure of the graph of the vector payoff function if $u \in \mathbb{R}^N$ is the limit of the vector of player payoffs for some sequence of strategies converging to $s$. That is, if $u = \lim_{s^N \rightarrow s} (u_1(s^N), \ldots, u_N(s^N))$ for some $s^N \rightarrow s$.

Definition: . A game $G = (S_i, u_i)_{i=1}^N$ is better-reply secure if whenever $(s^*, u^*)$ is in the closure of the graph of its vector payoff function and $s^*$ is not a Nash equilibrium, some player $i$ can secure a payoff strictly above $u^*_i$ at $s^*$.

All games with continuous payoff functions are better-reply secure. This is because if $(s^*, u^*)$ is in the closure of the graph of the vector payoff function of a continuous game, we must have $u^* = (u_1(s^*), \ldots, u_N(s^*))$. Also, if $s^*$ is not a Nash equilibrium then some player $i$ has a strategy $\bar{s}_i$ such that $u_i(\bar{s}_i, s_{-i}^*) > u_i(s^*)$, and continuity ensures that this inequality is maintained even if the others deviate slightly from $s^*$. Consequently, player $i$ can secure a payoff strictly above $u^*_i = u_i(s^*)$.

The import of better-reply security is that it is also satisfied in many discontinuous games. For example, Bertrand's price-competition game, many auction games, and many games of timing are better-reply secure.

### 3.2 Pure strategy Nash equilibria

The following theorem provides a pure strategy Nash equilibrium existence result for discontinuous games.

**Theorem 2:** (Reny, 1999). If each $S_i$ is a non-empty, compact, convex subset of a metric space, and each $u_i(s_1, \ldots, s_N)$ is quasi-concave in $s_i$, then $G = (S_i, u_i)_{i=1}^N$ possesses at least one pure strategy Nash equilibrium if in addition $G$ is better-reply secure.

**Remark:** . Theorem 1 is a special case of Theorem 2 because every continuous game is better-reply secure.

**Remark:** . A classic result due to Sion (1958) states that every two-person zero-sum game with compact strategy spaces in which player 1's payoff is upper-semi-continuous and quasi-concave in his own strategy, and lower-semi-continuous and quasi-convex in the opponent's strategy, has a value and each player has an optimal pure strategy. (Sion does not actually prove the existence of optimal strategies, but this follows rather easily from his compactness assumptions and his result that the game has a value, that is, that $\text{infsup}=\text{supinf}$.) It is not difficult to show that Sion's result is a special case of Theorem 2.

**Remark:** . A related result that weakens quasi-concavity but adds conditions to the sum of the players' payoffs can be found in Baye, Tian and Zhou (1993). Dasgupta and Maskin (1986) provide two interesting pure strategy equilibrium existence results, both of which require each player's payoff
function to upper semi-continuous in the vector of all players' strategies.

3.3 Mixed strategy Nash equilibria

One easily obtains from Theorem 2 a mixed strategy equilibrium existence result (the analogue of Corollary 1) by treating each $M_i$ as if it were player $i$'s pure strategy set and by applying the definition of better-reply security to the mixed extension $\hat{G} = (M_i, u_i)$ of $G$. This observation yields the following result.

**Corollary 2:** (Reny, 1999). If each $S_i$ is a non-empty, compact, convex subset of a metric space, then $G = (S_i, u_i)_{i=1}^N$ possesses at least one mixed strategy Nash equilibrium if in addition its mixed extension, $\hat{G} = (M_i, u_i)$, is better-reply secure.

**Remark:** Better-reply security of $\hat{G}$ neither implies nor is implied by better-reply security of $G$. (See Reny, 1999, for sufficient conditions for better-reply security.)

**Remark:** Corollary 1 is a special case of Corollary 2 because continuity of each $u_i(s)$ in $s \in S$ implies (weak-*-) continuity of $u_i(m)$ in $m \in M$, which implies that the mixed extension, $\hat{G}$, is better-reply secure.

**Remark:** Corollary 2 has as special cases the mixed strategy equilibrium existence results of Dasgupta and Maskin (1986), Simon (1987) and Robson (1994).

**Remark:** Theorem 2 can similarly be used to obtain a result on the existence of mixed strategy equilibria in discontinuous Bayesian games by following Milgrom and Weber's (1985) seminal distributional strategy approach. One simply replaces Milgrom and Weber's payoff continuity assumption with the assumption that the Bayesian game is better-reply secure in distributional strategies. An example of this technique is provided in the next subsection.

3.4 An application to auctions

Auctions are an important class of economic games in which payoffs are discontinuous. Furthermore, when bidders are asymmetric, in general one cannot prove existence of equilibrium by construction, as in the symmetric case. Consequently, an existence theorem applicable to discontinuous games is called for. Let us very briefly sketch how Theorem 2 can be applied in this case.

Consider a first-price single-object auction with $N$ bidders. Each bidder $i$ receives a private value $v_i \in [0, 1]$ prior to submitting a sealed bid, $b_i \geq 0$. Bidder $i$'s value is drawn independently according to the continuous and positive density $f_i$. The highest bidder wins the object and pays his bid. Ties are broken randomly and equiprobably. Losers pay nothing.

Because payoffs are not quasi-concave in own bids, one cannot appeal directly to Theorem 2 to establish the existence of an equilibrium in pure strategy bidding functions. On the other hand, it is not difficult to show that all mixed strategy equilibria are pure and non-decreasing. Hence, to obtain an existence result for pure strategies, it suffices to show that there is an equilibrium in mixed, or equivalently in distributional, strategies. (In this context, a distributional strategy for bidder $i$ is a joint probability distribution over his values and bids with the property that the marginal density over his values is $f_i$; see Milgrom and Weber, 1985.)
Because the set of distributional strategies for each bidder is a non-empty compact convex metric space and each bidder's payoff is linear in his own distributional strategy, Theorem 2 can be applied so long as a first-price auction game in distributional strategies is better-reply secure. Better-reply security can be shown to hold by using the facts that payoff discontinuities occur only when there are ties in bids and that bidders can always break a tie in their favour by increasing their bid slightly. Consequently, a Nash equilibrium in distributional strategies exists and, as mentioned above, this equilibrium is pure and non-decreasing.

3.5 Endogenous sharing rules

Discontinuities in payoffs sometimes arise endogenously. For example, consider a political game in which candidates first choose a policy from the interval [0,1] and each voter among a continuum then decides for whom to vote. Voters vote for the candidate whose policy they most prefer, and if there is more than one such candidate it is conventional to assume that voters randomize equiprobably over them. The behaviour of voters in the second stage can induce discontinuities in the payoffs of the candidates in the first stage since a candidate can discontinuously gain or lose a positive fraction of votes by choosing a policy that, instead of being identical to another candidate's policy, is just slightly different from it.

Simon and Zame (1990) suggest an elegant way to handle such discontinuities. In particular, for the political game example above, they would not insist that voters, when indifferent, randomize equiprobably. Indeed, applying subgame perfection to the two-stage game would permit voters to randomize in any manner whatsoever over those candidates whose policies they most prefer. With this in mind, if $s$ is a joint pure strategy for the $N$ candidates specifying a location for each, let us denote by $U(s)$ the resulting set of payoff vectors for the $N$ candidates when all best replies of the voters are considered. If no voter is indifferent, then $U(s)$ contains a single payoff vector. On the other hand, if some voters are indifferent (as would be the case if two or more candidates chose the same location) and $U(s)$ is not a singleton, then distinct payoff vectors in $U(s)$ correspond to different ways the indifferent voters can randomize between the candidates among whom they are indifferent.

The significance of the correspondence $U(\cdot)$ is this. Suppose that we are able to select, for each $s$, a payoff vector $u(s) \in U(s)$ in such a way that some joint mixed strategy $m^*$ for the $N$ candidates is a Nash equilibrium of the induced policy-choice game between them when their vector payoff function is $u(\cdot)$. Then $m^*$ together with the voter behaviour that is implicit in the definition of $u(s)$ for each $s$, constitutes a subgame perfect equilibrium of the original two-stage game. Thus, solving the original problem with potentially endogenous discontinuities boils down to obtaining an appropriate selection from $U(\cdot)$. Simon and Zame (1990) provide a general result concerning the existence of such selections, which they refer to as 'endogenous sharing rules'. This method therefore provides an additional tool for obtaining equilibrium existence when discontinuities are present. Simon and Zame's main result is as follows.

**Theorem 3**: (Simon and Zame, 1990). Suppose that each $S_i$ is a compact subset of a metric space and that $U: S \rightarrow \mathbb{R}^N$ is a bounded, upper hemi-continuous, non-empty-valued, convex-valued correspondence. Then for each player $i$, there is a measurable payoff function, $u_i: S \rightarrow \mathbb{R}$, such that
non-cooperative games (equilibrium existence) : The New Palgrave Dictionary of Economics

for every $s \in S$ and such that the game $(S, u_i)_{i=1}^N$ possesses at least one mixed strategy Nash equilibrium.

**Remark:** Theorem 3 applies to the political game example above because for any policy choice $s$ of the $N$ candidates, the resulting set of payoff vectors $U(s)$ is convex, a fact that follows from the presence of a continuum of voters. It can also be shown that, as a correspondence, $U(\cdot)$ is upper hemi-continuous.

**Remark:** In the context of Bayesian games, an even more subtle endogenous-sharing rule result can be found in Jackson et al. (2002). This result, too, can be very helpful in dealing with discontinuous games. Indeed, Jackson and Swinkels (2005) have shown how it can be used to obtain equilibrium existence results in a variety of auction settings, including double auctions.

non-expected utility theory

Mark J. Machina
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Beginning with the work of Allais and Edwards in the early 1950s and continuing through the present, psychologists and economists have uncovered a growing body of evidence that individuals do not necessarily conform to many of the key assumptions or predictions of the expected utility model of choice under uncertainty, and seem to depart from this model in systematic and predictable ways. This has led to the development of alternative models of preferences over objectively or subjectively uncertain prospects, which seek to accommodate these systematic departures from the expected utility model while retaining as much of its analytical power as possible.

Article

Although the expected utility model has long been the standard theory of individual choice under objective and subjective uncertainty, experimental work by both psychologists and economists has uncovered systematic departures from the expected utility hypothesis, which has led to the development of alternative models of preferences over uncertain prospects.

The expected utility model

In one of the simplest settings of choice under economic uncertainty, the objects of choice consist of finite-outcome objective lotteries of the form $P = (x_1, p_1; \ldots; x_n, p_n)$, yielding a monetary payoff of $x_i$ with probability $p_i$, where $p_1 + \ldots + p_n = 1$. In such a case, the expected utility model of risk preferences assumes (or posits axioms sufficient to imply) that the individual ranks these prospects on the basis of an expected utility preference function of the form

$$V_{EU}(P) = V_{EU}(x_1, p_1; \ldots; x_n, p_n) = U(x_1) \cdot p_1 + \ldots + U(x_n) \cdot p_n$$

in the standard economic sense that the individual prefers lottery $P^* = (x_1^*, p_1^*; \ldots; x_n^*, p_n^*)$ over lottery $P = (x_1, p_1; \ldots; x_n, p_n)$ if and only if $V_{EU}(P^*) > V_{EU}(P)$, and is indifferent between them if and only if $V_{EU}(P^*) = V_{EU}(P)$. $U(\cdot)$ is termed the individual’s von Neumann–Morgenstern utility function (von Neumann and Morgenstern, 1944; 1947;
and its various mathematical properties serve to characterize various features of the individual's attitudes toward risk, for example:

- \( V_{EU} (\cdot) \) exhibits first-order stochastic dominance preference (a preference for shifting probability from lower to higher outcome values) if and only if \( U(x) \) is an increasing function of \( x \).
- \( V_{EU} (\cdot) \) exhibits risk aversion (an aversion to all mean-preserving increases in risk) if and only if \( U(x) \) is a concave function of \( x \).
- \( V_{EU}^{*} (\cdot) \) is at least as risk averse as \( V_{EU} (\cdot) \) (in several equivalent senses) if and only if its utility function \( U^{*}(\cdot) \) is a concave transformation of \( U(\cdot) \) (that is, if and only if \( U^{*}(x) = \rho(U(x)) \) for some increasing concave function \( \rho(\cdot) \)).

As shown by Bernoulli (1738), Arrow (1965), Pratt (1964), Friedman and Savage (1948), Markowitz (1952) and others, this model admits of a tremendous flexibility in representing attitudes towards risk, and can be applied to many types of economic decisions and markets.

But in spite of its flexibility, the expected utility model has testable implications which hold regardless of the shape of the utility function \( U(\cdot) \), since they follow from the linearity in the probabilities property of the preference function \( V_{EU} (\cdot) \). These implications can be best expressed by the concept of an \( \alpha \cdot (1 - \alpha) \) probability mixture of two lotteries

\[
P = (x_1, p_{1\cdot}, \ldots, x_n, p_{n\cdot}) \text{ and } P^* = (x_1^*, p_{1\cdot}^*, \ldots, x_n^*, p_{n\cdot}^*),
\]

which is defined as the single-stage lottery

\[
\alpha \cdot P + (1 - \alpha) \cdot P^* = (x_1, \alpha \cdot p_{1\cdot}, \ldots, x_n, \alpha \cdot p_{n\cdot}, x_1^*, (1 - \alpha) \cdot p_{1\cdot}^*, \ldots, x_n^*, (1 - \alpha) \cdot p_{n\cdot}^*).
\]

The mixture \( \alpha \cdot P + (1 - \alpha) \cdot P^* \) can be thought of as a coin flip yielding lotteries \( P \) and \( P^* \) with probabilities \( \alpha : (1 - \alpha) \), where the uncertainty in the coin and in the subsequent lottery is resolved simultaneously. Linearity in the probabilities is equivalent to the following property, which serves as the key foundational axiom of the expected utility model (Marschak, 1950):

**Independence Axiom:** If lottery \( P^* \) is preferred (indifferent) to lottery \( P \), then the probability mixture \( \alpha \cdot P^* + (1 - \alpha) \cdot P^{**} \) is preferred (indifferent) to \( \alpha \cdot P + (1 - \alpha) \cdot P^{**} \) for every lottery \( P^{**} \) and every mixture probability \( \alpha \in (0, 1) \).

This axiom can be interpreted as saying ‘given an \( \alpha : (1 - \alpha) \) coin, the individual's preferences for receiving \( P^* \) versus \( P \) in the event of a head should not depend upon the prize \( P^{**} \) that would be received in the event of a tail, nor upon the probability \( \alpha \) of landing heads (so long as this probability is positive)’. The strong normative appeal of this axiom has contributed to the widespread adoption of the expected utility model.

The property of linearity in the probabilities, as well as the senses in which it has been found to be empirically violated, can be illustrated in the special case of preferences over all outcomes \( \bar{x}_1, \bar{x}_2, \bar{x}_3 \) over a fixed set of outcome values \( \bar{x}_1 < \bar{x}_2 < \bar{x}_3 \). Since we must have \( p_2 = 1 - p_1 - p_3 \), each such lottery can be completely summarized by its pair of probabilities \( (p_1, p_3) \), as plotted in the ‘probability triangle’ of Figure 1. Since upward movements in the diagram (increasing \( p_3 \) for fixed \( p_1 \)) represent shifting probability from outcome \( \bar{x}_3 \) to \( \bar{x}_2 \) and leftward movements represent shifting probability from \( \bar{x}_1 \) to \( \bar{x}_3 \), such movements constitute first-order stochastically dominating shifts and will thus always be preferred. Expected utility indifference curves (loci of constant expected utility) are given by the formula

\[
U(\bar{x}_1) \cdot p_1 + U(\bar{x}_2) \cdot (1 - p_1 - p_3) + U(\bar{x}_3) \cdot p_3 = \text{constant}
\]

and are thus seen to be parallel straight lines of slope \( [U(\bar{x}_2) - U(\bar{x}_1)] / [U(\bar{x}_3) - U(\bar{x}_2)] \), as indicated by the solid lines in the figure. The dotted lines in Figure 1 are loci of constant expected value, given by the formula \( \bar{x}_1 \cdot p_1 + \bar{x}_2 \cdot (1 - p_1 - p_3) + \bar{x}_3 \cdot p_3 = \text{constant} \), with slope \( [\bar{x}_2 - \bar{x}_1] / [\bar{x}_3 - \bar{x}_2] \). Since north-east movements along the constant expected value lines shift probability from \( \bar{x}_2 \) down to \( \bar{x}_1 \) and up to \( \bar{x}_3 \) in a manner that preserves the mean of the distribution, they represent simple increases in risk (Rothschild and Stiglitz, 1970; 1971). When \( U(\cdot) \) is concave (that is, risk averse), its indifference curves will have a steeper slope than these constant expected value lines, and such increases in risk move the indifference curves from more to less preferred indifference curves, as illustrated in the figure. It is straightforward to show that the indifference curves of any expected utility maximizer with a more risk-averse (that is, more concave) utility function \( U^{*}(\cdot) \) will be steeper than those generated by \( U(\cdot) \).
non-expected utility theory: The New Palgrave Dictionary of Economics

Increasing preference

$p_3$
Systematic violations of the expected utility hypothesis

In spite of its normative appeal, researchers have uncovered several types of widespread systematic violations of the expected utility model and its underlying assumptions. These can be categorized into (a) violations of the Independence Axiom (such as the common consequence and common ratio effects), (b) violations of the hypothesis of probabilistic beliefs (such as the Ellsberg Paradox) and (c) violations of the model's underlying assumptions of descriptive and procedural invariance (such as reference-point and response-mode effects).

Violations of the Independence Axiom

The best-known violation of the Independence Axiom is the so-called Allais Paradox, in which individuals are asked to rank the lotteries in each of the following pairs, where $1M = 1,000,000:

\[
\begin{align*}
\text{a}_1: & \{1.00 \text{ chance of } \$1M \text{ versus } a_2: \{.10 \text{ chance of } \$5M \\
& \text{.89 chance of } \$1M \text{ versus } .01 \text{ chance of } \$0 \\
\text{a}_3: & \{.10 \text{ chance of } \$5M \text{ versus } a_4: \{.11 \text{ chance of } \$1M \\
& \text{.90 chance of } \$0 \text{ versus } .89 \text{ chance of } \$0
\end{align*}
\]

Researchers such as Allais (1953), Morrison (1967), Raiffa (1968), Slovic and Tversky (1974) and others have found that the modal if not majority preference of subjects is for $a_1$ over $a_2$ in the first pair of choices and for $a_3$ over $a_4$ in the second pair. However, such preferences violate expected utility, since the first ranking implies the inequality $U(\$1M) > .10 \cdot U(\$5M) + .89 \cdot U(\$1M) + .01 \cdot U(\$0)$ whereas the second implies the inconsistent inequality $10 \cdot U(\$5M) + .90 \cdot U(\$0) > 11 \cdot U(\$1M) + .89 \cdot U(\$0)$.

By setting $x_1 = \$0$, $x_2 = \$1M$ and $x_3 = \$5M$, the lotteries $a_1$, $a_2$, $a_3$ and $a_4$ are seen to form a parallelogram when plotted in the probability triangle (Figure 2), which explains why the parallel straight line indifference curves of an expected utility maximizer must either prefer $a_1$ and $a_4$ (as illustrated for the relatively steep indifference curves of the figure) or else prefer $a_2$ and $a_3$ (for relatively flat indifference curves). Figure 3 illustrates non-expected utility indifference curves which fan out, and are seen to exhibit the typical Allais Paradox rankings of $a_1$ over $a_2$ and $a_3$ over $a_4$.

Figure 2
Expected utility indifference curves and the Allais Paradox choices

![Image of expected utility indifference curves and the Allais Paradox choices](http://www.dictionaryofeconomics.com.proxy.library.csi.cuny.edu/article?id=pde2008_N0000081&goto=B&result_number=1215)
Figure 3
Allais Paradox choices and indifference curves which ‘fan out’
Although the Allais Paradox was originally dismissed as an isolated example, subsequent experimental work by psychologists, economists and others have uncovered a similar pattern of violations over a range of probability and payoff values, and the Allais Paradox is now seen to be a special case of a widely observed phenomenon known as the common consequence effect. This effect involves pairs of prospects (probability mixtures) of the form:

\[ b_1: \begin{cases} \alpha \text{ chance of } x \\ 1 - \alpha \text{ chance of } P'' \end{cases} \text{ versus } b_2: \begin{cases} \alpha \text{ chance of } P \\ 1 - \alpha \text{ chance of } P'' \end{cases} \]

\[ b_3: \begin{cases} \alpha \text{ chance of } x \\ 1 - \alpha \text{ chance of } P' \end{cases} \text{ versus } b_4: \begin{cases} \alpha \text{ chance of } P \\ 1 - \alpha \text{ chance of } P' \end{cases} \]

where the lottery \( P \) involves outcomes both greater and less than the amount \( x \), and \( P'' \) first order stochastically dominates \( P' \) (in Allais's example, \( x = $1M \)).
non-expected utility theory: The New Palgrave Dictionary of Economics

Although the Independence Axiom clearly implies choices of either \( b_1 \) and \( b_3 \) (if \( x \) is preferred to \( P \)) or else \( b_2 \) and \( b_4 \) (if \( P \) is preferred to \( x \)), researchers have found a tendency for subjects to choose \( b_1 \) in the first pair and \( b_4 \) in the second. When the distributions \( P, P^* \) and \( P^{**} \) are each over a common outcome set \( \{x_1, x_2, x_3\} \) with \( x_2 = \chi \), the prospects \( \{b_1, b_2, b_3, b_4\} \) again form a parallelogram in the \((p_1, p_3)\) triangle, and a choice of \( b_1 \) and \( b_4 \) again implies indifference curves which fan out.

The intuition behind this phenomenon can be described in terms of the above ‘coin-flip’ scenario. According to the Independence Axiom, one’s preferences over what would occur in the event of a head ought not depend upon what would occur in the event of a tail. However, they may well depend upon what would otherwise happen (as Bell, 1985, p. 1, notes, ‘winning the top prize of $10,000 in a lottery may leave one much happier than receiving $10,000 as the lowest prize in a lottery’). The common consequence effect states that the better off individuals would be in the event of a tail (in the sense of stochastic dominance), the more risk averse their preferences over what they would receive in the event of a head.

That is, if the distribution \( P^{**} \) in the pair \( \{b_1, b_2\} \) involves very high outcomes, one may prefer not to bear further risk in the unlucky event that one doesn't receive it, and hence opt for the sure outcome \( x \) over the risky distribution \( P \) (that is, choose \( b_1 \) over \( b_2 \)). But, if \( P^* \) in \( \{b_3, b_4\} \) involves very low outcomes, one might be more willing to bear risk in the lucky event that one doesn't receive it, and prefer going for the lottery \( P \) rather than the sure outcome \( x \) (choose \( b_4 \) over \( b_3 \)).

A second type of systematic violation of linearity in the probabilities, also noted by Allais and subsequently termed the common ratio effect, involves prospects of the form:

\[
\begin{align*}
c_1: & \quad \frac{\rho}{1 - \rho} \text{ chance of } x \quad \text{versus} \quad c_2: \quad \frac{q}{1 - q} \text{ chance of } y \\
c_3: & \quad \frac{\alpha \cdot \rho}{1 - \alpha \cdot \rho} \text{ chance of } x \quad \text{versus} \quad c_4: \quad \frac{\alpha \cdot q}{1 - \alpha \cdot q} \text{ chance of } y
\end{align*}
\]

where \( \rho > q, 0 < x < y \) and \( \alpha \in (0, 1) \). (The term ‘common ratio effect’ comes from the common value of \( \text{prob}(x)/\text{prob}(y) \) in the upper and lower pairs.) Setting \( \{x_1, x_2, x_3\} = \{0, x, y\} \) and plotting these prospects in the probability triangle as in Figure 4, the line segments \( \overline{c_1c_2} \) and \( \overline{c_3c_4} \) are seen to be parallel, so that the expected utility model again predicts choices of \( c_1 \) and \( c_3 \) (if the indifference curves are relatively steep) or else \( c_2 \) and \( c_4 \) (if they are flat). However, experimental studies by MacCrimmon (1968), Tversky (1975), MacCrimmon and Larsson (1979), Kahneman and Tversky (1979), Hagen (1979), Chew and Waller (1986) and others have found a systematic tendency for choices to depart from these predictions in the direction of preferring \( c_1 \) over \( c_2 \) and \( c_4 \) over \( c_3 \), which again suggests that indifference curves fan out, as in the figure. For example, Kahneman and Tversky (1979) found that, while 86 per cent of their subjects preferred a .90 chance of winning $3,000 to a .45 chance of $6,000, 73 per cent preferred a .001 chance of $6,000 to a .002 chance of $3,000. Kahneman and Tversky (1979) observed that, when the positive outcomes $3000 and $6000 in the above gambles are replaced by losses of these magnitudes, to obtain the lotteries \( c_1, c_2, c_3 \) and \( c_4 \), preferences typically ‘reflect,’ to prefer \( c_2 \) over \( c_1 \) and \( c_3 \) over \( c_4 \). Setting \( x_1 = -$6000, x_2 = -$3000 \) and \( x_3 = -$0 \) (to preserve the ordering \( x_1 < x_2 < x_3 \)) and plotting as in Figure 5, such preferences again suggest that indifference curves in the probability triangle fan out.

Battalio, Kagel and MacDonald (1985) found that laboratory rats choosing among gambles involving substantial variations in their daily food intake also exhibited this pattern of choices.

Figure 4
Common ratio effect and fanning out indifference curves
Figure 5
Common ratio effect for losses and fanning out indifference curves
One criticism of this evidence has been that individuals whose initial choices violated the Independence Axiom in the above manners would typically 'correct' themselves once the nature of their violations was revealed by an application of the above type of coin-flip argument. Thus, while even Leonard Savage chose \( a_1 \) and \( a_3 \) when first presented with such choices by Allais, he concluded upon reflection that these preferences were in error (Savage, 1954, pp. 101–3). Although Moskowitz found that allowing subjects to discuss opposing written arguments led to a decrease in the proportion of violations, 73 per cent of the initial fanning-out type choices remained unchanged after the discussions (1974, pp. 232–7, Table 6). When written arguments were presented but no discussion was allowed, there was a 93 per cent persistency rate of such choices (1974, p. 234, Tables 4, 6). In experiments where subjects who responded to Allais-type problems were then presented with written arguments both for and against the expected utility position, neither MacCrimmon (1968), Moskowitz (1974) nor Slovic and Tversky (1974) found predominant net swings toward the expected utility choices.

Non-existence of probabilistic beliefs

Although the expected utility model was first formulated in terms of preferences over objective lotteries \( P = (x_1, P_1; \ldots; x_n, P_n) \) with pre-specified probabilities, it has also been applied to preferences over subjective acts \( f (\cdot) = \{x_1 \text { on } E_1; \ldots; x_n \text { on } E_n\} \), where the uncertainty is represented by a set \( \{E_1, \ldots, E_n\} \) of mutually exclusive and exhaustive events (such as the alternative outcomes of a horse race) (Savage, 1954). As long as an individual possesses well-defined subjective probabilities \( \mu (E_1), \ldots, \mu (E_n) \) over these events, their subjective expected utility preference function takes the form

\[
W_{SEU}(f (\cdot)) = W_{SEU}(x_1 \text { on } E_1; \ldots; x_n \text { on } E_n) = U(x_1) \cdot \mu (E_1) + \ldots + U(x_n) \cdot \mu (E_n)
\]

However, researchers have found that individuals may not possess such well-defined subjective probabilities, in even the simplest of cases. The best-known example of this is the Ellsberg Paradox (Ellsberg, 1961), in which the individual must draw a ball from an urn that contains 30 red balls, and 60 black or yellow balls in an unknown proportion, and is offered the following bets based on the colour of the drawn ball:
Most individuals exhibit a preference for \( f_1(\cdot) \) over \( f_2(\cdot) \) and \( f_4(\cdot) \) over \( f_3(\cdot) \). When asked, they explain that the chance of winning under \( f_2(\cdot) \) could be anywhere from 0 to 2/3 whereas under \( f_1(\cdot) \) it is known to be exactly 1/3, and they prefer the bet that offers the known probability. Similarly, the chance of winning under \( f_3(\cdot) \) could be anywhere from 1/3 to 1 whereas under \( f_4(\cdot) \) it is known to be exactly 2/3, so the latter is preferred. However, such preferences are inconsistent with any assignment of subjective probabilities \( \mu(\text{red}), \mu(\text{black}), \mu(\text{yellow}) \) to the three events. If the individual were to be choosing on the basis of such probabilistic beliefs, the choice of \( f_1(\cdot) \) over \( f_2(\cdot) \) would ‘reveal’ that \( \mu(\text{red}) > \mu(\text{black}) \), but the choice of \( f_4(\cdot) \) over \( f_3(\cdot) \) would reveal that \( \mu(\text{red}) < \mu(\text{black}) \). A preference for gambles based on probabilistic partitions such as \{red, black \cup yellow\} over gambles based on subjective partitions such as \{black, red \cup yellow\} is termed *ambiguity aversion*.

In an even more basic example, Ellsberg presented subjects with a pair of urns, the first containing 50 red balls and 50 black balls, and the second with 100 red and black balls in an unknown proportion. When asked, a majority of subjects strictly preferred to stake a prize on drawing red from the first urn over drawing red from the second urn, and strictly preferred staking the prize on drawing black from the first urn over drawing black from the second. It is clear that there can exist no subjective probabilities \( p:(1-p) \) of red:black in the
second urn, including 1/2:1/2, which can simultaneously generate both of these strict preferences. Similar behaviour in this and related problems has been observed by Raiffa (1961), Becker and Brownson (1964), MacCrimmon (1965), Slovic and Tversky (1974) and MacCrimmon and Larsson (1979).

Violations of descriptive and procedural invariance

Researchers have also uncovered several systematic violations of the standard economic assumptions of stability of preferences and invariance with respect to problem description in choices over risky prospects. In particular, psychologists have found that alternative means of representing or framing probabilistically equivalent choice problems lead to systematic differences in choice. Early examples of this were reported by Slovic (1969), who found that offering a gain or loss contingent on the joint occurrence of four independent events with probability $p$ elicited different responses than offering it on the occurrence of a single event with probability $p^4$ (all probabilities were stated explicitly). In comparison with the single-event case, making a gain contingent on the joint occurrence of events was found to make it more attractive, and making a loss contingent on the joint occurrence of events made it more unattractive.

One class of framing effects exploits the phenomenon of a reference point. According to economic theory, the variable which enters an individual's von Neumann–Morgenstern utility function should be total (that is, final) wealth, and gambles phrased in terms of gains and losses should be combined with current wealth and re-expressed as distributions over final wealth levels before being evaluated. However, risk attitudes towards gains and losses tend to be more stable than can be explained by a fixed utility function over final wealth, and utility functions might be best defined in terms of changes from the reference point of current wealth. In his discussion of this phenomenon, Markowitz (1952, p. 155) suggested that certain circumstances may cause the individual's reference point to temporarily deviate from current wealth. If these circumstances include the manner in which a problem is verbally described, then differing risk attitudes towards gains and losses from the reference point can lead to different choices, depending upon the exact description of an otherwise identical problem. A simple example of this, from Kahneman and Tversky (1979, p. 273), involves the following two choices:

In addition to whatever you own, you have been given 1,000 (Israeli pounds). You are now asked to choose between a 1/2:1/2 chance of a gain of 1,000 or 0 or a sure chance of a gain of 500.

and

In addition to whatever you own, you have been given 2,000. You are now asked to choose between a 1/2:1/2 chance of a loss of 1,000 or 0 or a sure loss of 500.

These two problems involve identical distributions over final wealth. But, when put to two different groups of subjects, 84 per cent chose the sure gain in the first problem but 69 per cent chose the 1/2:1/2 gamble in the second.

In another class of examples, not based on reference point effects, Moskowitz (1974), Keller (1985) and Carlin (1990) found that the proportion of subjects choosing in conformity with the Independence Axiom in examples like the Allais Paradox was significantly affected by whether the problems were described in the standard matrix form, decision tree form, roulette wheels, or as minimally structured written statements. Interestingly, the form judged the ‘clearest representation’ by the majority of Moskowitz's subjects (the tree form) led to the lowest degree of consistency with the Independence Axiom, the highest proportion of Allais-type (fanning out) choices, and the highest persistency rate of these choices Moskowitz (1974, pp. 234, 237–8).

In other studies, Schoemaker and Kunreuther (1979), Hershey and Schoemaker (1980), Kahneman and Tversky (1982; 1984), and Slovic, Fischhoff and Lichtenstein (1977) found that subjects' choices in otherwise identical problems depended upon whether they were phrased as decisions whether or not to gamble as opposed to whether or not to insure, whether statistical information for different therapies was presented in terms of cumulative survival probabilities or cumulative mortality probabilities, and so on (see the references in Tversky and Kahneman, 1981).

Whereas framing effects involve alternative descriptions of an otherwise identical choice problem, alternative response formats have also been found to lead to different choices, leading to what have been termed response-mode effects. For example, under expected utility, an individual's von Neumann–Morgenstern utility function can be assessed or elicited in a number of different manners, which typically involve a sequence of pre-specified lotteries $P_1$, $P_2$, $P_3$, ..., and ask for (a) the individual's certainty equivalent $CE(P_i)$ of each lottery $P_i$, (b) the gain equivalent $G_i$ that would make the gamble $(G_i,1/2; 0,0)$ indifferent to $P_i$, or (c) the probability equivalent $\varphi_i$ that would make the gamble $(1000,\varphi_i; 0,1-\varphi_i)$ indifferent to $P_i$. Although such procedures should generate equivalent assessed utility functions, they have been found to yield systematically different ones (for example, Hershey, Kunreuther and Schoemaker, 1982; Hershey and Schoemaker, 1985).

In a separate finding now known as the preference reversal phenomenon, subjects were first presented with a number of pairs of lotteries and asked to make one choice out of each...
pair. Each pair of lotteries took the following form:

\[
\begin{align*}
p\text{-bet: } & \begin{cases} p \text{ chance of } \$X \\ 1-p \text{ chance of } \$0 \end{cases} \text{ versus } \begin{cases} q \text{ chance of } \$Y \\ 1-q \text{ chance of } \$0 \end{cases}
\end{align*}
\]

where \(0 < X < Y\) and \(p > q\). The terms ‘\(p\text{-bet}’ and ‘\(q\text{-bet}’ derive from the greater probability of winning in the first bet, and greater possible gain in the second bet. Subjects were next asked for their certainty equivalents of each of these bets, via a number of standard elicitation techniques. Standard theory predicts that, for each such pair, the prospect selected in the direct choice problem would also be assigned the higher certainty equivalent. However, subjects exhibit a systematic departure from this prediction in the direction of choosing the \(p\text{-bet} in a direct choice, but assigning a higher certainty equivalent to the \(q\text{-bet} (Lichtenstein and Slovic, 1971). Although this finding initially generated widespread scepticism, it has been replicated by both psychologists and economists in a variety of settings involving real-money gambles, patrons in a Las Vegas casino, group decisions and experimental market trading. By expressing the implied preferences as \(‘q\text{-bet} \sim CE(q\text{-bet}) \cdot CE(p\text{-bet}) \sim p\text{-bet } \cdot q\text{-bet}\), some economists have categorized this phenomenon as a violation of transitivity and tried to model it as such (see the ‘regret theory’ model below). However, most psychologists and economists now view it as a response-mode effect: specifically, that the psychological processes of valuation (which generates certainty equivalents) and direct choice are differentially influenced by the probabilities and payoffs involved in a lottery, and that under certain conditions this can lead to choices and valuations which ‘reveal’ opposite preference rankings over a pair of gambles.

### Non-expected utility models of risk preferences

#### Non-expected utility functional forms

Researchers have responded to departures from linearity in the probabilities in two manners. The first consists of replacing the expected utility form

\[
V_E(P) = U(x_1) \cdot P_1 + \ldots + U(x_n) \cdot P_n
\]

by some more general form for the preference function

\[
V(P) = V(x_1, P_1; \ldots; x_n, P_n)
\]

Several such forms have been proposed (for the Rank Dependent, Dual and Ordinal Independence forms, the payoffs must be labelled so that \(x_1 \leq \ldots \leq x_n\) and \(G(\cdot)\) must satisfy \(G(0) = 0\) and \(G(1) = 1\):

- **Prospect theory** \(\sum_{i=1}^{n} V(x_i) \cdot n(P_i)\)
- **Subjectively weighted utility** \(\sum_{i=1}^{n} V(x_i) \cdot n(P_i) / \sum_{i=1}^{n} n(P_i)\)
- **Rank-dependent expected utility** \(\sum_{i=1}^{n} V(x_i) \cdot \left[ C\left(\sum_{j=1}^{i-1} P_j\right) - C\left(\sum_{j=1}^{i-1} P_j\right) \right]\)
- **Dual expected utility** \(\sum_{i=1}^{n} x_i \cdot \left[ C\left(\sum_{j=1}^{i-1} P_j\right) - C\left(\sum_{j=1}^{i-1} P_j\right) \right]\)
- **Ordinal independence** \(\sum_{i=1}^{n} h(x_i, \sum_{j=1}^{i-1} P_j) \cdot \left[ C\left(\sum_{j=1}^{i-1} P_j\right) - C\left(\sum_{j=1}^{i-1} P_j\right) \right]\)
- **Moments of utility** \(\sum_{i=1}^{n} V(x_i) \cdot P_i / \sum_{i=1}^{n} V(x_i) \cdot P_i\)
- **Weighted utility** \(\sum_{i=1}^{n} V(x_i) \cdot g(P_i, x_1, \ldots, x_n)\)
- **Optimism–pessimism** \(\sum_{i=1}^{n} V(x_i) \cdot P_i \quad \sum_{i=1}^{n} V(x_i) \cdot P_i\)
- **Quadratic in the probabilities** \(\sum_{i=1}^{n} \sum_{j=1}^{n} K(x_i, x_j) \cdot P_i \cdot P_j\)
- **Regret theory** \(\sum_{i=1}^{n} \sum_{j=1}^{n} R(x_i, x_j) \cdot P_i \cdot P_j\)

Most of these forms have been formally axiomatized, and, under the appropriate monotonicity and/or curvature assumptions on their constituent functions \(V(\cdot), G(\cdot)\), and so on, most are capable of exhibiting first-order stochastic dominance preference, risk aversion, and the above types of systematic violations of the Independence Axiom. Researchers such as Konrad and Skaperdas (1993), Schlesinger (1997) and Gollier (2000) have used these forms to revisit many of the applications previously modelled by expected utility theory, such as asset and insurance demand, in order to determine which expected-utility-based results are, and which are not, robust to departures from linearity in the probabilities, and which additional properties of risk-taking behaviour can be modelled.
Although the form \( \sum_{j=1}^{n} \pi_j \cdot U(x_j) \) was the earliest non-expected utility model to be proposed, it was largely abandoned when it was realized that, whenever the weighting function \( \pi(\cdot) \) was nonlinear, the generic inequalities \( \pi(p_1) + \pi(p_2) + \pi(p_3) + \cdots \neq \sum_{j=1}^{n} \pi_j \cdot U(x_j) \) and \( \pi(p_1) + \pi(p_2) + \pi(p_3) + \cdots \neq \sum_{j=1}^{n} \pi_j \cdot U(x_j) \) implied discontinuities in the payoffs and inconsistency with first-order stochastic dominance preference. Both problems were corrected by adopting weights \( \{ C(\sum_{j=1}^{n} \pi_j) - C(\sum_{j=1}^{n-1} \pi_j) \} \) based on the cumulative probability values \( P_1, P_1 + P_2, P_1 + P_2 + P_3, \ldots \), to obtain the Rank-Dependent form. Under the above-mentioned restrictions on this form, these weights necessarily sum to unity, and the Rank-Dependent form has emerged as the most widely adopted model in both theoretical and applied analyses. The Dual Expected Utility and Ordinal Independence forms are based on similar weighting formulas.

Unlike the other models, the regret theory form dispenses with the assumption of a preference function over lotteries, and instead derives choice from the psychological notions of rejoice and regret – that is, the reaction to receiving outcome \( x \) when an alternative decision would have led to outcome \( x^* \). The primitive of this model is a \( \text{regret:}\text{rejoice} R(x, x^*) \) which is positive if \( x \) is preferred to \( x^* \), negative if \( x^* \) is preferred to \( x \), zero if they are indifferent, and satisfies the skew-symmetry condition \( R(x, x^*) = -R(x^*, x) \). In a choice between lotteries \( \mathbf{P} = (\pi_1, \pi_2; \cdots; \pi_n, \pi_n) \) and \( \mathbf{P}^* = (\pi_1^*, \pi_2^*; \cdots; \pi_n^*, \pi_n^*) \) which are realized independently, the individual's expected rejoice from choosing \( \mathbf{P} \) over \( \mathbf{P}^* \) is given by \( \sum_{i=1}^{n} \pi_i * R(x_i, x_i^*) \cdot \pi_i \cdot \pi_i^* \), and the individual is predicted to choose \( \mathbf{P} \) if this value is positive, \( \mathbf{P}^* \) if it is negative, and be indifferent if it is zero (various proposals for extending this approach beyond pairwise choice have been offered). Since this model specifies choice in pairwise comparisons rather than preference levels of individual lotteries, it allows choice to be intransitive, so the individual might select \( \mathbf{P} \) over \( \mathbf{P}^* \), \( \mathbf{P}^* \) over \( \mathbf{P}^{**} \), and \( \mathbf{P}^{**} \) over \( \mathbf{P} \). Though some have argued that such cycles allow for the phenomenon of ‘money pumps’, it has allowed the model to serve as a proposed solution to the Preference Reversal Phenomenon.

**Generalized expected utility analysis**

An alternative approach to non-expected utility preferences does not rely upon any specific functional form, but links properties of attitudes toward risk directly to the probability derivatives of a general ‘smooth’ preference function \( V(P) = V(x_1, P_1; \cdots; x_n, P_n) \). Such analysis reveals that the basic analytics of the expected utility model are in fact quite robust to general smooth departures from linearity in the probabilities. This approach is based on the observations that for the expected utility function \( V(EU)(x_1, P_1; \cdots; x_n, P_n) = \sum_{j=1}^{n} \pi_j \cdot U(x_j) \cdot P_n \), the value \( U(x_j) \) can be interpreted as the coefficient of \( P_n \), and that many theorems involving a linear function’s coefficients continue to hold when generalized to a nonlinear function’s derivatives. By adopting the notation \( U(x; \mathbf{P}) = \partial V(P) / \partial \text{prob}(\mathbf{P}) \) and the term ‘local utility function’ for the function \( U(\cdot; \mathbf{P}) \), standard expected utility characterizations such as those listed at the beginning of this article can be generalized to any smooth non-expected utility preference function \( V(P) \) in the following manners (Machina, 1982):

- \( V(\cdot) \) exhibits global **first order stochastic dominance preference** if and only if, at each lottery \( \mathbf{P} \), its local utility function \( U(x; \mathbf{P}) \) is an increasing function of \( x \).
- \( V(\cdot) \) exhibits global **risk aversion** (aversion to small or large mean-preserving increases in risk) if and only if, at each lottery \( \mathbf{P} \), its local utility function \( U(x; \mathbf{P}) \) is a concave function of \( x \).
- \( V(\cdot) \) is globally **at least as risk averse** as \( V(\cdot) \) if and only if, at each lottery \( \mathbf{P} \), \( V^{\prime}(\cdot) \)’s local utility function \( U^{\prime}(x; \mathbf{P}) \) is a concave transformation of \( V(\cdot) \)’s local utility function \( U(x; \mathbf{P}) \).

Similar generalizations of expected utility results and characterizations can be obtained for general comparative statics analysis, the theory of asset demand, and the demand for insurance. With regard to the Allais Paradox and other observed violations of the Independence Axiom, it can be shown that the indifference curves of a smooth preference function \( V(\cdot) \) will fan out in the probability triangle if and only if \( U(x; \mathbf{P}^*) \) is a concave transformation of \( U(x; \mathbf{P}) \) whenever \( \mathbf{P}^* \) first-order stochastically dominates \( \mathbf{P} \). This analytical approach has been extended to larger classes of preference functionals and distributions by Chew, Karni and Safra (1987), Karni (1987; 1989) and Wang (1993), formally axiomatized by Allen (1987), and applied to the analysis of choices under uncertainty by Chew, Epstein and Zilcha (1988), Chew and Nishimura (1992), Dekel (1989), Green and Jullien (1988), Machina (1984; 1989; 1995) and others.

**Non-expected utility preferences under subjective uncertainty**

Recent years have seen a growing interest in models of choice under subjective uncertainty, with efforts to represent and analyse departures from both expected utility risk preferences and probabilistic beliefs. A non-expected utility preference function \( W(f(\cdot); P) = W(x_1 \text{ on } E_1; \cdots; x_n \text{ on } E_n) \) over subjective acts \( f(\cdot) = \{ x_1 \text{ on } E_1; \cdots; x_n \text{ on } E_n \} \) is said to be
probabilistically sophisticated if it takes the form $W(f(\cdot)) = V(x_1, \mu(E_1); \ldots; x_n, \mu(E_n))$ for some subjective probability measure $\mu(\cdot)$ over the space of events and some non-expected utility preference function $V(\mathbf{P}) = V(x_1, P_1; \ldots; x_n, P_n)$. Such preferences have been axiomatized in a manner similar to Savage's (1954) axiomatization of the subjective expected utility form $W_{SEU}(f(\cdot)) = \sum U(x_1) \cdot \mu(E_1) + \ldots + U(x_n) \cdot \mu(E_n)$ (Machina and Schmeidler, 1992). Although such preferences can be consistent with Allais-type departures from linearity in (subjective) probabilities, they are not consistent with Ellsberg-type departures from probabilistic beliefs.

Efforts to accommodate the Ellsberg Paradox and the general phenomenon of ambiguity aversion have led to the development of several non-probabilistically sophisticated models of preferences over subjective acts (see the analysis of Epstein, 1999, as well as the surveys of Camerer and Weber, 1992, and Kelsey and Quiggin, 1992). One such model, the maximin expected utility form, replaces the unique probability measure $\mu(\cdot)$ of the subjective expected utility model by a finite or infinite family $\mathcal{M}$ of such measures, to obtain the preference function

$$W_{\text{maximin}}(x_1 \text{ on } E_1; \ldots; x_n \text{ on } E_n) = \min_{\mu(\cdot) \in \mathcal{M}} [U(x_1) \cdot \mu(E_1) + \ldots + U(x_n) \cdot \mu(E_n)]$$

When applied to the Ellsberg Paradox, the family of subjective probability measures $\mathcal{M} = \{(\mu(\text{red}), \mu(\text{black}), \mu(\text{yellow})) = (1 / 3, \gamma, 2 / 3 - \gamma) | \gamma \in [0, 2 / 3]\}$ will yield the typical Ellsberg-type choices of $f_1(\cdot)$ over $f_2(\cdot)$ and $f_3(\cdot)$ over $f_4(\cdot)$ (Gilboa and Schmeidler, 1989).

Another important model for the representation and analysis of ambiguity averse preferences, based on the Rank Dependent form under objective uncertainty, is the Choquet expected utility form:

$$W_{\text{Choquet}}(x_1 \text{ on } E_1; \ldots; x_n \text{ on } E_n) = \sum_{j=1}^{n} U(x_j) \cdot \left[ C\left(\bigcup_{j=1}^{n} E_j\right) - C\left(\bigcup_{j=1}^{n-1} E_j\right)\right]$$

where for each act $f(\cdot) = [x_1 \text{ on } E_1; \ldots; x_n \text{ on } E_n]$, the payoffs must be labelled so that $x_1 \leq \ldots \leq x_n$, and $C(\cdot)$ is a nonadditive measure over the space of events which satisfies $C(\emptyset) = 0$ and $C(\bigcup_{i=1}^{n} E_i) = 1$ (Gilboa, 1987; Schmeidler, 1989). This model has been axiomatized in a manner similar to the subjective expected utility model, and with proper assumptions on the shape of the utility function $U(\cdot)$ and the nonadditive measure $C(\cdot)$ it is capable of demonstrating ambiguity aversion as well as a wide variety of observed properties of risk preferences.

The technique of generalized expected utility analysis under objective uncertainty has also been adopted to the analysis of general non-expected utility/non-probabilistically sophisticated preference functions $W(f(\cdot)) = W(f_1 \text{ on } E_1; \ldots; f_n \text{ on } E_n)$ over subjective acts. So long as such a function is ‘smooth in the events’ it will possess a ‘local expected utility function’ (which may be state-dependent) and a ‘local probability measure’ at each act $f(\cdot)$, and classical results involving expected utility risk preferences and probabilistic beliefs can typically be generalized in the manner described above (Machina, 2005).

non-governmental organizations

Caren Grown
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article defines the term ‘non-governmental organizations’ (NGOs) and describes how they operate. It reviews the growth of the NGO sector since the 1980s, examines the reasons why NGOs have proliferated, reviews evidence on NGO impact, and summarizes how economists have modelled and tested hypotheses about the role of NGOs in development assistance.

Keywords

charitable giving; contract theory; development assistance; foreign aid; Grameen Bank; humanitarian and relief work; imperfect information; incomplete contracts; international development; international donors; non-governmental organizations; non-profit organizations; participation of the poor; poverty alleviation; principal agent; private voluntary organizations; public goods; volunteerism

Article

The term ‘non-governmental organization’ came into currency in 1945 when the United Nations Charter distinguished between participation rights for intergovernmental specialized agencies and international organizations (Willetts, 2002). Non-governmental organizations (NGOs) form that subset of non-profit organizations working in development assistance, international disaster relief, poverty alleviation, and human rights in developing countries (see non-profit organizations). In the literature and in practice, the term ‘NGO’ is often used interchangeably with ‘private voluntary organization’, a term used to refer to organizations based in the United States engaged in overseas provision of services (Anheier and Salamon, 1998).

As the NGO sector has grown, so too has the number of definitions, classifications, and taxonomies (Vakil, 1997). According to Bebbington (2004, p. 729), ‘discussions of NGOs continue to be plagued by the vexed and ultimately unanswerable question of “what is an NGO” and haunted by endless typologies. While some of these clarify functional differences, they are less helpful in an explanatory sense – why NGOs emerge, why they do what they do and where, and why certain ideas underlie their actions.’ Despite the lack of a uniform definition, most commentators agree that NGOs can be characterized as private, autonomously managed, value-based organizations that depend, in whole or in part, on charitable donations and voluntary service. Although the sector has become increasingly professionalized since the mid-1980s, principles of altruism and volunteerism remain key defining characteristics.

The lack of a uniform definition reflects the heterogeneity of NGOs around the world. They can be structured as large global federated entities, small community-based organizations, local or national cooperatives, or large national or international membership organizations. They can carry out a range of functions, from advocacy on behalf of vulnerable or other groups, to direct service (such as providing credit, education and health), research, organizing and public education, humanitarian and relief operations, and peacekeeping operations. Their geographic reach may be in a local community or an entire country, or they may operate across many countries. They are not part of the public sector nor are they dependent on the political process, but in many countries, they may seek to influence the formal political process. In many countries, they are exempt from taxes on corporate income. Some NGOs receive funding in the form of grants and contracts from governments and private foundations, others from membership dues and individual contributions, and still others from fees for goods or services. Some receive funding from all these sources.
Examples of organizations that fall in the broad category of NGOs include:

- Centro Mujeres, a small community health organization with 12 staff in 2004 dedicated to fostering the empowerment and well-being of women and adolescents in La Paz, Mexico;
- the Bangladesh Rural Advancement Committee (BRAC), a nationwide organization dedicated to poverty alleviation in Bangladesh with branches in 65,000 villages and more than 97,000 employees in 2006;
- Amnesty International, a global organization with over 1.8 million members in over 150 countries in 2006 and local chapters that undertake research and campaigns to protect human rights and prevent abuses.

Given their heterogeneity of purpose, form and function, NGOs are a multidisciplinary topic, and studies on this topic tend to be published in multidisciplinary journals such as *World Development*, the *Journal of International Development* and *Third World Quarterly*. By contrast, the non-profit sector has its own specialized journals. Research on NGOs is far more common in disciplines other than economics; it is an active field in international relations and development studies. Much of the literature is descriptive, relying on historical analysis or contemporary case studies of single countries, single sectors, or single organizations (Bebbington, 2004; Edwards and Hulme, 1996). There is surprisingly little survey-based research on NGOs in developing countries, especially Africa (Barr, Fafchamps and Owens, 2005). The broad literature explores the growth, evolution, and impact of NGOs in development and relief work in different contexts, NGO relationships with states and donors (and firms in a few instances), and community-based action and social change (Lewis and Opoku-Mensah, 2006). NGOs are frequently cast in a favourable light. It is quite common to read articles about the potential of NGOs to transform the development process as opposed to articles about corruption or project failure.

By contrast, the economics literature has tended to develop a narrow range of theoretical models and to take a more critical view of NGOs. Theoretical models explore imperfect information, contracting problems, and accountability in developing countries, using the broad descriptive literature to provide support. With a few exceptions, empirical work by economists has focused mostly on NGOs that provide micro-finance services (Morduch, 1999; Pitt and Khandker, 1998). The exceptions include Barr, Fafchamps and Owens (2005), who conducted a survey to document the funding sources and examine monitoring and oversight procedures of NGOs in Uganda; Gauri and Galef (2005), who analysed data from a nationally representative survey of NGOs in Bangladesh; Gauri and Fruttero (2003), who used the Bangladesh Household Income and Expenditure Survey to examine location decisions of NGO programs; and Leonard (1998), who analysed data on health care providers in Cameroon.

**Growth of the NGO sector**

Although statistics are hard to come by and what is covered in the numbers can be unclear, Figure 1 shows spectacular growth of the NGO sector since the 1980s.

**Figure 1**

The NGO sector has also proliferated in various countries. A recent survey by Gauri and Galef (2005) shows that Bangladesh has one of the largest and most sophisticated NGO sectors in the developing world: over 90 per cent of villages in the country had at least one NGO in 2000 (Gauri and Fruterro, 2003) and foreign assistance channelled through NGOs has been above ten per cent since 1993 (Gauri and Galef, 2005). As Phinney (2002) notes, ‘In some villages in Bangladesh, you can send your child to an NGO school, have a vasectomy arranged by an NGO health worker, sell your milk to an NGO dairy, and talk on an NGO phone. And, there’s usually a choice of NGO banks.’ International NGOs were responsible for the creation of the NGO community in Bangladesh, although they have withdrawn in recent years and now play a secondary role to local NGOs (Stiles, 2002). Price (1999) has noted a significant concentration of NGOs in Latin America, although they are unevenly distributed across countries. In Uganda, Barr, Fafchamps and Owens (2005) identified 3,500 NGOs registered with the government. Ghanaian NGOs provide 40 per cent of clinical care needs, 27 per cent of hospital beds, and 35 per cent of outpatient services, and in Tanzania NGOs provide half of all hospitals and beds and receive half of all curative visits (Leonard and Leonard, 2004). Few national surveys have been undertaken to identify NGO prevalence and incidence in other African countries.
What explains the rise of NGOs?

Development studies scholars (geographers, political scientists, anthropologists) argue that NGO involvement in public projects in developing countries has grown in response to budgetary stringency and public sector cutbacks often imposed by macroeconomic stabilization policies (Bebbington and Farrington, 1993; Edwards and Hulme, 1996). Economists take a less political position, arguing that NGOs are a response to the undersupply of public goods. Bebbington (1997) provides empirical support, noting that Latin American states shifted away from direct implementation of development initiatives in the 1980s and increasingly subcontracted or financed programmes implemented by non-state institutions. In Bolivia, NGOs manage national parks, reserves, and protected areas. In Chile, since the mid-1980s, governments have subcontracted extension services to the private sector; beginning in the 1990s, NGOs and farmers' organizations can also bid for these contracts.

Political scientists and others also highlight the changing preferences of international funders to direct money through private channels due to increasing donor frustration with the public sector because of corruption, inefficiency, and poor results in reducing poverty (Clark, 1991; Edwards and Hulme, 1996). Empirical evidence suggests that donors have played a key role in the proliferation of international and national NGOs. According to Woods (2003, p. 9), ‘resources channeled through NGOs in all OECD member countries rose from 0.2 percent of the total bilateral ODA [official development assistance] of members of the Development Assistance Committee in 1970 to 17.0 percent in 1996, to reach, in absolute terms an amount equal to twice the total 1996 ODA of the United Kingdom, the DAC’s sixth largest donor by volume.’ OECD Development Assistance Committee (DAC) figures show that net grants by NGOs rose from five per cent of total net flows in 2000 to eight per cent of flows in 2004 (OECD, 2005, Table 2).

The data have many limitations, and these numbers are likely to be an underestimate. There are complex reporting requirements that are interpreted differently by different governments. For example, donors must choose between designating a disbursement as ‘emergency and distress relief’ or a grant to an NGO (Agg, 2006). Nor do the data include US funds channeled through NGOs. Nonetheless, the OECD data are the only aid data collected over time and from all donor governments. Meyer (1995) concurs that NGOs arise in part because of donor dissatisfaction with the level of public goods in developing countries, so donors turn to NGOs, which are seen to have some comparative advantages over governments. A number of contributions to the *World Development* special issue on NGOs in 1987 claim that NGOs have better information on the needs of poor people than do governments; have lower transaction costs; are more flexible than governments and better able to respond to crises such as drought or floods. Because they are part of dense networks with close ties to the community, they are also better at fostering community participation and responding to local needs (Bebbington, 2004). Bebbington (2004), for instance, documents how NGOs use methodologies and actions that strengthen capacity and involve poor people in project activities in Latin America. Finally, NGOs are seen to promote new ideas and practices (Scott and Hopkins, 1999; Meyer, 1995).

What is the evidence on NGO impact?

There is little systematic empirical evidence to either support or refute the notion that NGOs are more cost-effective than governments. Some country case studies find that large NGOs working in some sectors do provide some services more cost-effectively than governments (Hasan, 1993; AFK/NOVIB 1993; Riddell and Robinson, 1992), while others find little difference between governments and NGOs (Tendler, 1982; 1989).

Similarly, the evidence on whether NGOs are better at reaching the poorest is also mixed (Fowler, 2000; Edwards and Hulme, 1996; Arellano-Lopez and Petras, 1994; Riddell and Robinson, 1992; Tendler, 1982). Most NGOs reach the poor, but not necessarily the poorest (UNRISD, 2000). An analysis of NGO activity in Bangladesh found that NGO assistance reached those in the second wealth quintile but not those in the poorest (Gauri and Galef, 2005). Even the most well-known NGO in Bangladesh, the Grameen Bank, was found to reach less than 20 per cent of landless households in the country (Farrington and Lewis, 1993).

There is greater empirical support for the notion that NGOs have pioneered and used instruments that emphasize the participation of the poor in poverty and development projects (Clark, 1995; Bratton, 1990). Kilby (2006) finds that formal participation measures and ‘downward’ accountability practices (for example, to members, clients, other beneficiaries) are correlated with empowerment outcomes in India. Bebbington and Farrington (1993) observe that NGOs that emphasized project methodologies and actions that promote participation have increased the impacts of agricultural development projects.

A number of studies document NGO innovations in various sectors of service delivery, for example in financial services for the poor (Hulme and Mosely, 1996), in the creation of debt-for-nature swaps (Meyer, 1995), in agriculture technology development (Bebbington and Farrington, 1993), and in oral rehydration therapy (Howes and Sattar, 1992). The literature also highlights concerns about the effects of donor financing on NGOs. Edwards and Hulme (1996) argue that increasing reliance on donor funding weakens key attributes that make NGOs attractive to donors in the first place. It can reduce advocacy efforts on behalf of poor and vulnerable groups, negatively affect NGO institutional development, weaken their legitimacy as independent actors, distort their accountability away from internal constituencies to donors and patrons, and lead to an overemphasis on short-term outputs. Fyvie and Ager (1999) argue that donor requirements constrain NGO capacity for innovation. Bebbington (1997; 2005) shows that donor funding of three poverty-
Concerns have also been raised about the nature of NGO, government and donor relations. Scholars have uncovered a range of relationships between NGOs and government, from strongly adversarial to tight partnerships, and between NGOs and donors, from dependent recipient to co-financers/implementers of projects. They have also identified the institutional, economic and political factors that condition which types of relationship emerge and are sustained in different contexts (Bebbington, 1997; Nelson, 2006; Atack, 1999; Anheier and Salamon, 1998; Ahmad, 2006). By contrast, the economics literature has focused largely on the relationship between NGOs and donors and the conditions for different types of partnerships.

**NGO role in development assistance: theoretical models**

The theoretical economics literature has yet to reflect the diversity of NGO types, the varied impacts of NGO projects, and the multiplicity of NGO, donor, and government relations. Most of this literature focuses on how NGOs compensate for the undersupply of government-provided public goods or are a device to overcome imperfect information and incomplete contracts. Economists have applied principal–agent models with NGOs to the African health-care sector and foreign assistance chains. Scott and Hopkins (1999) identify the organizational comparative advantage of NGOs and develop a model that explains the circumstances under which they emerge and dominate other types of firms/entities. NGOs predominate in environments where public goods are undersupplied to citizens whose demand for that good exceeds demand of the median voter. The authors argue that the potential superiority of NGOs derives from an institutional environment that selectively attracts altruists who have a lower reservation wage than egotists, and who have the ability to develop efficient technologies for converting the effort of their staffs into local outputs highly valued by the target group of beneficiaries.

The technical superiority of NGOs stems from the way NGOs operate – their interaction with local communities, which enables them to articulate and aggregate local demands. Additionally, NGOs recruit field staff from among beneficiaries and target groups, which facilitates communication and assists in creation of trust between beneficiaries and the target agency. As donors get to know the field and seek the most efficient organizations, NGOs would generally dominate when they have the same or better development technologies than public agencies and wages are similar in both sectors. They may dominate even when wages paid by public agencies are higher, if NGO technology is superior and warm-glow effects are strong enough to outweigh the wage differential.

Besley and Ghatak (2001) develop a model of NGO involvement in public goods provision and enumerate several propositions based on observations from the case study literature. Pure NGO involvement will be more prevalent in projects where the marginal cost of public funds is high and/or the public sector is relatively less efficient in input provision. In activities where performance is hard to measure, NGOs are perceived to be committed to high quality or serve some groups better than others due to their religious or ideological orientation. NGO involvement in supplying services is less dominant in types of projects that are infrastructure-intensive and in countries where the government manages infrastructure well. Decentralization initiatives have often resulted in increased NGO involvement, in part because resource constraints are more severe. NGO provision will also be more prevalent in projects where the NGO cares more about the beneficiaries. Support for this proposition is provided by the *World Development Report* 1997 (World Bank, 1997), which described how governments typically prefer NGOs for delivery of social services while preferring for-profit contractors for the management of infrastructure, such as road maintenance in Brazil.

The models of Leonard (2002) and Leonard and Leonard (2004) address imperfect information and incomplete contracts in the health-care sector in Africa. In sectors where goods or services are characterized by asymmetric information, such as in health care, mechanisms other than prices are needed for the market to function well. In Africa, NGOs are one mechanism to solve the asymmetric information problem. Leonard (2002) and Leonard and Leonard (2004) show they have a stock of attributes which, when combined with the institutional environment in Africa, make them more successful than governments with similar values in providing quality services and reducing the transaction costs of asymmetric information. (There are few private providers in Africa so the relevant comparison is between government and non-governmental services.)

Finally, Azam and Laffont (2003) apply contract theory to shed light on the aid relationship between a donor and recipient country, where consumption of the poor is assumed to be an international public good. The authors model the intricacies of coordinating the efforts of government and NGOs in the fight against poverty. When aid is introduced, several possibilities emerge. Most importantly, free riding problems arise in the provision of aid to the poor when there are several providers. Yontaeva (2003) models a dynamic game between a principal (donor) and agent (NGO), where the model's objective is to identify the long-term determinants of the principal's choice of whether to delegate a project to an NGO and to verify the impact of the allocation on the principal's payoff and the agent's effort.

**Conclusion**

NGOs are a burgeoning field of cross-disciplinary study. Economists can learn from this voluminous literature both to enrich their models and to contribute theoretical and empirical rigour to a rather messy descriptive literature. They can develop richer theorizations of NGOs roles, relationships and power vis-à-vis governments and donors. They can also work with other social scientists to gather better data on the range of NGO motivations, roles and impacts in various country contexts. This information can help fill an important gap in
non-governmental organizations: The New Palgrave Dictionary of Economics

understanding the dynamic and growing NGO sector in developing countries.

nonlinear panel data models

Ekaterini Kyriazidou
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
conditional maximum likelihood; conditioning variables; fixed effects; heteroskedasticity; incidental parameters; individual effects; logit models; longitudinal data; nonlinear panel data models; quadrature procedures; random effects; random variables; Tobit models

Article
Panel or longitudinal data are becoming increasingly popular in applied work as they offer a number of advantages over pure cross-sectional or pure time-series data. They allow researchers to model unobserved heterogeneity at the level of the observational unit, where the latter may be an individual, a household, a firm or a country. This article describes several estimation methods that are available for nonlinear panel data models, that is, models which are nonlinear in the parameters of interest and which include models that arise frequently in applied work, such as discrete choice models and limited dependent variable models, among others.

1 Introduction
Panel or longitudinal data are becoming increasingly popular in applied work as they offer a number of advantages over pure cross-sectional or pure time-series data. A particularly useful feature is that they allow researchers to model unobserved heterogeneity at the level of the observational unit, where the latter may be an individual, a household, a firm or a country. Standard practice in the econometric literature is to model this heterogeneity as an individual-specific effect which enters additively in the model, typically assumed to be linear, that captures the statistical relationship between the dependent and the independent variables. The presence of these individual effects may cause problems in estimation. In particular in short panels, that is, in panels where the time-series dimension is of smaller order than the cross-sectional dimension, their estimation in conjunction with the other parameters of interest usually yields inconsistent estimators for both. Notable exceptions are the static linear and the Poisson count panel data models, where estimation of the individual effects along with the finite dimensional coefficient vector yields consistent estimators of the latter.) This is the well-known incidental parameters problem (Neyman and Scott, 1948). In linear regression models, this problem may be dealt with by taking transformations of the model, such as first differences or differences from time averages (`within transformation’), which remove the individual effect from the equation under consideration. However they do not apply to nonlinear econometric models, that is, models which are nonlinear in the parameters of interest and which include models that arise frequently in applied work, such as discrete choice models, limited dependent variable models, and duration models, among others. This article describes several estimation methods that are available for nonlinear panel data models. An approach that is available for estimating certain linear and nonlinear parametric models with individual effects is the conditional maximum likelihood approach. This is described in Section 2. Section 3 describes estimation techniques that have been recently developed for several semiparametric nonlinear panel data models. A common feature in the methods discussed in that section is that we do not make any assumptions about the nature of these individual effects, that is, whether they are fixed constants or random variables. Thus, we do not make any assumptions about whether they are related to the conditioning variables and, if so, in what manner. This approach is typically referred to as the fixed effects approach. Section 4 describes the so-called random effects approach in estimating nonlinear panel data models. In contrast to the fixed effects approach, the random effects approach does make assumptions about the individual effects. The discussion distinguishes between two types of models, static and dynamic. In static models, the conditioning set includes past, present and future values of the variables. In this case the conditioning variables are said to be strictly exogenous. In dynamic models, the conditioning set may also include lags of the dependent variable and other endogenous variables, that is, variables that are only weakly exogenous or predetermined.

Our discussion is limited in several aspects. First, we focus only on the case when the time series dimension of the panel ($T$) is short so that it makes sense to consider the asymptotic properties of the estimators when the cross-sectional dimension ($N$) is large while $T$ remains fixed. Second, we do not consider estimation of random coefficient models, that is, models where all the parameters are varying at the individual level. Finally, we do not discuss the Bayesian approach to estimating panel data models.

2 The conditional maximum likelihood (CML) approach
Suppose that a random variable $y_{i,t}$ has density $f(y_{i,t}; \Theta)$ where $\Theta$ is the parameter of interest which is common across all units $i$, whereas $\alpha_i$ is a nuisance parameter which is allowed to differ across $i$. A sufficient statistic $S_i$ for $\alpha_i$ is a function of the data such that the conditional distribution of the data given $S_i$ does not depend on $\alpha_i$. However, the conditional distribution may depend on $\Theta$. In this case, one can estimate $\Theta$ by maximizing the conditional likelihood, which conditions on the sufficient statistic(s). Such sufficient statistics are readily available for the exponential family that includes the normal, Poisson, gamma, logistic, and binomial distributions.

The conditional maximum likelihood approach in estimating nonlinear panel data models. In contrast to the fixed effects approach, the random effects approach does make assumptions about the individual effects. In this model it turns out that $T$ is a sufficient statistic for $\alpha_i$. Indeed, let $T = 2$. Note that

$$P(y_{i,1}=1|y_{i,2}=0, \alpha_i, \beta) = \frac{1}{1 + \exp((\beta_{i1} - \beta_{i2})y_{i2})},$$

and

$$P(y_{i,1}=1|y_{i,2}=0, \alpha_i, \beta) = \frac{1}{1 + \exp(\beta_{i1}y_{i2})}.$$
In other words, conditional on the individual switching states (from 0 to 1 or from 1 to 0), the probability that $y_{it}$ is 1 or 0 depends on $\beta_0$ (that is, contains information about $\beta_0$) but is independent of $\alpha_i$.

The conditional log-likelihood is

$$L(c) = \sum_{i=1}^{N} 1\{y_{it} \neq y_{i0}\} \ln \left( \frac{\exp((\gamma_2 - x_{2i0}) \beta_0 + \gamma_2) + \exp((\gamma_2 - x_{2i0}) \beta_0 + y_{it} - y_{i0})}{1 + \exp((\gamma_2 - x_{2i0}) \beta_0)} \right)$$

and may be maximized over $\beta_0$ to produce a consistent and root-$N$ asymptotically normal estimator of $\beta_0$. Note that the approach uses a subset of the data, since only individuals who switch states enter the likelihood. For the expression of the conditional log-likelihood in the general $T$ case, see Chamberlain (1984).

2.2 The dynamic panel data logit model

Chamberlain (1985) noticed that the conditional maximum likelihood approach also applies to the ‘AR(1)’ logit model with individual effects:

$$y_{it} = 1(y_{i0} + \delta_0 i + \epsilon_{it} + y_{it} - \delta_0 i) = 1(y_{i0} + \delta_0 i, y_{i0} = 1, \delta_0 = 1, \delta_0 = 0)$$

where the error term $\epsilon_{it}$ is distributed i.i.d. with a logistic distribution conditional on $\alpha_i$, and the initial observation of the sample $y_{i0}$. Note that we are not making any assumption about the distribution of the initial $y_{i0}$. As we will see, the approach requires at least four observations for each individual (including the initial observation). In fact, let that be the case and consider the events:

$$A^* = \{y_{i0} = \delta_0 i, y_{i0} = 1, \delta_0 = 1, \delta_0 = 0\} = \{y_{i0} = \delta_0 i, y_{i0} = 1, \delta_0 = 0, y_{i0} = \delta_0 i\}$$

where $\delta_0$ and $\delta_1$ are either 0 or 1. It is rather easy to derive the following probabilities which condition on the individual switching states in the two middle periods

$$P(A^* | \alpha_0) = \frac{1}{1 + \exp((\gamma_2 - x_{2i0}) \beta_0 + \gamma_2)}$$

Note that these depend on $\gamma_2$ but are independent of $\alpha_0$. The conditional log-likelihood of the model for four periods is:

$$L(c) = \sum_{i=1}^{N} 1\{y_{i0} = 1\} \ln \left( \frac{\exp((\gamma_2 - x_{2i0}) \beta_0 + \gamma_2) + \exp((\gamma_2 - x_{2i0}) \beta_0 + y_{it} - y_{i0})}{1 + \exp((\gamma_2 - x_{2i0}) \beta_0)} \right)$$

and maximizing it with respect to $\gamma_2$ produces a consistent and root-$N$ asymptotically normal estimator. The approach generalizes to logit models with more than one lags of $y_{it}$ (see Mancac, 2000).

It is important to note that the CML approach described above does not work in the logit model

$$y_{it} = 1(y_{i0} + \delta_0 i + \delta_0 i + \epsilon_{it} + y_{it} - \delta_0 i) = 1(y_{i0} + \delta_0 i, y_{i0} = 1, \delta_0 = 0, y_{i0} = \delta_0 i)$$

that is, when the conditioning set also includes exogenous variables. Honoré and Kyriazidou (2000a) show that $\beta_0$ and $\gamma_2$ in the model above are in fact identified both for the case when the errors $\epsilon_{it}$ are logistic and when they are only assumed to have the same distribution over time conditional on $(x_{it}, y_{i0})$ (see below). In the logistic case identification is based on the fact that the following probabilities

$$P(A^* | x_{it}) = \frac{1}{1 + \exp((\gamma_2 - x_{2i0}) \beta_0 + \gamma_2 + x_{it} - x_{2i0}) \beta_0 + \gamma_2 + y_{it} - y_{i0})}$$

are independent of $\alpha_0$. Note that the probabilities above condition not only on the individual switching states in the middle two periods so that $y_{i2} = y_{i0}$ but also on the event that $x_{i2} = x_{i0}$. Honoré and Kyriazidou (2000a) propose estimating $\beta_0$ and $\gamma_2$ by maximizing

$$\sum_{i=1}^{N} 1\{y_{i2} = y_{i0}\} \ln \left( \frac{\exp((\gamma_2 - x_{2i0}) \beta_0 + y_{i2} - y_{i0})^2) + \exp((\gamma_2 - x_{2i0}) \beta_0 + y_{i2} - y_{i0})^2)}{1 + \exp((\gamma_2 - x_{2i0}) \beta_0 + y_{i2} - y_{i0})^2)} \right)$$

where $K(i)$ is a kernel density function and $h_N$ is a bandwidth sequence, chosen so as to satisfy certain assumptions that guarantee consistency and asymptotic normality of the proposed estimators.

3 The fixed effects approach

The conditional maximum likelihood approach is not always available. For example, there are no sufficient statistics for the binary choice model with individual effects when the errors are normally distributed. Furthermore, like all ML approaches, the approach suffers from the fact that the distribution of the unobserved idiosyncratic errors needs to be parametrically specified. There do exist, however, methods for some semiparametric nonlinear panel data models with individual effects where the distribution of the underlying idiosyncratic errors is left unspecified. These include the binary choice model, the censored and truncated regression models, and the sample selection model.

3.1 The semiparametric panel data binary choice model

Manski (1987) considers the model

$$y_t = 1(\beta_0' X_t + \varepsilon_t > 0) + \delta T, t = 1, \ldots, T$$

where \(\varepsilon_t\) is identically distributed over time conditional on \((x_t, \delta))\), with distribution function \(F\) that is a continuous and strictly increasing function on \(\mathbb{R}\). Note that, in contrast to the models considered above, \(F\) here is not assumed to have a specific functional form, hence the characterization of the model as semiparametric.

He observes that for \(T = 2\) the time invariance of \(F\) implies that

$$\Pr(y_1 = 1|x_1) = \Pr(y_2 = 1|x_2)$$

or equivalently that

$$\text{sgn}(x_t) = \text{sgn}(x_{t+1})$$

In fact it can be shown that, under appropriate regularity conditions on the joint distribution of \(\varepsilon_t = (\varepsilon_t - \varepsilon_{t+1})\), \(\beta_0\) uniquely (up to scale) maximizes the so-called population ‘score function’

$$E(\delta_t; \beta_0' X_t, \varepsilon_t)$$

where \(\text{sgn}(x)\) equals 1 if \(x > 0\) equals -1 if \(x < 0\) and is equal to 0 if \(x = 0\). This suggests estimating \(\beta_0\) by the so-called conditional maximum score estimator which maximizes the sample analog of the population score function

$$\hat{\beta} = \arg\max_{\beta} \sum_{t=1}^T \text{sgn}(y_t) \cdot \text{sgn}(x_t') \cdot \text{sgn}(\varepsilon_t)$$

Note that only observations for which \(y_t = 1, y_{t+1} = 0\) are used here, similarly to conditional logit. The estimator is consistent under some additional assumptions but is not asymptotically normal and its rate of convergence is not root-N.

Honoré and Kyriazidou (2000a) show that it is possible to extend the conditional maximum score approach to the dynamic binary choice model:

$$y_{t+1} = 1(\beta_0' X_{t+1} + \varepsilon_{t+1} > 0) + \delta_{t+1}$$

where \(y_{t+1}\) is assumed to be observed and \(F\) is strictly increasing.

We will next demonstrate their identification scheme: Assume \(\delta = 0\) and define the events A and B as above. Then

$$\Pr(A_t, x_t, x_{t+1} = x_{t+1}) = \Pr(A_t, x_t, x_{t+1} = x_{t+1}) \cdot \Pr(x_{t+1} = x_{t+1} | x_t)$$

$$= \frac{1}{1 - (1 - F(x_{t+1} + \gamma T_0 + \delta_0))} \cdot \frac{1}{1 - (1 - F(x_{t+1} + \gamma T_0 + \delta_0))} \cdot \frac{1}{1 - (1 - F(x_{t+1} + \gamma T_0 + \delta_0))}$$

$$= \frac{1}{1 - (1 - F(x_{t+1} + \gamma T_0 + \delta_0))} \cdot \frac{1}{1 - (1 - F(x_{t+1} + \gamma T_0 + \delta_0))} \cdot \frac{1}{1 - (1 - F(x_{t+1} + \gamma T_0 + \delta_0))}$$

$$= \frac{1}{1 - (1 - F(x_{t+1} + \gamma T_0 + \delta_0))} \cdot \frac{1}{1 - (1 - F(x_{t+1} + \gamma T_0 + \delta_0))} \cdot \frac{1}{1 - (1 - F(x_{t+1} + \gamma T_0 + \delta_0))}$$

while if \(\delta \neq 0\), then

$$\Pr(A_t, x_t, x_{t+1} = x_{t+1}) = \frac{1}{1 - (1 - F(x_{t+1} + \gamma T_0 + \delta_0))} \cdot \frac{1}{1 - (1 - F(x_{t+1} + \gamma T_0 + \delta_0))} \cdot \frac{1}{1 - (1 - F(x_{t+1} + \gamma T_0 + \delta_0))}$$

$$= \frac{1}{1 - (1 - F(x_{t+1} + \gamma T_0 + \delta_0))} \cdot \frac{1}{1 - (1 - F(x_{t+1} + \gamma T_0 + \delta_0))} \cdot \frac{1}{1 - (1 - F(x_{t+1} + \gamma T_0 + \delta_0))}$$

This last equation suggests that \(\hat{\beta}_0\) and \(\hat{\gamma}_0\) can be estimated by conditional maximum score using only the observations satisfying \(y_{t+1} = 1\) and \(x_{t+1} = x_0\), that is, by maximizing

$$\sum_{t=1}^T \text{sgn}(y_t) \cdot \text{sgn}(x_t') \cdot \text{sgn}(\varepsilon_t)$$
\[
\sum_{i=1}^{N} \sum_{t=1}^{T} \left( y_{it} - x_{it} \beta \right) = 0; \quad \gamma \left( y_{it} - x_{it} \beta \right) = x_{it} \beta + \gamma (y_{it} - \gamma) \beta.
\]

Similar to the logit case, when \( y_{it} - x_{it} \beta \) is continuously distributed with support around 0, estimation of \( \beta \) and \( \gamma \) can be obtained by maximizing

\[
\sum_{i=1}^{N} \sum_{t=1}^{T} \left( y_{it} - x_{it} \beta \right) \gamma \left( y_{it} - x_{it} \beta \right) = x_{it} \beta + \gamma (y_{it} - \gamma) \beta.
\]

3.2 Semi-parametric panel data censored regression model

The standard censored panel data (or Type I Tobit) model with individual effects is given by

\[
\gamma_{it} = \max \left( x_{it} \beta_{0} + \epsilon_{it}, 0 \right) = L_{it} \quad \text{for } i = 1, \ldots, N, \quad t = 1, \ldots, T.
\]

Estimation of this model was first considered by Honoré (1992) and later by Honoré and Kyriazidou (2000b), who extend the results of the former paper. We will present here Honoré (1992), who assumes that \((\epsilon_{it}, \epsilon_{is})\) are pairwise exchangeable conditional on \((x_{it}, a_{i})\). This implies that \(\epsilon_{it}\) and \(\epsilon_{is}\) are identically distributed conditional on \((x_{it}, a_{i})\) although it does not require (conditional) independence over time. (Fristedt and Gray, 1997, give the following definition of exchangeability: Let \(\mathcal{X}\) be a countable set. A sequence \((x_{1}, \ldots, x_{N})\), finite or infinite, of random variables on a probability space \((\Omega, \mathcal{F}, \mathbb{P})\) is exchangeable if, for every permutation \(\pi\) of \(\mathcal{X}\), the distribution of \((x_{\pi(1)}, \ldots, x_{\pi(N)})\) is identical. Note that a finite or infinite i.i.d. sequence is exchangeable and that exchangeability allows for certain types of serial correlation. Furthermore, exchangeability implies strict stationarity although the converse is not true.)

Consider the 'pseudo-error':

\[
\epsilon_{it} = \max (x_{it} \beta + \epsilon_{it}, 0) - x_{it} \beta - \gamma_{it}.
\]

With this definition, at the true \( \beta_{0} \)

\[
E_{it}(\epsilon_{it}) = \max (x_{it} \beta + \epsilon_{it}, 0) - x_{it} \beta = \max (\max (x_{it} \beta + \epsilon_{it}, 0) + \epsilon_{it}, 0) - x_{it} \beta = \max (\max (\max (x_{it} \beta + \epsilon_{it}, 0) + \epsilon_{it}, 0) - x_{it} \beta).
\]

The conditional exchangeability assumption implies that \((\epsilon_{it}(\beta_{0}), \epsilon_{is}(\beta_{0}))\) is distributed like \((\epsilon_{it}(\beta_{0}), \epsilon_{is}(\beta_{0}))\) conditional on \((x_{it}, x_{is}, a_{i})\) and hence the difference \(\epsilon_{it}(\beta_{0}) - \epsilon_{is}(\beta_{0})\) is distributed symmetrically around 0 conditional on \((x_{it}, x_{is}, a_{i})\). Since this is true for any \( \alpha \), this symmetry holds conditional only on \((x_{it}, x_{is})\).

Therefore for any odd function \( \xi \) (that is, a function \( \xi \) that satisfies \( \xi(-x) = -\xi(x) \)) we have

\[
E_{it}(\xi(\epsilon_{it}))/\epsilon_{it} = 0
\]

which also implies the following moment restriction:

\[
E_{it}(\xi(\epsilon_{it}))/\epsilon_{it} = 0.
\]

The left-hand side of the moment condition above may be thought of as the first order condition for the following population minimization problem

\[
\min_{\beta} E_{it}(\xi(\epsilon_{it})) = 0.
\]

where

\[
\xi(\epsilon_{it}) = \begin{cases} 
2(\xi(\epsilon_{it}) - \gamma) & \text{if } \xi(\epsilon_{it}) \geq 0, \\
0 & \text{if } \xi(\epsilon_{it}) < 0
\end{cases}
\]

\(\xi(\epsilon_{it}) = 0\) is an even function (that is, \(\xi(-\epsilon_{it}) = \xi(\epsilon_{it})\)) which is convex, strictly increasing for \(\xi > 0\) and has \(\xi(0) = 0\), and \(\xi(\epsilon) = 2(\xi(\epsilon))\) where \(\xi(0) = 0\). Note that for \(\xi\) to be convex, \(\xi\) has to be monotone. Obvious choices for \(\xi\) are \(\xi(\epsilon) = \epsilon^{\tau}\) (which corresponds to \(\xi(\epsilon) = 2(\epsilon)\)) and \(\xi(\epsilon) = |\epsilon|\) (which corresponds to \(\xi(\epsilon) = \max(\epsilon, 0)\)).

Honoré (1992) shows that the estimators corresponding to \(\xi(\epsilon) = \epsilon^{\tau}\) and \(\xi(\epsilon) = |\epsilon|\) are root-\(N\) consistent and asymptotically normal.

Honoré (1992) shows that the estimators corresponding to \(\xi(\epsilon) = \epsilon^{\tau}\) and \(\xi(\epsilon) = |\epsilon|\) are root-\(N\) consistent and asymptotically normal.

Honore (1993) considers a dynamic version of the model where the lag of the observed (censored) dependent variable appears in the model instead of the latent one. Hu (2002) considers the case where one lag of the latent (unobserved) dependent variable is included along with the set of exogenous variables \( x_t \).

### 3.3 The semiparametric panel data sample selection model

The standard panel data sample selection (or Type 2 Tobit) model is defined as:

\[
\left\{
\begin{array}{l}
Y_{it} = \beta' x_{it} + \varepsilon_{it} \\
\varepsilon_{it} = \delta \xi_{it} + \eta_{it}
\end{array}
\right.
\]

where \( i = 1, \ldots, N \) and \( t = 1, \ldots, T \).

Kyriazidou (1997) considers estimation without any parametric assumptions on the form of the joint distribution of \((\varepsilon_{it}, \delta)\) or on the individual effects \((\alpha_t, \eta_t)\).

Consider the case where \( T = 2 \) and only those individuals for whom \( \delta = \delta_0 = 1 \). Let \( \delta \equiv (\delta_1, \delta_2, \delta_3, \delta_4, \delta_5, \delta_6, \delta_7, \delta_8) \) denote all the information about individual \( i \). Note that

\[
E(\varepsilon_{it} - \varepsilon_{it}^0 | \delta = \delta_0) = \delta_{\delta_0} + \delta \xi_{it} - \delta \xi_{it}^0
\]

and hence OLS estimation of the first differenced model will not yield consistent estimation of \( \beta \) since in general the so-called ‘sample selection bias term’

\[
\lambda_0 \equiv E(\varepsilon_{it}^0 | \delta = \delta_0, \delta_{\delta_0}) = E(\varepsilon_{it}^0 | \delta = \delta_0, \xi_{it} - \xi_{it}^0)\delta
\]

is not zero. Nor do we have in general that \( \lambda_0 = \lambda_0(\delta) \), so that first differencing removes the sample selection bias along with the individual effects. Kyriazidou (1997) makes a conditional exchangeability assumption that \( E(\varepsilon_{it}, \varepsilon_{it}^0 | \delta, \delta_{\delta_0}) \) and \( E(\varepsilon_{it}, \varepsilon_{it}^0 | \delta, \delta_{\delta_0}) = E(\varepsilon_{it}, \varepsilon_{it}^0) \) are identically distributed conditional on \( \xi_j \). Under this assumption, it is easy to see that if \( \xi_j(Y_{it} = \gamma Y_{it}) \) then

\[
\lambda_0 = E(\varepsilon_{it} | \delta = \delta_0, \delta_{\delta_0}) = E(\varepsilon_{it} | \delta = \delta_0, \xi_{it} - \xi_{it}^0) = E(\varepsilon_{it} | \delta = \delta_0, \xi_{it} - \xi_{it}^0) = \lambda_0(\delta)
\]

so that first differencing will eliminate both \( \alpha \) and \( \lambda_0(\delta) \) simultaneously. So \( \hat{\beta} \) can be estimated by first difference OLS for the subsample of individuals that are observed in both periods (that is, that have \( \delta_1 = \delta_2 = 1 \)) and also have the selection index \( \gamma(y_{it}, \delta_{\delta_0}) \) constant (that is, \( \xi_j(Y_{it} = \gamma Y_{it}) \)). Of course, this estimation scheme cannot be directly implemented since \( \gamma \) is unknown. And it is quite possible that no observation has \( \xi_j(Y_{it} = \gamma Y_{it}) \) if \( \gamma \) is continuously distributed. If, however, \( \lambda_0(\delta) \) is a sufficiently smooth function and \( \gamma(t, \delta_{\delta_0}) \) is a consistent estimator of \( \gamma(t, \delta_{\delta_0}) \), \( \lambda_0(\delta) \) and the preceding segment holds approximately. Kyriazidou proposes a two-step estimation procedure, in the spirit of Powell (2001), and Ahn and Powell (1993) who consider estimation of cross-section versions of the sample selection model. In the first step, \( \gamma(t, \delta_{\delta_0}) \) is consistently estimated based on the selection equation. In the second step, the estimate \( \hat{\gamma} \) is used to estimate \( \hat{\beta} \) based on those pairs of observations for which \( \gamma(t, \delta_{\delta_0}) \) and \( \gamma(t, \delta_{\delta_0}) \) are ‘close’. To this end define

\[
\hat{\gamma} = \frac{1}{h_0} \sum_{i=1}^{N} \sum_{t=1}^{T} W(\lambda(t, \delta_{\delta_0} - \delta_i)) \lambda(t, \delta_{\delta_0} - \delta_i)
\]

where \( W(\cdot) \) is a kernel density function and \( h_0 \) is a bandwidth sequence. The proposed estimator takes the form:

\[
\hat{\beta} = \left( \sum_{i=1}^{N} \sum_{t=1}^{T} \psi(\lambda(t, \delta_{\delta_0} - \delta_i)) \lambda(t, \delta_{\delta_0} - \delta_i) x_{it} \right)^{-1} \sum_{i=1}^{N} \sum_{t=1}^{T} \psi(\lambda(t, \delta_{\delta_0} - \delta_i)) \lambda(t, \delta_{\delta_0} - \delta_i) x_{it} y_{it}
\]

Under some assumptions and by appropriately choosing \( h_0 \) the estimator can be shown to be asymptotically normal although the rate of convergence is slower that the parametric \( \sqrt{N} \) rate. Apart from the conditional exchangeability assumption, another important assumption that underlies the approach is that there is at least one variable in \( z_{it} \) not contained in \( x_{it} \), which is an exclusion restriction common in semiparametric sample selection models.

A dynamic version of the panel data sample selection model, with the own lagged dependent variable appearing in each equation, is considered by Kyriazidou (2001).

### 4.1 Random effects approach

Fixed-effects methods and conditional maximum likelihood methods (when they exist) estimate the coefficients of time-varying regressors consistently without making any assumptions on how the individual effects are related to the observed covariates or to the time-varying errors or to the initial observations of the sample. However, these methods do not deliver estimates of coefficients of time-invariant regressors and of the individual effects, and hence cannot be used for prediction, or for computation of marginal effects and elasticities which are often the quantities of interest. Furthermore, none of these approaches allows for non-stationary errors and hence for time-series heteroskedasticity. These problems do not arise in the random effects approach. The approach essentially consists of treating \( \alpha(t) + \delta(t) \) as a two-component error term and making assumptions about its relationship with the observed covariates and, in the case of dynamic models, with the initial conditions as well. A downside of the approach is that misspecification of any part of the model typically yields inconsistent estimates.

### 4.4 Static case

In the static panel data linear regression model, the traditional random effects approach (sometimes also called the uncorrelated random effects approach) assumes that the individual effects \( \alpha(t) \) along with the time-varying errors \( \delta(t) \) are uncorrelated with the observed covariates \( x_{it} \). Then the coefficients of both time-varying and time-invariant regressors may be estimated consistently (albeit not efficiently) by pooled OLS. In static nonlinear models, the traditional random effects approach apart from parameterizing the conditional distribution of \( \delta(t) \) given \( x_{it} \), also assumes that \( \alpha(t) \) is independent of \( x_{it} \) and \( \delta(t) \) for all \( t \), and has a distribution, say \( H \), that depends on a finite set of unknown parameters, say \( \delta_0 \). For example, in the binary choice model,

\[
\gamma(t) = 1 \text{I}(x_{it} \beta_0 + \eta(t) + \delta(t) > 0) \quad i = 1, \ldots, N; \quad t = 1, \ldots, T
\]
assuming that $\varepsilon_{it}$ are i.i.d. over time and independent of $x_{it}$ and $u_t$ with known distribution $F$ (say, standard normal or logistic), we may estimate the unknown parameters $(\beta, \delta, \phi)$ via ML. The log-likelihood is

$$
\ln L(\beta, \delta) = \sum_{t=1}^{T} \ln \int f(\varepsilon_{it} + \phi) \sqrt{1 - F(\varepsilon_{it} + \phi)^2} d\varepsilon_{it}
$$

and involves a one-dimensional integral which may be calculated numerically, for example, by quadrature procedures (see Butler and Moffitt, 1982).

However, things become quite complicated if we want to allow for arbitrary serial correlation in the $\varepsilon_{it}$. Consider the binary choice model

$$
\Pr(y_{it} = 1) = F(x_{it} + \alpha_i)
$$

where $\varepsilon_{it} = \alpha_i + \eta_{it}$ is the composite error term. For $T = 3$ there are $2^n$ possible sequences of 0’s and 1’s. The likelihood for an individual for whom the sequence of observed $y_{it}$’s is (0,1,0) takes the form

$$
\Pr(y_{it} = 1) = \int f(u_1, u_2, u_3) du_1 du_2 du_3
$$

where $f$ is the trivariate density of $(u_1, u_2, u_3)$ conditional on $x_i$. The log-likelihood is

$$
\ln L(\beta, \delta) = \sum_{t=1}^{T} \ln \int f(u_1, u_2, u_3) \Pr(y_{it} = 1 | u_1, u_2, u_3) du_1 du_2 du_3
$$

which requires the computation of multiple trivariate integrals. Multivariate integration is basically infeasible for large $T$. This is where simulation methods come in very handy.

The assumption that $\alpha_i$ is independent of $x_{it}$ is often found unsatisfactory. A possible solution is to assume a specific functional form for the relationship of $\alpha_i$ with $x_{it}$. This approach (recently also called the correlated random effects approach) was first proposed by Chamberlain (1984). Suppose that

$$
\eta_{it} = \sum_{j=1}^{T} \gamma_j x_{ij} + \nu_{it}
$$

where $\nu_{it}$ is independent of $x_{it}$ similarly to the time varying error component $\varepsilon_{it}$, and that the composite new error term $\nu_{it} + \epsilon_{it}$ follows a specific distribution, say normal. In the case of the binary choice model, for example, assuming that $\epsilon_{it} + \nu_{it}$ has a specific distribution $F$, implies that

$$
\Pr(y_{it} = 1 | x_{it}) = \Phi(x_{it} \beta)
$$

For computational simplicity, Chamberlain proposes to estimate the unknown parameters $\theta_{it}$ via period-by-period probit. The ‘structural parameters’ $\beta$ are then recovered by minimum distance estimation. Note that the approach allows for time series heteroskedasticity and requires only one normalization e.g. that $\gamma_1 \cdot 1 = 1$.

Newey (1994) generalizes Chamberlain’s approach by postulating that

$$
\eta_{it} = p(x_{it}, ..., x_{it}) + \nu_{it}
$$

where $p(\cdot)$ is an unknown function of $x_{it}$. Assuming again that $\nu_{it}$ and $\varepsilon_{it}$ are independent of $x_{it}$, and that the composite new error term $\nu_{it} + \epsilon_{it}$ follows a specific distribution, say $F$, we obtain

$$
\Pr(y_{it} = 1 | x_{it}) = F(x_{it} \beta)
$$

which for a strictly monotonic $F$, implies that

$$
F^{-1}(y_{it}) = \beta(x_{it} \beta)
$$

For example in the normal case

$$
F^{-1}(y_{it}) = \frac{\beta(x_{it} \beta)}{\sqrt{2\pi}}
$$
Thus for two periods \(t\) and \(s\) we obtain:

\[
\mathbf{e}^{\mathrm{-1}}(\mathbf{p}_t) = \frac{\mathbf{v}_t}{\mathbf{q}_t} \cdot \mathbf{e}^{\mathrm{-1}}(\mathbf{p}_s) = \frac{\mathbf{v}_s}{\mathbf{q}_s} \cdot \mathbf{e}^{\mathrm{-1}}(\mathbf{p}_0) - \mathbf{v}_0 \cdot \mathbf{e}^{\mathrm{-1}}(\mathbf{p}_0)
\]

Normalizing \(\sigma_{0,t}^{-1}\) and estimating \(\pi_t\) and \(\pi_s\) nonparametrically, we can recover \(\sigma_{0,s}\) and \(\beta_0\) from the regression of \(\mathbf{e}^{\mathrm{-1}}(\mathbf{p}_0)\) on \(\mathbf{e}^{\mathrm{-1}}(\mathbf{p}_t)\) and \(\mathbf{e}^{\mathrm{-1}}(\mathbf{p}_s)\).

A criticism of all these correlated random effects approaches is that, although in the linear model writing \(\mathbf{y}_i = \mathbf{z}_i' \mathbf{\beta} + \mathbf{x}_i' \mathbf{\alpha}_i + \mathbf{u}_i\) for all \(t\) does not impose any restrictions on the joint distribution of \(\mathbf{\alpha}_i\) and \(\mathbf{x}_i\) (apart from the requirement that it has second moments) since this is just the best linear projection of \(\mathbf{\alpha}_i\) on \(\mathbf{x}_i\), in the nonlinear model assuming \(\mathbf{y}_i = \mathbf{z}_i' \mathbf{\beta} + \mathbf{x}_i' \mathbf{\alpha}_i + \mathbf{u}_i\) even without specifying the functional form of \(\mathbf{\rho}_i\), imposes implausible restrictions in the sense that, if this relationship holds for the \(T\) observations, a similar one will not in general hold for \(T + 1\).

4.2 Dynamic case

In the case where there are genuine dynamics in the model in the form of lags of the dependent variable or other endogenous regressors, random effects methods become even more complicated and require additional assumptions about the relationship of the individual effects with the initial observations. We next describe a general approach for estimating dynamic random effects models suggested by Wooldridge (2000). For simplicity we will drop the subscripts \(i\).

We are interested in the conditional distribution of \(\mathbf{y}_t\) given a vector of strictly exogenous variables \(\mathbf{z}_t^T = (z_{1t}, \ldots, z_{kt})\), own lags and lags of other endogenous variables \(\mathbf{x}_{t-1} = (x_{1t-1}, x_{2t-1}, \ldots, x_{kt-1})\), and an unobserved scalar or vector random effect \(\mathbf{\alpha}_t\). Here \(z_t\) is strictly exogenous in the sense that

\[
f(\mathbf{y}_t^T, \mathbf{x}_{t-1}^T, 0) = f(\mathbf{y}_t^T, \mathbf{x}_{t-1}^T, 0).
\]

The conditional density of \(\mathbf{y}_t\) \(\mathbf{\mid} \mathbf{y}_T, \mathbf{x}_0\) is

\[
f(\mathbf{y}_t^T, \mathbf{x}_{t-1}^T, 0) = f(\mathbf{y}_t^T, \mathbf{x}_{t-1}^T, 0) \cdot f(\mathbf{y}_t^T, \mathbf{x}_{t-1}^T, 0) \cdot f(\mathbf{y}_t^T, \mathbf{x}_{t-1}^T, 0)\]

and the joint density for all \(T\) periods is

\[
f(\mathbf{y}_1, \mathbf{y}_2, \ldots, \mathbf{y}_T^T, \mathbf{x}_0) = \prod_{t=1}^{T} f(\mathbf{y}_t^T, \mathbf{x}_{t-1}^T, 0).
\]

But \(\mathbf{\alpha}_t\) is unobserved. We need to integrate it out. One solution is to parameterize the distribution of \(\mathbf{\alpha}_t\) conditional on \(\mathbf{z}_t^T\) and \(\mathbf{x}_0\), say \(h(\mathbf{z}_t^T, \mathbf{x}_0)\). Then

\[
f(\mathbf{y}_1, \mathbf{y}_2, \ldots, \mathbf{y}_T^T, \mathbf{x}_0) = \prod_{t=1}^{T} f(\mathbf{y}_t^T, \mathbf{x}_{t-1}^T, 0) h(\mathbf{z}_t^T, \mathbf{x}_0) 0\).
\]

Notice that in the traditional random effects approach (in the line of Anderson and Hsiao, 1981) we would have to make assumptions about the conditional distribution of \(\mathbf{\alpha}_t\) conditional on \(\mathbf{z}_t^T\) and \(\mathbf{x}_0\).

The problem of nonlinear programming is that of maximizing (or minimizing) a given function subject to a set of inequality constraints. Such problems arise in many areas of economics, such as the microeconomic theory of the household and the firm. It has also had wide applicability in game theory and operations research. Historically, the subject developed from the work of mathematicians, primarily John in studying extremum problems with inequalities as side constraints and Kuhn and Tucker who made the fundamental contribution of characterizing the nature of the solution to such problems (John, 1948; Kuhn and Tucker, 1951).

The nonlinear programming problem is a special case of the general mathematical programming problem of maximizing a function subject to constraints. The linear programming problem can be considered a special case of the nonlinear programming problem, namely one of maximizing a given linear form subject to a set of linear inequality constraints.

1 Mathematical programming: resource allocation in economics

The more general problem of mathematical programming is that of maximizing a function subject to constraints. Using standard notation the problem can be written

$$\max F(x) \text{ subject to } x \in X.$$
Here \( \mathbf{x} \) is a (column) vector of \( n \) choice variables \((x_1, x_2, \ldots, x_n)'\) (the prime denoting the transpose of the row vector); \( F(\mathbf{x}) \) is a given real-valued function of these variables \( F(x_1, x_2, \ldots, x_n) \); and \( X \) is a given non-empty subset of Euclidean \( n \)-space (the space of all \( n \)-tuples of real numbers) (Hadley, 1964; Intriligator, 1971; 1981; Aoki, 1971; Luenberger, 1973; Hestenes, 1975).

In economics the vector \( \mathbf{x} \) is frequently called the vector of instruments, the function \( F(\mathbf{x}) \) is frequently called the objective function (or criterion function), and the set \( X \) of feasible instrument vectors \((\mathbf{x} \text{ satisfying } \mathbf{x} \in X)\) is frequently called the opportunity set. The basic economic problem of allocating scarce resources among competing ends can thus be interpreted as one of mathematical programming, where a particular resource allocation is represented by the choice of a particular vector of instruments, the scarcity of the resources is represented by the opportunity set, reflecting constraints on the instruments; and the competing ends are represented by the objective function, which gives the value attached to each of the alternative allocations. Problem (1) can therefore be interpreted in the language of economics as that of choosing instruments within the opportunity set so as to maximize the objective function (Lancaster, 1968; Intriligator, 1971; 1981; Bazaraa and Shetty, 1976; Takayama, 1985).

2 Nonlinear programming

The problem of nonlinear programming, a special case of (1), is that of choosing non-negative values of \( n \) variables so as to maximize a function of these variables subject to inequality constraints. Using the same type of notation the problem is

\[
\max_{\mathbf{x}} F(\mathbf{x}) \text{ subject to } g(\mathbf{x}) \preceq \mathbf{b}, \; \mathbf{x} \succeq \mathbf{0}.
\]

(2)

Here the vector of instruments \( \mathbf{x} \) and the objective function \( F(\mathbf{x}) \) are as in (1), where \( F(\mathbf{x}) \) is assumed to be a real-valued continuously differentiable function of \( n \) variables. The vector-valued function \( g(\mathbf{x}) \) is a representation of \( m \) constraint functions,

\[
[g_1(x_1, x_2, \ldots, x_n), g_2(x_1, x_2, \ldots, x_n), \ldots, g_m(x_1, x_2, \ldots, x_n)]',
\]

and \( \mathbf{b} \) is a column vector of \( m \) constraint constants \((b_1, b_2, \ldots, b_m)'\), so the \( m \) inequality constraints in (2) can be written

\[
g_i(x_1, x_2, \ldots, x_n) \leq b_i, \; i = 1, 2, \ldots, m.
\]

(3)
The $n$ non-negativity constraints in (2) state that all $n$ instruments are non-negative. Thus the problem of nonlinear programming can be written

$$\max F(x_1, x_2, \ldots, x_n) \quad \text{by choice of} \quad x_1, x_2, \ldots, x_n$$

subject to

$$g_i(x_1, x_2, \ldots, x_n) \leq b_i, \quad i = 1, 2, \ldots, m$$

$$x_j \geq 0, \quad j = 1, 2, \ldots, n.$$  

This problem is a special case of (1) in which the opportunity set can be written

$$X = \{x \in \mathbb{R}^n | g(x) \leq b, \quad x \geq 0\}$$

where $\mathbb{R}^n$ is Euclidean $n$-space. Thus the problem is one of maximizing a given function subject to $m+n$ constraints – $m$ inequality constraints and $n$ non-negativity constraints (Kuhn and Tucker, 1951; Hadley, 1964; Mangasarian, 1969; Zangwill, 1969; Intriligator, 1971; 1981; Luenberger, 1973; Hestenes, 1975; Martos, 1975; Avriel, 1976; Bazaraa and Shetty, 1979; McCormick, 1983).

### 3 Linear programming

In spite of the contradictory terminology, the problem of linear programming is in fact an important special case of nonlinear programming. Here the problem is that of choosing non-negative values of $n$ variables so as to maximize a linear form in these variables subject to $m$ linear inequality constraints

$$\max_{x} cx \quad \text{subject to} \quad Ax \leq b, \quad x \geq 0,$$
where $A$ is a given $m \times n$ matrix, $b$ is a given $m \times 1$ column vector, and $c$ is a given $1 \times n$ row vector. Thus the linear programming problem represents the special case of nonlinear programming (2) which is doubly linear, being linear in the objective function $\mathbf{c} \mathbf{x} = \sum_{j=1}^{n} c_j x_j$ and in each of the constraint functions $g_i(x_1, x_2, \ldots, x_n) = \sum_{j=1}^{n} a_{ij} x_j$. Thus the problem of linear programming can be written

$$\max \sum_{j=1}^{n} c_j x_j \text{ by choice of } x_1, x_2, \ldots, x_n$$

subject to

$$\sum_{j=1}^{n} a_{ij} x_j \leq b_i, \quad i = 1, 2, \ldots, m$$

$$x_j \geq 0, \quad j = 1, 2, \ldots, n.$$  

(7)

4 Kuhn–Tucker conditions

The Kuhn–Tucker conditions provide a characterization of the solution to the problem of nonlinear programming (2). These conditions are defined in terms of the Lagrangian function

$$L(\mathbf{x}, \mathbf{y}) = F(\mathbf{x}) + \mathbf{y} [\mathbf{b} - \mathbf{g}(\mathbf{x})] = F(x_1, x_2, \ldots, x_n) + \sum_{i=1}^{m} y_i [b_i - g_i(x_1, x_2, \ldots, x_n)].$$

(8)

Here $\mathbf{y}$ is a (row) vector of $m$ Lagrange multipliers (sometimes written as $\lambda$ 's), one for each of the inequality constraints defined by the $g_i(x_1, x_2, \ldots, x_n)$ constraint functions and $b_i$ constraint constants in (3). The Kuhn–Tucker conditions are then defined at the point $\mathbf{x}^*, \mathbf{y}^*$ as the $2n + 2m$ inequalities and 2
equals 

$$\frac{\partial L}{\partial x} (x^*, y^*) \leq 0, \quad \frac{\partial L}{\partial y} (x^*, y^*) \geq 0$$ 

(n + m conditions) 

$$\frac{\partial L}{\partial x} (x^*, y^*) x^* = 0, \quad y^* \frac{\partial L}{\partial y} (x^*, y^*) = 0$$ 

(2 conditions) 

$$x^* \geq 0, \quad y^* \geq 0$$ 

(n + m conditions) 

(9) 

Half of the inequalities represent the constraints of the original problem 

$$\frac{\partial L}{\partial y} (x^*, y^*) = b - g(x^*) \geq 0$$ 

(m conditions) 

(10) 

$$x^* \geq 0$$ 

(n conditions) 

(11) 

while the added n+m inequalities require that 

$$\frac{\partial L}{\partial x} (x^*, y^*) = \frac{\partial F}{\partial x} (x^*) - y^* \frac{\partial g}{\partial x} (x^*) \leq 0$$ 

(n conditions) 

(12) 

$$y^* \geq 0$$ 

(m conditions) 

(13)
The first $n$ conditions, in (12), state that

$$\frac{\partial F}{\partial x_j} - \sum_{i=1}^{m} y_i^* \frac{\partial g_i}{\partial x_j} \leq 0, \quad j = 1, 2, \ldots, n,$$

(14)

and they are written as inequalities because of the non-negativity restrictions on $x$, which allow for the possibility of boundary solutions. The last $m$ conditions, in (13), state that the Lagrange multipliers are non-negative, and they stem from the fact that the constraints are written as inequalities rather than as equalities. (If any constraint is imposed as an equality, then the corresponding Lagrange multiplier $y_i^*$ is unrestricted.)

The two equality Kuhn–Tucker conditions

$$\frac{\partial L}{\partial x} \langle x^*, y^* \rangle x^* = \sum_{j=1}^{n} \left[ \frac{\partial F}{\partial x_j} \langle x^* \rangle - y^* \frac{\partial g}{\partial x_j} \langle x^* \rangle \right] x_j^* = 0$$

(15)

$$y^* \frac{\partial L}{\partial y} \langle x^*, y^* \rangle = \sum_{i=1}^{m} y_i^* \left[ b_i - g_i(x^*) \right] = 0$$

(16)

together with the other conditions in (9) require that every term in both of these sums vanishes. These **complementary slackness conditions of nonlinear programming** require that when one of the inequality constraints is satisfied at the solution as a strict inequality then the corresponding (dual) variable equals zero at the solution

$$\frac{\partial F}{\partial x_j} \langle x^* \rangle - y^* \frac{\partial g}{\partial x_j} \langle x^* \rangle < 0 \implies x_j^* = 0, \quad j = 1, 2, \ldots, n$$
At the solution the value of the Lagrangian is the maximized value of the objective function

$$\mathcal{L}(\mathbf{x}^*, \mathbf{y}^*) = \mathcal{F}(\mathbf{x}^*) = F^*$$

and the solutions for the Lagrange multipliers are to be interpreted as the sensitivities of the maximized value of the objective function to changes in the constraint constants

$$\mathbf{y}^* = \frac{\partial F^*}{\partial \mathbf{b}}, \text{ i.e. } y_i^* = \frac{\partial F^*}{\partial b_i}, \quad i = 1, 2, ..., m.$$

In particular, from the complementary slackness conditions (18), if a constraint is met as a strict inequality at the solution then the corresponding Lagrange multiplier is zero, so increasing the constraint constant by a ‘small’ amount will not change the maximized value of the objective function.

If a suitably strong constraint qualification condition is satisfied the Kuhn–Tucker conditions are necessary conditions for the nonlinear programming problem in that if $\mathbf{x}^*$ solves (2) then there exists a vector of Lagrange multipliers $\mathbf{y}^*$ satisfying (9). There are, in fact, many alternative forms of the constraint qualification condition. One is the Slater constraint qualification requiring that there exist a point $\mathbf{x}^0 \geq \mathbf{0}$ such that $\mathbf{g}(\mathbf{x}^0) < \mathbf{b}$, that is, there exists a non-negative point at which all inequality constraints are satisfied as strict inequalities, thus excluding outward pointing cusps (Arrow, Hurwicz and Uzawa, 1958; 1961; Mangasarian, 1969; Zangwill, 1969; Bazaraa, Goode, and Shetty, 1972; Bazaraa and Shetty, 1976; 1979). For problems not satisfying the constraint qualification condition it is necessary to add another Lagrange multiplier $\nu_0$ for the objective function (John, 1948).
As to sufficiency, a sufficient condition for \( x^* \) to solve the nonlinear programming problem (2) is that there exists a \( y^* \) such that \( x^*, y^* \) solves the saddle point problem

\[
\max \min \ l(x, y) \text{ subject to } x \geq 0, y \geq 0,
\]

(21)

where \( x^*, y^* \) solves this problem if and only if, for all \( x \geq 0, y \geq 0 \)

\[
l(x, y^*) \leq l(x^*, y^*) \leq l(x^*, y).
\]

(22)

Thus, if a pair of vectors \( x^*, y^* \) satisfies (22) then \( x^* \) solves the nonlinear programming problem. Conversely, assuming both that a suitable constraint qualification condition is met and that the problem is one of concave programming in which \( F(x) \) is a concave function and each constraint function \( g_i(x) \) is a convex function, then if \( x^* \) solves the nonlinear programming problem (2) there exists a non-zero vector \( y^* \) such that \( x^*, y^* \) solves the saddle point problem (21) and the two problems are equivalent. In fact, if the problem is one of concave programming and a suitable constraint qualification condition is met, then the nonlinear programming problem (2), the problem of finding a solution to the Kuhn–Tucker conditions (9), and the saddle point problem (21) are all equivalent in that if \( x^* \) solves (2) then and only then there exists a \( y^* \) such that \( x^*, y^* \) solves both (9) and (21).

Various computational approaches have been developed to solve nonlinear programming problems, and such approaches, in the form of computer codes, are widely available and routinely used to solve particular problems (Mangasarian, 1969; Zangwill, 1969; Polak, 1971; Avriel, 1976; Bazaraa and Shetty, 1979; Schittkowski, 1980; Dennis, 1984).

The Kuhn–Tucker conditions imply that for an interior solution \( x^* > 0 \) (or for a problem in which the non-negativity of the \( x \)'s is not part of the problem)

\[
\frac{\partial F}{\partial x}(x^*) = y^* \frac{\partial g}{\partial x}(x^*).
\]

(23)

Thus at the solution the gradient vector of the objective function (the vector of first-order derivatives of
the objective function, \( \frac{\partial F}{\partial x(x^*)} \) must be a non-negative weighted combination of the gradient vectors of the constraint functions, the weights being the Lagrange multipliers. Geometrically this condition means that the gradient vector of the objective function must, at the solution, lie within the cone spanned by the outward pointing normals to the opportunity set, where the gradient vectors for the constraint functions define the outward pointing normals to the opportunity set.

For the special case of linear programming (6) the saddlepoint problem is

\[
\max \max_{x} \min_{y} L(x, y) = cx + y(b - Ax)
\]

(24)

and the Kuhn–Tucker conditions (9) are

\[
\frac{\partial L}{\partial x} = c - y^*A = 0, \quad \frac{\partial L}{\partial y} = b - Ax^* = 0
\]

\[
\frac{\partial L}{\partial x} x^* = (c - y^*A)x^* = 0, \quad y^* \frac{\partial L}{\partial y} = y^*(b - Ax^*) = 0
\]

\[
x^* \geq 0, \quad y^* \geq 0,
\]

(25)

and they characterize the solution. The same conditions form the Kuhn–Tucker conditions for the dual problem

\[
\min \sum_{y} b \text{subject to} yA \geq c, y \geq 0,
\]

(26)

where the variables of the dual problem, \( y \), are the Lagrange multipliers of the original (primal) problem. The dual problem uses the same matrix \( A \) and vectors \( b \) and \( c \) as the primal problem, but it is one of minimization, rather than maximization, and the constraint constants of the primal problem become the coefficients of the objective function of the dual problem while the coefficients of the objective function of the primal problem become the constraint constants of the dual problem. Vectors \( x^*, y^* \) satisfying (24) or (25) solve both the primal problem (6) and dual problem (26). Geometrically, in the case of linear programming the opportunity set is a polyhedral closed convex set since it is the intersection of \( m + n \) half spaces defined by the \( m \) inequality and \( n \) non-negativity constraints. The contours of the linear
Objective function are hyperplanes, and the problem is solved on the highest hyperplane within the polyhedral set. A solution must occur at a vertex, in which case it is unique, or along a bounding face, in which case it is non-unique. As in the more general case of nonlinear programming, however, the solution always occurs at a point where the gradient vector of the objective function (here \( c \)) lies in the cone spanned by the outward pointing normals to the opportunity set (here the relevant columns of \( A \) or the relevant outward pointing unit vectors corresponding to the non-negativity constraints).

Another special case of nonlinear programming, one which subsumes linear programming, is that of quadratic programming. The problem of quadratic programming is that of

\[
\max_{x} F(x) = cx + \frac{1}{2} x' Q x \quad \text{subject to } Ax \leq b, \ x \geq 0
\]

(27)

where \( A, b, c \) are as in the linear programming problem and \( Q \) is a given \( n \times n \) negative semidefinite symmetric matrix. The problem is one of concave programming because \( Q \) is negative semidefinite and the linear transformation \( Ax \) is convex. Furthermore the constraint qualification is met. The Kuhn–Tucker conditions are therefore both necessary and sufficient, that is, the vector \( x^* \) solves (27) if and only if there is a vector of Lagrange multipliers \( y^* \) such that the pair \( x^*, y^* \) satisfies the Kuhn–Tucker conditions

\[
\frac{\partial L}{\partial x} = \left( c + x^* Q - y^* A \right) \leq 0, \quad \frac{\partial L}{\partial y} = b - Ax^* \geq 0
\]

\[
\frac{\partial L}{\partial x} x^* = \left( c + x^* Q - y^* A \right) x^* = 0, \quad y^* \frac{\partial L}{\partial y} = y^* \left( b - Ax^* \right) = 0
\]

\[
x^* \geq 0, \quad y^* \geq 0,
\]

(28)

where \( L(x, y) \) is the Lagrangian function

\[
L(x, y) = cx + \frac{1}{2} x' Q x + y(b - Ax).
\]

(29)
This case reduces to that of linear programming if \( \mathbf{Q} \), the matrix defining the quadratic form \( \frac{1}{2} \mathbf{x}' \mathbf{Q} \mathbf{x} \) in (27) vanishes.

5 Neoclassical theory of the household and the firm

The problem of nonlinear programming can be applied in economics to the neoclassical theory of both the household and the firm, the two most important units of microeconomics. For the household, assume there are \( n \) goods (and services) available where \( \mathbf{x} = (x_1, x_2, \ldots, x_n)' \) is the column vector of goods purchased and consumed by the household. Assume further that the household seeks to maximize a utility function, a real-valued function defined on these goods \( U(\mathbf{x}) = U(x_1, x_2, \ldots, x_n) \). Assume finally that the household purchases non-negative quantities of each good so as to maximize the utility function subject to a budget constraint that states that expenditure on all \( n \) goods cannot exceed available income. The *neoclassical problem of the household* is then

\[
\max_{\mathbf{x}} U(\mathbf{x}) \text{subject to } \mathbf{p} \mathbf{x} \leq \mathbf{l}, \mathbf{x} \geq \mathbf{0}.
\]

(30)

Here \( \mathbf{p} \) is a given row vector of (positive) prices of each of the \( n \) goods, and \( \mathbf{l} \) is the given (positive) income available to the household. Thus the household chooses non-negative amounts of goods \( \mathbf{x} \) so as to maximize the utility function \( U(\mathbf{x}) \) subject to the budget constraint \( \mathbf{p} \mathbf{x} \leq \mathbf{l} \), which states that expenditure on all \( n \) goods cannot exceed income.

This problem is one of nonlinear programming, so, introducing the (single) Lagrange multiplier \( \gamma \) the Lagrangian is

\[
\mathcal{L}(\mathbf{x}, \gamma) = U(\mathbf{x}) + \gamma(\mathbf{l} - \mathbf{p} \mathbf{x}).
\]

(31)

The Kuhn–Tucker conditions characterize an optimum point. Under the further regularity conditions that \( \mathbf{x}^* \succ \mathbf{0} \) and \( U(\mathbf{x}) \) is a twice continuously differentiable function in a neighbourhood of \( \mathbf{x}^* \) with a non-singular Hessian matrix of second-order derivatives there then exist solutions for the purchases of goods \( \mathbf{x}^* \) as functions of the \( n+1 \) parameters \( \mathbf{p}, \mathbf{l} \), which are the *demand functions* characterizing the optimum point (Hicks, 1946; Samuelson, 1947; Wold and Jureen, 1953; Intriligator, 1971; Barten and Böhm, 1982; Phlips, 1983).

For the firm, assume that the firm uses \( n \) inputs to produce a single output, where \( \mathbf{x} = (x_1, x_2, \ldots, x_n)' \) is a column vector of inputs, \( q \) is output, and \( f(\mathbf{x}) \) is the production function of the firm. Assume further
that the firm seeks to maximize a profit function, given as the difference between revenue and cost. Assume finally that the firm purchases non-negative inputs and produces non-negative output subject to the technology of the given production function so as to maximize profit. The neoclassical theory of the firm is then

$$\max_{x} \pi(x) = pf(x) - wx \text{subject to } x \geq 0.$$  
(32)

Here $pf(x)$ is total revenue, $p$ being the given price of output, and $wx$ is the cost of production, the total expenditure on all inputs, $w$ being the vector of given prices (wages) of inputs. This problem is also one of nonlinear programming, and the Kuhn–Tucker conditions characterize an optimum point. Under the further regularity conditions that $x^* > 0$ and $f(x)$ is twice continuously differentiable in a neighbourhood of $x^*$ with a non-singular Hessian matrix of second-order derivatives there exist solutions for the purchase of inputs $x^*$ and production of output $q$ as functions of the $n+1$ parameters $w, p$ which are the input demand functions and output supply function characterizing the optimum point (Hicks, 1946; Samuelson, 1947; Intriligator, 1971; Nadiri, 1982).

The problem of linear programming can be applied to a firm that produces output using an activity analysis technology. In such a case the firm produces $n$ outputs using $m$ inputs.

To produce one unit of output $x_j$ requires $a_{ij}$ units of input $i$. In the short run all inputs are fixed so the only choice for the firm is that of deciding what mix of outputs to produce given these inputs. The problem is then

$$\max_{x} \ cx \text{subject to } Ax \leq b, \ x \geq 0,$$

(33)
as in (6). Here the objective function to be maximized is total revenue, where $c_j$ is the given price of output $j$, so the problem is one of choosing non-negative outputs so as to maximize profit, given the technology (the $a_{ij}$) and the inputs (the $b_i$). The dual problem is

$$\min_{y} \ y^T b \text{subject to } y^T a \geq c, \ y \geq 0,$$

(34)
as in (26), which can be interpreted as choosing non-negative values (shadow prices) for the inputs $y_1, y_2, \ldots, y_m$ so as to minimize the cost of the inputs $\mathbf{y} = \sum y_i \mathbf{b}_i$ where $y_i$ is the chosen value and $b_i$ is the given level of input $i$. The $n$ constraints state that the unit cost of good $j$, obtained by summing the cost of producing one unit over all inputs, is no less than the price of this good. The dual to a problem of allocation, the primal problem (33), is one of valuation, the dual problem (34). According to the complementary slackness conditions in (25) if for any output $j$ unit costs exceeds price (that is, the output is produced at a loss) then this output is not produced ($x_j^* = 0$) and if for any input $i$ not all of the input is used then it is valued at zero ($y_i^* = 0$).

In conclusion, the problem of nonlinear programming is one with important applications to the microeconomic theory of the household and the firm, leading to conditions characterizing an equilibrium at an optimum point. The problem also has many other applications throughout economics.

nonlinear time series analysis

Bruce Mizrach
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Since the early 1980s, there has been a growing interest in stochastic nonlinear dynamical systems of the form
\[ x_{t+1} = f(x_t, x_{t-1}, \ldots, x_{t-p}) + \sigma(x_t) \varepsilon_t, \]
where \( \{ x_t \}_{t=0}^{\infty} \) is a zero mean, covariance stationary process, \( f : \mathbb{R}^{p+1} \rightarrow \mathbb{R} \), \( \sigma \) is the conditional volatility, and \( \{ \varepsilon_t \}_{t=0}^{\infty} \) is an independent and identically distributed noise process. The major recent developments in nonlinear time series are described using this canonical model: (a) representation theory; (b) nonparametric modelling; (c) ergodic properties; (d) piecewise linear models; (e) volatility modelling; (f) hypothesis testing for linearity and normality; (g) forecasting.

Article

Since the early 1980s, there has been a growing interest in stochastic nonlinear dynamical systems of the form
\[ x_{t+1} = f(x_t, x_{t-1}, \ldots, x_{t-p}) + \sigma(x_t) \varepsilon_t, \]
(1)

where \( \{ x_t \}_{t=0}^{\infty} \) is a zero mean, covariance stationary process, \( f : \mathbb{R}^{p+1} \rightarrow \mathbb{R} \), \( \sigma \) is the conditional volatility,
and \( \{\varepsilon_t\}_{t=0}^{\infty} \) is an independent and identically distributed noise process. The major recent developments in nonlinear time series are described here using this canonical model. The first section develops representation theory for a third order approximation. Nonparametric approaches follow; these rely on series expansions of the general model. Ergodic properties including path dependence and dimension are considered next. I then consider two widely utilized parametric models, piecewise linear models of \( f \) and autoregressive models for volatility. I conclude with a discussion of hypothesis testing and forecasting.

**Volterra expansion**

There is no general causal representation for nonlinear time series as in the linear case. Series approximations rely on the *Volterra expansion*,

\[
x_{t+1} \approx f(0) + \sum_{i_1=1}^{p} f_{1} \varepsilon_{t-i_1} + \sum_{i_1=1}^{p} \sum_{i_2=1}^{p} f_{1i} \varepsilon_{t-i_1-i_2} + \cdots
\]

(2)

Brockett (1976) shows any continuous map over \([0, T]\) can be approximated by a finite Volterra series. Mittnik and Mizrach (1992) examine forecasts using generalized polynomial expansions like (2). Potter (2000) shows that in the cubic case, a one-sided Wold-type representation in terms of white noise \( \varepsilon_t \) can be obtained,

\[
x_{t+1} \approx \sum_{i_1=1}^{\infty} g_{1} \varepsilon_{t-i_1} + \sum_{i_2=1}^{\infty} g_{1i} \varepsilon_{t-i_1-i_2} + \sum_{i_3=1}^{\infty} g_{1i2} \varepsilon_{t-i_1-i_2-i_3}.
\]

(3)

Koop, Pesaran and Potter (1996) note that the impulse response functions, \( E[x_{t+n|x_t}, \varepsilon_t] - E[x_{t+n|x_t}] \) will depend upon the size and sign of \( \varepsilon_t \) as well as the current state \( x_t \).

I now turn to nonparametric approaches which build on approximations like 2.

**Nonparametric estimation**

Consider the local polynomial approximation to \( f(\cdot) \) around \( x_0 \),

\[
\hat{f}(x) = \sum_{j=0}^{m} \beta_j (x - x_0)^j.
\]

(4)
In the case $j = 0$, this corresponds to the kernel regression estimator of Nadaraya and Watson,

$$
\hat{f}(x) = \frac{1}{T} \sum_{t=1}^{T} K_{h}(x_t - x_0) \frac{x_t}{K_{h}(x_t - x_0)}.
$$

The $K_{h}$ are kernels, usually functions with a support on a compact set, assigning greater weight to observations closer to $x_0$. $h$ is the bandwidth parameter, determining the size of the histogram bin. Nearest neighbours estimation is the case where $h$ is adjusted to find a fixed number of nearby observations $k$.

More generally, the local linear approximation solves,

$$
\alpha_0, \beta_0 \min \left( x_{t+1} - \alpha_0 - \beta_0(x_t - x_0) \right)^2 K_{h}(x_t - x_0).
$$

The estimator (5) corresponds to the case where the only regressor in (6) is the constant term. The application of these methods in the time series case is a fairly recent development. Conditions for consistency and asymptotic normality rely on mixing conditions where the dependence between $x_{t+j}$ and $x_t$ becomes negligible as $j$ grows large.

A closely related approach involves the use of a recurrent neural network,

$$
\Psi_i(x_t, h_{t-1}) = \Psi(Y_{i0} + Y_{i1}x_t + \sum_{k=1}^{r} \delta_{ik} h_{k,t-k}),
$$

$$
x_{t+1} = \Phi \left( \beta_0 + \sum_{i=1}^{p} \beta_i \Psi_i(x_t, h_{t-1}) \right).
$$

Kuan, Hornik and White (1994) provide convergence results for bounded $\Psi$ (most commonly the logistic) as $p$ grows large.

A popular approach in the frequency domain is wavelets. The discrete wavelet transform is
\[ x_{t+1} = \sum_{j=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} \gamma(j, k) \psi_{j,k}(t), \]  
(8)

where the *mother wavelet* \( \psi(t) \),

\[ \psi_{j,k}(t) = \frac{1}{\sqrt{s_0^j}} \psi \left( \frac{t - k\tau_0 s_0^j}{s_0^j} \right), \]  
(9)

is parameterized by scale \( s_0 \) and translation \( \tau \), and the wavelet coefficients are given by

\[ \gamma(j, k) = \{ \psi_{j,k}(t), x(t) \}. \]  
(10)

Daubechies (1992) orthonormal basis functions,

\[ E[\psi_{j,k}(t)\psi_{m,n}(t)] = 0, \quad \forall \ j \neq m, k \neq n, \]  
(11)

have received the widest application.

Even when very little is known about \( f \) or \( \sigma \), nonlinear time series analysis can shed light on the long run average or *ergodic* properties of the dynamical system.

**Ergodic properties**

Mathematicians have known since Poincaré that even simple maps like (1) can produce very complex dynamics. The nonlinear time series literature has developed tools for estimation of ergodic properties of these systems. Denote by \( Df(\overline{x}) \) the Jacobian matrix of partial derivatives of (1),
nonlinear time series analysis: The New Palgrave Dictionary of Economics

\[
\begin{bmatrix}
\frac{\partial f_1}{\partial x_1} & \cdots & \frac{\partial f_1}{\partial x_p} \\
\vdots & \ddots & \vdots \\
\frac{\partial f_p}{\partial x_1} & \cdots & \frac{\partial f_p}{\partial x_p}
\end{bmatrix}
\]

(12)

evaluated at \( \bar{x} \). Replacing 12 with a sample analog,

\[
J_t = \begin{bmatrix}
\frac{\Delta f_1}{\Delta x_1, t} & \cdots & \frac{\Delta f_1}{\Delta x_p, t} \\
\vdots & \ddots & \vdots \\
\frac{\Delta f_p}{\Delta x_1, t} & \cdots & \frac{\Delta f_p}{\Delta x_p, t}
\end{bmatrix}
\]

(13)

we compute eigenvalues \( \lambda_i \),

\[
\lambda_i \left( Q_T^T Q_T \right)
\]

(14)

rank ordered from \( 1, \ldots, \ p \), where

\[
Q_T = J_T - p \cdot J_{T-1} - \cdots - J_1
\]

(15)

The Lyapunov exponents are defined for the positive eigenvalues \( \lambda_i^+ \) as

\[
T \to \infty \lim \lambda_i = \frac{1}{2(T - p)} \ln \lambda_i^+,
\]

(16)

and a single exponent greater than 1 characterizes a system with sensitive dependence. Popularly known as
‘chaos’, this property implies that dynamic trajectories become unpredictable even when the state of the system is known with certainty. Gençay and Dechert (1992) and Shintani and Linton (2004) provide methods for estimating these. Shintani and Linton (2003; 2004) reject the presence of positive Lyapunov exponents in both real output and stock returns.

The sum of the Lyapunov exponents also provides a measure of the Kolmogorov–Sinai entropy of the system. This tells the researcher how quickly trajectories separate. Mayfield and Mizrach (1991) estimate this time at about 15 minutes for the S&P 500 index.

A final quantity of interest is the dimension $P$ of the dynamical system. Nonlinear econometricians try to estimate the dimension from a scalar $m$-history. A powerful result due to Takens (1981) says this can be done as long as $m \geq 2P + 1$. Diks (2004) has shown that the scaling of correlation exponents seems to be consistent with the stochastic volatility model.

A great deal of progress has been made with parametric models of (1) as well. I begin with the widely utilized piecewise linear models.

### Piecewise linear models

The most widely applied parametric nonlinear time series specification has been the Markov switching model introduced by James Hamilton (1989). The function $f$ is a piecewise linear function,

$$f(x_t) = \begin{cases} 
\mu^{(1)} + \sum_{j=0}^{P} \varphi_j^{(1)} (x_{t-j} - \mu^{(1)}) , S_t = s_t^{(1)} \\
\vdots \\
\mu^{(m)} + \sum_{j=0}^{P} \varphi_j^{(m)} (x_{t-j} - \mu^{(m)}) , S_t = s_t^{(m)} 
\end{cases}$$

where the changes among states are governed by an unobservable regime switching process, $S_t = s_t^{(i)}$, $i = 1, \ldots, m$, an $m \times m$ transition matrix $\Pi$, and $E [x_t | S_t = s_t^{(i)}] = \mu^{(i)}$. When $S_t$ is unobserved, $P_r(S_t | x_{t-1})$ is nonlinear in $x_{t-1}$. Hamilton has shown that a two-dimensional switching model describes well the business cycle dynamics in the United States. This model has been extended to include regime dependence in volatility (Kim, 1994) and time varying transition probabilities (Filardo, 1994).

The latent state vector requires forming prior and posterior estimates of which regime you are in. The EM algorithm (Hamilton, 1990) and Bayesian Gibbs sampling methods (Albert and Chib, 1993) have proven fruitful in handling this problem. Hypothesis testing is also non-standard because under the alternative of $m - 1$ regimes, the conditional mean parameters are nuisance parameters. Hansen (1996) has explored carefully these issues.

A closely related framework is the threshold autoregressive (TAR) model,
$f(x_t) = \left\{ \begin{array}{l}
\left[ \mu^{(1)} + \sum_{j=0}^{p} \varphi_{j}^{(1)}(x_{t-j} - \mu^{(1)}) \right] I(q(x_{t-d}, Z_t) \leq \gamma_1) \\
\left[ \mu^{(2)} + \sum_{j=0}^{p} \varphi_{j}^{(2)}(x_{t-j} - \mu^{(2)}) \right] I(\gamma_1 < q(x_{t-d}, Z_t) \leq \gamma_2) \\
\left[ \mu^{(m)} + \sum_{j=0}^{p} \varphi_{j}^{(m)}(x_{t-j} - \mu^{(m)}) \right] I(q(x_{t-d}, Z_t) > \gamma m - 1) 
\end{array} \right.$

(18)

$I(\cdot)$ is the indicator function, and $q(x_{t-d}, Z_t)$, the regime switching variable, is assumed to be an observable function of exogenous variables $Z_t$ and lagged $x$’s. The integer $d$ is known as the delay parameter. When $q$ depends only upon $x$, the model is called self-exciting.

Teräsvirta (1994) has developed a two-regime version of the TAR model in which regime changes are governed by a smooth transition function $G(x_{t-d}, Z_t): \mathbb{R}^k \rightarrow [0, 1]$,

$$f(x_t) = G(x_{t-d}, Z_t) \sum_{j=0}^{p} \varphi_{j}^{(1)}(x_{t-j} - \mu^{(1)}) + (1 - G(x_{t-d}, Z_t)) \sum_{j=0}^{p} \varphi_{j}^{(2)}(x_{t-j} - \mu^{(2)}).$$

(19)

Luukkonen, Saikkonen and Teräsvirta (1988) have shown that inference and hypothesis testing in this model is often much simpler than in the piecewise linear models. Van Dijk and Franses (1999) have extended this model to multiple regimes. Applications of this framework have been widespread from macroeconomics (Teräsvirta and Anderson, 1992) to empirical finance (Franses and van Dijk, 2000).

Krolzig (1997) considers the multivariate case where $x_t = (x_{1,t}, x_{2,t}, \ldots, x_{k,t})'$ is $k \times 1$. Balke and Fomby (1997) introduced threshold cointegration by incorporating error correction terms into the thresholds. Koop, Pesaran and Potter (1996) develop a bivariate model of US GDP and unemployment where the threshold depends upon the depth of the recession.

I now turn to models that introduce nonlinearity through the error term.

Models of volatility

Engle and Bollerslev have introduced the generalized autoregressive conditional heteroskedasticity (GARCH) model,

$$h_t = \alpha_0 + \sum_{i=1}^{q} \alpha_i \sigma_i^2 \varepsilon_{t-i}^2 + \sum_{i=1}^{p} \beta_i h_{t-i}$$

(20)
where $h_t = E[(x_t - E[x_t|\Omega_{t-1}])^2|\Omega_{t-1}]$ is the conditional variance. This is just a Box–Jenkins model in the squared residuals of 1 of order $(\max\{p, q\}, p)$. The model is nonlinear because the disturbances are uncorrelated, but their squares are not.

The GARCH model describes the volatility clustering and heavy-tailed returns in financial market data, and has found wide application in asset pricing and risk management applications.

Volatility modelling has been motivated by the literature on options pricing. Popular alternatives to the GARCH model include the stochastic volatility (SV) model (Ghysels, Harvey and Renault, 1996), and the realized volatility approach of Andersen et al. (2003) and Barndorff-Nielsen and Shephard (2002). The discrete-time SV model takes the form,

$$x_t = \sigma \exp(\alpha / 2) \epsilon_t,$$

(21)

$$h_t = \beta h_{t-1} + \sigma_t \eta_t,$$

where $x_t$ is the demeaned log asset return, and $\epsilon_t$ and $\eta_t$ are noise terms. Realized volatility sums high-frequency squared returns as an approximation of lower frequency volatility. Both GARCH and SV have been successful in explaining the departures from the Black–Scholes observed empirically.

The final two sections address the marginal contribution of nonlinear modelling to goodness of fit and forecasting.

**Testing for linearity and Gaussianity**

There is a large literature on testing the importance of the nonlinear components of a model. The most widely used test is due to Brock, Dechert, Scheinkman and LeBaron (BDSL, 1996). Their nonparametric procedure is built upon $U$-statistics. Serfling (1980) is a good introduction.

The first step is to form $m$-histories of the data,

$$x_t^m = (x_t, x_{t+1}, \ldots, x_{t+m-1}),$$

(22)
with joint distribution $F(x_t^m)$. Introduce the kernel $h: \mathbb{R}^m \times \mathbb{R}^m \to \mathbb{R}$,

$$h(x_t^m, x_s^m) = I(x_t^m, x_s^m, \varepsilon) \equiv I[\|x_t^m - x_s^m\| < \varepsilon].$$

(23)

where $I(\cdot)$ is the indicator function. The correlation integral of Grassberger and Procaccia (1983),

$$C(m, \varepsilon) \equiv \int_{X} \int_{X} I(x_t^m, x_s^m, \varepsilon) dF(x_t^m) dF(x_s^m),$$

(24)

is the expected number of $m$-vectors in an $\varepsilon$-neighbourhood. A $U$-statistic,

$$C(m, N, \varepsilon) \equiv \frac{2}{N(N-1)} \sum_{t=1}^{N-1} \sum_{s=t+1}^{N} I(x_t^m, x_s^m, \varepsilon),$$

(25)

is a consistent estimator of 24. BDSL demonstrate the asymptotic normality of the statistic

$$\sqrt{N} \frac{S(m, N, \varepsilon)}{\sqrt{\text{Var}[S(m, N, \varepsilon)]}} \xrightarrow{d} N(0, 1),$$

(26)

where

$$S(m, N, \varepsilon) = C(m, N, \varepsilon) - C(1, N, \varepsilon)^m.$$

(27)

There is a multi-dimensional extension due to Baek and Brock (1992). De Lima (1997) explores the use of
the BDSL under moment condition failure. There is a direct relationship between nonlinear and non-Gaussian time series. In the model (1), even if the disturbance term $\varepsilon_t$ is normal, nonlinear transformations of Gaussian noise will make $x_t$ non-Gaussian. Testing for Gaussianity is then an instrumental part of the nonlinear time series toolkit. Hinich (1982) has developed testing in the time domain using the bicorrelation,

$$\gamma(r, s) = \frac{1}{N-s} \sum_{t=1}^{N-s} x_t x_{t+r} x_{t+s} / (N - s), \quad 0 \leq r, s \leq N - s,$$

(28)

and in the frequency domain using the bispectrum,

$$B(\omega_1, \omega_2) = \sum_{r=-\infty}^{\infty} \sum_{s=-\infty}^{\infty} \gamma(r, s) \exp \left(-i(\omega_1 r + \omega_2 s)\right).$$

(29)

For a Gaussian time series, the bicorrelation should be close to zero, and the bispectrum should be flat across all frequencies. Both tests have good power against skewed alternatives. Ramsey and Rothman (1996) have proposed a related time domain procedure that looks for time reversibility,

$$F(X_t, X_{t+1}, \ldots, X_{t+r}) = F(X_{s-t}, X_{s-t-1}, \ldots, X_{s-t-r}),$$

(30)

for any $r, s$ and $t$, where $F(\cdot)$ is the joint distribution. This condition is stronger than stationarity because of the triple index. The authors find evidence of business cycle asymmetry using this diagnostic.

**Forecasting**

For many, the bottom line on nonlinear modelling is the ability to generate superior forecasts. In this respect, the results from the nonlinear literature are decidedly mixed. Harding and Pagan (2002) are prominent sceptics. Teräsvirta, van Dijk and Medeiros (2005) provide a very wide set of evidence in favour of nonlinear models. Aside from the comparison of point forecasts from model $i$, $u_i, t+1 = x_{t+1} - f_i(x_t)$, with a particular loss function $g(\cdot)$,
nonlinear time series analysis: The New Palgrave Dictionary of Economics

\[
H_0: E[g(u_{i,t+1}) - g(u_{j,t+1})] = 0,
\]

(31)

there has been growing interest in comparing forecast densities \( p_i(x_{t+1}|f_i(x_t)) \),

\[
H_0: \int [p_i(x_{t+1}|f_i(x_t)) - p_j(x_{t+1}|f_j(x_t))] \, dx = 0.
\]

(32)

Corradi and Swanson (2005) provide a comprehensive overview of available tools.

non-nested hypotheses

M. Hashem Pesaran and M. Rodrigo Dupleich Ulloa
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article provides an overview of the literature on hypotheses testing when the hypotheses or models under consideration are non-nested. Two models are said to be non-nested if neither can be obtained from the other by some limiting process, including the imposition of equality and/or inequality constraints on one of the model's parameters. Relevant concepts such as closeness measures and pseudo-true values are discussed and alternative approaches to testing non-nested hypotheses, including the Cox procedure, artificial nesting and the encompassing approach, are reviewed. The Vuong approach to model selection is also covered.

Keywords

artificial nesting; Cox's test; encompassing test; hypothesis testing; Kullback–Leibler information criteria; linear regression models; maximum likelihood estimation; model selection; non-nested hypotheses; pseudo-true values

Article

In economics, as in many other disciplines, there are competing explanations of the same phenomena, often characterized by alternative statistical models. Different models may represent, for example, different theoretical paradigms, or could be the result of alternative formulations from the same paradigm. Within the classical framework, the problem of model adequacy is approached through ‘general specification tests’, the ‘diagnostic tests’, and the ‘non-nested tests’. All three approaches can be used to test the same explanation or hypothesis of interest (the null or the maintained hypothesis), but they differ in their consideration of the alternative(s). General specification tests intentionally consider a broad class of alternatives, while the alternatives considered under diagnostic and non-nested testing procedures are much more specific. In the case of non-nested tests the null hypothesis is contrasted with a specific alternative. Non-nested tests are appropriate when rival hypotheses are advanced for the explanation of the same economic phenomenon, and the aim is to devise a powerful test against a specific
alternative. When the null hypothesis is nested within the alternative, standard classical procedures such as those based on the likelihood ratio, Wald and Lagrange multiplier (or score) principles can be utilized. But if the null and the alternative hypotheses belong to ‘separate’ families of distributions, classical testing procedures cannot be applied directly and need to be suitably modified. This article provides an overview of the concepts and some of the most widely used non-nested hypotheses tests and applies these procedures to the classical regression models. Our discussion of non-nested hypothesis testing will necessarily omit many topics. Survey articles on this subject include McAleer and Pesaran (1986), Gourieroux and Monfort (1994), and Pesaran and Weeks (2001).

Non-nested models

Suppose the object of interest is the process generating the random variable $Y$, observed over a sample of size $n$, $Y = (Y_1, Y_2, ..., Y_n)$. Assume that the true process generating $y$ is characterized by a joint probability density function, $f_0(y)$, which is unknown, and two models (hypotheses) are advanced as possible explanations of $Y$, represented by the joint probability density functions:

$$H_g = \{g(y; \theta), \theta \in \Theta\}, H_h = \{h(y; \gamma), \gamma \in \Gamma\}.$$  

These functions are known but depend on a finite number of unknown parameters denoted by $\theta \in \Theta$ and $\gamma \in \Gamma$, respectively. The sets $\Theta$ and $\Gamma$ represent the ‘admissible’ parameter space for which the respective densities $g(y; \theta)$ and $h(y; \gamma)$ are well defined. The aim is to ascertain which of the two alternatives, $H_g$ and $H_h$, if any, can be viewed as belonging to $f_0(y)$. In this set-up there is no natural null hypothesis; either of the two hypotheses under consideration can be taken as the null. In practice, the analysis of non-nested hypotheses is carried out with both alternatives taken in turn as the null hypothesis. Four outcomes are possible: (i) $H_g$ rejected against $H_h$ and not vice versa, (ii) $H_h$ rejected against $H_g$ and not vice versa, (iii) neither hypothesis is rejected against the other, and finally (iv) both hypotheses are rejected against one another. The first two outcomes are familiar from the classical test results and are straightforward to interpret. The third outcome can arise when the two models are very close to $f_0(y)$, and hence equivalent observationally. The fourth outcome suggests the existence of a third possible model which shares important features from both models under consideration.

Pseudo-true values and closeness measures

Given the observations $y$, the maximum likelihood (ML) estimators of $\theta$ and $\gamma$ are given by
where the corresponding log-likelihood functions are defined by $L_g(\theta) = \log \left(g(y; \theta)\right)$ and $L_h(\gamma) = \log \left(h(y; \gamma)\right)$. Throughout we shall assume that probability densities satisfy the usual regularity conditions as established, for example in White (1982), such that $\hat{\theta}_n$ and $\hat{\gamma}_n$ have asymptotically normal limiting distributions under the ‘true’ model, $f_0(y)$. In the general case where neither of the models under consideration coincide with $f_0(y)$, $\hat{\theta}_n$ and $\hat{\gamma}_n$ are known as quasi-ML estimators and their probability limits under $f_0(y)$ are referred to as (asymptotic) pseudo-true values, such that

$$
\theta^*_f = \arg \max_{\theta \in \Theta} \mathbb{E}_f \left\{ L_g(\theta) \right\}, \quad \gamma^*_f = \arg \max_{\gamma \in \Gamma} \mathbb{E}_f \left\{ L_h(\gamma) \right\}
$$

(2)

where $\mathbb{E}_f (\cdot)$ denotes expectations under the true density $f_0(y)$. In what follows, we assume that the above asymptotic pseudo-true values exist; and $\theta^*_f$ and $\gamma^*_f$ are the unique maxima to the respective optimization problem given in (2), such that global identifiability is ensured. For the case in which $f_0(y)$ belongs to $H_g$, we have that $\theta^*_g = \theta_0$ and $\gamma^*_g = \gamma^*(\theta_0)$, where the ‘true’ value of $\theta$ under $H_g$, is denoted by $\theta_0$. Given the symmetry of our setting, under $H_h$ we have $\theta^*_h = \theta^*(\gamma_0)$ and $\gamma^*_h = \gamma_0$, where $\gamma_0$ is the ‘true’ value of $\gamma$ under $H_h$. The relationship between the parameters of the two models under consideration is given by the functions $\gamma^*_g = \gamma^*(\theta_0)$ and $\theta^*_h = \theta^*(\gamma_0)$, known as the binding functions.

Using closeness measures and pseudo-true values, Pesaran (1987) provides a formalization of the concepts of nested and non-nested hypotheses. The closeness of $H_g$ with respect to $H_h$ is given by

$$
C_{gh}(\theta_0) = I_{gh}(\theta_0, \gamma^*(\theta_0)) = \min_{\gamma} I_{gh}(\theta_0, \gamma)
$$

(3)

$$
= \mathbb{E}_g \left\{ L_g(\theta_0) - L_h(\gamma^*(\theta_0)) \right\}
$$
non-nested hypotheses: The New Palgrave Dictionary of Economics

where \( I_{gh}(\theta_0, \gamma^*) \) is known as the Kullback–Leibler information criterion (KLIC) measure, introduced by Kullback (1959). Similarly, the closeness of \( H_g \) to \( H_h \) is defined by \( C_{hg}(\gamma^0) = I_{hg}(\gamma^0, \theta^*(\gamma^0)) \).

- \( H_g \) is nested within \( H_h \) if and only if \( C_{gh}(\theta^0) = 0 \), for all values of \( \theta^0 \in \Theta \), and \( C_{hg}(\gamma^0) \neq 0 \) for some \( \gamma^0 \in \Gamma \).
- \( H_g \) and \( H_h \) are globally non-nested if and only if \( C_{gh}(\theta^0) \) and \( C_{hg}(\gamma^0) \) are both non-zero for all values of \( \theta^0 \in \Theta \) and \( \gamma^0 \in \Gamma \).
- \( H_g \) and \( H_h \) are partially non-nested if \( C_{gh}(\theta^0) \) and \( C_{hg}(\gamma^0) \) are both non-zero for some values of \( \theta^0 \in \Theta \) and \( \gamma^0 \in \Gamma \).
- \( H_g \) and \( H_h \) are observationally equivalent if and only if \( C_{gh}(\theta^0) = 0 \) and \( C_{hg}(\gamma^0) = 0 \) for all values of \( \theta^0 \in \Theta \) and \( \gamma^0 \in \Gamma \).

Tests of non-nested hypotheses

There are three general approaches to testing non-nested hypotheses. The first, due to the pioneering contributions of Cox (1961; 1962), involves centring the log-likelihood ratio statistic under the null hypothesis and then deriving its asymptotic null distribution. This is known as the Cox test. A second approach, also suggested by Cox (1962) and explored extensively by Atkinson (1970), is based on an artificially constructed general model. The basic idea is to introduce a third hypothesis in which both \( H_g \) and \( H_h \) are nested as special cases. A third approach, originally considered by Deaton (1982) and Dastoor (1983), and further developed by Mizon and Richard (1986) known as the encompassing procedure, focuses on the ability of one model in explaining particular features of an alternative model. In a related contribution, Gourieroux, Monfort and Trognon (1983) extend the Wald and score-type tests to non-nested models. Their statistics are based on the difference between two estimators of the pseudo-true values.

The Cox test statistic is derived by modifying the log-likelihood ratio statistic, \( L_g(\hat{\theta}_n) - L_h(\hat{\gamma}_n) \), so that it is appropriately centred. Specifically, for testing \( H_g \) against \( H_h \), the numerator of the Cox statistic is given by

\[
S_{gh}^n = \left\{ L_g(\hat{\theta}_n) - L_h(\hat{\gamma}_n) \right\} - \mathbb{E} \left\{ L_g(\hat{\theta}_n) - L_h(\hat{\gamma}_n) \right\},
\]

(5)

where \( \hat{g} \left( \hat{\theta}_n \right) - L_h(\hat{Y}_n) \) is a consistent estimator of \( C_{gh}(\theta_0) \). In the case where \( H_g \) is nested within \( H_h \) we have \( C_{gh}(\theta_0) = 0 \) for all \( \theta_0 \), and \( S_{gh}^h \) reduces to the standard log-likelihood ratio statistic. An application to linear regression models has been proposed by Pesaran (1974) and subsequently extended to simultaneous nonlinear equations systems by Pesaran and Deaton (1978). As pointed out previously, since there is no natural null hypothesis in this testing framework, one also needs to consider the modified log-likelihood statistic for testing \( H_h \) against \( H_g \) which is denoted by \( S_{hg}^h \). Under a suitable normalization (that is \( \sqrt{n} \)), both statistics are asymptotically normally distributed under their respective nulls with a zero mean and a finite asymptotic variance. When the null hypothesis of \( H_g \) is considered against \( H_h \), we have

\[
N_{gh}^h = \frac{\sqrt{n} S_{gh}^h}{\sqrt{V_{gh}}} \overset{a}{\sim} N(0, 1)
\]

where \( V_{gh} \) is the asymptotic variance of \( \sqrt{n} S_{gh}^h \) and \( \overset{a}{\sim} \) denotes asymptotical equivalence in distribution (for details see Pesaran and Deaton, 1978). Based on the results of the two statistics, \( N_{gh}^h \) and \( N_{hg}^h \), four outcomes are possible:

- reject \( H_g \) but not \( H_h \) if \( N_{gh}^h < c_\alpha \) and \( N_{hg}^h \geq c_\alpha \),
- reject \( H_h \) but not \( H_g \) if \( N_{gh}^h \geq c_\alpha \) and \( N_{hg}^h < c_\alpha \),
- reject both \( H_g \) and \( H_h \) if \( N_{gh}^h \geq c_\alpha \) and \( N_{hg}^h \geq c_\alpha \),
- reject neither \( H_g \) and \( H_h \) if \( N_{gh}^h < c_\alpha \) and \( N_{hg}^h < c_\alpha \),

where the \((1 - \alpha)\) per cent critical value of the standard normal distribution is denoted by \( c_\alpha \). In the case of non-nested hypotheses, there is no way of ranking the models by the level of their generality. As a consequence, the test results may provide a consistent outcome such as the rejection of \( H_g \) (or \( H_h \)) by both tests. But it is also not unusual, given the data, for both non-nested models to be simultaneously rejected or fail to be rejected. For the case of a simultaneous rejection of \( H_g \) and \( H_h \), we need to find some other model that fits the data better. If neither model is rejected, this may indicate lack of power. The second approach, named Atkinson's comprehensive method (Atkinson, 1970), is based on an artificial
non-nested hypotheses: The New Palgrave Dictionary of Economics

nesting of the two models with a general model such as,

\[
t_c(y; \theta, \gamma, \lambda) = \frac{(g(y; \theta))^\lambda (h(y; \gamma))^{1-\lambda}}{\int (g(y; \theta))^\lambda (h(y; \gamma))^{1-\lambda} dy}, \quad \lambda \in [0, 1], \quad \theta \in \Theta, \quad \gamma \in \Gamma
\]

(6)

Atkinson's comprehensive approach considers families that are obtained by mixing the probability distributions of \(H_g\) and \(H_h\). It requires the existence of the integral appearing in the denominator in eq. (6). This component ensures that the combined function \(f_c(y; \theta, \gamma, \lambda)\), is in fact a proper density function. In equation (6), the comprehensive model is based on an exponential combination (that is, a geometric mean); alternatively the compound model can also be derived from an arithmetic mean (see for instance Quandt, 1974). In this set-up, the hypothesis \(H_g\) is obtained by imposing \(\lambda = 1\), while the hypothesis \(H_h\) is obtained by imposing \(\lambda = 0\). Thus, in principle, by testing \(\lambda = 1\) or \(\lambda = 0\), we can test \(H_g\) or \(H_h\), respectively. The ‘mixing’ parameter, \(\lambda\), varies over the range [0,1] and measures the relative weights attached to \(H_g\) and \(H_h\). As a consequence, tests for the restriction of \(\lambda = 1\) (\(\lambda = 0\)) against the alternative that \(\lambda \neq 1\) (\(\lambda \neq 0\)) can be performed based on standard techniques from the literature of nested hypothesis testing (see Atkinson, 1970; Pesaran, 1982b).

Atkinson's approach is, however, subject to a number of drawbacks. The first one arises from the fact that under \(\lambda = 1\) (or \(\lambda = 0\)), the unknown parameter vector \(\gamma\) (or \(\theta\)) disappears from the combined model written in (6). This is known as Davies' problem (Davies, 1977) which can be circumvented in various ways, as discussed, for example, by Pesaran (1982c). The second limitation is due to the fact that testing \(\lambda = 1\) against \(\lambda \neq 1\) is not equivalent to performing the test of \(H_g\) against \(H_h\), which is the primary object of the non-nested testing exercise. Finally, there is some degree of arbitrariness in the choice of the comprehensive model (see Pesaran, 1981).

The encompassing approach generalizes Cox's original idea and examines the extent to which \(H_g\) explains one or more features of the rival model, \(H_h\). When all the features of the model \(H_h\) can be explained by model \(H_g\), then \(H_g\) is said to encompass \(H_h\). This condition is denoted by

\[
H_g \in H_h: \gamma^* f = \gamma^* (\theta^* f).
\]

(7)

Likewise, \(H_h \in H_g\) implies that all features of model \(H_g\) can be explained by the model \(H_h\), that is \(H_h\) encompasses \(H_g\), such that
non-nested hypotheses: The New Palgrave Dictionary of Economics

\[ H_{h} \in H_{g}: \Theta^{*}_{f} = \Theta^{*}(\gamma^{*}_{f}). \]  (8)

Recall that \( \gamma^{*}_{f} \) and \( \theta^{*}_{f} \) are the pseudo-true values of \( \gamma \) and \( \theta \), with respect to the true model \( H_{f} \). Moreover, \( \gamma^{*}(\cdot) \) and \( \theta^{*}(\cdot) \) are the binding functions linking the parameters of the models under \( H_{g} \) and \( H_{h} \). The encompassing hypothesis \( H_{g} \in H_{h} \) (resp. \( H_{h} \in H_{g} \)) can be tested using the statistic \( \sqrt{n}(\hat{\gamma}_{n} - \gamma^{*}(\hat{\theta}_{n})) \), respectively \( \sqrt{n}(\hat{\theta}_{n} - \theta^{*}(\hat{\gamma}_{n})) \). Gourieroux and Monfort (1995) show that under the encompassing hypothesis, \( H_{g} \in H_{h} \) and a set of regularity conditions, \( \sqrt{n}(\hat{\gamma}_{n} - \gamma^{*}(\hat{\theta}_{n})) \) is asymptotically normal with zero mean and a finite covariance matrix. Based on this result, two testing procedures are proposed by Gourieroux and Monfort (1995): the Wald encompassing test (WET) and the score encompassing test (SET). In practice, the implementation of these tests tends to be difficult. First, the binding functions \( \gamma^{*}(\cdot) \) and \( \theta^{*}(\cdot) \) are not easy to derive and, second, the variance–covariance matrices appearing in the test statistics tend to be difficult to compute in practice. Chen and Kuan (2002) suggest the use of ‘pseudo-true score’ as a way of avoiding the need to estimate pseudo-true values.

**Vuong's model selection test**

Vuong's (1989) criterion is motivated by testing that \( H_{g} \) and \( H_{h} \) are observationally equivalent, using the Kullback–Leibler information criterion (KLIC) as a closeness measure. The focus of this approach is to test the hypothesis that the models under consideration are ‘equally’ close to the true unknown model, \( H_{f} : f \equiv (\gamma) \). It provides a natural link between model selection and hypothesis testing approaches. Under model selection, a model is selected even if the ‘best’ model happens to be very close to the second best model. Vuong's approach allows the statistical significance of the differences between models to be tested using classical testing procedures. It is based on the closeness measures of \( H_{g} \) and \( H_{h} \) with respect to the true model, \( H_{f} \), namely (for closeness of \( H_{g} \) to \( H_{f} \))

\[ C_{fg}(\theta^{*}_{f}) = E_{f}\{L_{f}(\cdot) - L_{g}(\theta^{*}_{f})\}. \]

and (for closeness of \( H_{h} \) to \( H_{f} \))

\[ C_{fh}(\gamma^{*}_{f}) = E_{f}\{L_{f}(\cdot) - L_{h}(\gamma^{*}_{f})\}. \]
The null hypothesis of interest, ‘\(H_g\) and \(H_h\) are equivalent’, is then formally defined by

\[
H_V : C_{f_g(\Theta^*f)} = C_{f_h(Y^*f)}
\]

(9)

which is equivalent to the unknown quantity

\[
\mathbb{E}_f \left\{ L_g(\Theta^*f) - L_h(Y^*f) \right\} = 0,
\]

that depends on \(f_0(y)\), the unknown true distribution. However, the latter difference can be consistently estimated by

\[
\bar{T}^{-1} \left\{ L_g(\hat{\Theta}) - L_h(\hat{Y}) \right\},
\]

an average of the log-likelihood ratio statistic. Vuong derives an asymptotic standard normal distribution for the related test statistic under \(H_V\).

Rivers and Vuong (2002) provide a number of generalizations and show that the test can be applied to nonlinear dynamic models and other closeness measures.

**Application to linear regression models**

An important application of the non-nested tests in econometrics has been to linear regression models. Consider the following classical normal regression models:

\[
\begin{align*}
H_g: & \quad y = X\beta + u_g, \quad u_g \sim N(0, \sigma^2 I_n), \quad 0 < \sigma^2 < \infty, \quad H_h: \quad y = Z\alpha + u_h, \quad u_h \sim N(0, \omega^2 I_n), \quad 0 < \omega^2 < \infty,
\end{align*}
\]

(10)

where \(X\) and \(Z\) are \(n \times k_g\) and \(n \times k_h\) matrices of observations on the explanatory variables of models \(H_g\) and \(H_h\), respectively. These variables are assumed to be distributed independently of the \(n \times 1\) disturbance vectors \(u_g\) and \(u_h\). The parameters \(\theta = (\beta', \sigma^2)\) and \(\gamma = (\alpha', \omega^2)\) are the \((k_g + 1) \times 1\) and \((k_h + 1) \times 1\) vectors of unknown regression coefficients, and \(I_n\) is the identity matrix of order \(n\). It is also assumed that the probability limits of \(\hat{\Sigma}_{xx} = n^{-1}(X'X), \hat{\Sigma}_{zz} = n^{-1}(Z'Z)\) and \(\hat{\Sigma}_{xz} = n^{-1}(X'Z)\) exist with population values denoted by the non-singular matrices \(\Sigma_{xx}, \Sigma_{zz}\) and \(\Sigma_{xz}\). At the same time, define

\[
\hat{\Sigma}_g = \hat{\Sigma}_{xx} - \hat{\Sigma}_{xz}\hat{\Sigma}_{zz}^{-1}\hat{\Sigma}_{zx} > 0 \quad \text{and} \quad \hat{\Sigma}_h = \hat{\Sigma}_{zz} - \hat{\Sigma}_{zx}\hat{\Sigma}_{xx}^{-1}\hat{\Sigma}_{xz} > 0.
\]

The link between these strict inequality restrictions and the nesting properties of the models in (10) will be made clear below.

Suppose that neither \(H_g\) nor \(H_h\) belong to the true DGP, and the data is generated by

\[
H_f: \quad y = W\delta + u_f, \quad u_f \sim N(0, \nu^2 I_n), \quad 0 < \nu^2 < \infty.
\]
As before, assume that \( \Sigma_{ww} = n^{-1}(W'W) \), \( \Sigma_{wx} = n^{-1}(W'X) \) and \( \Sigma_{wz} = n^{-1}(W'Z) \) can be replaced by their population values given by \( \Sigma_{ww}, \Sigma_{wx} \) and \( \Sigma_{wz} \). The pseudo-true values given in (2) can be obtained for this case by maximizing \[ \mathbb{E}_f \left\{ n^{-1}L_g(\theta) \right\} \] with respect to \( \theta \) which yields

\[
\theta^*_f = \begin{pmatrix}
\beta^*_f \\
\omega^2_f
\end{pmatrix} = \begin{pmatrix}
\Sigma_{XX}^{-1} \Sigma_{XW} \delta \\
\Sigma_{XX} \Sigma_{XW} \delta
\end{pmatrix} \left( \Sigma_{WW} - \Sigma_{WX} \Sigma_{XX}^{-1} \Sigma_{XW} \right) \delta.
\]

(12)

Similarly, for model \( H_h \) we have

\[
\gamma^*_f = \begin{pmatrix}
\alpha^*_f \\
\omega^2_f
\end{pmatrix} = \begin{pmatrix}
\Sigma_{ZZ}^{-1} \Sigma_{ZW} \delta \\
\Sigma_{ZZ} \Sigma_{ZW} \delta
\end{pmatrix} \left( \Sigma_{WW} - \Sigma_{WX} \Sigma_{XX}^{-1} \Sigma_{XW} \right) \delta.
\]

(13)

Note that, for the case in which \( H_f \) belongs to the family of models given by \( H_g \), the latter result can be rewritten as

\[
\gamma^*_g = \begin{pmatrix}
\alpha^*_g \\
\omega^2_g
\end{pmatrix} = \begin{pmatrix}
\Sigma_{ZZ}^{-1} \Sigma_{ZX} \delta \\
\Sigma_{ZZ} \Sigma_{ZX} \delta
\end{pmatrix} \left( \Sigma_{WW} - \Sigma_{WX} \Sigma_{XX}^{-1} \Sigma_{XW} \right) \delta.
\]

(14)

In terms of our previous discussion, these regression models are non-nested if it is not possible to write \( X \) as an exact linear function of \( Z \) and vice versa, or more formally if \( X \not\subset Z \) and \( Z \not\subset X \). The model \( H_g \) is said to be nested in \( H_h \) if \( X \subset Z \) and \( Z \not\subset X \). The two models are observationally equivalent if \( X \subset Z \) and \( Z \subset X \). These conditions can be written in terms of the KLIC measure given by (3) as in McAleer and Pesaran.
non-nested hypotheses: The New Palgrave Dictionary of Economics (1986), who derive the closeness measure of $H_h$ with respect to $H_g$ as

$$C_{gh}(\theta) = \frac{1}{2} \log \left[ 1 + \frac{\beta' \Sigma_g \beta}{\sigma^2} \right].$$

Similarly, the KLIC measure of closeness of $H_g$ with respect to $H_h$ is

$$C_{hg}(\gamma) = \frac{1}{2} \log \left[ 1 + \frac{\alpha' \Sigma_h \alpha}{\omega^2} \right].$$

It can be easily seen from this example that a necessary and sufficient condition for $H_g$ to be nested within $H_h$ is $\beta' \Sigma_g \beta / \sigma^2 = 0$ for all admissible values of $\beta$ with $\alpha' \Sigma_h \alpha / \omega^2 \neq 0$ for some $\alpha$. Note that $\beta' \Sigma_g \beta / \sigma^2 = 0$ is implied by either $\Sigma_g \beta = 0$ or $\Sigma_g = 0$.

Given the linear set-up and using results in Pesaran (1974), the adjusted log-likelihood ratio statistic for testing $H_g$ against $H_h$ is given by

$$S_{n}^{gh} = \frac{n}{2} \log \left( \frac{\tilde{\omega}_g}{\tilde{\omega}_n} \right)$$

(15)

where $\tilde{\omega}_n$ is the estimate of $\omega^2$ under the alternative $H_h$, and $\tilde{\omega}_g$ is the estimated pseudo-true value of the residual variance of $H_h$ under $H_g$, such that

$$\tilde{\omega}_n = n^{-1} (y - \hat{X} \hat{\alpha}_n)' (y - \hat{X} \hat{\alpha}_n) \tilde{\omega}_n = \hat{\sigma}_n^2 + \hat{\beta}_n' \hat{\Sigma}_g \hat{\beta}_n$$
in which the estimates under the true model $H_g$ are given by
\[ \hat{\beta}_n = n^{-1}(y - x\hat{\beta}_n)'(y - x\hat{\beta}_n), \]
\[ \hat{\alpha}_n = (x'x)^{-1}x'y \] and \[ \hat{\sigma}_n = (z'z)^{-1}z'y. \] As pointed out earlier, since we do not have a natural null hypothesis in this framework, one also needs to evaluate $H_g$ against $H_h$, for which the modified log-likelihood statistic is given by

\[ S_{ng} = \frac{n}{2} \log \left( \frac{n^{-1}(y - x\hat{\beta}_n)'(y - x\hat{\beta}_n)}{\hat{\sigma}_n} \right). \]  

(16)

For the statistic given by (15), the asymptotic variance of $\sqrt{n\sigma_{gh}^2}$, denoted by $V_{gh}$, can be computed as follows:

\[ V_{gh} = \frac{\hat{\sigma}_n^2 \left( \hat{\beta}_n x'M_zx'M_zx'x\hat{\beta}_n' \right)}{n \left( \hat{\sigma}_n^2 + \hat{\beta}_n^2 \hat{\sigma}_{gh} \right)} \]

(17)

where $M_x = I_n - x'(x'x)^{-1}x'$ and $M_z = I_n - z'(z'z)^{-1}z'$ are orthogonal projection matrices.

Combining (15) and (17), the associated standardized Cox statistic, 
\[ N_{ng} = \sqrt{n\sigma_{gh}^2} / \sqrt{V_{gh}}, \] can now be calculated as described in Pesaran (1974). Similar derivations lead to the analogue statistic for the test of $H_h$ against $H_g$, $N_{gh}^g$.

The application of the comprehensive approach to the above linear regression models yields the following exponential combination as presented in (6):

\[ H_\lambda: y = (1 - \xi)x\beta + \xi z\alpha + u, \quad u \sim N(0, \sigma_\lambda^2 I_n) \]

(18)
where \( \xi = \lambda \sigma_x \sigma_e \) and \( \sigma_x^2 = (1 - \xi) \sigma_e^2 + \xi \omega^2 \). Given that the error variances \( \sigma^2 \) and \( \omega^2 \) are strictly positive, performing a test of \( \xi = 0 \) is equivalent to testing \( \lambda = 0 \) when we consider the null hypothesis of \( H_g \) against \( H_h \). As pointed out earlier, the Davies problem arises when under the null hypothesis of \( H_g (\lambda = 0) \), the unknown parameter vector \( \alpha \) disappear from the mixture model. The presence of this nuisance parameter results in a Student-type of test statistic associated with \( \lambda \) that depends on the value of \( \alpha \), such that

\[
\tau_\lambda(a) = \frac{a'Z'M_xY}{\sigma^2_\lambda (a'Z'M_xZa)^{1/2}}
\]

(19)

where \( \sigma^2_\lambda \) denotes the usual estimator of the variance of the errors. One possible way to solve this identification problem would be to construct a test statistic based on \( F_\lambda = \max_\alpha \tau_\lambda(\alpha) \).

A different approach to deal with the identification problem was proposed by Davidson and MacKinnon (1981), who propose a J-test by replacing the nuisance parameter \( \alpha \) by its estimator, \( \hat{\alpha}_n \), under \( H_h \). An exact version of this test, proposed by Fisher and McAleer (1981) and known as the JA-test (indicating the Atkinson variation of this test), substitutes \( \alpha \) by the estimate of its pseudo-true value under \( H_h \) given in (14), that is \( \hat{\alpha}*(\hat{\theta}_n) = \Sigma_{ZZ}^{-1} \Sigma_{ZX} \hat{\theta}_n \). By symmetry of our testing problem, the J and JA versions of the test can also be calculated for \( H_h \) against \( H_g \). Davidson and MacKinnon (1981) show that the t-ratio statistic, \( \tau_\lambda(\hat{\alpha}_n) \), has asymptotically a standard normal distribution under the null.

Based on the application of Roy's union-intersection principle, McAleer and Pesaran (1986) show that the test for \( \xi = 0 \) in (18) is equivalent to the standard F-statistic for the test of \( \delta_2 = 0 \) in the combined model \( y = X\delta_1 + Z\delta_2 + u \).

In order to frame the linear regression models into the encompassing type tests, we can focus on the discrepancy between the OLS estimator of the regression coefficients, denoted by \( \hat{\alpha}_n \), and the estimator of the pseudo-true value in finite samples, such that \( \sqrt{n}(\hat{\alpha}_n - \hat{\alpha}*(\hat{\theta}_n)) = \sqrt{n}(Z'Z)^{-1}Z'M_xY \). Using this, we can build an encompassing statistic for testing \( H_g \varepsilon H_h \), as follows:

\[
\sqrt{n}(\hat{\alpha}_n - \hat{\alpha}*(\hat{\theta}_n)) = \sqrt{n}(Z'Z)^{-1}Z'M_xW\delta + \sqrt{n}(Z'Z)^{-1}Z'M_xu_f,
\]

if \( H_f \) is taken as the true model given in (11). As a consequence, under some regularity conditions,
non-nested hypotheses: The New Palgrave Dictionary of Economics

\[ \sqrt{n}(\hat{\alpha}_n - \hat{\alpha}(\hat{\theta}_n)) \] is asymptotically normally distributed with mean zero and the covariance matrix

\[ \frac{1}{n} \sum_{t=1}^{n} (X_t'X_t)^{-1} \sum_{t=1}^{n} X_t'X_t. \]

Using these results the WET statistic for testing \( H_g \in H_h \), is given by

\[ \varepsilon_{gh} = \frac{Z_1'M_1(Z_1'M_1)^{-1}Z_1'M_1Y}{\sqrt{\hat{\gamma}^2}} \tag{20} \]

where \( Z_1 \) are the components in \( Z \) that are orthogonal to \( X \). Similarly, a variance encompassing test of \( H_g \in H_h \) can be constructed for the discrepancy between a consistent estimate of \( \omega^2 \) and its pseudo-true value \( \omega^2_{\pi f} \), which takes the form of \( \hat{\omega}^2_n - \omega^2_{\pi f}(\hat{\theta}_n) \). For the case in which \( H_g \) contains the true model, \( H_h \), the variance encompassing test is asymptotically equivalent to the Cox and the J-tests.

Vuong's test criterion for the comparison of \( H_g \) and \( H_h \) is computed as

\[ G_{gh} = \frac{\Sigma_{i=1}^{n} d_i}{\left[ \Sigma_{i=1}^{n} (d_i - \bar{d})^2 \right]^{1/2}} \tag{21} \]

where \( \bar{d} = \frac{1}{n} \sum_{i=1}^{n} d_i \), \( d_i = -1/2 (\hat{\sigma}^2_n / \hat{\omega}^2_n) - 1/2 (\hat{\omega}^2_{\pi f} / \hat{\omega}^2_n) - 1/2 ((\hat{\omega}^2_{\pi f} / \hat{\sigma}^2_n) - (\hat{\omega}^2_{\pi f} / \hat{\omega}^2_n)) \); and \( \hat{\omega}^2_{\pi f} \) and \( \hat{\omega}^2_n \) are the estimated residuals of the underlying linear models given by (10). Under the null hypothesis \( H_V \), \( H_g \) and \( H_h \) are equivalent and \( G_{gh} \) is approximately distributed as a standard normal variate.

Extensions and empirical applications

Non-nested tests have also been derived for a number of other models, including tests of non-nested linear regression models with serially correlated errors (McAleer, Pesaran and Bera, 1990), regression models estimated by instrumental variables (Ericsson, 1983), models estimated by generalized method of moments (Smith, 1992), generalized empirical likelihood (Ramalo and Smith, 2002), conditional empirical likelihood (Otsu and Whang, 2005), non-nested Euler equations (Ghysels and Hall, 1990), autoregressive versus moving average models (Walker, 1967), autoregressive conditional heteroskedastic models (Bera and Higgins, 1997; McAleer and Ling, 1998), logit and probit models (Pesar and Pesar, 1993), non-nested threshold autoregressive models (Altissimo and Violante, 2001; Pesa...
Potter, 1997), and stochastic volatility models (Kim, Shephard and Chib, 1998).
Further theoretical contributions include a robust version of Cox-type statistics that controls for the effect of contamination in the data (Victoria-Feser, 1997), conditional tests on sufficient statistics (Pace and Salvan, 1990), asymptotic improvements to Davidson and MacKinnon's approach (Royston and Thompson, 1995), score-type statistics which are constructed from linear combinations of the likelihood functions (Santos Silva, 2001) and the enhancement of finite-sample performance of non-nested tests by bootstrap methods (Godfrey, 1998; Davidson and MacKinnon, 2002).
Various economic applications of non-nested hypothesis testing have appeared in the literature. Among them, savings and consumption functions (Deaton, 1982), Keynesian and new classical models of unemployment (Pesaran, 1982a), wage-employment bargaining models (Vannetelbosch, 1996), effects of dividend taxes on corporate investment decisions (Poterba and Summers, 1983), money demand functions (McAleer, Fisher and Volker, 1982; Elyasiani and Nasseh, 1994), autoregressive and moving-average schemes for unanticipated inflation series (Pagan, Hall and Trivedi, 1983), exchange rates models (Backus, 1984), alternative crop response models (Ackello-Ogutu, Paris and Williams, 1985; Frank, Beattie and Embleton, 1990), agricultural marketing margins (Lyon and Thompson, 1993), economic growth models (Ram, 1986; Dowrick and Gemmell, 1991; Bleaney and Nishiyama, 2002), and hedonic house prices (Dubin and Sung, 1990; Goodman and Dubin, 1991). In the literature of empirical industrial organization, non-nested hypothesis testing is applied to compare a Nash and collusive pricing in an industry with vertical product differentiation (Bresnahan, 1987). Non-nested tests are also applied in game-theoretic contexts by Gasmi, Laffont and Vuong (1992) and Sandler and Murdoch (1990), in sociological research by Halaby and Weakliem (1993), and in political science by Clarke (2001).
Non-nested tests for rival linear regression models can be computed using various econometric packages. See, for example, Pesaran and Pesaran (1997).

Abstract

Nonparametric structural models facilitate the analysis of counterfactuals without making use of parametric assumptions. Such methods make use of the behavioural and equilibrium assumptions specified in economic models to define a mapping between the distribution of the observable variables and the primitive functions and distributions that are used in the model. Using these methods, one can infer elements of the model, such as utility and production functions, that are not directly observed. We review some of the latest works that have dealt with the identification and estimation of nonparametric structural models.

Article

The interplay between economic theory and econometrics comes to its full force when analysing structural models. These models are used in industrial organization, marketing, public finance, labour economics and many other fields in economics. Structural econometric methods make use of the behavioural and equilibrium assumptions specified in economic models to define a mapping between the distribution of the observable variables and the primitive functions and distributions that are used in the model. Using these methods, one can infer elements of the model, such as utility and production functions, that are not directly observed. This allows one to predict behaviour and equilibria outcomes under new environments and to evaluate the welfare of individuals and profits of firms under alternative policies, among other benefits.
To provide an example, suppose that one would like to predict the demand for a new product. Since the product has not previously been available, no direct data exists. However, one could use data on the demand for existent products together with a structural model, as shown and developed by McFadden (1974). Characterize the new product and the existent competing products by vectors of common attributes. Assume that consumers derive utility from the observable and unobservable attributes of the products, and that each chooses the product that maximizes his or her utility of those attributes among the existent products. Then, from the choice of consumers among existent products, one can infer their preferences for the attributes, and then predict what the choice of each of them would be in a situation when a new vector of attributes, corresponding to the new product, is available. Moreover, one could get a measure of the differences in the welfare of the consumers when the new product is available.

Economic theory seldom has implications regarding the parametric structures that functions and distributions may possess. The behavioural and equilibrium specifications made in economic models typically imply shape restrictions, such as monotonicity, concavity, homogeneity, weak separability, and additive separability, and exclusion restrictions, but typically not parametric specifications, such as linearity of conditional expectations, or normal distributions for unobserved variables. Nonparametric methods, which do not require specification of parametric structures for the functions and distributions in a model, are ideally fitted, therefore, to analyse structural models, using as few a priori restrictions as possible. Nonparametric techniques have been applied to many models, such as discrete choice models, tobit models, selection models, and duration models. We will concentrate here, however, on the basic models and on those, indicate some of the latest works that have dealt with identification and estimation.

Nonparametric structural econometric models

As with parametric models, a nonparametric econometric model is characterized by a vector $X$ of variables that are determined outside the model and are observable, a vector $\varepsilon$ of variables that are determined outside the model and are unobservable, a vector $\Upsilon$ of outcome variables, which are determined within the model and are unobservable, and a vector $Y$ of outcome variables that are determined within the model and are observable. These variables are related by functional relationships, which determine the causal structure by which $\Upsilon$ and $Y$ are determined from $X$ and $\varepsilon$. The functional relationships are characterized by some functions that are known and some that are unknown. Similarly, some distributions may be known, some are unknown, and the others should be derived from the functional relationships and the known and unknown functions and distributions. Let $\nu^*$ denote the vector of all the unknown functions in the model, $E^*$ denote the vector of all unknown distributions, and $\zeta^* = (\nu^*, E^*)$. In contrast to parametric models, in nonparametric models, none of the coordinates of $\zeta^*$ is assumed known up to a finite dimensional parameter. Only restrictions such as continuity or values of the conditional expectations are assumed. The specification of the model should be such that from any vector $\zeta = (\nu, E)$, satisfying those same restrictions that $\zeta^*$ is assumed to satisfy, one is able to derive a distribution for the observable variables, $F_{Y|X}(\cdot, \zeta)$.

Nonparametric identification
When specifying an econometric model, we may be interested in testing it, or we may be interested in estimating \( \zeta^* = \left( h^*, F^* \right) \) or some feature of \( \zeta^* \), such as only one of the elements of \( h^* \), or even the value of that element at one point. Suppose that interest lies on estimating a particular feature, \( \psi(\zeta^*) \) of \( \zeta^* \). The first question one must answer is whether that feature is identified. Let \( \Omega \) denote the set of all possible values that \( \psi(\zeta) \) may attain, when \( \zeta \) is restricted to satisfy the properties that \( \zeta^* \) is assumed to satisfy. Given \( \psi \in \Omega \), define \( \Gamma_{Y,X}(\psi) \) to be the set of all probability distributions of \( (Y, X) \) that are consistent with \( \psi \). This is the set of all distributions that can be generated by a \( \zeta \), satisfying the properties that \( \zeta^* \) is assumed to satisfy, and with \( \psi(\zeta) = \psi \). We say that two values \( \psi, \psi' \in \Omega \) are observationally equivalent if

\[
\left[ \Gamma_{Y,X}(\psi) \cap \Gamma_{Y,X}(\psi') \right] \neq \emptyset,
\]

that is, they are observationally equivalent if there exist a distribution of the observable variables that could have been generated by two vectors \( \zeta \) and \( \zeta' \) with \( \psi(\zeta) = \psi \) and \( \psi(\zeta') = \psi' \). The feature \( \psi^* = \psi(\zeta^*) \) is said to be identified if there is no \( \psi \in \Omega \) such that \( \psi \neq \psi^* \) and \( \psi \) is observationally equivalent to \( \psi^* \). That is, \( \psi^* = \psi(\zeta^*) \) is identified if a change from \( \psi^* \) to \( \psi \neq \psi^* \) cannot be compensated by a change in other unknown elements of \( \zeta \), so that a same distribution of observable variables could be generated by both, vectors \( \zeta^* \) and \( \zeta' \) with \( \psi^* = \psi(\zeta^*) \) and \( \psi = \psi(\zeta') \). When \( \psi^* \) can be expressed as a continuous functional of the distribution of observable variables \( (Y, X) \) one can typically estimate \( \psi^* \) nonparametrically by substituting the distribution by a nonparametric estimator for it.

**Additive and nonadditive models with exogenous explanatory variables**

The current literature on nonparametric econometrics methods considers additive and nonadditive models. In **additive models**, the unobservable exogenous variables \( \varepsilon \) are specified as affecting the value of \( Y \) though an additive function. Hence, for some functions \( m \) and \( v \) and some unobservable \( \eta \)

\[
Y = m(X) + v(X, \varepsilon) = m(X) + \eta.
\]

In these models, the object of interest is typically the function \( m \). Depending on the restrictions that one may impose on \( \eta \), \( m \) may denote a conditional expectation, a conditional quantile, or some other function. Many methods exist to estimate conditional means and conditional quantiles nonparametrically. Prakasa Rao (1983), Härdle and Linton (1994), Matzkin (1994; 2007b), Pagan and
Ullah (1999), Koenker (2005), and Chen (2007), among others, survey parts of this literature. Some nonparametric tests for these models include Wooldridge (1992), Yatchew (1992), Hong and White (1995), and Fan and Li (1996).

In nonadditive models, one is interested in analysing the interaction between the unobservable and observable explanatory variables. These models are specified, for some function $m$ as

$$Y = m(X, \varepsilon).$$

**Dependence between observable and unobservable explanatory variables**

In econometric models, it is often the case that in an equation of interest, some of the explanatory variables are endogenous; they are not distributed independently of the unobservable explanatory variables in that same equation. This typically occurs when restrictions such as agent's optimization and equilibrium conditions generate interrelationships among observable variables and unobservable variables, $\varepsilon$, that affect a common observable outcome variable, $Y$. In such cases, the distribution of the observable outcome and observable explanatory variables does not provide enough information to recover the causal effect of those explanatory variables on the outcome variable, since changes in those explanatory variables do not leave the value of $\varepsilon$ fixed. A typical example of this is when $Y$ denotes quantity demanded for a product, $X$ denotes the price of the product, and $\varepsilon$ is an unobservable demand shifter. If the price that will make firms produce a certain quantity increases with quantity, this change in $\varepsilon$ will generate an increment in the price $X$. Hence, the observable effect of a change in price in demanded quantity would not correspond to the effect of changing the value of price when the value $\varepsilon$ stays constant. Another typical example arises when analysing the effect of years of education on wages. An unobservable variable, such as ability, affects wages and also affects the decision about years of education.

**Estimation techniques for additive and nonadditive functions of endogenous variables**

The estimation techniques that have been developed to estimate nonparametric models with endogenous explanatory variables typically make use of additional information, which provides some exogenous variation on either the value of the endogenous variable or on the value of the unobservable variable. The common procedures are based on conditional independence methods and on instrumental variable methods. In the first set of procedures, independence between the unobservable and observable explanatory variables in a model is typically achieved by either conditioning on observable variables, or conditioning on unobservable variables. A control function approach (Heckman and Robb, 1985)
nonparametric structural models: The New Palgrave Dictionary of Economics

models the unobservable as a function, so that conditioning on that function purges the dependence between the explanatory observable and unobservable variables in the model. Instrumental variable methods derive identification from an independence condition between the unobservable and an external variable (an instrument) or function, which is correlated with the endogenous variable and which might be estimable.

Conditioning on unobservable variables often requires the estimation of those unobservable variables. Two-step procedures, where they are first estimated, and then used as additional regressors in the model of interest have been developed for additive models by Ng and Pinkse (1995), Pinkse (2000), and Newey, Powell and Vella (1999), among others. Two-step procedures for nonadditive models have been developed by Altonji and Matzkin (2001), Blundell and Powell (2003), Chesher (2003), and Imbens and Newey (2003), among others. Conditional moment estimation methods or quasi-maximum likelihood estimation methods can also be used (see, for example, Ai and Chen, 2003). Altonji and Ichimura (2000), Altonji and Matzkin (2001; 2005), and Matzkin (2004), among others, considered conditioning on observables for estimation of nonadditive models with endogenous explanatory variables. Matzkin (2004) provides insight into the sources of exogeneity that are generated when conditioning on either observables or unobservables, and which allow identification and estimation in nonadditive models. In particular, if \( Y = m(X, \varepsilon) \), with \( m \) strictly increasing in \( \varepsilon \), and \( \varepsilon \) is independent of \( X \) conditional on \( W \), she shows that there exists functions \( s(W, \eta) \) and \( r(W, \delta) \) such that \( \delta \) is independent \( \eta \) conditional on \( W \), \( X = s(W, \eta) \) and \( \varepsilon = r(W, \delta) \). Hence,

\[
Y = m(X, \varepsilon) = m(s(W, \eta), r(W, \delta)).
\]

Instrumental variable methods for additive models were considered by Newey and Powell (1989; 2003), Ai and Chen (2003), Darolles, Florens and Renault (2003), and Hall and Horowitz (2003), among others. To develop estimators for \( m \) in the model

\[
Y_1 = m(Y_2) + \varepsilon E[\varepsilon|Z] = 0.
\]

they use the moment condition

\[
E[Y_1|Z = z] = \int m(y_2) f_{Y_2|Z = z}(y_2) dy_2,
\]
which depends on the conditional expectation $E[Y_1|Z=z]$ and the conditional density $f_{Y_1|Z=z}(y_1)$, which can be estimated nonparametrically. For nonadditive models, of the form

$$Y_1 = m(Y_2, \varepsilon)$$

where $m$ is strictly increasing in $\varepsilon$, Chernozhukov and Hansen (2005) and Chernozhukov, Imbens and Newey (2007) developed estimation methods using the moment condition that for all $\tau$

$$\tau = E[1(\varepsilon < \tau)] = E[1(\varepsilon < \tau)|Z]$$

from which $m$ can be estimated using the conditional moment restriction

$$E[1(Y_1 < m(Y_2, \varepsilon)) - \varepsilon|Z] = 0.$$ 

Matzkin (2006) considered the model

$$Y_1 = m_1(Y_2, \varepsilon)Y_2 = m_2(Y_1, Z, \eta)$$

where $Z$ is distributed independently of $(\varepsilon, \eta)$. She established restrictions on the functions $m_1$ and $m_2$ and on the distribution of $(\varepsilon, \eta, Z)$ under which

$$[\frac{\partial r_1(y_1, y_2)}{\partial y_2}]^{-1}[\frac{\partial r_1(y_1, y_2)}{\partial y_1}]$$

can be expressed as a function of the conditional density $f_{Y_1, Y_2|Z=z^*}(y_1, y_2)$, where $r_1$ is the inverse of $m_1$ with respect to $\varepsilon$, and the value $z^*$ of the instrument $Z$ is easily identified (see also Matzkin, 2005; 2007a; 2007b).
Estimation of averages and average derivatives

Nonparametric estimators are notorious by their slow rate of convergence, which worsens as the dimension of the number of arguments of the nonparametric function increases. A remedy for this is to consider averages of the nonparametric function. The average derivative method in Powell, Stock and Stoker (1989) and the partial integration methods of Newey (1994) and Linton and Nielsen (1995), for example, show how rates of convergence can increase by averaging a nonparametric function or its derivatives. This approach has been extended to cases where the explanatory variables are endogenous, using additional variables to deal with the endogeneity, and averaging over them. Examples are Blundell and Powell's (2003) average structural function, Imbens and Newey's (2003) average quantile function, and Altonji and Matzkin's (2001; 2005) local average response function.

Suppose, for example, that the model of interest is

\[ Y_1 = m(Y_2, \varepsilon) \]

and \( W \) is such that \( Y_2 \) and \( \varepsilon \) are independent conditional on \( W \). Then, the Blundell and Powell (2003) average structural function is

\[ G(y_2) = \int m(y_2, \varepsilon) f_\varepsilon(\varepsilon) d\varepsilon \]

which can be derived from a nonparametric estimator for the distribution of \( (Y_1, Y_2, W) \) as

\[ G(y_2) = \int \mathbb{E}(Y_1|Y_2 = y_2, W = w) f_W(w) dw. \]

Imbens and Newey's (2003) quantile structural function is defined for the \( \tau \)-th quantile of \( \varepsilon, q_\varepsilon(\tau) \), as

\[ r(y_2, y_1) = \mathbb{P}(m(Y_2, q_\varepsilon(\tau)) \leq Y_1|Y_2 = y_2) \]
which can be estimated by

$$r(y_2, y_1) = \int \Pr(y_1 \leq y_1 | y_2 = y_2, W = w) f(W(w)) dy.$$ 

Altonji and Matzkin's (2001; 2005) local average response function is

$$\beta(y_2) = \int \frac{\partial m(y_2, \varepsilon)}{\partial y_2} f_{\varepsilon|y_2} = y_2(\varepsilon) d\varepsilon$$

which can be derived from a nonparametric estimator for the distribution of $(y_1, y_2, W)$ as

$$\beta(y_2) = \int \frac{\partial E(y_1 | y_2 = y_2, W = w)}{\partial y_2} f_{W|y_2} = y_2(w) dw.$$ 

Conclusions

The literature on nonparametric structural models has been rapidly developing in recent years. The new methods allow one to analyse counterfactuals without making use of parametric assumptions. Estimation of some features of the model rather than the functions themselves may reduce the curse of dimensionality, therefore providing improved properties and reducing the need for large data-sets.

Non-profit organizations are hybrids – private but with restricted ownership rights. This defining 'nondistribution constraint' reduces incentives to exploit underinformed customers and allows non-profits to depart from profit-maximizing behaviour, although costly enforcement of this constraint limits effectiveness. Non-profits' GDP share in the United States is about 30 per cent of the governmental non-defence share. Worldwide they employ about four per cent of the labour force. Non-profits receive public subsidies potentially justifiable by their provision of public goods. Sales of goods and services constitute the main source of non-profit revenues, but government grants and private donations are also important. Extensive research on the economic behaviour of non-profit, for-profit, and governmental organizations in mixed industries has disclosed systematic differences.

Keywords
agency problems; crowding out; free-rider problem; Lindahl prices; nondistribution constraint; non-profit organizations; price discrimination

Article
Variously termed voluntary, philanthropic and charitable, non-governmental, as well as non-profit, these organizations constitute a sizeable and growing share of economic activity. Non-profit organizations contribute some four per cent of GDP in the United States, up from three per cent in 1970 and two per cent during the Second World War, but their GDP share is about 40 per cent of that of government. In the social service sector where they predominate, non-profits account for some 20–25 per cent of outputs. There are at least 1.6 million non-profit organizations in the United States, a number that grew by 27 per cent during the decade 1994–2004 alone. The United States is not alone in the prominence or growth of the non-profit sector. Figures gathered by the Johns Hopkins International Comparison Project reveal a ‘global associational revolution’, with paid and volunteer labour in non-profits involving an average of 4.4 per cent of the economically active population in the 35 countries studied, ranging from a
high of 14 per cent in the Netherlands to a low of 0.4 per cent in Mexico. Non-profits are a form of institutional hybrid, combining attributes of profit-maximizing firms with those of government. Their organization and control are exercised through private initiatives rather than through the political process, and they cannot levy taxes. But, like government, they are constrained from distributing any profit or surplus to managers – the ‘non-distribution constraint’ (NDC). Many non-profits are granted a variety of tax subsidies such as eligibility for tax-deductible donations, special postal rates and exemption from taxation of income, property and sales. The NDC implies that non-profits cannot sell ownership shares, and so they can pursue social objectives other than profit maximization without fearing a hostile takeover. The NDC also implies that non-profits must rely for capital on sources other than equity shares. Thus, non-profits have both advantages and disadvantages in relation to private firms, with which they compete in industries such as health care (hospitals, nursing homes, hospices), education, and the arts.

Non-profits have provided public-type services, similar to those of government, for centuries. Jews created communal soup kitchens for travellers and collective charity funds for the needy in the second century BCE. In 16th-century England, private ‘philanthropies’ were engaged in such wide-ranging social services as schools, hospitals, non-toll roads, fire-fighting apparatus, public parks, bridges, dykes and causeways, drainage canals, docks, harbour cleaning, libraries, care of prisoners in jails, and charity to the poor. In short, non-profits supplied the gamut of non-military goods and services that we identify today as governmental responsibilities.

Recent economic theorizing about the role of non-profits has examined both the nature of demand and the source of supply. Research on demand has two strands, one emphasizing failures of private markets, the other emphasizing governmental failures. In markets where valued attributes of the product are hard for consumers to observe and not verifiable by third parties, profit-maximizing firms can exploit their informational advantage. Alone, this outcome is inefficient, but the inefficiency is reduced if consumers deal with non-profit organizations. Non-profits have less incentive to short-change consumers because there are no shareholders or managers who can lawfully profit from this act. Nursing homes, day care for children, blood banks, medical research, environmental protection, and organizations claiming to aid the needy illustrate industries in which consumer information problems are not left to the private market alone. It is difficult for a nursing home patient or family member to determine whether the supplier is providing ‘tender loving care’; it is difficult to determine whether a day care centre is providing the attention that parents expect; and it is sometimes difficult for a patient or even a physician to determine the quality of blood available for a transfusion. Non-profits are a major force in all these industries characterized by informational asymmetries.

The quality assurance provided by the non-profit label, however, is limited. Enforcement of the NDC is spotty, and it is difficult to prevent distribution of profits in non-financial forms. Even when the NDC is well enforced, non-profits may short-change some under-informed customers in order to cross-subsidize missions that are not popular enough to generate direct donations. On the other hand, the sorting of entrepreneurs and consumers across ownership sectors, and the religious affiliation of many non-profits, enhances their credibility. The occasional failure of all these mechanisms is revealed, for example, by the collapse in 1995 of the Foundation for New Era Philanthropy following the revelation that the founder was benefiting from an illegal ‘Ponzi’ scheme in which colleges and universities, religious charities and individual donors were assured that their donations to the Foundation would be matched by a secret donor, resulting in grants that would double their ‘investment’ in three months.
Non-profits are a response to government failures as well as private market failures. The quantity and quality of outputs financed by government represent political decisions. Rather than setting individualized tax shares (Lindahl prices) to equate marginal benefits, governments use generalized systems of taxation, and so few voters get the quantity of governmentally provided goods that they would like, given the price each person confronts in the form of tax rates. Those who prefer less output and lower taxes have little recourse, but high demanders, who prefer more services at the tax prices they pay, and those seeking an alternative type or quality of service, may turn to non-profits to supplement governmental provision. Demanders of high-quality education, for example, often send their children to private non-profit schools. Non-profit schools also accommodate diverse minority demands relating to religion or educational philosophy. Thus, it is understandable that the United States, with a population unusually diverse in religion, culture, and ethnicity, has an unusually large non-profit sector, and not only in education.

Less is known about the supply of non-profit services. Non-profits are often created by churches and fraternal organizations, although over their life cycle they may disassociate from their founders. Religious organizations sometimes create health, education and welfare organizations as a way of attracting new adherents, binding the faithful, and meeting the moral obligations of their faith. In addition, religious and fraternal associations form communities of repeated interaction between like-minded individuals that help overcome free-rider problems and the transactions costs involved in creating a new organization. Nonetheless, the non-profit form solves an agency problem between the organization's founders and later donors. Thus, the organization's founder rationally chooses the non-profit form if the value of donor-supported public goods exceeds the value of the option to receive a share of future profits. But the entrepreneur may also be a profit-motivated organizer who sees the patina of a non-profit organization as little more than access to the subsidies and donations non-profits receive, and weak governmental enforcement of the NDC as providing opportunities for reaping greater personal financial gains than would be possible by founding a for-profit firm.

At any point in time, the number of non-profits is also affected by inter-sectoral conversions (particularly in the hospital industry), mergers, and tax and regulatory policies. Very little work has been done on the life cycles of non-profit organizations, but there is some evidence that non-profits are slower than for-profits to enter, expand, exit and contract. A limited supply of socially oriented entrepreneurs, an organizational preference for selectivity over expansion, non-profit inattention or incompetence, a preference to hold ‘excess capacity’ in case of medical emergencies, a reluctance to lay off employees, or differential capital constraints could explain these findings.

The non-profit form is far from a panacea; it, too, can fail. Revenue challenges abound. Non-profits cannot solve the free-rider problem because they cannot compel payments. The NDC encourages donations, but it also eliminates equity sales as a source of finance. Moreover, while the NDC reduces non-profits' incentives to take advantage of their patrons, it also reduces incentives for productive efficiency and responsiveness to changing market demand.

Non-profits rely on a mixture of revenue sources, varying greatly across industries, but sales of goods and services – especially tuition at colleges, patient fees at hospitals, and admission fees at museums, zoos and theatres – together with government grants and private donations are the three predominant sources. Research on donations has been extensive, examining the returns to fundraising expenditures and the efficacy of various fundraising mechanisms, as well as the effect of the charitable income tax deduction for private donors, the extent of crowding-out (or in) of private donations by direct...
government expenditures or by governmental service contracts with non-profit organizations, and the
determinants of time donations (volunteering). Laboratory and field experiments on fundraising
techniques are proliferating, revealing, for example, the positive effects of raffle mechanisms and
information disclosures on net funds raised. Studies of donations' crowd-out – the effect on donations of
an exogenous change in other revenues – run the gamut from ‘near 100 per cent’ to ‘small but
significant’ to ‘crowding in’ (that is, negative crowd-out).
Determining the full effects of any fundraising mechanism is complex. Government grants, for example,
are not only a source of revenue but may also certify quality to other donors; private donations may be
affected differently for persons who derive utility from their own giving to a non-profit – the ‘warm-
glow’, private-good effect – and for those who do not, being indifferent between their own contribution
and the same amount given by someone else; and giving of money and volunteering of time are still not
clearly identified as complements or substitutes.
Sales of goods and services are the dominant overall source of non-profits' revenue, and they come in
diverse forms. First, many non-profits sell services that constitute their charitable mission rather than
simply generating revenue, as in tuition charged by non-profit schools or payments for health services
by non-profit hospitals, whether paid by the consumer or some third party. This is often accompanied by
price discrimination designed to generate revenue when doing so does not compromise the tax-exempt
mission, while providing the service at low cost – even free – to the poor or other ‘deserving’
consumers. A second form of programme service revenue has become increasingly prominent around
the world – governmental purchase-of-service contracts with non-profits for the delivery of social
services. Finally, some non-profits derive income from sales of goods and service that are unrelated to
their charitable purpose, denoted ‘unrelated business’ (UB) income. Thus, non-profit universities have
become major sellers of computer software; non-profit hospitals have opened pharmacies, hotels, and
fitness centres; and non-profit museums’ gift shops have become major purveyors of art objects.
Controversy surrounds the social-welfare impact of having tax-privileged non-profits competing with
taxable for-profits in commercial markets – the ‘unfair competition’ issue. In addition, analysts disagree
about the impact of UB commercial activity on the social missions of non-profits, as they do about
interpretation of the fact that half of all non-profits engaged in UB activities report no profit at all.
The impact of each revenue source on non-profits' social mission remains an area of controversy.
Conceptually, the links reflect the non-profit's need to satisfy the wants of whoever is providing revenue
– consumers, corporations, governments, alumni, and so on – and the consequences of doing so for the
non-profit mission. With that mission typically being quite general, there is concern about ‘mission
creep’ – the mutating definition of mission so as to justify taking advantage of a new revenue source. All
revenue sources pose this potential problem, but it is particularly acute for collaborative ventures
between non-profit and for-profit organizations. The issue often arises between research universities and
firms in the pharmaceutical and information sciences fields, but similar issues arise, for example, in non-
profit hospital relationships with for-profit medical groups, and in food pantries' relationships with food
manufacturers.
Financing non-profits involves more than monetary flows. A major resource for the non-profit sector is
volunteer labour – another form of donation. Of trivial importance in the for-profit sector, volunteer
labour is, in the United States, similar in value to the total amount of money donations, although
controversy persists as to how such labour, with an explicit transaction price of zero, should be valued
for various purposes – replacement cost to the organization, opportunity cost to the volunteer, and the
average market wage being the three prominent alternatives. Not counted in official labour force
statistics, and generally overlooked as a contributor to output, volunteer labour in the United States
equals about five per cent of the hours worked by the entire national labour force. Research on the
supply of volunteer time indicates that it is affected by the same type of price, income and income tax
rate variables that affect the supply of money donations. The identification of the separate effects
of volunteer supply and organization demand, however, remains largely unstudied. The mission of non-
profits may be more conducive to the use of volunteers than the profit-oriented goal of private firms.

There is some evidence that even paid labour in non-profit organizations is partially volunteered, that is,
workers accept a lower salary, in effect donating some of the opportunity cost of their time. However,
differences between wages in the non-profit sector and in other sectors appear to be specific to particular
industries and job titles.

Hundreds of studies compare the performance of non-profit organizations with similar organizations in
other sectors, but severe methodological challenges remain. Reviewing the vast evidence on health care
organizations with respect to economic performance, quality of care, and accessibility to unprofitable
patients, Schlesinger and Gray (2006) note that some authors conclude there are no clear differences.
However, they dispute this interpretation, arguing instead that the literature is persuasive that there are
clear differences, but the extent and direction of such differences depend on the nature of the service
provided, market conditions, and external constraints on behaviour.

Non-profit organizations sometimes convert to for-profit and vice versa, especially in three industries –
hospitals, health maintenance organizations (HMOs) and higher education. When non-profits convert,
they first sell their assets to the new for-profit entity, using the proceeds to create or support non-profit
organizations with closely related charitable purposes. Controversy surrounds conversions because of
the difficulty of establishing a fair market value for these assets, particularly in leveraged conversions by
insiders. If the assets are sold too cheaply, the new owners receive windfall profits and the NDC is
violated.

Both theory and quantitative evidence suggest that all forms of institutions – non-profits included – fail
to be efficient or equitable under particular circumstances. The key public policy questions are: do non-
profits behave in systematically different ways from proprietary organizations or governments? If so,
under what conditions and in which realms of economic activity should each form be encouraged,
mandated, discouraged or prohibited?

non-standard analysis

Peter A. Loeb and Salim Rashid
Edited by Steven N. Durlauf and Lawrence E. Blume

Article

Non-standard analysis is an area of mathematics that provides a natural framework for the discussion of
infinite economies. It is more suitable in many ways than Lebesgue measure theory as a source of
models for large but finite economies since the sets of traders in such models are infinite sets which can
be manipulated as though they were finite sets. The number system used to describe non-standard
economies is an extension of the real numbers $\mathbb{R}$; it is denoted by $^*\mathbb{R}$. The set $^*\mathbb{R}$ contains ‘infinite
natural numbers’ and their multiplicative inverses, which are positive infinitesimals. It was with the
development in 1960 of such a number system that Abraham Robinson (1974) solved an age-old
problem by making rigorous the use of infinitesimals in mathematical analysis. Robinson gave a model-
theoretic approach to his theory that is relevant to any infinite mathematical structure; that approach
starts by listing the basic properties of the new number system. Before taking up this approach, however,
it will be helpful to consider a simple nonstandard extension of the real numbers system that is
constructed from sequences of real numbers.

The real numbers can be embedded in the set of sequences by associating a constant sequence $\{c_i\}$ with
each real number $c$ so that $c_i = c$ for all $i$. The relation on the set of sequences defined by setting $\{r_i\} > \{s_i\}$
if $r_i > s_i$ for an infinite number of indices $i$ has the property that if $r_i = i$ and $s_i = 1/i$ for all $i$, then $\{r_i\} > c$ and
$c > \{s_i\}$ for any positive real number $c$. Here $\{r_i\}$ represents a positive infinite number and $\{s_i\}$ represents
a positive infinitesimal. The relation $>$ is not yet an ordering on a number system since, for example, if $t_i = 0$
when $i$ is even and $t_i = 3$ when $i$ is odd, then $\{t_i\} > 2$ and $1 > \{t_i\}$. To fix the situation, one forms an
equivalence relation in the set of sequences. The above sequence $\{t_i\}$ for example should either be
equivalent to the constant sequence 0 or the constant sequence 3.

An equivalence relation appropriate to the formation of a simple non-standard model of the real numbers
from the set of real sequences is obtained by fixing a free ultrafilter $U$ in the natural numbers $\mathbb{N}$ (i.e. a
collection of subsets of $\mathbb{N}$ such that finite intersections of sets in $U$ are in $U$, but the empty set and
singleton sets are not in $U$, and if a subset of $\mathbb{N}$ is not in $U$, its complement is in $U$). Two sequences of
real numbers $\{r_i\}$ and $\{s_i\}$ are equivalent if $r_i = s_i$ for all $i$ in an element $A$ of $U$. In this case, we say that
$r_i = s_i$ almost everywhere. The equivalence classes form the non-standard real numbers $^*\mathbb{R}$. As before, the
constant sequence \( r_i = c \) represents the standard real number \( c \), while the sequence \( r_i = \frac{1}{i} \) represents a nonzero infinitesimal. In general, a property holds for elements of \( *R \) if for representing sequences it holds on some set in \( U \); one says that the property holds almost everywhere, or ‘a.e.’. An element \( r \) of \( *R \) is finite if for some standard \( c \) in \( R \), \(|r_i| < c\) a.e., and \( r \) is infinitesimal if for every positive \( c \) in \( R \), \(|r_i| < c\) a.e.; the elements of \( *R \) that are not finite are called infinite.

Properties true for the real numbers are again true for \( *R \), but quantification over sets must be interpreted as quantification over ‘internal’ subsets of \( *R \). For our simple model, these subsets correspond to equivalence classes of sequences of subsets of \( R \); the element of \( *R \) represented by \( \{r_i\} \) is in the set represented by \( \{A_i\} \) if and only if \( r_i \) is in \( A_i \) a.e. Not all subsets of \( *R \) are internal. Those that are not are called external. Some internal sets, called hyperfinite sets, have all of the formal properties of finite sets. Such a set \( A \) is represented by a sequence of subsets \( A_i \) from \( R \) with \( A_i \) finite a.e. The ‘internal’ cardinality of \( A \) is represented by the sequence \( \{\text{Card}(A_i)\} \) with 0 replacing infinite cardinals in the sequence. Thus, for example, if \( A_i = \{1, 2, \ldots, i\} \), then \( A \) is the set of all non-standard natural numbers less than or equal to the infinite natural number \( \gamma \) where \( \gamma \) is represented by the sequence \( \langle 1, 2, 3, \ldots \rangle \). The internal cardinality of \( A \), which we denote by \( |A| \), is in this case equal to \( \gamma \).

In working with non-standard analysis, it is usually best to ignore any particular construction of non-standard models and think only of the properties they satisfy. For general applications, one starts with a set theoretic structure \( V(S) \) where \( S \) is a set containing \( R \) and \( V(S) \) consists of all the sets one can obtain from \( S \) in a finite number of steps using the usual operations of set theory. For example, the number 5 and the set of all Lebesgue measurable sets is in \( V(S) \); so is the set of all Borel measures on \( R \). Let \( L \) be a formal language for \( V(S) \); \( L \) contains a name for each object in \( V(S) \), variables, connectives (such as the symbols \( V \) for ‘and’ and \( \land \) for ‘or’), quantifiers, brackets, and sentences formed with these symbols. The main result of Robinson’s theory establishes the existence of a (not unique) structure \( V(*S) \) built from a set of individuals \(*S\) with the following properties; (1) Every name of an object in \( V(S) \) names something of the same type (i.e. constructed with exactly the same operations) in \( V(*S) \) We write \(*A\) for the object in \( V(*S) \) with the same name as \( A \) in \( V(S) \); \(*A\) is called standard and \(*A\), the (nonstandard) extension of \( A \). (2) (Transfer Principle) Every sentence in \( L \) that is true for \( V(S) \) is true when interpreted in \( V(*S) \); quantification, however, is over ‘internal’ objects in \( V(*S) \). (3) If \( A \in V(S) \) is a set, then there is a ‘hyperfinite’ set \( B \) which is a member of the extension \(*P_F(A)\) of the set of all finite subsets of \( A \) such that for each \( a \in A \), \(*a \in B \). Thus \( B \) contains the extension of each standard element of \( A \).

The extension \(*s\) of an individual \( s \) is usually denoted by \( s \) instead of \(*s\); one thinks of a subset \( A \) of \( S \) as being imbedded in \(*A\). Internal objects in \( V(*S) \) are those objects which are members of the extensions of standard objects; the non-internal objects in \( V(*S) \) are called external. Any object that can be described in the formal language \( L \) using the names of internal objects is itself internal. The illuminating fact that the set \( N \) of finite natural numbers forms an external set in the non-standard natural numbers \(*N\) can be established as follows: If \( N \) were an internal set, then by applying the transfer principle to the theorem that every non-empty subset of \( N \) has a first element, it would follow that there is a first infinite element of \(*N\), that is, a first element of \(*N–N\), and thus a last element of \( N \).

Hyperfinite sets are internal sets in internal one-to-one correspondence with an initial segment of \(*N\).
Such sets are useful in economics because they are treated like finite sets. To illustrate this fact and Property 3 above, we note that if $\gamma$ is an infinite element of $^*N$, then the initial segment $T = \{n \in ^*N: 1 \leq n \leq \gamma\}$ of $^*N$ is a hyperfinite set containing every element of $N$. Every formal property true for an initial segment of the natural numbers is true for the set $T$, whence $T$ can be used as the set of traders in a ‘hyperfinite economy’.

The set of non-standard real numbers $^*R$ contains infinite elements which are positive, infinite elements which are negative, and finite elements. Any finite element $\alpha$ of $^*R$ is infinitely close to a unique standard real number $a \in R$ that is, $\alpha \approx a$ is infinitesimal. We write $\alpha \approx a$ and also $\alpha - a \approx 0$ in this case; $a$ is called the standard part of $\alpha$. The standard part of $\alpha$ is denoted by $\text{st}(\alpha)$ or $0^*\alpha$. The set of all points infinitely close to $a$ is called the monad of $a$. A subset $0$ of $R$ is open if and only if for each point $x$ in $0$, the monad of $x$ is contained in $^*0$.

As an application of these ideas, we note that a real-valued sequence $s_n$ (i.e. a mapping $s$ from $N$ into $R$) has a limit $l$ if and only if for each infinite $s_n \approx l$ where $^*s_n$ is the image of $n$ with respect to the non-standard extension $^*s$ of the function $s$. A real-valued function $f$ defined on a subset $A$ of $R$ is continuous at a point $x \in A$ if and only if for all $y$ with $y \approx x$, $^*f(y) \approx f(x)$; is uniformly continuous on $A$ if and only if for all $y$ and $z$ with $y \approx z$, $^*f(y) \approx ^*f(z)$. A subset $A$ of $R$ is compact if and only if for each $x$ there is a standard $x$ in $A$ with $y \approx x$, whence $A$ is compact if and only if it is closed and bounded. It is immediate that if $f$ is continuous on a compact set $A$ then $f$ is uniformly continuous on $A$.

Brown and Robinson (1975) introduced the use of non-standard analysis in economics as a source of models for infinite exchange economies. The set of traders in non-standard economies is a hyperfinite set $T = \{1, 2, \ldots, \gamma\}$ where $\gamma$ is an infinite element of $^*N$. The preferences and endowments are internal mappings defined on $T$ analogous to the corresponding mappings in finite economies. Each trader's commodity endowment is an infinitesimal part of the market, and so that trader's influence on the formation of prices is infinitesimal but not zero. One can show in such economies, even without the usual convexity assumptions, that approximate competitive equilibria and approximate cores exist and that these cores can be approximately decentralized by the price system.

Given a hyperfinite set $T$, such as the set of traders in a non-standard economy, one can apply to $T$ all of the combinatorial methods that are available for finite sets. For example Loeb (1973) obtained a form of the Lyapunov convexity theorem that is appropriate for the hyperfinite economies described above by applying a ‘packing theorem’ concerning a finite set of vectors in Euclidean space. Using another construction of P.A. Loeb (1975) one can form on $T$ a standard measure space which is rich with structures inherited from the underlying point set. This construction starts by noting that the set $M$ of all internal subsets of $T$ forms an algebra in the usual sense. One obtains a finitely additive probability measure $P$ on $(T, M)$ by setting $P(A)$ equal to the standard part of the ratio $|A|/|T|$ for each $A$ in $M$. One may assume that any ordinary sequence $\{A_i: i \in N\}$ from $M$ is the initial segment of an internal sequence $\{A_i: i \in ^*N\}$ from $M$. This will be the case, for example, if the superstructure is constructed via an ultrafilter as indicated above. Now, if an ordinary sequence $\{A_i: i \in N\}$ from $M$ is pairwise disjoint and $\cup A_i$ equals some element $A$ in $M$, then all but a finite number of the $A_i$'s are empty. (Extend $\{A_i: i \in N\}$
to \( \{ A_i : i \in \ast \, N \} \) for every infinite \( n \in \ast \, N \) and therefore for some finite \( n \in N \) \( A \) is contained in the union of the \( A_i \)'s, \( 1 \leq i \leq n \).) The condition one checks to apply the Carathéodory extension theorem to \(( T, M, P )\) is thus vacuously satisfied. Therefore \( P \) has a \( \sigma \) -additive extension \( \mu \) to the smallest \( \sigma \) -algebra \( \sigma ( M ) \) generated by \( M \). The space \(( T, \sigma ( M ), \mu )\) is a standard probability space which is very close in structure to the internal hyperfinite space \(( T, M, P )\).

Rashid (1979) first established the connection between the standard measure spaces that exist on hyperfinite economies and the models of infinite economies using Lebesgue measure. Measure spaces on hyperfinite economies have the great advantage of an underlying structure that closely parallels finite economies. This parallelism has been exploited by H.J. Keisler in his forthcoming work detailing the price adjustment processes in nonstandard exchange economies. Emmons (1984) has obtained results for economies using measure spaces on hyperfinite sets of traders that are not available for general measure space economies. Nonstandard economies also have the advantage of making readily apparent regularities in the asymptotic behaviour of large but finite economies. Anderson's (1978) core equivalence theorem, for example, was obtained by translating a result originally proved with nonstandard analysis. Similarly, a translation of Khan and Rashid (1982) produced the existence theorem of Anderson, Khan and Rashid (1982).

A further advantage inherent in the use of the number system \( \ast R \) in economics is the ability to distinguish behaviour on the finite part of \( \ast R \) from that on the infinite part and to distinguish different orders of infinities and infinitesimals. The first type of distinction was used by K.D. Stroyan (1983) to provide an elegant non-standard characterization of myopia in the evaluation of infinite consumption streams. The second distinction was central in Brown and Loeb’s (1976) short, nonstandard proof of Aumann’s theorem showing that the Shapley value of infinite economies under appropriate differentiability conditions coincides with the competitive equilibria.

A non-substitution theorem asserts that under certain specified conditions an economy will have one particular price structure for each admissible value of the profit rate, regardless of the pattern of final demand. The theorem has two forms. As first stated, it applies to an economy with single production and therefore no fixed capital (Arrow, 1951; Koopmans, 1951; Samuelson, 1951; Levhari, 1965). In its later formulation, some special joint products are considered to take account of fixed capital (Samuelson, 1961; Mirrlees, 1969; Stiglitz, 1970).

Consider first the single production form. The non-substitution theorem asserts that if (i) there exists one primary input (call it labour); (ii) all processes of production are perfectly divisible, with constant returns to scale, and have the same production period (this period is taken as the time unit for the analysis); (iii) each process produces one perfectly divisible commodity, making use of definite amounts of produced commodities and, perhaps, perfectly divisible labour; (iv) for each commodity there exists at least one process producing it; (v) labour is indispensable for the reproduction of commodities; (vi) the exchange of commodities takes place at the end of each period in fully competitive markets (that is the profit rate, the wage rate, and the price of each commodity are uniform); (vii) producers operate a process if and only if it is cost-reducing at current prices; then for each admissible value of the profit rate only one vector of relative prices (including the wage rate) is possible for the economy, so that relative prices are independent of demand.

In order to understand why the theorem works, let us denote with vector $p$ and scalar $w$ the equilibrium commodity price vector and the equilibrium wage rate, respectively, when the rate of profit equals $r$ and the net output vector equals vector $d$. Hence, (a) no process is able to pay extra profit at prices $p$, wage rate $w$, profit rate $r$; (b) for each commodity there exists at least one operable process producing it (an operable processes is a process whose costs, including normal profits, are not larger than the price of the product); (c) operable processes can be operated in such a way to produce net output $d$. 

Keywords

joint production; non-substitution theorem; substitution
The non-substitution theorem asserts that

1. \((\alpha)\) if the net output is \(\hat{d} \neq d\) then \(p\) and \(w\) are still an equilibrium price-vector and an equilibrium wage rate;

2. \((\beta)\) if more than one solution exists, they are characterized by the fact that price vectors and wage rates are respectively equal each other (if the same numéraire is utilized).

To prove statement \((\alpha)\) we just need to prove that operable processes can be operated in such a way to produce net output \(\hat{d}\), since statements (a) and (b) hold. This is shown in the following way. Take one operable process for each commodity (they exist because of (b)) to arrange the material input matrix \(A\) and the labour input vector \(1\). It is easily shown that matrix \((I-A)\) is invertible and \((I-A)^{-1} \succeq 0\) where \(I\) is the identity matrix of appropriate size. Hence, statement \((\alpha)\) is a consequence of the fact that if the operation intensities of these processes are \(\hat{d}^T(I-A)^{-1} \succeq 0\) all the others being zero, then the net output vector equals \(\hat{d}\). This procedure can also be utilized if a uniform growth rate not larger than \(r\) is assumed.

To prove statement \((\beta)\) let \((p_1, w_1)\) and \((p_2, w_2)\) be the price vector and the wage vector relative to two equilibrium solutions, respectively. Similarly as in the proof of \((\alpha)\) we can arrange material input matrices \(A_1\) and \(A_2\) and labour input vectors \(1_1\) and \(1_2\) from the first and the second solution respectively. Hence,

\[
p_1 = (1 + r)A_1 p_1 + w_1 1 p_2 = (1 + r)A_2 p_2 + w_2 1_2.
\]

Moreover, axiom (vii) requires that

\[
p_1 \preceq (1 + r)A_2 p_2 + w_1 1_2 p_2 \preceq (1 + r)A_1 p_2 + w_2 1_1
\]

and since \([I - (1+r)A_i]\) is invertible and \([I - (1+r)A_i]^{-1} \succeq 0\) (\(i=1, 2\)),

\[
p_1 \preceq w_1 [I - (1 + r)A_2]^{-1/2} = (w_1 / w_2) p_2
\]

\[
p_2 \preceq w_2 [I - (1 + r)A_1]^{-1/1} = (w_2 / w_1) p_1.
\]
Thus,

\[ p_1 = (w_1 / w_2) p_2. \]

Then, by introducing the common numeraire we obtain that

\[ w_1 = w_2 \]

and, therefore,

\[ p_1 = p_2. \]

More recent formulations of the non-substitution theorem weaken the previously stated assumption (iii) to allow the introduction of some particular joint production cases. Assumptions are introduced to divide commodities into ‘final goods’ and ‘used machines’. Each process is assumed to produce one final good, but some joint products are allowed since used machines are produced jointly with final goods. Used machines are not transferable, that is an oven utilized once to produce bread cannot be utilized later to produce biscuits.

If machines are not used jointly, then a non-substitution theorem is stated as in the single production form. If machines can be used jointly, then the growth rate plays a role in determining prices and the wage rate, as does the profit rate. This fact has been recognized by Stiglitz (1970), who, however, failed to recognize that when this is so the uniqueness of the relative prices and wage rate does not need to hold even if prices are still independent of demand.

The label ‘non-substitution’ is appropriate to these theorems in so far as it assumed that there is only one scarce factor (primary input). Relaxation of any or all of the other assumptions, for example that of constant returns to scale, will mean that prices vary in response to changes in the structure of demand, but will not mean that there is ‘substitution’ in any meaningful sense.

In a neoclassical model prices are determined by the relation between demands (direct and derived) for endowment and the magnitude of the components of the endowment (typically conceived as stocks of factor services). The prices of produced commodities are equal to their costs of production, that is to the sum of rentals paid for the factor services used in their production. The possibility of substitution between factors, due either to substitution between commodities consumed or substitution in production, or to a combination of both, is the source of variation in derived demand, and hence in relative rentals. If, by comparison with a given situation, preferences were different, relative demands for factor services would typically be different, and hence their rentals and the prices of the commodities in the production
of which they are used would be different. But, if there is only one factor of production, no substitution is possible whatever the composition of demand or the range of technical possibilities. Hence the relative prices of produced commodities will be determined by the least amounts of the single factor by means of which (directly and indirectly) they are produced. If, as is the case in the examples discussed above, the minimum cost technique is invariant to changes in demand, then prices too will not change as demand changes. If, however, the minimum cost technique does change as demand changes, say because of increasing returns to scale, then prices will change, but this will not be due to any substitution. There cannot be any substitution because there is only one factor. Similarly, in those cases of joint production in which a change in the structure of demand does lead to a change in relative prices, the change derives not from substitution between factors but from a change in the minimum cost combination of production processes.

Non-tariff barriers (NTBs) refer to the wide range of policy interventions other than border tariffs that affect trade of goods, services and factors of production. Most taxonomies of NTBs include market-specific trade and domestic policies affecting trade in that market. Extended taxonomies include macroeconomic policies affecting trade. NTBs have gained importance as tariff levels have been reduced worldwide. Common measures of NTBs include tariff equivalents of the NTB policy(ies), and count and frequency measures of NTBs. These NTB measures are subsequently used in various trade models, including gravity equations, to assess trade and/or welfare effects of the measured NTBs.

Article

Nontariff barriers (NTBs) refer to the wide and heterogeneous range of policy interventions other than border tariffs that affect and distort trade of goods, services and factors of production. Common taxonomies of NTBs include market-specific trade and domestic policies such as import quotas, voluntary export restraints, restrictive state-trading interventions, export subsidies, countervailing duties, technical barriers to trade (TBTs), sanitary and phytosanitary (SPS) policies, rules of origin and domestic content requirements schemes. Extended taxonomies also include macro-policies affecting trade. No taxonomy can be complete since NTBs are defined as what they are not (Deardorff and Stern, 1998). This article is complemented by related articles on antidumping, border effects, countertrade, gravity equation, tariff versus quota, and trade costs. Deardorff and Stern (1998) suggest the following taxonomy with five categories.
A first broad category covers quantitative NTBs and similar restrictions. It includes import quotas and their administration methods (licensing, auctions, and other); export limitations and bans; voluntary export restraints, a limit on imports but managed by exporters; foreign exchange controls often based on licensing; prohibitions such as embargoes; domestic content and mixing requirements forcing the use of local components in a final product; discriminatory preferential trading agreements and rules of origin; and countertrade such as barter and payments in kind.

A second category covers fees other than tariffs, and associated policies affecting imports. This category includes variable levies triggered once prices reach a threshold or target level; advanced deposit requirements on imports, antidumping and countervailing duties imposed on landing goods allegedly exported ‘below cost’ or with the help of export subsidies provided by foreign governments; and border tax adjustment such as value-added taxes potentially imposed asymmetrically on imported and domestic competing goods.

A third category is extensive. It collects various forms of government policies including a wide set of macroeconomic policies. This category covers direct governmental participation and restrictive practices in trade, such as state-trading and state-sponsored monopoly and monopsony; government procurement policies with domestic preferences; and industrial policy favouring domestic firms with associated subsidies and aids. In addition, the category extends to macroeconomic and foreign exchange policies, competition policies, foreign direct investment policies, national taxation and social security policies, and immigration policies. Where to draw on the NTB definition is context-dependent.

Two better-targeted categories deal with customs procedure and administrative practices, and technical barriers to trade, which are central to NTBs. The former covers custom valuation methods that may depart from the actual import valuation; customs classification procedures other than the international harmonized system of classification to levy further fees; and customs clearance procedures such as inspections and documentation creating trading cost. Technical barriers to trade relate to health, sanitary, animal welfare and environmental regulations; quality standards; safety and industrial standards; packaging and labelling regulations and other media/advertising regulations. With the exception of export subsidies and quotas, NTBs have become more prominent than tariffs. Tariffs on manufacturing goods have been reduced to low levels through eight successive rounds of the World Trade Organization (WTO) and its predecessor, the General Agreement on Tariffs and Trade (GATT). As of 2005, the unweighted average tariff is roughly three per cent in high-income countries, and 11 per cent in developing countries according to the World Bank, from respective levels at least three times as high in 1980. Exports subsidies have almost disappeared except in a few agri-food markets. Quotas have become less important since they have been converted into two-tier tariff schemes, the so-called tariff-rate quotas. As tariffs have been lowered, demands for protectionism have induced new NTBs, such as TBT interventions. The United Nations Conference on Trade and Development (UNCTAD) estimates that the use of NTBs based on quantity and price controls and finance measures has decreased dramatically from slightly less than 45 per cent of tariff lines faced by NTBs in 1994 to 15 per cent in 2004, reflecting commitments made during the last round of WTO negotiations, the Uruguay Round. However, the use of NTBs other than quantity and price controls and finance measures increased from 55 per cent of all NTB measures in 1994 to 85 per cent in 2004. The use of TBTs almost doubled, from 32 to 59 per cent of affected tariff lines during the same period. The use of quantity control measures associated with TBTs showed a small increase, from 21 to 24 per cent of affected tariff lines, suggesting that trade impediments within TBTs are rising. Kee, Nicita and Olarreaga compute a 9 per cent tariff...
equivalent of NTBs including price and quantity controls, finance measures, and TBTs, on average for all goods. The average tariff equivalent is about 40 per cent for the goods affected by these NTBs. Increased consumer demand for safety and environment-friendly attributes have also translated into an increase in the number of TBTs. Many NTBs are regulated by the WTO agreements that came out of the Uruguay Round (the TBT Agreement, SPS Measures Agreement, the Agreement on Textiles and Clothing), and articles of the original GATT among others. NTBs in service industries have recently become more important as trade in services has been expanding (Dee and Ferrantino, 2005).

Most NTBs are intrinsically protectionist whenever they do not address market failures such as externalities and information asymmetries between consumers and producers of goods being traded. Safety standards and labelling requirements are examples of the latter case. Some NTBs may restrict trade but improve welfare in the presence of negative externalities or informational asymmetries. Other NTBs can expand trade as they enhance demand and trade of a good through better information about the good or by enhancing the good’s characteristics. Whether an NTB is protectionist is sometimes difficult to identify in the presence of market failure. If an NTB is equal to the measure that a social planner would implement for domestic purposes (that is, all firms are domestic firms or all agents belong to a single economy), that NTB is presumably non-protectionist (Fisher and Serra, 2000).

Measuring NTBs and their effects is a challenge, because of the heterogeneity of policy instruments and lack of systematic data. A unified approach to the measuring of NTBs does not exist. Most measurement methods start from a simple partial equilibrium approach looking at a single commodity, and attempt to develop a producer, consumer or trade tax equivalent to the NTBs, that explains by how much supply, and/or demand, or trade are affected by the policy intervention. Most NTB analyses implicitly rely on a framework that accounts for three economic effects: the regulatory protection effect providing rents to the domestic sector; the ‘supply shift’ effect, that reflects the increased costs of enforcing compliance of the NTBs on foreign and sometime domestic suppliers; and the ‘demand-shift’ effect, that takes into account the fact that a regulation may enhance demand with new information or by reducing an externality.

The measurement of an NTB is hard to disentangle from the measurements of its effects on market equilibrium and trade. Most NTB measures and analyses focus on the increase in the price of imports resulting from the NTB, the resulting import reduction, the change in the price responsiveness of the demand for imports, the variability of the effects of the NTB, and the welfare cost of the NTB (Deardorff and Stern, 1998; Dee and Ferrantino, 2005).

Several NTBs based on a price intervention (for example, export subsidies, countervailing duties), are a tax instrument. More complex NTBs can sometimes be represented by a set of taxes, such as in the case of a domestic content requirement (Vousden, 1990). These NTBs can be analysed as such taxes. To develop a tax equivalent, a basis of equivalence has to be chosen (Vousden, 1990). The tax equivalent has to lead to either an equivalent protection level (same profit under the tax equivalent or the NTB), or to a price increase equivalence (a price wedge), or to consumption, production or trade equivalent. This choice of basis depends on the intended policy analysis.

However, many NTBs do not easily translate into a tax-equivalent instrument. They require more sophisticated and indirect approaches to be measured and to quantify their effects on import volume, price, and welfare. Roundabout approaches are also used because of lack of data on the direct implications of an NTB on cost of production and consumer decisions (Beghin and Bureau, 2001).
common measurement approaches of nTBs

The price-wedge method measures the impact of an nTB on the domestic price of a good in comparison to a reference price, often the border price of a comparable good. The aim of this method is to derive a tariff/tax equivalent to the nTB as discussed above, and use the tariff/tax equivalent in further analysis that measures implications of the nTB on resource allocation in the given markets affected by the nTB. Deardorff and stern (1998) provide price-wedge equivalent formulas for an extended coverage of NTBs. Conceptually, the measure compares the domestic price that would prevail without the nTB to the domestic price prevailing in the presence of the nTB, on the assumption that the price paid to suppliers remains unchanged. However, these prices are practically unobservable. Implementations of the price-wedge measure of an nTB compare the domestic and foreign prices of comparable goods in the presence of the nTB accounting for tariffs, transportation costs, and other known and observed trading costs. Adjustments can be made to recover a price estimate that would prevail in the absence of the nTB, using observed levels of quantities and prices, and own-price elasticities of demand and supply and imported goods.

The price-wedge method has several drawbacks. First, if several nTBs are jointly in place, the price-wedge measures the price effect of these policies without being informative about their respective contributions or even their nature. Second, quality differences are hard to account for precisely although they are a pivotal element of the price-wedge computation. The price-wedge estimate of an nTB is usually sensitive to the assumptions made on the substitution between the imported and domestic goods. This method has also some limitations in large empirical studies for which data are aggregated, resulting in loss of information on quality differences between import and domestic comparable goods. Finally, trading costs may be present but not accounted for and the price-wedge method may falsely attribute these trading costs to a nTB.

Inventory-based frequency measures count the number or frequency of regulations and barriers present in a given market. They are used in both quantitative and qualitative assessments of the incidence of the nTBs. Common measures include the number of regulations and policies, which can be further elaborated to indicators such as the number of pages of national regulations. Frequency of trade detentions at borders is also used, and so are survey-based frequency and number of complaints reported by exporters for perceived discriminatory regulatory practices.

When implemented, quantitative estimates often rely on catalogues of technical barriers (identification and description) using datasets such as UNCTAD's TRAINS data-set. Measures include simple frequency of occurrence of NTBs, frequency ratios for product categories subject to an nTB, and coverage ratio based on the value of imports of products within a category subject to the nTB, expressed as a share of import value of the corresponding category. Relative measures can also be developed comparing the latter frequency measures in a given country with respect to accepted international norms or best practice, for example, for the SPS or food safety regulations. Alternatively, frequency measures can be compared across commodities or across countries to identify large deviations from average frequencies, flagging potential protectionist issues.

nTBs vary in importance across sectors and products. Even for a given nTB type, its effects may vary across products. A major drawback of the frequency measures is that a correlation between the number of NTBs and their effect on trade and welfare may be low in absolute value. International data-sets on
NTBs inventories may also suffer from uneven reporting by countries and heterogeneous coverage of measures across countries and commodities. Survey-based measures focus on effective barriers rather than just an NTBs count. However, they may suffer from various reporting biases as surveys and respondents are often motivated by mercantilism to facilitate exports by the responding exporters. Frequency measures do not identify the trade restrictiveness of NTBs but can be used in gravity equations to identify the effects of NTBs on trade flows. When trying to quantify NTBs, an obvious technique is to consider the forgone trade that cannot be explained by tariffs and known trading costs. The NTB frequency measures, or in certain cases the level of standards themselves, can help identify the trade effects of these NTBs. Provided there is enough variability across countries or over time in the measure (for example, the level of toxic residues) they can explain the variation in trade flow not explained by other explanatory variables included in the gravity equation (respective incomes of trading countries, distance, tariff, and other variables measuring border effects).

Gravity-equation techniques attempt to measure the trade impact of NTBs, not their welfare impact, and may therefore ignore some of the beneficial effect of the regulations that correct negative externalities but restrict trade. NTBs are appropriate if trade is the vector of negative externalities such as unsafe food imports or pest-infested imports. In addition, the direction of the effect of the ‘NTB’ variable on trade flows in the regression is not constrained. It is possible to capture a trade or demand-enhancing effect of regulations and standards. This enhancement occurs when the NTB facilitates trade and induces consumers to consume more of a product although the product's price is higher because of the NTB. Such expansion through standards has been observed in OECD food trade (Disdier, Fontagné and Minouni, 2006).

Risk assessment approaches and scientific knowledge can contribute to gauging a subset of NTBs, especially safety and SPS standards and regulations. The latter approach can contribute to assessing the welfare effects and the potential protectionism of these types of NTBs. Scientific knowledge can determine if a regulation is science-based or not, or if a risk simply does not exist or is negligible. This criterion is used by the WTO in its assessment of TBT and SPS regulations. Cost–benefit calculations combined with risk assessment provide expected cost and benefits of such types of NTBs. Risk-assessment measures provide an economic criterion to gauge the desirability of an NTB and its likely protectionist nature if externalities are small and if its costs greatly exceed its benefits in expected terms. The combined use of scientific knowledge and cost–benefit assessment of an NTB is a demanding process suitable for a detailed analysis of a specific case study, rather than for large-scale multi-market analyses. Another limitation of this approach is the partial knowledge of health, environmental and other risks associated with trade and their economic significance.

NTBs measures are an essential step to computing the welfare effects of the NTBs. Beyond welfare effects, these measures are also useful for policy purposes. WTO disputes frequently arise, alleging that some NTBs impede trade more than necessary to achieve some legitimate objective, or that they are just protectionist. These NTB measures are used in the formal dispute process to estimate export market losses and price-lowering effects of the incriminated policy.

North American Free Trade Agreement (NAFTA)

Gordon H. Hanson
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The North American Free Trade Agreement (NAFTA) eliminated trade barriers on most products between Canada, Mexico, and the United States. NAFTA included provisions to remove restrictions on cross-border investment, expand service trade, and address environmental and labour standards. Post-NAFTA increases in trade between member countries were matched by comparable decreases in their trade with the rest of the world. Freer trade has brought a shift in economic activity within Mexico and the United States towards their shared border and an increase in direct investment from the United States to Mexico. In Mexico these developments have contributed to greater wage inequality.

Article

The North American Free Trade Agreement (NAFTA), which entered into force in 1994, eliminated trade barriers on most products between Canada, Mexico, and the United States. The agreement culminated a decade of liberalization in North America, which included the Canada–United States free trade agreement in 1989 and Mexico's joining the General Agreement on Trade and Tariffs (GATT) in 1986. (On the impact of the Canada–United States Free Trade Agreement, see Trefler, 2005.) For Mexico, NAFTA was the final step in reversing four decades of protectionist trade policies. For Canada and the United States, NAFTA completed three decades of promoting closer economic ties. Upon its implementation, NAFTA eliminated tariffs on goods accounting for approximately one-half of trade between the three countries. Tariffs on other goods (primarily those with relatively high pre-
North American Free Trade Agreement (NAFTA) was phased out over 5 to 15-year periods. Among the industries with the slowest tariff phase-outs were Canadian textiles, Mexican corn and US sugar. A few industries (mainly in agriculture, energy and services) were excluded from NAFTA altogether. The agreement incorporates stringent rules of origin, which apply a country's external tariff to NAFTA imports whose North American content (in terms of the share of value added) fails to meet mandated thresholds (Estevadeordal and Suominen, 2005). Rules of origin prevent three-way trade in which, say, Canada imports a good from Japan at an external tariff that is below that for Mexico and then re-exports the good to Mexico at a zero NAFTA tariff. If allowed, such trade would effectively impose a common external tariff across North America equal to the minimum tariff for each good among the three countries. Content requirements vary across sectors, with those for the auto industry being among the highest.

NAFTA was broad in its scope and included provisions for removing restrictions on cross-border investment between member countries, expanding service trade and protecting intellectual property. A novel feature of the agreement was the adoption of side accords for environmental and labour standards, which created a mechanism under which citizens of member countries can adjudicate disputes over the violation of standards (which in their essence state that NAFTA members are obliged to uphold environmental and labour laws that each has on its books). While the standards were controversial at the time of NAFTA's passage, few cases of significance involving environmental or labour infractions have been resolved under the agreement.

The economic rationale for creating a regional free trade area is that it eliminates price distortions caused by tariffs, quotas and other policy barriers, which induce countries to allocate too many resources to import-competing industries and too few resources to exporting industries. In the early 1990s, results from computable general equilibrium models suggested that NAFTA would raise welfare by an amount equal to between two and four per cent of GDP in Mexico and one per cent or less of GDP in Canada and the United States (Brown, Deardorff and Stern, 1992). Low estimated gains from trade associated with NAFTA are not surprising, given that prior to the agreement Canada and the United States already had a free trade agreement in place, Canadian and US external tariffs on most products were already quite low, and Mexico had begun to unilaterally liberalize its trade following its joining the GATT.

While a free trade area creates trade between member countries, it also diverts trade between the trade bloc and the rest of the world. Between 1993 and 2004, trade between Canada, Mexico and the United States increased by 2.6 times in real terms; over the same period, trade between NAFTA countries and the rest of the world increased by only 1.9 times (Hufbauer and Schott, 2005). In sectors that had the highest protection prior to NAFTA, nearly all of the increase in trade within the NAFTA region was matched by comparable decreases in trade between NAFTA members and the rest of the world (Romalis, 2005), consistent with the agreement causing trade diversion.

Even where the net change in income associated with freer trade is small, gross changes in income for particular groups may be large. Because trade agreements redistribute income, they tend to provoke political conflict. The politics surrounding NAFTA were perhaps most contentious in the United States. President Clinton's support for NAFTA became an issue in the 1996 US presidential campaign, with opposition candidate Ross Perot memorably claiming that increased trade with Mexico would create a 'giant sucking sound' as US jobs moved across its southern border.

In the United States, one would expect groups allied with labour to oppose freer trade with a low-wage country and groups allied with capital-intensive industries to support it. NAFTA was narrowly approved by the US Congress, with its outcome uncertain until the final hour. Consistent with standard models of
political economy, US politicians receiving donations from labour groups tended to vote against NAFTA, while those receiving donations from business groups tended to vote for NAFTA (Baldwin and Magee, 2000). There was also a regional dimension to NAFTA's politics, with US politicians representing districts near the US border with Mexico being much more likely to support the agreement. This in part reflects the fact that, as US trade with Mexico has expanded, US border states have seen their manufacturing and trade-related industries grow relative to the rest of the country (Hanson, 2001).

In Mexico, also, NAFTA has had a varied regional impact. Following Mexico's opening to trade, Mexican states near the US border have had high growth in manufacturing employment, exports, and foreign direct investment (FDI) relative to the rest of the country. The shift in economic activity towards Mexico's border region has increased regional income differences in the country, which had been declining until Mexico began to liberalize trade (Chiquiar, 2005).

Economic theory suggests that trade may either complement or substitute for factor flows, depending on the magnitude of transport costs, fixed production costs and cross-country differences in technology and factor supplies. Following NAFTA, there has been a substantial increase in FDI by the United States in Mexico. Much of the FDI has involved US multinational firms setting up export assembly plants, known as maquiladoras, in Mexico. FDI in assembly plants has resulted from US firms outsourcing production to Mexico and has created substantial intra-industry trade flows in which the US exports parts and components to Mexico, and Mexico exports finished goods back to the United States. Similar trade patterns have existed between the United States and Canada since the 1960s, when the two countries liberalized trade in the auto industry. By moving labour-intensive production activities out of the United States, NAFTA has decreased the relative demand for less skilled labour in the country. And by moving capital, technology and new production operations into Mexico, NAFTA has increased the relative demand for skilled labour in Mexico. Thus, United States–Mexico economic integration appears to have contributed to a widening of the skilled–unskilled wage gap in both countries (Feenstra and Hanson, 1997).

At the time of NAFTA's signing, the agreement was touted as a means of reducing United States–Mexico wage differences and the incentive for workers in Mexico to migrate to the United States. By the 1980s, Mexico–United States migration had become an important policy issue on both sides of the border. NAFTA was justified in part as a way to reduce international migration flows. However, since NAFTA's implementation there has been an increase rather than a decrease in the flow of labour from Mexico to the United States (Hanson, 2006). At least some of the increased migration appears associated with the collapse of the peso in 1994 and the ensuing economic contraction in Mexico (Hanson and Spilimbergo, 1999). Partly as a result of the peso collapse, the difference in per capita income between the United States and Mexico was larger in 2002 than in 1990 (Tornell, Westermann and Martinez, 2003). Other evidence suggests that, whatever its long-run effects, NAFTA may have contributed to a transitory increase in Mexico-to-United States migration. By contributing to gross job destruction in agriculture and manufacturing, NAFTA may have displaced workers who then migrated to the United States.

For Canada and Mexico, NAFTA helped increase the importance of the US economy for their economic development. For the United States, NAFTA was a milestone in the country's approach to trade policy. Since 1994, the United States has concluded bilateral trade agreements with a dozen other countries, but has not succeeded in helping complete a multilateral trade agreement under the auspice of the World Trade Organization.
Trade Organization. One interpretation of this pattern is that NAFTA signalled a shift in US trade policy away from multilateralism and toward bilateralism, perhaps weakening multilateral trade institutions in the process.

North, Douglass Cecil (born 1920)

Avner Greif

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

A pioneer of the New Institutional Economics, Douglass North has built upon the property rights and transaction cost approaches of Coase and others to explain economic growth in terms not of changes in technology and productive factors but of institutional and organizational change. His most recent work stresses the need to integrate insights from cognitive science into the examination of the interplay among belief systems, institutions, and economic performance. Institutions reduce the uncertainties that would otherwise overwhelm cognitive capacity in complex social situations, but the resulting bias in our beliefs can lead to the persistence of inefficient institutions.

Article

A native of Cambridge, Massachusetts, who was born in 1920, North received his undergraduate and doctoral degrees from the University of California, Berkeley. His 1952 Ph.D. dissertation focused on the history of the American insurance industry. Most of his professional career has been spent at two institutions: the University of Washington in Seattle and, from 1983, Washington University in Saint Louis. North was among the founders of cliometrics (also known as the New Economic History). Later he was a pioneering researcher of the New Institutional Economics. In 1993 North and Robert Fogel shared the Nobel Prize in Economics. In 1997–8 he served as the first president of the Society for the New Institutional Economics.
North's publications are numerous and space limitation precludes presenting all of them or even doing justice to particular ones. Accordingly, the following discussion of his books highlights some of North's main contributions.

Neoclassical analyses

North initially studied American economic growth. Under the influence of Simon Kuznets, he compiled the first quantitative historical series of the US balance of payments. This work, in conjunction with his studies of regional development, led to his first published book in 1961, *The Economic Growth of the United States, 1790–1860*. In this book North developed an export-based growth model to argue that the expansion of one sector (cotton plantations) in the United States stimulated development in other sectors, and led to specialization and interregional trade.

By relying on economic theory and quantitative analysis, this line of work contributed to the rise of cliometrics (or the New Economic History). In contrast to traditional economic historians who relied on narratives and non-qualitative analysis, cliometrics combines economic theory, quantitative methods, hypothesis testing, counterfactual analysis, and traditional techniques of historical analysis to explain economic outcomes, evaluate and develop economic theories, and deepen our historical knowledge. North further fostered this development by helping to found the Cliometric Society and serving as co-editor of the *Journal of Economic History* for five years.

Towards institutional analysis

In the late 1960s North began expanding his analysis of economic growth beyond the confines of neoclassical economics by considering the importance of organizational changes to increasing efficiency. In his 1968 article on productivity in overseas shipping, North argued that organizational changes had more important effects than technological changes in reducing transportation costs between 1600 and 1850. Market integration and growth followed due to organizational rather than technological changes.

More generally, North began to emphasize that, in order to understand growth, one had to go beyond the neoclassical framework, which at that time attributed growth to changes in technology and factors of production. In sharp contrast, North argued that changes in technology and factors of production are not the sources of growth but, in fact, constitute growth. This implies that, to understand growth, we must examine the forces that cause beneficial technological changes and increase the utilization of factors of production. North argued that institutions constitute such forces and his subsequent research focused on them.

In developing the analysis of the relationship between institutions and economic growth, North built on and expanded the property rights and transaction costs approaches advanced by Ronald H. Coase, Armen A. Alchian, Steven N.S. Cheung, Harold Demsetz, and others. His subsequent books were ambitious attempts to place institutions at the centre of economic growth analysis. Good institutions promote growth by bringing private return from economic activities closer to their social return. Economic growth transpires in response to low-cost enforcement of contracts when property rights are secured and when governments pursue growth-oriented policies rather than prey on the wealth of their subjects. Institutions that achieve these goals encourage technological innovations, foster capital
accumulation, and increase labour input. Growth follows as technology improves, capital accumulates, and specialization occurs.

Institutions in the Northian framework consist of rules and regulations which, together with their enforcement mechanisms, determine the incentives faced by economic agents. Similar focus on the relationships between institutions and economic outcomes has also been the hallmark of old institutionalism (associated with such scholars as John R. Commons, Friedrich A. von. Hayek, and Wesley C. Mitchell). Old institutionalism, however, considered institutions either as exogenous and immutable or as reflecting spontaneous, uncontrolled processes. In contrast, North attempted to consider institutions as endogenous and to understand the forces that shaped their development. To do this, he particularly concentrated on the state as setting the rules of the economic game.

Institutions and American growth

North's first book on this issue, *Institutional Change and American Economic Growth*, was co-authored with Lance Davis and published in 1971. It outlines a theoretical perspective on the role and dynamic of institutions. The main theoretical assertion is that new institutions – specifically, new property-rights assignments – arise when groups in the society perceive that there are opportunities for profit that cannot be consummated given the existing institutions, but that would be feasible if these institutions were changed. Perceptions of benefits of institutional change and the details of the political system are what determine whether socially beneficial institutional change will transpire.

The book demonstrates the merits of this assertion by considering growth in the United States during the 19th century. It advances a new interpretation of American economic growth as one that reflects the pursuit of profit opportunities by economic agents through changing politically determined rules. Commodity markets expanded, for example, because canals reduced transportation – and hence transaction – costs. Investments in canals, however, didn't occur automatically. Public investment, state-mandated changes in property rights, and changes in perceptions of the profitability of these investments were prerequisites. Similarly, political decisions and changes in property rights were crucial to other factors that directly contributed to growth: the evolution of capital markets, the rise of large corporations and of the manufacturing sector, investment in human capital and the expansion of service industries.

Institutional evolution was central to American economic growth. More generally, North's work illustrates that in order to understand economic growth, the evolution of laws and regulations governing property rights must first be analyzed. Changes in property rights are often required before individuals and societies can gain from increasing the scale and efficiency of production and exchange.

Institutions and the rise of the West

A subsequent book (co-authored with Robert Paul Thomas) published in 1973, *The Rise of the Western World: A New Economic History*, further applied these ideas to explain the performance of various western European economies. By examining economic outcomes from the feudal period to the Industrial Revolution, the book sought answers to two questions. First, do differences in institutions account for patterns of economic growth and stagnation in European economies, and does the rise of the West reflect the efficiency of its property-rights regime? Second, what determines whether more or less efficient institutions will prevail?
The book argues that patterns of growth and stagnation in Europe reflect whether property rights were assigned efficiently and secured. The feudal system ended in economic stagnation and crises because of the misallocation of property rights to land. Peasants had few incentives to increase land productivity because they did not own it. Later, the Dutch Republic and England outpaced Spain and France because their property right's assignments were better designed to close the gap between private and social rates of return from economic activities. England's rising technological superiority, for example, reflected its effective system of patenting. In the long run, other European economies adopted similarly efficient systems of property rights.

Two forces determine institutions’ relative efficiency. Institutions’ degrees of efficiency respond to changes in relative prices, which, in turn, are due to changes in population and technology. As the relative price of a factor of production increases, property rights will be altered to better align incentives. The collapse of the state in medieval Europe rendered protection a valuable commodity. The feudal system, in which specialists in protection held property rights to land, reflected the relatively high value of protection. The large decline in the European population during the 14th century, however, increased the relative price of labour. This undermined the feudal system, and property rights in land were transferred to the peasants who toiled on it.

The tendency towards efficiency in institutional change is countered by the transaction costs of tax collection. Specifically, a ruler assigns property rights in a manner that maximizes his net revenue rather than efficiency. The transaction costs of tax collection place a wedge between efficient property right regimes and those that are optimal to a ruler. France’s geographical scale and diversity, for example, implied that the taxation regime that was optimal to its rulers entailed a high efficiency cost. France's economic growth therefore lagged behind England's.

Given the importance of the state in this analysis, North advanced a theory of the state in his 1981 book, *Structure and Change in Economic History*. He departed from the common view of the state as an efficiency-enhancing social contract aimed at increasing security or providing other public goods, and characterized it as a ruler-predator, utilizing a bargaining framework, to consider a ruler's relationship with his subjects. In a state, citizens contract with a specialist in enforcement to provide them with protection. The terms of the deal – the extent of absolutism and predation – reflect the relative bargaining power of these parties, which, in turn, depends on such factors as military technology and the threat of entry by competing rulers. This analysis contributes to the argument that interstate competition within Europe was growth-enhancing by emphasizing that this competition may have constrained predation by rulers.

The 1981 book is also a departure from North's previous lines of analysis in that it focuses on ideology. North's previous writings noted the importance of informal institutions, such as ideology, social norms, and values, but they had not been explicitly integrated into the analysis. This book, however, claims that ideology develops as a justification for existing institutions and hence it is both endogenous to institutions and a strengthening factor. Although North's earlier analyses were rooted in history, they developed an ahistorical theory of institutions. These analyses sought a deterministic theory of institutions: a mapping from exogenous, contemporaneous conditions (such as population, technology, and geography) to institutions. Subsequently, North developed a more elaborate view of institutional change that attempted to capture how past institutions influence ensuing ones.

Recent theoretical developments
North's 1990 book, *Institutions, Institutional Change and Economic Performance*, develops an historical theory of institutional change. The argument revolves around the interplay between organizations and institutions. Institutions provide the incentives for establishing some organizations – for example, firms or political interest groups – but not others, and influence their activities. Through such activities, the organizations that institutions promote acquire new knowledge and information. This new knowledge enables them to recognize how they can improve their ability to advance their interests through institutional change. Therefore, these organizations act as players in the politics of setting the rules that govern economic interactions. Hence, institutional change is a path-dependent process. Institutions induce the emergence of particular organizations which later engage in institutional change. Such changes are incremental because organizations don't set out to destroy the institutions that gave rise to them. History matters.

Complementary forces that render institutional dynamics a historical process are the focus of North's 2005 book, *Understanding the Process of Economic Change*. More generally, the book emphasizes that economic stagnation emerges when and where institutions fail to adjust efficiently. The focus of the analysis is on the cognitive capabilities and limitations of individuals and how they influence institutional change. Institutions constructed by individuals reflect their understanding of reality and determine the growth of their understanding. Dissimilar initial cognitive views of reality can therefore lead societies to develop distinct institutions in the same objective situation. The different processes of individual and social learning that these initial institutions imply keep each society on a distinct institutional trajectory.

Hence, for example, the establishment of institutions in the Soviet Union was based on a particular concept of reality. Once established, however, these institutions led to particular learning processes as well as the emergence of organizations with vested interests in the institutions. The result was initial economic success followed by decades of decline because the initial concept of reality was wrong but the organizations it led to had an interest in maintaining the system.

While this book provides new answers to an important question, it more generally calls attention to the need to integrate insights from cognitive science into the examination of the interplay among belief systems, institutions, and economic performance. It particularly emphasizes the relevance of theories of connected or embedded cognition, which argue that human cognition is a social phenomenon shaped by man-made constructs. Institutions shape individual cognition by reducing the uncertainties that would otherwise overwhelm cognitive capacity in complex social situations. At the same time, the resulting bias in our beliefs about this environment can lead to a lock-in of these institutions.

Sir Dudley North, knitted for his service as a sheriff of London in 1682, was born at Westminster in 1641, the third of five sons of the fourth Baron Guilford. He died at Covent Garden on the last day of December 1691. After a highly successful merchant career in the Levant, he returned to England in 1680 and was appointed a Commissioner of the Customs in 1683. He was promoted to Commissioner of the Treasury in 1685, and when that Commission was dissolved a few months later he returned to the Customs where he remained until the Revolution of 1688.

North's place in the history of economic theory is due to his essay *Discourses upon Trade*, published in 1691 (or early 1692). His clear-sighted advocacy of free trade principles, his opposition with John Locke, to the proposals advocated by Sir Thomas Culpeper and Sir Josiah Child for a legal maximum rate of interest, and his advanced views of the beneficial effects of monetary circulation make the *Discourses* a high-water mark in the pre-classical literature.

The *Discourses*, first published anonymously, were summarized in the biography of Sir Dudley published by his brother Roger in 1744. The Preface to the *Discourses*, the concluding paragraph of the second Discourse, and the final paragraph of the Postscript appear to be the work of Roger. The work was rediscovered and evaluated very highly by the classical economists and J.R. McCulloch published a reprint of the *Discourses* in 1822.

Applying a general supply and demand theory of prices to the determination of interest rates, North argued that a law to restrict the interest rate to a specified maximum level would be ineffective. The market rate of interest depended heavily on the availability of loanable funds which depended on the savings made out of income, a ‘surplus’ that provides an accumulation of investable ‘stock’. A fourfold proposition follows. First, ‘as more buyers than sellers raiseth the price of a commodity, so more borrowers than lenders will raise interest’. Second, ‘as the landed man letts his land, so these still let their stock; … thus to be a landlord or a stock-lord is the same thing’. Third, ‘it is not low interest that
makes trade, but trade increasing, the stock of the nation makes interest low.’ Fourth, as the largest part of the demand for loanable funds was for consumption purposes (leading to a prodigality and thrift theory of interest, rather than one of productivity and thrift) ‘an ease of interest will rather be a support to luxury than to trade’.

North argued that it was not so much that trade depended on money as that the money supply depended on trade. For ‘nations which are very poor, have scarce any money, and in the beginnings of trade have often made use of something else, … as wealth increased, gold and silver hath been introduced and drove out the other’. A money supply adequate to the needs of trade would be assured, moreover, by the ‘ebbing and flowing of money’, the coining, melting, and recoining of bullion. ‘The buckets work alternately.’ Emphasizing the significance of monetary expenditure and circulation, and not simply the money supply as such, complaints against a shortage of money were met by the argument that the remedy for a depressed economy was not ‘the increase of specific money’ but a disposition to spend rather than hoard. ‘The nation … never thrives better than when riches are tost from hand to hand.’

Article

Born in Leningrad, of a Polish–Jewish family Novakovski, Alec Nove would say he felt like a Russian. His father was a Menshevik and his uncle a Bolshevik. He used as a small boy to listen to them arguing, and respected his uncle more. His native language was Russian. The family emigrated to London shortly after the Revolution.

Nove was educated at the London School of Economics (B.Sc. Econ. 1936). His first civilian job was at the Board of Trade and he entered academic life in 1958 as Reader at the London School of Economics. He was Professor Emeritus at Glasgow University at the time of his death.

Impatience with orthodox theory and its whole implementarium did not conceal a sharp economic mind. This was applied mainly to Sovietology and to socialism generally. Nove comes after the great pioneers of Sovietological economics: Sergei Prokopovich, Naum Jasny, Solomon Schwarz and (slightly younger) Abram Bergson. Less Soviet or at least less Russian than the first three, he was also less Western than the last, and this from personal choice, since his whole education was Western. But he always cultivated an understanding of the system in its own terms, and this fit in with his anti-neoclassical bent. A flaw here however was his extreme reluctance to master Marxist ideology in its many varieties: it was a strictly practical view of the Soviet system that was taken.

His methodology can only be called breadth of mind, energy and intuition: foraging through the wasteland of the current Russian literature and making new and important insights. Nove was the first to write seriously about the variety of the success indicators imposed upon planned enterprises; the first to note that in about 1980 Soviet economists were producing and almost publishing their own price indices (these rose far quicker than the official ones); one of the first to spot the brave scholars who were revising the harvest figures during the collectivization and the famine.

Much of his work was political economy: Trotsky and socialism; Stalinism and planning; the decision as to when to collectivize agriculture; glasnost. There is a also a cornucopia of minor contributions on
Soviet literature; pre-revolutionary Russian opera; Poland; Hungary; and the misuse of economic criteria by the British public sector (this sideline however was flawed by Scottish nationalism, if that is a correct name for the disgruntlement of a Glaswegian globetrotter who finds he must go everywhere via London). Here as everywhere inspired common sense and strong empirical knowledge produced work that was occasionally wrong-headed, usually brilliant, very seldom dull, never unclear.

capital intensity; depreciation; inversely related expenditures; Kantorovich, L. V.; labour theory of value; Nemchinov, V. S.; Novozhilov, V. V.; opportunity cost; resource allocation; value theory

Article

Novozhilov was born in Khar'kov, and died in Leningrad. He was instrumental, along with the mathematician Leonid Vital'evich Kantorovich, in reviving a mathematical approach to economic theory in the USSR after Stalin's death, and in laying a basis for a modern theory of value and allocation. Educated at Kiev University before the revolution, Novozhilov taught at several institutions in the Ukraine, but from 1922 lived in Leningrad, teaching and working in research institutes. From 1935 he taught at the Leningrad Polytechnical Institute, and from 1944 until 1952 was also professor and head of the Department of Statistics at the Leningrad Engineering–Economics Institute. His work with project-making institutes involved Novozhilov in the issue of capital intensity choices, which became the basis for his doctoral dissertation. In illuminating the question of effective allocation of capital among competing projects, he developed a more general theory for allocation of all resources, the centrepiece of which was the concept of ‘inversely related expenditures’ (zatraty obratnoi sviazi) equivalent to opportunity cost. His analytic framework was dynamic, incorporating capital allocation over time, as well as the impact of depreciation and obsolescence.

His original and elegant theoretical ideas were presented in papers published in 1939, 1941, 1946 and 1947 that were largely ignored. The most comprehensive exposition of Novozhilov's ideas is a book he was finally able to publish in 1967, which illustrates his ideas on investment choices and the time factor in economics, places his innovative approach in its doctrinal context, and defends it against domestic and foreign critics. His economic theory is expounded within the limits of political orthodoxy. Novozhilov took the structure of demand as given (by the Party), which enabled him to spell out resource-allocating criteria for the Soviet economy very similar to those familiar in the West, except that with the demand blade of the scissors held fixed, only the supply side cut the paper. By casting the resource allocation problem in terms of minimizing labour input (direct and indirect) he sought to
preserve Marx's labour theory of value. Both his contribution and the absence of an explanation of demand were soon recognized abroad (see Grossman, 1953; Campbell, 1961). In the mid-1950s, when V.S. Nemchinov organized a revival of serious economic analysis in the USSR, Novozhilov, along with Kantorovich, was a central figure in training a new generation of economists. The three men were awarded Lenin Prizes in 1965. As a result of the pioneering work of Novozhilov and Kantorovich, the basis for a correct and comprehensive theory of value has already been to hand for several decades. Additional biographic and bibliographical details, and interpretations of Novozhilov's work may be found in Campbell (1961), Ellman (1973), Grossman (1953), Holubnychy (1982), and Petrakov (1972).

numéraire

Michael Allingham
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
money; numéraire

Article

In general equilibrium theory the price of one good in terms of another is interpreted as the amount of the second which can be exchanged for a given amount of the first. There is thus no essential role for a standard of value, or numéraire, though it is frequently helpful to introduce this. Such a numéraire is a commodity in terms of which, by convention, other commodities are valued.

The concept seems to have been introduced by Steuart (1767), albeit with some confusion between the properties of ‘money’ and ‘units of account’. Walras (1874–7) clarified the concept, and showed how prices expressed in terms of one numéraire could be translated into prices in terms of another, without any introduction of ‘money’. In the present discussion we commence with a justification of the use of a numéraire. We then discuss the choice of a numéraire and some problems which may arise through the use of this.

We may represent an economy with $n$ commodities by the excess demand function $f: S \rightarrow \mathbb{R}^n$ where $S = \mathbb{R}^n_+ - \mathbb{0}$. The interpretation is that $f(p)$ is the vector of aggregate excess demands (positive) or excess supplies (negative) expressed at the price system $p$. A basic property of $f$ is that it is homogeneous of degree zero, that is $f(tp) = f(p)$ for all positive $t$.

It is this property which justifies the use of a numéraire. We can, for example, take commodity $n$ to be numéraire, that is, ensure that $p_n = 1$, by setting the scalar $t$ appropriately. Thus the price system $q$ can be replaced by the numéraire price system $p$ with $p_n = 1$ by multiplying $q$ by $t=1/q_n$; nothing real changes, since $f(p) = f(q)$. However, this is only possible if we can ensure that $q_n$ is positive; since $q$ is restricted only to $S$ this may prove difficult.

The problem of the price of a chosen numéraire possibly being zero may be avoided by using a composite numéraire, that is a basket of goods. The scalar $t$ may then be set as $u \cdot q_n$ where $u$ is the unit vector in $\mathbb{R}^n$: this has the effect of restricting $p$ to the unit simplex in $\mathbb{R}^n$. Alternatively, a nonlinear
normalization may be used, for example setting $\mathbf{q} = \mathbf{q} \cdot \mathbf{Q}$; this has the effect of restricting $p$ to the surface of a sphere in $\mathbb{R}^n$.

However, in reality prices are usually quoted in terms of some single unit of account, or *numéraire*, and it may be useful for the model of the economy to recognize this. Provided that all commodities are desirable, in the sense that $f_i(p)$ is infinite if $p_i=0$, there is no possibility of any price being zero in equilibrium, that is some $p$ where $f(p)=0$. But there may be a problem of $p_i$ being zero on some adjustment path of prices. Whether this is indeed a problem will depend on both the nature of $f$ and on the adjustment process governing this path. For example, if the adjustment process is given by $\dot{p} = h(f(p))$ where $h$ is a continuous sign-preserving function (and a dot indicates differentiation with respect to time) and if $f$ has the above desirability property, then there is no problem. Alternatively, if the adjustment process is $\dot{p}_i = 0$ if $p_i \leq 0$ and $f_i(p)<0$, while $\dot{p}_i = h_i(f_i(p))$ otherwise, then again there is no problem, provided of course that initial prices are positive (Arrow and Hahn, 1971). However, if these properties do not apply, and particularly if the adjustment process is discrete, there may be a problem.

Provided we can use a simple *numéraire* it is clear that if equilibrium is unique in terms of one *numéraire* then it will be unique in terms of another. However, the choice of *numéraire* may be relevant to considerations of stability: that is, for some given adjustment process involving a *numéraire* the economy may be stable for some *numéraire* but not for some other. Some sufficient conditions for stability, such as the condition that $f$ have the revealed preference property, are clearly independent of any choice of a *numéraire*, while others are not (Hahn, 1982). For example, the diagonal dominance condition that all commodities are normal and that there are some units in which commodities can be measured such that each of their excess demands is more sensitive to a change in its own price than it is to a change in all other non-*numéraire* prices combined, is clearly dependent on the choice of *numéraire*; indeed, because of homogeneity it makes no sense to attempt to extend it to include the *numéraire*. An economy may have this property, which is sufficient for stability, for one *numéraire* but not for some other. Since this condition is not necessary for stability it does not follow that the economy will be unstable with the second *numéraire*, but neither can stability be guaranteed.

The reason why uniqueness, for example, does not depend on the choice of *numéraire* while stability may, is that stability depends on the adjustment process. Strictly speaking, a change of *numéraire* is simply a change of adjustment process: it is quite natural that the economy may be stable under one adjustment process but not under another.

The question of a *numéraire* has a practical as well as a theoretical importance. In many cases ‘money’ is the natural *numéraire* – though the introduction of money in an essential sense, as opposed to simply as a unit of account, introduces its own problems (Clower, 1967).

numerical optimization methods in economics

Karl Schmedders
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Optimization problems are ubiquitous in economics. Many of these problems are sufficiently complex that they cannot be solved analytically. Instead economists need to resort to numerical methods. This article presents the most commonly used methods for both unconstrained and constrained optimization problems in economics; it emphasizes the solid theoretical foundation of these methods, illustrating them with examples. The presentation includes a summary of the most popular software packages for numerical optimization used in economics, and closes with a description of the rapidly developing area of mathematical programs with equilibrium constraints, an area that shows great promise for numerous economic applications.

Article

Optimizing agents are at the centre of most economic models. In our models we typically assume that consumers maximize utility or wealth, that players in a game maximize payoffs, that firms minimize costs or maximize profits, or that social planners maximize welfare. But it is not only the agents in our models that optimize. Econometricians maximize likelihood functions or minimize sums of squares. Clearly optimization is one of the key techniques of modern economic analysis.

The optimization problems that appear in economic analysis vary greatly in nature. We encounter finite-dimensional problems such as static utility maximization problems with a few goods. An optimal solution to such a problem is a finite-dimensional vector. We analyse finite-dimensional problems such as infinite-horizon social planner models or continuous-time optimal control problems. Here the solution is an infinite-dimensional object, a vector with countably infinitely many elements or even a function over an interval. Our agents may face constraints such as budget equations, short-sale restrictions or incentive-compatibility constraints. There are also unconstrained problems such as nonlinear least-square problems. Decision variables may even be restricted to be discrete. Agents' objective functions may be linear or nonlinear, convex or nonconvex, many times differentiable or discontinuous. Finally, an economic optimization problem may be deterministic or stochastic.

Unless we consider stylized models in theoretical work or make very stringent and often quite unrealistic assumptions in applied models, the optimization problems that we encounter cannot be solved analytically. Instead we need to resort to numerical methods. The numerical methods that we employ to solve economic optimization models vary just as much as the optimization problems we encounter. It is therefore impossible to cover the wide variety of numerical optimization methods that are useful in economics in a short article. For the purpose of the exposition here we focus on deterministic finite-dimensional nonlinear optimization problems including linear programs. This is a natural choice because such
problems are ubiquitous in economic analysis. Moreover, the techniques for these problems play also an important part in many other numerical methods such as those for solving economic equilibrium and infinite-dimensional problems. The interested reader should consult computation of general equilibria (new developments), computational methods in econometrics and dynamic programming.

We first indicate some of the fundamental technical difficulties that we need to be aware of when we apply numerical methods to our economic optimization problems. We then highlight the basic theoretical foundations for numerical optimization methods. The popular numerical optimization methods have strong theoretical foundations. Unfortunately, current textbooks in computational economics, with the partial exception of Judd (1998), neglect to emphasize these foundations. As a result some economists are rather sceptical about numerical methods and view them as rather ad hoc approaches. Instead, a good understanding of the theoretical foundations of the numerical solution methods gives us an appreciation of the capabilities and limitations of these methods and can guide our choice of suitable methods for a specific economic problem. We outline the most fundamental numerical strategies that form the basis for most algorithms. All presented numerical strategies are implemented in at least one of the those computer software packages for solving optimization problems that are most popular in economics. We close our discussion with a look at mathematical programs with equilibrium constraints (MPECs), a promising research area in numerical optimization that has useful applications in economics.

1 Newton's method in one dimension

We start with the one-dimensional unconstrained optimization problem

$$\min_{x \in \mathbb{R}} f(x).$$

Perhaps the first (if any) numerical method that most of us learnt in our calculus classes is Newton's method. Newton's method attempts to minimize successive quadratic approximations to the objective function $f$ in the hope of eventually finding a minimum of $f$. To start the computations we need to provide an initial guess $x^{(0)}$. The quadratic approximation $q(x)$ of $f(x)$ at the point $x^0$ is

$$q(x) = f(x^0) + f'(x^0)(x-x^0) + \frac{1}{2} f''(x^0)(x-x^0)^2$$

where $f'$ and $f''$ denote the first and second derivative of the function $f$, respectively. Solving the first-order condition

$$q'(x) = f'(x^0) + f''(x^0)(x-x^0) = 0$$

on the assumption that $f'(x^0) \neq 0$ yields the solution

$$x^{(1)} = x^{(0)} - \frac{f'(x^0)}{f''(x^0)}.$$
Now we repeat this process using a quadratic approximation to \( f \) at the point \( x^{(1)} \). The result is a sequence of points, \( \{x^{(k)}\} = x^{(0)}, x^{(1)}, x^{(2)}, \ldots, x^{(k)}, \ldots \), that we hope will converge to the solution of our minimization problem. This approach is based on the following theoretical result.

**Theorem:** Suppose \( x^* \) is the solution to the minimization problem (1). Suppose further that \( f \) is three times continuously differentiable in a neighborhood of \( x^* \) and that \( f'(x^*) \neq 0 \). Then there exists some \( \delta > 0 \) such that if \( |x^* - x^{(0)}| < \delta \), then the sequence \( \{x^{(k)}\} \) converges quadratically to \( x^* \), that is,

\[
\lim_{k \to \infty} \frac{|x^{(k+1)} - x^*|}{|x^{(k)} - x^*|^2} = \kappa
\]

for some finite constant \( \kappa \). □

We illustrate this theorem with a simple example.

**Example 1:** A consumer has a utility function \( u(x, y) = \ln(x) + 2 \ln(y) \) over two goods. She can spend $1 on buying quantities of these two goods, both of which have a price of $1. After substituting the budget equation, \( x+y=1 \), into the utility function the consumer wants to maximize \( f(x) = \ln(x) + 2 \ln(1-x) \). Setting the first order condition equal to 0 yields the solution \( x^* = \frac{1}{3} \). (This quantity is globally optimal because the function \( f \) is strictly concave.)

Suppose we start Newton’s method with the initial guess \( x^{(0)}=0.5 \). Then the first Newton step yields

\[
x^{(1)} = 0.5 - \frac{f'(0.5)}{f''(0.5)} = 0.5 - \frac{-2}{12} = \frac{1}{3}.
\]

Newton’s method found the exact optimal solution in one step. This (almost) never happens in practice. Much more usual is the behaviour we observe when we start with \( x^{(0)}=0.8 \). Then Newton’s method delivers as its first five steps

\[
0.63030303, 0.407373702, 0.328873379, 0.333302701, 0.333333332.
\]

We observe that the sequence rapidly converges to the optimal solution. The corresponding errors \( |x^{(k)}-x^*| \),

\[
0.2969697, 0.07404037, 0.00445995, 3.0632 \cdot 10^{-5}, 1.4078 \cdot 10^{-9}
\]

converge to but never exactly reach zero. The rate of convergence is called quadratic since \( |x^{(k+1)} - x^*| < L|x^{(k)} - x^*|^2 \) for some constant \( L \) once \( k \) is sufficiently large. □

But, of course, contrary to this simple example, we typically do not know \( x^* \) and so cannot compute the errors \( |x^{(k)}-x^*| \). Instead, we need a stopping rule that indicates when the
procedure terminates. The requirement that \( f'(x^{(k)}) < \varepsilon \) may appear to be an intuitive stopping rule. But that rule may be insufficient for functions that are very ‘flat’ near the optimum and have large ranges of non-optimal points satisfying this rule. Therefore, a safer stopping rule requires both \( f'(x^{(k+1)}) < \varepsilon \) and \( |x^{(k+1)} - x^{(k)}| < \varepsilon(1 + |x^{(k)}|) \) for some pre-specified small error tolerance \( \varepsilon, \delta > 0 \). So the Newton method terminates once two subsequent iterates are close to each other and the first derivative almost vanishes.

Observe that Newton's method found a maximum, and not a minimum, of the utility function. The reason for this fact is that this method does not search directly for an optimizer. Note that the key step in the algorithm is finding a stationary point of the quadratic approximation \( q(x) \), that is, a point satisfying \( q'(x) = 0 \). Before we can claim to have found a maximum or minimum of \( f \) we need to do more work. In this example the strict concavity of the utility function ensures that a stationary point of \( f \) yields a maximum. So an assumption of our economic model assures us that the numerical method indeed finds the desired maximum.

**Example 2:** Consider the simple polynomial function \( f(x) = (x - 2)^2 \). Starting with \( x^{(0)} = 1 \) leads to the sequence

\[
0.5, 0.65, 0.666463415, 0.6666666626, ...
\]

converging to \( \frac{2}{3} \). Starting with \( x^{(0)} = 1.5 \) leads to the sequence

\[
2.75, 2.198529412, 2.02277454, 2.000376254
\]

converging to 2. Neither of these two points yields a global optimum, the function \( f \) is actually unbounded above and below. The point \( \frac{2}{3} \) is a local maximizer (\( f''(\frac{2}{3}) = -4 < 0 \)) while 2 is a local minimizer (\( f''(2) = 4 > 0 \)). The stationary point that we find greatly depends on our initial guess.

Our simple observations about the behaviour of Newton's method for one-dimensional optimization problems apply in practice to higher-dimensional nonlinear optimization problems and to almost all optimization methods. We will almost always face these fundamental issues in our economic applications. First, most practical optimization methods for unconstrained problems search only for a stationary point (with possibly additional favourable properties). They do not directly attempt to compute an optimizer. Second, as a result, most practical methods may terminate with a non-optimal point. To ensure global optimality we need to perform additional checks. Third, it is rather unusual in practice to explicitly solve for an exact solution. Usually we can only hope for a sequence of points \( \{x^{(k)}\} \) generated by an iterative process that converges to a limit having some desired property. Therefore, we need a stopping rule that indicates when the iterative process stops. Fourth, the algorithm may not terminate and diverge even if a globally optimal solution exists. Newton's method is a special instance of a family of methods for solving multidimensional optimization problems. Before we examine more general methods we provide some basic intuition for the theoretical underpinnings of these solution methods.

**2 Theoretical foundation: Taylor’s th**

The gradient of the function \( f \) at a point \( x = (x_1, x_2, \ldots, x_n) \) is the column vector

\[
\nabla f(x) = \begin{pmatrix} \frac{\partial f}{\partial x_1}(x) \\ \frac{\partial f}{\partial x_2}(x) \\ \vdots \\ \frac{\partial f}{\partial x_n}(x) \end{pmatrix}^T
\]

of partial derivatives of \( f \) with respect to the variables \( x_1, x_2, \ldots, x_n \). The Hessian of \( f \) at \( x \) is the \((n \times n)\)-matrix
of the second derivatives \( \frac{\partial^2 f}{\partial x_i \partial x_j}(x) \) of \( f \). The inner product of two (column) vectors \( x, y \in \mathbb{R}^n \) is denoted by \( x^T y \).

Many numerical methods rely on linear or quadratic approximations of the function \( f \). Taylor's theorem provides a justification for this approach. Here we give a simple version of this theorem for functions with Lipschitz continuous derivatives. Consider a function \( F : X \rightarrow \gamma \) for open sets \( X \subset \mathbb{R}^n \) and \( Y \subset \mathbb{R}^m \). Then \( F \) is Lipschitz continuous at \( x \in X \) if there exists a constant \( \gamma(x) \) such that

\[
\| F(y) - F(x) \| \leq \gamma(x) \| y - x \|
\]

for all \( y \in X \), where \( \| \cdot \| \) denotes the standard Euclidean norm.

**Theorem:** Suppose the function \( f : X \rightarrow \mathbb{R} \) is continuously differentiable on the open set \( X \subset \mathbb{R}^n \) and that the gradient function \( \nabla f \) is Lipschitz continuous at \( x \) with Lipschitz constant \( \gamma'(x) \). Also suppose that for \( s \in \mathbb{R}^n \) the line segment \( x + \theta s \in X \) for all \( \theta \in [0,1] \). Then, the linear function \( l \) with \( l(s) = f(x) + \nabla f(x)^T s \) satisfies

\[
|f(x + s) - l(s)| \leq \frac{1}{2} \gamma'(x) \| s \|^2.
\]

Moreover, if \( f \) is twice continuously differentiable on \( X \) and the Hessian \( H \) is Lipschitz continuous at \( x \) with Lipschitz constant \( \gamma''(x) \), then the quadratic function \( q \) with \( q(s) = f(x) + \nabla f(x)^T s + \frac{1}{2} s^T H(x) s \) satisfies

\[
|f(x + s) - q(s)| \leq \frac{1}{6} \gamma''(x) \| s \|^3.
\]

3 Unconstrained optimization

The multidimensional generalization of the unconstrained optimization problem (1) is given by

\[
\min_{x \in \mathbb{R}^n} f(x).
\]
Solving this optimization problem entails finding a global minimizer $x^*$ satisfying $f(x^*) \leq f(x)$ for all $x \in \mathbb{R}^n$. With the exception of a few algorithms for problems that are either very small or have very special structure, there are no algorithms that are guaranteed to find a global minimum. Thus, we need to think in terms of local minima. A local minimizer is a point $x^*$ that satisfies $f(x^*) \leq f(x)$ for all $x \in N(x^*)$ where $N(x^*)$ denotes a neighborhood of $x^*$. The point $x^*$ is called an isolated local minimizer if it is the only local minimizer in $N(x^*)$.

All these definitions by themselves are not all that helpful for finding a minimum. Instead, just as Newton’s method in one dimension does, all practical numerical methods for unconstrained optimization problems rely on optimality conditions to find candidates for local minima. For functions with sufficient differentiability properties these are the following well-known conditions.

**Theorem:** [Optimality conditions for unconstrained minimization]

1. If $f$ is continuously differentiable and $x^*$ is a local minimizer of $f$, then $\nabla f(x^*) = 0$.
2. If $f$ is twice continuously differentiable and $x^*$ is a local minimizer of $f$, then $\nabla f(x^*) = 0$ and $s^T \mathcal{H}(x^*) s \geq 0$ for all $s \in \mathbb{R}^n$.
3. If $f$ is twice continuously differentiable and if $x^*$ satisfies $\nabla f(x^*) = 0$ and $s^T \mathcal{H}(x^*) s > 0$ for all $s \in \mathbb{R}^n$, $s \neq 0$, then $x^*$ is an isolated local minimizer of $f$. □

But when can we be assured that a local minimizer of $f$ is actually a solution to the unconstrained optimization problem (2)? The perhaps easiest sufficient condition is that the function $f$ is convex, that is, $s^T \mathcal{H}(x) s \geq 0$ for all $x \in \mathbb{R}^n$ if $f$ is twice differentiable. Then any local minimizer $x^*$ is a solution to problem (2), in fact, any stationary point $x^*$ is a solution to (2).

The optimality conditions provide the foundation for all practical unconstrained optimization methods. The focus of all these algorithms is to find (actually, to approximate) a stationary point of $f$, that is, a solution to $\nabla f(x) = 0$. They do so by generating a sequence of iterates $\{x^{(k)}\}$ that ideally terminates once a stopping rule is satisfied indicating that an approximate solution has been found. The key step for these methods is to generate a new iterate $x^{(k+1)}$ from a current iterate $x^{(k)}$. A vast majority of optimization routines uses one of two basic strategies for moving from $x^{(k)}$ to $x^{(k+1)}$, a line search approach or a trust region method.

### 3.1 Line search methods

The general set-up of a line search method is as follows. From a point $x^{(k)}$ (with $\nabla f(x^{(k)}) \neq 0$) we look for a search direction $s^{(k)}$ that leads us to lower function values for $f$. Using the linear approximation $l$ with $l(s) = f(x^{(k)}) + \nabla f(x^{(k)})^T s$ we determine a descent direction $s^{(k)}$ satisfying

$$\nabla f(x)^T s^{(k)} < 0,$$

which in turn implies $l(s^{(k)}) < f(x^{(k)})$. Because of Taylor’s theorem we hope that along a step in the direction $s^{(k)}$ the function value $f(x)$ will be reduced. We calculate a suitable step length $\alpha > 0$ to ensure that $f(x^{(k+1)}) < f(x^{(k)})$ where

$$x^{(k+1)} = x^{(k)} + \alpha s^{(k)}.$$

Observe that at a given point $x^{(k)}$ and for a descent direction $s^{(k)}$ finding the optimal value of $\alpha$ requires us to solve a one-dimensional optimization problem. In principle we could apply Newton’s method to this problem. In practice, however, this one-dimensional problem does not need to be solved exactly because repeatedly finding the optimal step length is...
both unnecessary for convergence of line search methods and computationally rather inefficient. Instead modern line search methods prefer to use inexact line searches that just pick a step length that leads to a sufficient decrease in the objective function value. One such approach is the backtracking Armijo line search, which requires that

\[ f\left(x^{(k)} + \alpha_k s^{(k)}\right) \leq f(x^{(k)}) + \alpha_k \beta f(x^{(k)})^\top s^{(k)} \]

for some \( \beta \in (0,1) \). The idea of this requirement is to link the step size \( \alpha_k \) to the decrease in \( f \). The longer the step the larger the decrease must be. Starting with an initial guess for \( \alpha_k \), say 1, we can now stepwise reduce the value of \( \alpha_k \) until the above condition is satisfied. At that point we set \( x^{(k+1)} = x^{(k)} + \alpha_k s^{(k)} \).

While the basic line search method seems very intuitive, it can fail if the search direction and the gradient tend to a point where they are orthogonal to each other, that is, the product \( \nabla f(x^{(k)})^\top s^{(k)} \) tends to zero without the gradient itself approaching zero. This kind of failure can be avoided by a proper choice of search direction.

3.1.1 Method of steepest descent

The perhaps most intuitive choice for a descent direction is

\[ s^{(k)} = -\nabla f(x^{(k)}) , \]

because this search direction gives the greatest possible decrease in the linear approximation \( l \) (for a fixed step length). It is thus called the steepest descent direction. And indeed, a line search with the steepest descent direction has very nice theoretical properties.

Theorem: Suppose that \( f \) is continuously differentiable and that \( \nabla f \) is Lipschitz continuous on \( \mathbb{R}^n \). Then for the sequence \( \{x^{(k)}\} \) of iterates generated by a line search method using the steepest descent direction and the backtracking Armijo line search one of the following three conditions must hold.

- (C1) \( \nabla f(x^{(k)}) = 0 \) for some \( k \geq 0 \).
- (C2) \( \lim_{k \to \infty} \nabla f(x^{(k)}) = 0 \).
- (C3) \( \lim_{k \to \infty} f(x^{(k)}) = -\infty \).

The method of steepest descent has the global convergence property, that is, independent of the starting point the sequence of gradients will converge to a stationary point (but that does not mean that the sequence \( x^{(k)} \) converges, think of \( \ln(x^{(k)}) \)) or the function values diverge and indicate that no minimum exists.

Example 3: A consumer has a utility function \( u(x_1, x_2, x_3) = \sqrt{x_1} + 2\sqrt{x_2} + 3\sqrt{x_3} \) over three goods. She can spend $1 on buying quantities of these three goods, all of which have a price of $1. After substituting the budget equation, \( x_1 + x_2 + x_3 = 1 \), into the utility function the consumer wants to maximize \( \sqrt{x_1} + 2\sqrt{x_2} + 3\sqrt{1 - x_1 - x_2} \). (We can trivially solve this problem with pencil and paper and find the optimal solution \( (\frac{1}{14}, \frac{4}{14}, \frac{9}{14}) \).) We solve the consumer's optimization problem by minimizing the function \( f(x_1, x_2) = \frac{1}{2}\sqrt{x_1} + \frac{1}{2}\sqrt{x_2} + \sqrt{1 - x_1 - x_2} \) with a steepest descent method (using the optimal step length in each step). Figure 1 indicates some of the early steps and Table 1 lists details of some of the steps. (To show convergence of variable values and the optimal function value we report six digits for these terms. The search direction and norm of the gradient are converging to zero and so for simplicity we report fewer and not always the same number of digits. We abbreviate numbers like \( 6.7\cdot10^{-8} \) by \( 6.7(\cdot8) \).

The steepest descent method makes good progress in the first few iterations but then slows down considerably. Note the comparatively little change in the values of \( x^{(k)} \) during the last 10 to 15 iterations. The figure shows a lot of 'zigzagging' from iterate to iterate.

Steps of a steepest descent method
### Numerical Optimization Methods in Economics

#### The New Palgrave Dictionary of Economics

The table below presents the first steps of a steepest descent method.

| k | x₁(0) | x₂(0) | s(0) | ||∇f(x(0))|| | f(x(0)) |
|---|---|---|---|---|---|
| 0 | 0.1 | 0.5 | -0.7906 | -0.9575 | 1.2417 | -3.6278 |

#### Figure 1

First steps of a steepest descent method.

![Graph](http://www.dictionaryofeconomics.com/proxy.library.csi.cuny.edu/article?id=pde2008_N000034&goto=B&result_number=1232)
The behaviour of the steepest descent method in the example is quite typical. As a result the convergence of the method is rather slow. And so, despite having the global convergence property, it is useless in practice. The slow convergence (see Nocedal and Wright, 2006, ch. 3) of this method renders it impractical. The convergence problems are essentially due to the reliance on a first-order approximation, which ignores the curvature properties of $f$. Newton's method takes advantage of a second-order approximation.

### 3.1.2 Newton methods

The quadratic approximation $q$ of the objective function $f$ at an iterate $x^{(k)}$ is given by

$$q(s) = f(x^{(k)}) + \nabla f(x^{(k)})^\top s + \frac{1}{2} s^\top H(x^{(k)}) s.$$
The first-order condition $q'(s)=0$ yields the search direction

$$s^{(k)} = -H(x^{(k)})^{-1} \nabla f(x^{(k)}).$$

Only under very strong conditions is Newton's method globally convergent.

**Theorem:** Suppose that $f$ is continuously differentiable and that $\nabla f$ is Lipschitz continuous on $\mathbb{R}^n$. If for the sequence $\{x^{(k)}\}$ of iterates generated by a line search method using the Newton direction and the backtracking Armijo line search the Hessian matrices $H(x^{(k)})$ are positive definite with eigenvalues that are uniformly bounded away from zero, then one of the conditions (C1), (C2), (C3) must hold. □

**Example 4:** We revisit the consumer's optimization problem from Example 3 and minimize the function $f(x_1, x_2) = -\left(\sqrt{x_1} + 2\sqrt{x_2} + 3\sqrt{1 - x_1 - x_2}\right)$ with a Newton method (using the optimal step length in each step). Table 2 lists all the steps of this method and Figure 2 displays some of the early steps. Newton's method converges very rapidly. Unlike the steepest descent method it does not slow down near the solution, instead we see a quadratic rate of convergence just like in the one-dimensional problem in Example 1. □

**Figure 2**
First steps of a Newton method
The condition that the Hessian matrix $H(x^{(k)})$ is positive definite for the entire sequence $\{x^{(k)}\}$ is rarely satisfied for general problems. But if the Hessian is not positive definite then the search direction $s^{(k)}$ may be an ascent instead of a descent direction. The modified Newton methods address this problem by modifying the Hessian matrix $H(x^{(k)})$. These methods choose a search direction.
where the matrix $M(x^{(k)})$ is chosen so that $H(x^{(k)}) + M(x^{(k)})$ is ‘sufficiently’ positive definite. If $H(x^{(k)})$ is sufficiently positive definite itself then, of course, $M(x^{(k)}) = 0$. A proper choice of $M(x^{(k)})$ is crucial for the effectiveness of this approach; see Gould and Leyffer (2002) and Nocedal and Wright (2006) for many more details.

The most tedious task in Newton’s method is the computation of the Hessian matrix $H(x^{(k)})$. Therefore, for decades it was fashionable to develop methods, the so-called quasi-Newton methods, that rely on approximations of the exact Hessian matrix. Interest in these methods has somewhat diminished due to the development of automatic differentiation techniques. These techniques allow a very fast and reliable computation of derivatives and so make the task of calculating the Hessian feasible even for large problems. Nocedal and Wright (2006, ch. 6) discuss quasi-Newton methods in detail.

Before we continue our discussion of optimization algorithms we pause for a quick comment on some potential name confusion. In addition to Newton methods for unconstrained optimization there is also a Newton method for solving nonlinear systems of equations. To avoid confusion and for historical reasons the root-finding methods for nonlinear systems of equations are sometimes called Newton–Raphson methods; see Judd (1998) and references therein. In particular, Newton methods for solving unconstrained optimization problems should not be confused with so-called global Newton methods. In economic theory the term ‘Smale’s global Newton method’ appears to be well known. This term refers to a solution method for solving nonlinear systems of equations (see Smale, 1976) which is closely related to homotopy continuation methods. Clearly, we could use methods for nonlinear equations to solve the first-order conditions $\nabla f(x) = 0$. This approach, however, does not use other information from the underlying optimization problem and thus is often inefficient. Here we do not discuss methods for solving nonlinear equations, and refer to Allgower and Georg (1979), Judd (1998) and Miranda and Fackler (2002).

### 3.2 Trust region methods

Line search methods use an approximation of the objective function $f$ to generate a search direction. Subsequently they determine a suitable step length along this direction. Trust region methods also rely on an approximation of $f$, but they first define a region around the current iterate in which they trust the approximation to be adequate. Then they simultaneously choose the direction and step length.

For the purpose of our discussion here we consider a quadratic approximation of $f$ around $x^{(k)}$,

$$q_k(s) = f(x^{(k)}) + \nabla f(x^{(k)})^T s + \frac{1}{2} s^T B(x^{(k)}) s,$$

where $B(x^{(k)})$ is a symmetric approximation of the Hessian matrix $H(x^{(k)})$. Trust region methods do not require the Hessian matrix of the function $q_k$ to be positive definite. Therefore, we could use $B(x^{(k)}) = H(x^{(k)})$. In that case, the algorithm is called a trust region Newton method. Given a trust region radius $\Delta_k > 0$ in each iteration, the algorithm seeks an (approximate) solution to the trust region sub-problem

$$\min_{s \in \mathbb{R}^n} q_k(s) \text{ subject to } ||s|| \leq \Delta_k.$$

Before we discuss how we may solve this sub-problem we need to decide on a proper choice for the trust region radius. Note that $q_k(0) - q_k(s^{(k)})$ is the predicted reduction for a step $s^{(k)}$. Similarly, $f(x^{(k)}) - f(x^{(k)} + s^{(k)})$ is the actual decrease in the objective. The ratio
\[
\rho_k = \frac{f(x^{(k)}) - f(x^{(k)} + s^{(k)})}{q_k(0) - q_k(s^{(k)})}
\]
gives an indication on how well the quadratic approximation predicts the reduction in the function value. Ideally we would like the step \(s^{(k)}\) to yield a value of \(\rho_k\) of close to or larger than 1. In that case we accept the step and may possibly increase the radius for the next iteration. If, however, \(\rho_k\) is close to zero or even negative, then we would decrease the trust region radius, set \(x^{(k+1)} = x^{(k)}\), and attempt to solve the sub-problem again.

Recall that line search methods do not require the step length to be chosen optimally in order to be globally convergent. Similarly, it is unnecessary and in fact computationally inefficient to solve the trust region sub-problem exactly. Instead, it suffices to search for a step giving a sufficient reduction in \(q_k\). Such a sufficient reduction is achieved by requiring a decrease that is at least as large at that obtained by a step in the direction of steepest descent. The solution to

\[
\min_{\alpha \in \mathbb{R}} q_k(\alpha \nabla f(x^{(k)})) \quad \text{subject to} \quad \|\alpha \nabla f(x^{(k)})\| \leq \Delta_k
\]
yields the Cauchy point

\[
s_k^C = -\tau_k \Delta_k \frac{\nabla f(x^{(k)})}{\|\nabla f(x^{(k)})\|}
\]

where the constant \(\tau_k \in (0,1]\) depends on the curvature of \(q_k\) and the radius \(\Delta_k\); see Nocedal and Wright (2006) for a closed-form solution. The approximate solution \(s^{(k)}\) of the trust region subproblem must now satisfy \(q_k(s^{(k)}) \leq q_k(s_k^C)\).

**Theorem:** Let \(q_k\) be the second-order approximation of the objective function \(f\) at \(x^{(k)}\) and let \(s_k^C\) be its Cauchy point in the trust region defined by \(\|s\| \leq \Delta_k\). Then

\[
q_k(0) - q_k(s_k^C) - f(x^{(k)}) - q_k(s_k^C) \leq \frac{1}{2} \|\nabla f(x^{(k)})\| \min \left\{ \frac{\|\nabla f(x^{(k)})\|}{1 + \|\nabla f(x^{(k)})\|}, \Delta_k \right\}.
\]

Theorem: Consider the sequence \(\{x^{(k)}\}\) of iterates generated by the described trust region method. Suppose that \(f\) is twice continuously differentiable and both the Hessian of \(f\) and the quadratic approximation \(q_k\) are bounded for all \(k\). Then one of the conditions (C1), (C2), (C3) must hold.

The trust region method based on the Cauchy point is effectively a steepest descent (line search) method where the choice of the step length is bounded by the trust region radius. Therefore, this method also suffers from very poor convergence in practice. Better algorithms start from the Cauchy point and try to improve upon it. There is a variety of such

4 Constrained optimization

Now we consider the constrained optimization problem

\[
\min_{x \in \mathbb{R}^n} f(x) \\
\text{s.t. } g_i(x) \geq 0, i \in I \\
\quad h_j(x) = 0, j \in E.
\]

We define the feasible region \( \mathcal{G} \) of this optimization problem to be the set of all points that satisfy the constraints, so

\[
\mathcal{G} = \{ x \in \mathbb{R}^n | g_i(x) \geq 0, i \in I, h_j(x) = 0, j \in E \}.
\]

Just as for the unconstrained optimization problem, we can define global and local solution. Of course, a desired optimal solution \( x^* \) to this optimization problem satisfies \( f(x^*) \leq f(x) \) for all \( x \in \mathcal{G} \). A point \( x^* \) is a local minimizer if it satisfies \( f(x^*) \leq f(x) \) for all \( x \in \mathcal{N}(x^*) \cap \mathcal{G} \) for some neighbourhood \( \mathcal{N}(x^*) \) of \( x^* \). The vector \( x^* \) is an isolated local minimizer if there exists a neighbourhood \( \mathcal{N}(x^*) \) in which it is the only local minimizer.

The conditions of these definitions, just like their counterparts for unconstrained optimization problems, are pretty much useless for the computation of optimal solutions – with one major exception. The simplex method for solving linear programming problems relies on the comparison of objective function values at some special points in the feasible region. Most other practical numerical methods, however, rely again on optimality conditions. Penalty methods transform the problem (NLP) into (a sequence of) unconstrained optimization problems and then rely on their respective first-order conditions. Many methods rely directly on optimality conditions for constrained optimization. These optimality conditions require that certain degenerate behaviour does not occur at potential minimizers. Conditions that rule out such degenerate points are called ‘constraint qualifications’. These conditions are important but do not always get the proper attention in economics, but see Simon and Blume (1994) for a rigorous treatment. Numerous such constraint qualifications exist; here we just mention one such condition.

The set of constraints that hold with equality at a feasible point \( x \in \mathcal{G} \) is called the active set \( \mathcal{A}(x) \). Formally,

\[
\mathcal{A}(x) = \{ i \in I | g_i(x) = 0 \} \cup \mathcal{E}.
\]

The linear independence constraint qualification (LICQ) holds at a point \( x \in \mathcal{G} \) if the gradients of all active constraints are linearly independent. Now we can state the well-known first-order necessary conditions, which most of us learnt as Kuhn–Tucker or Karush-Kuhn-Tucker (KKT) conditions.

**Theorem:** Suppose \( x^* \) is a local solution of the problem (NLP) that satisfies the (LICQ). Then there exist unique Lagrange multipliers \( \lambda_i^*, i \in I \), and \( \lambda_j^*, j \in \mathcal{E} \), such that the following conditions are satisfied.
\[ \nabla f(x^*) - \sum_{i \in I} \nu_i^* \nabla g_i(x^*) - \sum_{j \in E} \lambda_j^* \nabla h_j(x^*) = 0, \]

(3)

\[ g_i(x^*) \geq 0, \text{ for all } i \in I, \]

(4)

\[ h_j(x^*) = 0, \text{ for all } j \in E, \]

(5)

\[ \nu_i^* g_i(x^*) = 0, \text{ for all } i \in I, \]

(6)

\[ \nu_i^* \geq 0, \text{ for all } i \in I. \]

(7)

Again we may ask when we can be assured that a solution to the KKT conditions is actually a solution to the nonlinear optimization problem (NLP). If the feasible region \( \mathcal{G} \) is a convex set (see Simon and Blume, 1994), and the objective function \( f \) is convex on \( \mathcal{G} \), then the problem (NLP) is called a convex programming problem, and any local solution is also a (global) solution of (NLP). For example, if the functions \( h_j, j \in E \), are all linear and the functions \( -g_i, i \in I \), are all convex, then \( \mathcal{G} \) is a convex set. In this case, if \( f \) is convex, too, indeed any solution to the KKT conditions is a solution to (NLP).

Many of the most popular numerical methods for solving nonlinear constrained optimization problems take advantage of the KKT conditions in one form or another. First, however, we describe the basic version of the simplex method for linear programming which does not rely on first-order conditions.

41 The simplex method
When the objective function \( f \) and the constraint functions \( g_i, i \in I \), and \( h_j, j \in E \), are all linear functions in the variables \( x \in \mathbb{R}^n \), then the constrained optimization problem is a linear programming problem, or 'linear program' for short. Linear programs have a standard form,

\[
\begin{align*}
\min_{x \in \mathbb{R}^n} & \quad c^T x \\
\text{s.t.} & \quad Ax = b \quad (LP) \\
& \quad x \geq 0
\end{align*}
\]

where \( c \in \mathbb{R}^n \), \( b \in \mathbb{R}^m \), and \( A \) is an \( m \times n \) matrix. We can easily transform any linear programming problem with arbitrary linear inequalities and unbounded variables into this standard form.

The development of the simplex method in the late 1940s (Dantzig, 1949) for solving linear programs is generally regarded as the beginning of the modern era of optimization (Nocedal and Wright, 2006). The simplex method is, however, not only of historical importance but to this day the perhaps most widely used tool in optimization outside economics.

Here we describe the fundamental idea of the basic version of the simplex method.

The system of equality constraints, \( Ax = b \), has \( m \) equations in the \( n \) decision variables. For the LP to be an interesting optimization problem it must be the case that \( m < n \). If \( m > n \) then either the linear system is overdetermined and so the feasible region is empty and the LP has no solution, or the system can be simplified so that the number of equations does not exceed the number of variables. The same conclusions apply for the case \( m = n \) if the matrix \( A \) is singular. If \( m = n \) and \( A \) has full rank, then the feasible region consists of at most one point and the LP is trivial. We can therefore assume that the system of equality constraints is underdetermined, that is, it has fewer equations than variables. Modern computer implementations of the simplex method start with a pre-processing phase, which transforms a given linear programming problem by removing redundancies and possibly even also eliminating some variables.

We can easily calculate some of the solutions to the system \( Ax = b \). If we choose \( m \) of the \( n \) variables and set the remaining \( n - m \) variables to zero, then the system reduces to a square system of \( m \) linear equations, which can be solved via Gaussian elimination. The chosen variables for which we solve the system are called 'basic variables', while those variables that we set to zero are called 'non-basic variables'. Solving the \( m \) linear equations in the \( m \) basic variables can lead to three possible outcomes. First, we may detect that the system has no solution. Second, a solution, called basic solution, may exist and it also satisfies the remaining constraints of the LP, namely the sign restrictions \( x \geq 0 \). In this case the solution is called a 'basic feasible solution'. Third, the solution to the linear system may entail a negative value for at least one variable and thus violate the sign restriction. Such a solution is called 'basic infeasible'. Two basic solutions are called adjacent if their respective sets of basic variables have all but one element in common. The next theorem explains why the basic feasible solutions are of central importance to the linear program.

**Theorem:** If the problem \((LP)\) has a non-empty feasible region, then there is at least one basic feasible solution. If the problem \((LP)\) has an optimal solution then it has the following properties.

1. 1. At least one optimal solution is a basic feasible solution.
2. 2. If \((LP)\) has a unique solution, then this optimal solution is basic feasible.
3. 3. If a basic feasible solution \(x^*\) has an objective function value that is not larger than the objective function values at all its adjacent basic feasible solutions, then \(x^*\) is a solution of \((LP)\).
4. 4. If the feasible region is bounded and a basic feasible solution \(x^*\) has an objective function value that is strictly less than the objective function value at all its adjacent basic feasible solutions, then \(x^*\) is the unique solution of \((LP)\). □

This theorem provides the foundation for the basic approach of the simplex method. According to the first statement of the theorem, if an optimal solution exists then there must be a basic feasible solution that is optimal. Thus, for solving the problem \((LP)\) it suffices to only examine basic feasible solutions. In principle we could now find a solution to the problem \((LP)\) by simply calculating all its basic solutions and then choosing a basic feasible solution with the smallest objective function value. We would not want to do this in practice, however, since the number of possible basic solutions is \( \binom{n}{m} \) and thus is huge for many applications. The simplex method prescribes a smart way of searching through the basic feasible solutions. Starting from some basic feasible solution, the simplex searches for another basic feasible solution with a lower objective function value.
standpoint it is much quicker to examine only adjacent basic feasible solutions. The information we have from having solved a linear system in, for example, the variables \( x_1, x_2, x_3 \), greatly simplifies finding a solution in the variables \( x_2, x_3, x_5 \). Therefore, the simplex considers only adjacent feasible solutions and chooses one of them by exchanging one basic variable against one non-basic variable and solving the resulting system of linear equations. On most (but not all) steps of the method the objective function value decreases. This process repeats itself until the method reaches a basic feasible solution without any adjacent basic feasible solutions having a lower objective function value. The third statement of the theorem (which is a special version of the convex programming property for linear programs) then ensures that the simplex method has found an optimal solution.

We illustrate the basic ideas underlying the simplex method in the following example.

**Example 5:** Consider the following linear programming problem.

\[
\begin{align*}
\text{max} & \quad 3x_1 + 4x_2 \\
\text{s.t.} & \quad x_1 + 2x_2 \leq 10 \\
& \quad x_1 + x_2 \leq 8 \\
& \quad x_2 \leq 4 \\
& \quad x_1 \geq 0 \\
& \quad x_2 \geq 0
\end{align*}
\]

Linear programming problems with two variables allow a beautiful graphical representation, which greatly helps us to gain some intuition for the simplex method. Figure 3 shows the feasible region of this linear programming problem.

This problem has three inequality constraints and two sign restrictions. The introduction of three so-called slack variables transforms the inequalities into equations. This introduction of new variables is just one of several simple transformations that allow us to rewrite any linear programming problem into a linear program in standard form; see Dantzig (1963) or many other linear programming books. Here we obtain the following linear program.

\[
\begin{align*}
\text{min} & \quad -3x_1 - 4x_2 \\
\text{s.t.} & \quad x_1 + 2x_2 + x_3 = 10 \\
& \quad x_1 + x_2 + x_4 = 8 \\
& \quad x_2 + x_5 = 4 \\
& \quad x_1, x_2, x_3, x_4, x_5 \geq 0
\end{align*}
\]

This linear program has \( n = 5 \) variables and \( m = 3 \) constraints.

Table 3 lists all \( \binom{5}{3} = 10 \) possible combinations of basic variables, the corresponding basic solution (if it exists), whether this solution is feasible, and the objective function values \( z = -3x_1 - 4x_2 \) for the basic feasible solutions. For example, the basic solution \((4, 4, -2, 0, 0)\) is obtained by setting \( x_4 = x_5 = 0 \) and then solving the remaining three equations:

\[
\begin{align*}
x_1 + 2x_2 + x_3 = 10, \\
x_1 + x_2 = 8, \\
x_2 = 4,
\end{align*}
\]
in the three basic variables $x_1, x_2, x_3$. This basic solution is infeasible since $x_3 = -2$ violates the non-negativity constraint on this variable. The basic variables $x_1, x_2, x_3$ lead to the three equations

$$x_1 + x_3 = 10, x_1 + x_4 = 8, 0 = 4,$$

which obviously have no solution. We can relate the nine basic solutions to points in the graph of the feasible region in Figure 3. The five feasible solutions are represented by disks while the four infeasible solutions are given by circles. We can easily identify the coordinates of the nine indicated points with the values of the original variables $x_1$ and $x_2$ in the nine basic solutions. But where are the later introduced slack variables? The values of these variables at a basic solution show us where the corresponding point in the figure is in relation to the three constraints. The basic solution $(4, 4, -2, 0, 0)$ is represented by the point $(4, 4)$ in the graph. This point lies on the lines representing the second and third constraints, since $x_4 = x_5 = 0$, and outside the first constraint, since $x_3 < 0$.

The simplex method quickly solves this problem. Starting from the basic feasible solution that corresponds to the origin in Figure 3 it moves through the basic feasible solutions (‘BFS’) listed in Table 4 to find the optimal basic feasible solution $(6, 2, 0, 0, 2)$. Figure 4 illustrates the steps of the simplex method. Starting from the point $(0,0)$ it moves upwards to the point $(0,4)$ with an objective function value of $z = -16$, then to $(2,4)$ with $z = -22$ and finally to $(6,2)$ with $z = -26$. The basic feasible solution corresponding to this last point has a strictly lower objective function value than both its adjacent basic feasible solutions at $(2,4)$ and $(8,0)$ and hence it must be the unique optimal solution. In Figure 4 only the visited points are indicated by disks and the iso-objective function lines for the values $-z$ of the original objective function (from the maximization problem) at these points. □

Figure 3

Feasible region of the (LP)
Figure 4
Solving the (LP)
We have conveyed only the basic principle of the simplex method for solving linear programming problems. Of course, an efficient and robust implementation of the simplex algorithm must address many technical details; see Fletcher (1987) or once again Nocedal and Wright (2006). The classical reference for the theory of the simplex method is the book by Dantzig (1963).

The simplex method is highly efficient on virtually all practical problems, but there do exist pathological problems on which it shows very poor performance. In these worst-case problems the running time of the simplex method grows exponentially in the dimension of the problems. (In a nutshell, the method visits far too many basic feasible solutions until it finds the optimal one.) Therefore, the simplex method is of exponential complexity. Although these examples are irrelevant for practical applications, they generated interest in the development of different algorithms that would show better worst-case running times, in particular, that would have running times that grow only polynomially in the size of the problems. The first linear programming algorithm with polynomial complexity was the ellipsoid method of Khachiyan (1979). Although this method has polynomial complexity it is useless for actual computations, and apparently there has never been a serious practical implementation. The projective algorithm of Karmarkar (1984) started what is nowadays called the ‘interior-point revolution’. This algorithm both has polynomial complexity and is of practical use, although the initial claims about its supposedly stellar practical performance were shown to be outrageous. The projective algorithm has long been superseded by more efficient methods, and the field of interior-point methods remains an active area of research to this day.

4.2 The idea of interior-point methods
Primal-dual methods are an important subclass of interior-point methods for solving constrained optimization problems. Here we give a basic outline of such a method for solving linear programs. The Karush–Kuhn–Tucker conditions for a linear programming problem in standard form are as follows.

\[ \mathbf{A}^T \mathbf{\lambda} + \mathbf{s} = \mathbf{c} \]  
(8)

\[ \mathbf{A} \mathbf{x} = \mathbf{b} \]  
(9)

\[ x_i s_i = 0, \quad i = 1, 2, \ldots, n \]  
(10)

\[ \mathbf{x} \succeq \mathbf{0} \]  
(11)

\[ \mathbf{s} \succeq \mathbf{0} \]  
(12)

These first-order conditions characterize both the optimal solution of the given linear program and of its dual. (See Dantzig, 1963, or any book on linear programming for the definition of the dual of a linear program.) That fact motivates the name ‘primal-dual’ method.

Interior-point methods (approximately) solve a sequence of perturbed problems. Consider the following perturbation of the first-order conditions.

\[ \mathbf{A}^T \mathbf{\lambda} + \mathbf{s} = \mathbf{c} \]  
(13)
Observe that the complementarity condition (10) has been replaced by the equations (15) for some positive scalar $\mu > 0$. Assuming that a solution $(x^{(0)}, \lambda^{(0)}, s^{(0)})$ to this system is given for some initial value of $\mu^{(0)} > 0$, interior-point methods decrease the parameter $\mu$ and thereby generate a sequence of points $(x^{(k)}, \lambda^{(k)}, s^{(k)})$ that satisfy the non-negativity constraints on the variables strictly, $x^{(k)} > 0$ and $s^{(k)} > 0$. This property led to the name ‘interior-point’ method. In the limit, as $\mu$ is decreased to zero, a point satisfying the original first-order conditions is reached. The set of solutions to the perturbed system, \[ C = \{ x(\mu), \lambda(\mu), s(\mu) | \mu > 0 \} \]
is called the central path.

The method is rather intuitive at this point. Given an iterate $(x^{(k)}, \lambda^{(k)}, s^{(k)})$ for some parameter value $\mu^{(k)}$ decrease the parameter to $\mu^{(k+1)} < \mu^{(k)}$ and determine the next iterate $(x^{(k+1)}, \lambda^{(k+1)}, s^{(k+1)})$. Implementing this method requires handling of many details. For example, it is often difficult to find a feasible starting point $(x^{(0)}, \lambda^{(0)}, s^{(0)})$ of the perturbed system. The most important step in the method is to solve the system (13)–(15) in each iteration (while maintaining the inequalities (16, 17)). Observe that this system consists of $2n$
+m linear and bilinear equations in as many variables. We can apply a nonlinear equations solver to this model. A popular approach is to use Newton’s method for solving nonlinear systems of equations; see Judd (1998) or Miranda and Fackler (2002). The difficulty is to maintain the strict non-negativity constraints on the variables \( x^{(k+1)} \) and \( s^{(k+1)} \). An alternative approach for solving the parameterized system of equations is the application of path-following methods; see Nocedal and Wright (2006). Intuitively we can think of interior-point methods to be closely related to homotopy continuation methods for solving nonlinear systems of equations; see Allgower and Georg (1979).

**Example 6:** We revisit the linear program from Example 5. The perturbed first-order conditions (13)–(17) for this (LP) are as follows.

\[
\begin{align*}
\gamma_1 + \gamma_2 + s_1 + 3 &= 0 \\
2 \gamma_1 + \gamma_2 + \gamma_3 + s_2 + 4 &= 0 \\
\gamma_1 + s_3 &= 0 \\
\gamma_2 + s_4 &= 0 \\
\gamma_3 + s_5 &= 0 \\
x_1 + 2x_2 + x_3 - 10 &= 0 \\
x_1 + x_2 + x_4 - 8 &= 0 \\
x_2 + x_5 - 4 &= 0 \\
x_i \cdot s_i &= \mu, \quad i = 1, 2, \ldots, n \\
x_1, x_2, \ldots, x_5 &> 0 \\
s_1, s_2, \ldots, s_5 &> 0
\end{align*}
\]

Table 5 displays the values for the variables \( x_1, x_2, \ldots, x_5 \) at some points on the central path for small values of \( \mu \). We observe how the central path moves through the interior of the feasible region, see Figure 3, and converges to the optimal solution as \( \mu \to 0 \).

\[
\begin{array}{cccccc}
\mu & x_1(\mu) & x_2(\mu) & x_3(\mu) & x_4(\mu) & x_5(\mu) \\
1 & 5.9775 & 1.5451 & 0.9323 & 0.4774 & 2.4549 \\
0.5 & 6.0305 & 1.7311 & 0.5073 & 0.2384 & 2.2689 \\
0.1 & 6.0029 & 1.9478 & 0.1014 & 0.0492 & 2.0522 \\
0.01 & 6.0000 & 1.9950 & 0.0100 & 0.0050 & 2.0050 \\
0 & 6 & 2 & 0 & 0 & 2
\end{array}
\]

By now the conceptual differences between the simplex method and interior-point methods are transparent. In geometric terms, the simplex method moves on specific points around the boundary of the feasible region until it finds a corner point corresponding to an optimal basic feasible solution. Interior-point methods move through the interior (or some methods even through the exterior) of the feasible region but they do not move within the boundary. Instead they approach the boundary only in the limit. In computational terms, the typical iteration of an interior-point method is relatively expensive to compute but can make significant progress towards the solution. Conversely, an iteration of the simplex method is relatively inexpensive but the method often requires a larger number of iterations.

Obviously the question arises of which of these two basic approaches is better for solving linear programs in practice. The answer depends very much on the nature of the problem. Currently the best available computer programs are efficient implementations of the dual simplex method (a special variant of the described standard simplex method) and primal–dual interior-point methods. Simplex method computer programs are usually faster on problems of small or medium size (say, of fewer than a million variables and constraints) while interior-point methods tend to do better on many but certainly not all large problems. If the user has significant prior information about the optimal solution, such as a good initial guess for an optimal basic feasible solution, then the simplex method is often much faster. The reason for this is that the simplex method is much easier to ‘warm-start’ than interior-point methods. In summary, interior-point methods and the simplex method are both important and useful algorithms for solving linear programs in practice.
Before we turn to interior-point methods for nonlinear optimization problems, we outline the basic concepts of another class of optimization algorithms. Penalty methods are quite intuitive and some of their ideas are relevant for interior-point methods but they are also of interest on their own.

### 4.3 Penalty methods

The basic idea of penalty methods is to replace the constrained optimization problem (NLP) by an unconstrained optimization problem and to solve the new problem instead. The objective function for the new unconstrained problem is the original objective plus a new term for each constraint. The new term is zero when the original constraint is satisfied but is positive if the original constraint is violated. The simplest and perhaps most intuitive penalty function is the quadratic penalty function.

To start we consider a nonlinear optimization problem with only equality but no inequality constraints,

\[
\begin{align*}
\min_{x \in \mathbb{R}^n} f(x) \\
\text{s.t. } h_j(x) = 0 & \quad j \in E.
\end{align*}
\]

For such a problem we can define a penalty function

\[
Q(x; \mu) = f(x) + \mu \left( \sum_{j \in E} h_j^2(x) \right)
\]

with a penalty parameter \( \mu > 0 \). The idea of the penalty function method is to minimize the function \( Q \) for increasing values of \( \mu \). Observe that the function \( Q \) inherits its differentiable properties from the functions \( f \) and \( h_j, j \in E \), of the original problem, and so we can use unconstrained optimization methods for minimizing \( Q(x; \mu) \). In addition, as we generate a sequence \( \mu^{(k)}, k=0,1,2,\ldots \), we can use the previously calculated minimizer \( x^{(k)}(\mu^{(k)}) \) as initial guesses for the problem with \( \mu^{(k+1)} \). This intuitive approach has a strong theoretical foundation, as the following theorem reveals; see Nocedal and Wright (2006).

**Theorem:** Consider a sequence \( \{\mu^{(k)}\} \) of penalty parameters with \( \mu^{(k)} \to \infty \). Suppose that \( x^{(k)} \) is the exact global minimizer of \( Q(x; \mu) = f(x) + \mu \left( \sum_{j \in E} h_j^2(x) \right) \). Then every limit point \( x^* \) of the sequence \( \{x^{(k)}\} \) is a global solution of the (NLP).

Although this result is nice from a theoretical viewpoint, it does not directly apply to practical applications. Of course, we typically cannot determine the exact minimizer of the penalty function and have to account for errors in the numerical approximation. The discussion in Nocedal and Wright (2006) shows that things get more complicated in practice once we allow for approximation errors. In addition, the penalty function may have many other stationary points that are not global or even local minimizers. The penalty function may even be unbounded if the penalty parameter \( \mu \) is too small. At the other extreme, for very large values of \( \mu \), the unconstrained minimization problem becomes more difficult, and the Hessian of \( Q \) gets ill-conditioned. All kinds of numerical problems arise that need to be carefully addressed in robust computer implementations of the quadratic penalty method; see Nocedal and Wright (2006).

For the general problem (NLP) with inequality and equality constraints we can define the penalty function as

\[
Q(x; \mu) = f(x) + \mu \left( \sum_{i \in I} (\max(-g_i(x), 0))^2 + \sum_{j \in E} h_j^2(x) \right)
\]

http://www.dictionaryofeconomics.com.proxy.library.csi.cuny.edu/article?id=pde2008_N_0000148&goto=B&result_number=1232
Now, however, things get more complicated since $Q$ will typically not be twice differentiable. As a result the new unconstrained problem becomes more difficult to solve.

In addition to the quadratic penalty method several other such approaches exist and are used in practice. Nocedal and Wright (2006) describe non-differentiable penalty functions and the augmented Lagrangian method. Here we finish our discussion with an illustration of the quadratic approach.

**Example 7:** Consider a simple example of the classical portfolio optimization problem (Markowitz, 1952). An investor wants to allocate her entire wealth across three securities with respective expected returns of 4 per cent, 8 per cent and 12 per cent. If she invests the respective portions $x_1, x_2, x_3$ in the three assets, then the variance of such a portfolio is $x_1^2 + 5x_2^2 + 3x_2x_3 + 10x_3^2$. The investors wants to minimize this variance under the condition that the expected return of her portfolio is at least 9 per cent. To simplify this illustration of the quadratic penalty method we exploit the fact that at the optimal solution the lower bound on the expected return is binding and thus write the investor's portfolio allocation problem as a nonlinear optimization problem with only equality constraints.

\[
\begin{align*}
\min_{x_1, x_2, x_3} & \quad x_1^2 + 5x_2^2 + 3x_2x_3 + 10x_3^2 \\
\text{s.t.} & \quad x_1 + x_2 + x_3 - 1 = 0 \\
& \quad 4x_1 + 8x_2 + 12x_3 - 9 = 0
\end{align*}
\]

The quadratic penalty function for the investor's portfolio optimization problem is

\[Q(x; \mu) = x_1^2 + 5x_2^2 + 3x_2x_3 + 10x_3^2 + \mu((x_1 + x_2 + x_3 - 1)^2 + (4x_1 + 8x_2 + 12x_3 - 9)^2).\]

We can easily solve the unconstrained problem with the basic Newton method as described in Section 3.1.2. Table 6 shows the solution to the unconstrained minimization of the penalty function for increasing values of $\mu$.

<table>

</table>

Observe that the nonlinear optimization problem in this example has a quadratic objective function and linear constraints. Such optimization problems constitute a special and important subclass of problems called quadratic programs. Their special properties give rise to efficient solution methods, and we would not want to solve large quadratic programs with a penalty method. Nocedal and Wright (2006) present several algorithms for quadratic programming. Since solving quadratic programs is comparatively easy, an integral part of some algorithms for more general nonlinear optimization problems, such as the sequential quadratic programming methods, is to repeatedly solve quadratic programs that are derived as approximations for the more general problem.

### 4.4 The logarithmic barrier method
Logarithmic barrier methods are a particular type of interior-point methods for the solution of nonlinear optimization problems. We illustrate the basic idea of these methods for an inequality-constrained minimization problem.

\[
\min_{x \in \mathbb{R}^n} f(x) \\
\text{s.t.} \quad g_i(x) \geq 0 \quad i \in I.
\]

We can combine the objective function and the constraints and define a penalty function for this optimization problem by

\[
P(x, \mu) = f(x) - \mu \sum_{i \in I} \ln g_i(x),
\]

where \( \mu > 0 \) is called the barrier parameter and the expression \( \sum_{i \in I} \ln g_i(x) \) is called a logarithmic barrier function. Each logarithmic term \( \ln g_i(x) \) tends to infinity as \( x \) approaches the boundary given by \( g_i(x) \approx 0 \) from the interior of the feasible region. This effect of the logarithmic terms will decrease as the barrier parameter \( \mu \) becomes smaller. The idea of the logarithmic barrier method is now to let the parameter \( \mu \) converge to zero. Under some conditions the optimal solution \( x^*(\mu) \) of the unconstrained optimization problem \( \min_{x \in \mathbb{R}^n} P(x, \mu) \) converges to the optimal solution of the original constrained optimization problem as \( \mu \) tends to zero. Note that the logarithm ensures that \( g_i(x^*(\mu)) > 0 \) for all \( \mu > 0 \), that is, the solution to the unconstrained minimization problem is in the strict interior of the original constraints. This property represents a crucial distinction between this variant of an interior-point method and an active-set method such as the simplex method, which always tracks the set of binding constraints at a given iterate. Observe that the first-order conditions for the penalty function problem are given by

\[
\nabla_x P(x, \mu) = \nabla f(x) - \sum_{i \in I} \frac{\nu}{g_i(x)} \nabla g_i(x) = 0.
\]

Now define for all \( i \in I \)

\[
\nu_i(\mu) = \frac{\mu}{g_i(x)}.
\]

Note that since \( \mu > 0 \) by definition we have that \( \nu_i(\mu) > 0 \). Thus, at a stationary point of the penalty function the following conditions hold.

\[
\nabla f(x) - \sum_{i \in I} \nu_i \nabla g_i(x) = 0 \text{ for all } i \in I; \nu_i = \mu \text{ for all } i \in I; > 0 \text{ for all } i \in I; > 0 \text{ for all } i \in I.
\]
This set of conditions is just the primal-dual interior-point conditions for our original problem. We see that conditions (13)–(17) are just the specialization of these conditions for the linear programming model. And just like in the illustration of the section 4.2 we are interested in taking the parameter $\mu$ to zero. Unfortunately we do not have the space here to properly state a formal theorem. To make a long story short, under a few additional technical conditions, most notably second-order conditions of optimality, the following statements hold for a local solution $x^*$ at which the KKT conditions are satisfied for some Lagrange multipliers $\nu$.

1. The local minimizer $x^*(\mu)$ of $P(x;\mu)$ in some neighbourhood of $x^*$ with $\lim_{\mu \downarrow 0} x^*(\mu) = x^*$ uniquely defines a continuously differentiable vector function $x^*(\mu)$ for all sufficiently small $\mu$.

2. The function $x^*(\mu)$ yields Lagrange multipliers $\nu(\mu)$ satisfying $\lim_{\mu \downarrow 0} \nu(\mu) = \nu^*$ where $\nu^* = g(x^*) = 0$.

An algorithm for solving the constrained problem is apparent now. For a given value of $\mu$ solve the unconstrained optimization problem with the objective function $P$. Then reduce $\mu$ stepwise to zero and follow the path of solutions $x^*(\mu)$. In the limit we can find the local solution $x^*$ of the original problem. While this approach works in principle, it entails various difficulties. For example, the Hessian matrix of $P$ becomes ill-conditioned for small values of $\mu$. For this and many other technical issues see Gould and Leyffer (2002).

Example 8: We revisit the consumer’s utility maximization problem from Example 3 once again. The consumer has a utility function $u(x_1, x_2, x_3)$ over three goods and faces the budget constraint $x_1 + x_2 + x_3 \leq 1$. We formulate the consumer’s problem as the constrained minimization problem

$$
\min_{x_1, x_2, x_3} \quad - \left( \sqrt{x_1} + 2\sqrt{x_2} + 3\sqrt{x_3} \right) \\
\text{s.t.} \quad 1 - x_1 - x_2 - x_3 \geq 0.
$$

The unconstrained function including a logarithmic barrier function for this minimization problem is

$$
P(x_1, x_2, x_3; \mu) = - \left( \sqrt{x_1} + 2\sqrt{x_2} + 3\sqrt{x_3} \right) - \mu \ln \left( 1 - x_1 - x_2 - x_3 \right).
$$

Table 7 displays solutions to this unconstrained problem for a few values of $\mu$. Note that as $\mu \to 0$ the optimal solution approaches the optimal solution of the original utility maximization problem.

In all our examples so far we ignored the sign restriction of the variables. We could do that since the utility functions exhibit an Inada property, that is, $\lim_{x_i \to 0} \frac{\partial u}{\partial x_i} = +\infty$, and so we hope that a solver starting at a strictly positive solution will only iterate through such solutions (although we have to be careful in practice). But, of course, we can easily take the non-negativity constraints explicitly into account and consider the following problem.
\[
\begin{align*}
\min_{x_1, x_2, x_3} & \quad -(\sqrt{x_1} + 2\sqrt{x_2} + 3\sqrt{x_3}) \\
\text{s.t.} & \quad 1 - x_1 - x_2 - x_3 \geq 0 \\
& \quad x_1 \geq 0 \\
& \quad x_2 \geq 0 \\
& \quad x_3 \geq 0 
\end{align*}
\]

Note that the condition (LICQ) is always satisfied since not all four constraints can be satisfied simultaneously. As long as three constraints are binding (LICQ) holds. The unconstrained function including a logarithmic barrier function for this minimization problem is

\[
P(x_1, x_2, x_3; \mu) = -(\sqrt{x_1} + 2\sqrt{x_2} + 3\sqrt{x_3}) - \mu(\ln(1 - x_1 - x_2 - x_3) + \ln(x_1) + \ln(x_2) + \ln(x_3)).
\]

Table 8 displays solutions to this unconstrained problem for a few values of \(\mu\). Again we observe that \(x^*(\mu) \to x^*\) as \(\mu \to 0.\)

Strangely enough, some of the modern and best interior-point algorithms are based on work predating Karmarkar (1984). For example, Frisch (1955) had already proposed an interior-point method based on logarithmic barrier functions for solving linear programs. A full early history with many results on barrier functions is Fiacco and McCormick (1968).

4.5 Sequential quadratic programming

Sequential quadratic programming (SQP) methods are among the most effective constrained optimization techniques, particularly when nonlinear constraints are present. These algorithms belong to the class of active-set methods that keep track of the binding constraints at each step. For a description of the basic ideas we consider a minimization problem with only equality constraints. (But these methods are much more widely applicable.)
numerical optimization methods in economics: The New Palgrave Dictionary of Economics

\[
\min_{x \in \mathbb{R}^n} f(x) \text{ s.t. } h_j(x) = 0, \quad j \in E. \quad (18)
\]

The KKT conditions for this problem are as follows.

\[
\nabla f(x) - \sum_{j \in E} \lambda_j \nabla h_j(x) = 0,
\]

\[
h_j(x) = 0, \quad j \in E. \quad (19)
\]

These conditions are a system of \(n+m\) nonlinear equations in the \(n\) variables \(x\) and the \(m\) Lagrange multipliers \(\lambda\). Newton’s method for solving nonlinear equations is now a natural approach for solving this system. The Jacobian of the left-hand side of the system (19)–(20) is given by

\[
\begin{bmatrix}
H(x) - \sum_{j \in E} \lambda_j \nabla h_j(x) - A(x)^T \\
A(x) \\
0
\end{bmatrix},
\]

where the matrix \(A(x)^T = [\nabla h_1(x), ..., \nabla h_M(x)]\) is the collection of the gradient vectors of all constraints \(h(x) = (h_j(x))_{j \in E = \{1, 2, ..., J\}}\). The matrix \(H_j(x)\) denotes the Hessian matrix of the constraint function \(h_j\) at the point \(x\). For a given point \((x^{(k)}, \lambda^{(k)})\) the Newton step is then determined by the linear system

\[
\begin{bmatrix}
H(x^{(k)}) - \sum_{j \in E} \lambda_j^{(k)} \nabla h_j(x^{(k)}) - A(x^{(k)})^T \\
A(x^{(k)}) \\
0
\end{bmatrix}^{-1} \begin{bmatrix}
\nabla f(x^{(k)}) - \sum_{j \in E} \lambda_j^{(k)} \nabla h_j(x^{(k)}) \\
\nabla h(x^{(k)})
\end{bmatrix} = \begin{bmatrix}
0 \\
0 \\
h(x^{(k)})
\end{bmatrix}
\]
resulting in the new iterate \((x^{(k+1)}, \lambda^{(k+1)}) = (x^{(k)} + s_x^{(k)}, \lambda^{(k)} + s_x^{(k)})\). Note that this last system is equivalent to the following linear system.

\[
\begin{bmatrix}
H(x^{(k)}) - \sum_{j \in E} \lambda_j^{(k)} H_j(x^{(k)}) & \nabla f(x^{(k)})^T \\
A(x^{(k)}) & 0
\end{bmatrix}
\begin{bmatrix}
s_x^{(k)} \\
- \lambda^{(k+1)}
\end{bmatrix}
= - \begin{bmatrix}
\nabla f(x^{(k)}) \\
h(x^{(k)})
\end{bmatrix}
\tag{21}
\]

Now consider the following quadratic optimization problem (QP).

\[
\min_{s \in \mathbb{R}^n} \frac{1}{2} s^T \left( H(x) - \sum_{j \in E} \lambda_j H_j(x) \right) s + \nabla f(x)^T s \\
\text{s.t. } A(x)s + h(x) = 0
\]

The left-hand side of the constraints are a first-order (Taylor) approximation of the constraint function \(h\) of the original optimization problem. The objective function of (QP) is a second-order approximation of the difference \(f(x+s) - f(x)\). The KKT conditions for the problem (QP) are as follows.

\[
\begin{bmatrix}
H(x) - \sum_{j \in E} \lambda_j H_j(x) \\
\nabla f(x) - A^T(x)v
\end{bmatrix}
v = 0
\tag{22}
\]

\[
A(x)s + h(x) = 0
\tag{23}
\]

Observe that these KKT conditions at a point \((x^{(k)}, \lambda^{(k)})\) are equivalent to (21). Solving the first-order conditions of the original optimization problem with Newton’s method is, under some technical conditions, equivalent to solving the quadratic optimization problem (QP). A Newton step at a given point \((x^{(k)}, \lambda^{(k)})\) is the same as solving the (QP) at this point. The idea of SQP methods is now to repeatedly solve this quadratic problem to generate a sequence of iterates that converges to a local solution of the original problem. Various good methods for solving quadratic optimization problems exist and can be applied to the problem (QP). Moreover, when combined with line search or trust region methods the approach has useful global convergence properties. Gould and Leyffer (2002) and Nocedal and Wright (2006) discuss details of line search and trust region SQP methods.
5 Global Optimization

We emphasized repeatedly that most practical algorithms for solving nonlinear optimization problems search for a solution only to the (necessary) first-order conditions, that is, they search for a local solution. Unless we are solving a convex programming problem or an unconstrained minimization problem of a convex function, we often cannot be sure that a computed local solution is indeed an approximate solution to the problem at hand; recall Example 2. Only occasionally other additional knowledge, perhaps some particular property of an underlying economic model, may assure us that we found an optimal solution. Obviously it would be helpful to have methods for general non-convex problems that may not, or are at least less likely to, get stuck in only locally optimal solutions. Here we lay out two approaches for global optimization. We describe the basic ideas of some popular metaheuristics and, subsequently, the very promising area of research in polynomial optimization, which is likely going to produce powerful tools for economic problems.

5.1 Metaheuristics

Metaheuristics provide a general framework and basic guidelines for developing specific heuristics for solving optimization problems. While the underlying principles are very general, typically a method must be carefully tailored in order to obtain an effective algorithm for the special problem at hand. Most metaheuristics were originally developed for solving discrete optimization problems, such as integer or combinatorial problems. Their principal ideas can also be applied to come up with heuristics for continuous nonlinear optimization problems.

The central problem of most nonlinear optimization methods is the possibility of getting stuck at a locally optimal solution. Many methods allow only for iterative steps that lead to an improvement in the objective function value, but, for an exception, see the discussion on nonmonotone techniques in Conn, Gould and Toint (2000) and Nocedal and Wright (2006). Such methods cannot get away from a locally optimal solution. In order to escape from such a local solution we must allow our search procedure, at least sometimes, to move into a non-improving search directions; that is, temporarily the objective function value of the sequence of iterates may increase (in a minimization problem). Three metaheuristics that are supposed to escape local solution are tabu search, simulated annealing, and genetic algorithms. The latter two methods are examples of stochastic approaches for optimization. Here we give a description of the basic ideas underlying these three methods and refer to Brandimarte (2006), Judd (1998) and the citations in those books for details.

5.1.1 Tabu search

The choice of non-improving search directions must be carefully managed to avoid repeatedly returning to a previously found optimal solution. Such cycling may occur if, after a non-improving step away from a local solution, the algorithm takes an improving step and immediately returns to the previously found local solution. A tabu search procedure imposes at every iteration a list of search directions that the algorithm is not allowed to pursue. For example, if the method just took a step in the direction \( s(k) \) then it may not be allowed to examine a neighbourhood of search directions around \( -s(k) \) for the next few iterations. In order to avoid memory problems in practical implementations, the tabu list usually consists only of the most recent steps taken. Of course, many technical issues need to be addressed to obtain a robust and efficient algorithm. The treatment of these issues usually depends greatly on the specific problem.

5.1.2 Simulated annealing

Simulated annealing is another metaheuristic that helps an algorithm to escape from locally optimal solutions. Instead of choosing only iterates that decrease the objective function in a minimization problem, simulated annealing methods also accept with some probability new iterates that increase the objective. The probability of accepting an iterate \( x^{(k+1)} \) if \( f(x^{(k+1)}) > f(x^{(k)}) \) is

\[
\pi = \frac{f(x^{(k+1)}) - f(x^{(k)})}{\eta}
\]

with a parameter \( \eta > 0 \). Simulated annealing methods typically start out with a fairly large value for \( \eta \) and then decrease it to 0. Observe that for large values of \( \eta \) the heuristic is likely to accept non-decreasing iterates, and so it allows the method to explore the feasible region. As \( \eta \) decreases the probability of acceptance of non-decreasing iterates of a fixed size also decreases. In the limit \( \eta \to 0 \) the method allows only iterates that decrease the objective function value. The perhaps simplest rule for reducing \( \eta \) is to start from a high value \( \eta_0 \) and
then to set

\[ T_{j+1} = \alpha T_j \text{ for some } 0 < \alpha < 1. \]

The basic ideas of simulated annealing are derived from an analogy of minimization with the physical annealing process of slowly cooling metals in order to reach a strong low-energy solid state. This analogy motivates the particular probability function for accepting increasing iterates and explains why the parameter \( T \) is called the temperature of the process. The rule of decreasing \( T \) is analogously called the cooling schedule. The earliest applications of simulated annealing were combinatorial problems; see Kirkpatrick, Gelatt and Vecchi (1983) as well as Cerny (1985).

### 5.1.3 Genetic algorithms

Genetic algorithms are derived from the analogy of finding better and better solutions with the theory of biological evolution of selecting fitter and fitter members of a species. As a result the literature on genetic algorithms uses terminology from evolutionary biology. Iterates in tabu search and simulated annealing algorithms are a single point. Contrary to that, genetic algorithms work with a set (‘generation’) of several current points. A genetic algorithm constructs a sequence of such sets. In a given iteration the objective function is evaluated at the points in the set (‘fitness of a member’). The method then chooses elements of the set in a probabilistic fashion in order to build new elements for the next set. Usually the probability of an element being chosen is the higher the better its objective function value. Several ways to construct new elements exist. A standard operation is the so-called crossover. Given two elements (‘parents’) \( x^{(k)} \) and \( y^{(k)} \) in the set the crossover operation leads to

\[
x^{(k+1)} = \begin{bmatrix} x_1^{(k)} & \cdots & x_j^{(k)} & v_j+1^{(k)} & \cdots & v_n^{(k)} \end{bmatrix},
\]

\[
y^{(k+1)} = \begin{bmatrix} v_1^{(k)} & \cdots & v_j^{(k)} & x_j+1^{(k)} & \cdots & x_n^{(k)} \end{bmatrix},
\]

where the method chooses some arbitrary break point \( l \) in the \( n \)-dimensional vectors. The idea behind crossover is to preserve some parts of the original elements and at the same time generate quite arbitrarily new elements (‘children’) that are far away from the original ones, and thereby to escape local solution. Another type of operation aimed at achieving this goal is to randomly exchange an element in a member \( x^{(k)} \) by another value (‘mutation’). While these approaches have proven useful in combinatorial optimization, it is quite apparent that they may run into severe difficulties for constrained problems. Many technical details must, therefore, be resolved before these ideas yield a useful heuristic approach for solving an optimization problem.

The monograph by Holland (1975) popularized genetic algorithms. The basic ideas of computer simulations of evolution are much older. Any heuristic method derived from a metheuristic will always be an ad hoc approach to the problem at hand. Just like the standard methods of nonlinear optimization presented in this article, they are not guaranteed to find the solution of a problem. And, while such heuristics have proven useful in discrete optimization, they are generally regarded as inferior to the modern standard optimization techniques for continuous optimization. An economist’s first choice of a solution method for a continuous optimization problem, particularly when nonlinear constraints are present, should always be one of the standard methods.
5.2 Polynomial functions

A substantial number of prominent economic models involve only polynomial functions, equations or inequalities. Even problems that at first appear to be non-polynomial can sometimes be transformed into having only polynomial expression. For example, the first-order conditions for the standard log-utility maximization problem

\[ \max_{x \in \mathbb{R}^n} \sum_{i=1}^{n} \ln(p_i x_i) \quad \text{subject to} \quad \sum_{i=1}^{n} p_i (x_i - \omega_i) = 0 \]

for prices \( p_i \) and endowments \( \omega_i, i=1, \ldots, n \), can be written in polynomial form,

\[ 1 - \lambda p_i x_i = 0, \quad i \in \{1, \ldots, n\} \]

\[ \sum_{i=1}^{n} p_i (x_i - \omega_i) = 0, \]

where \( \lambda \) denotes the Lagrange multiplier. Polynomial functions and equations can be analysed using tools from computational algebraic geometry (Cox, Little and O'shea, 1997). Global optimization with polynomials is an active field of research in mathematics; see, for example Lasserre (2001), Parrilo and Sturmfels (2003), and the book by Sturmfels (2002) and the citations therein. It is possible (at least in theory) to compute all local minima of polynomial functions. Similarly, it is possible to compute all solutions to a polynomial system of equations. With further expected advances in the theory of polynomial optimization and ever increasing speed of modern computers, these tools will soon have an impact in economics. For first results see computation of general equilibria (new developments).

6 Popular optimization software in economics

This section covers software packages and modelling languages that are frequently used in economics to solve optimization problems. This list is by no means exhaustive, and many other software products for solving optimization problems exist.

Perhaps the most popular software for numerical work in economics is MATLAB (MATLAB is a registered trademark of The MathWorks, Inc.). Computational economics and finance textbooks such as Brandimarte (2006), Kendrick, Mercado and Amman (2006) and Miranda and Fackler (2002) use MATLAB to solve economic problems. Other popular packages include GAUSS (GAUSS is a registered trademark of Aptech Systems, Inc.) and Mathematica (Mathematica is a registered trademark of Wolfram Research, Inc.) All three languages offer solvers for nonlinear optimization problems, which are continuously enhanced to solve larger and more difficult problems. Here we just list a few features of these software packages.

MATLAB has an optimization toolbox containing routines for solving both unconstrained and constrained nonlinear optimization problems. Methods for unconstrained problems include quasi-Newton and trust region techniques. The solvers for constrained optimization include an SQP method. MATLAB also has specialized methods for nonlinear least
square problems; however, most of these solvers are considered to be of only mediocre quality. Much better solvers in MATLAB are available through the NAG toolbox (NAG is a registered trademark of The Numerical Algorithms Group, Inc.) The NAG Foundation Toolbox provides access to the large set of numerical routines contained in the Fortran-based NAG Foundation Library, which contains routines for constrained and unconstrained optimization.

The high-level matrix programming language GAUSS includes an applications module for constrained optimization that uses an SQP method in conjunction with several line search methods or a trust region method. GAUSS has some specialized modules for constrained maximum likelihood problems. For Mathematica there exists a global optimization package, which contains various functions for optimization. These functions are designed to search for global optima for problems with hundreds of variables. The monograph by Bhatti (2000) comes with an optimization toolbox for Mathematica that includes all the methods presented in this article.

These high-level languages are popular in economics because they are easy to learn and quickly facilitate solving problems of moderate size. For larger problems with thousands or even hundreds of thousands of variables, however, they are not reliable and certainly too slow. Economists interested in solving large problems need to use alternative software. An excellent alternative is the use of algebraic modelling languages.

The General Algebraic Modeling System (GAMS) is a high-level modelling language designed for mathematical programming and optimization; see Rosenthal (2006) for a user’s guide. GAMS consists of a language compiler and a family of integrated high-performance solvers. GAMS is tailored for complex, large-scale modelling applications, and allows the user to build large models. It has a long history of successful applications in economics, particularly in solving large-scale computable general equilibrium (CGE) models. AMPL (Fourer, Gay and Kernighan, 2003) is an algebraic modelling language for mathematical programming, which allows users to set up and solve a great variety of optimization problems. The user has access to many popular and sophisticated solvers.

An exciting environment for solving optimization problems is the Network-Enabled Optimization System (NEOS); see Czyzyk, Mesnierand and Moré (1998) and Ferris, Mesnier and Moré (2000). NEOS is an optimization site that allows users to submit optimization problems over the Internet. The user does not need to download any solver but can just send optimization problems to NEOS and choose from a list of solvers. NEOS has access to many of the most current and powerful optimization routines. NEOS returns a solution and some runtime statistics to the user. Unfortunately, NEOS has been largely ignored by many economists.

7 Mathematical programs with equilibrium constraints

Mathematical programs with equilibrium constraints (MPECs) are currently at the frontier of numerical analysis. Economic models that can be classified as ‘leader-follower’ games are examples of MPECs. Suppose that the economic variables can be partitioned into $x$, those chosen by the ‘leader’ (government, employer, market maker, mechanism designer, and so on), and $y$, those chosen by the ‘followers’ (taxpayers, employees, traders, and so on) or determined in equilibrium (such as price). Suppose that the leader’s payoff is $f(x, y)$ and that the equilibrium value $y$ given $x$ is represented by a combination of inequality conditions, $c(x, y) \geq 0$, and complementarity constraints, $0 \leq y \perp F(x, y) \geq 0$, where $0 \leq y \perp F(x, y) \geq 0$ if and only if $0 \leq y$, $F(x, y) \geq 0$, and $y^TF(x, y)=0$. Equality constraints can be added without difficulty. The constraints correspond to, for example, budget and incentive constraints, and the complementarity constraints model the optimality conditions of the followers including any Lagrange multipliers. Then the leader’s problem and the corresponding equilibrium are given by the solution to the MPEC

$$\max_{x,y} \quad f(x, y)$$

$$\text{s.t.} \quad c(x, y) \geq 0$$

$$0 \leq y \perp F(x, y) \geq 0.$$

MPECs present many mathematical challenges; the constraints are non-convex and reformulations as standard nonlinear optimization problems violate fundamental stability assumptions. Despite these facts, nonlinear optimization methods applied to such reformulations have been successful at solving some MPECs. For example, Chen et al. (2006) solve MPECs derived from some large-scale electricity market models. But they also show the limitations of the nonlinear optimization approach, and advocate the development of robust algorithms for solving MPECs that directly exploit the structure of the complementarity constraints. The development of such methods is under way. The ability to solve large and complicated MPECs will greatly enhance economic modelling in many areas and will likely make MPECs a key tool of computational economic analysis in the future.

Nurkse, Ragnar (1907–1959)

Kaushik Basu
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
balanced growth; development economics; full employment; international policy coordination; international trade; Nurkse, R.; poverty traps

Article

Nurkse was born on 5 October 1907 on an estate where his father was an overseer, near the village of Viru in Estonia. His father was Estonian and his mother of Swedish origin. Ragnar Nurkse was educated in Tallinn, Tartu, Edinburgh and Vienna. From 1934 to 1945 he worked as an economist with the League of Nations and from 1945 until his death he was a professor at Columbia University. He wrote on international currency questions, trade, vicious circles of poverty and on balanced growth. In 1959 he delivered the Wicksell Lectures in Stockholm. Exhausted by the lectures, he went to Geneva and while taking a stroll on Mont Pèlerin he collapsed and died of a heart attack or stroke on 6 May 1959. The Wicksell Lectures were published posthumously (Nurkse, 1961).

One of Nurkse's two most important books was International Currency Experience: Lessons of the Inter-War Period (1944). It was published by the League of Nations, and though it did not carry the name of any author, this was (excepting chapter 6) the work of Nurkse. From this and several other of his writings, what comes out most clearly is Nurkse's pragmatism. Though he was one of the originators of the doctrine of balanced growth, he never minimized the role of international trade. However, he believed that the scope for trade-based expansion for Third World countries was much less in the 20th century than it was in the 19th century. Balanced growth could supplement this and even enlarge the scope for trade. Balanced growth and international trade, Nurkse argued, ‘are really friends, not enemies’ (Haberler and Stern, 1961, p. 257).

Nurkse had a deep concern for full employment. He viewed exchange rate adjustments and trade restrictions as legitimate measures for preventing balance of payments difficulties from translating into unemployment and domestic instability. He stressed that trade restrictions ought to be used as temporary measures. With the emergence of Keynesian macroeconomics, Nurkse came to have faith in effective-demand management as a tool for maintaining employment in the face of trade adversities. This also led
him to argue for some international coordination of domestic policies. Nurkse's other important (and, in my opinion, more important) book was *Problems of Capital Formation in Underdeveloped Countries* (1953). Here he developed the important idea that though the producer of each commodity may find an expansion unprofitable because of limitations of the market, a coordinated expansion of all productive activities could be profitable for all producers. Hence, atomistic behaviour on the part of producers could trap an economy within its production possibility frontier. This idea had been discussed earlier – most notably by Rosenstein-Rodan (1943) and more distantly by Young (1928) – but Nurkse took it further. While this work has been the basis of several debates in development economics (for critiques and formalizations, see Flemming, 1955; Findlay, 1959), it has the scope for further research, especially in the light of recent advances in non-Walrasian equilibrium analysis (see Basu, 1984).

The lack of formalization in Nurkse's work led to much misunderstanding – handsomely contributed to by Nurkse himself – about the policy implications of the poverty-trap doctrine. Nurkse tried to clarify these in his Ankara lectures in 1957 and his posthumously published note in *Oxford Economic Papers* (1959), both reprinted in Haberler and Stern's (1961) collection. The potential of this branch of development economics remains large.

nutrition and development

Paul Glewwe
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The nutritional status of children and adults is primarily determined by consumption of foodstuffs that contain macronutrients and micronutrients and by the incidence of gastro-intestinal diseases. Insufficient nutrition among young children has particularly severe negative consequences. Factors that lead to better nourished children include better-educated mothers, higher household income, potable water and sanitary toilet facilities. The most effective nutrition programmes target children during their first two years of life; such programmes increase life cycle income by raising children's levels of education. Economists should focus their research efforts on empirical studies that use panel data and data from randomized trials.

Keywords

bargaining power; education; labour productivity; Malthus, T.; medical care; nutrition; panel data; random experiments; simultaneity bias

Article

Economists have studied human nutrition since Thomas Malthus published his Essay on the Principle of Population in 1798. His pessimistic predictions about economic growth and human welfare proved to be incorrect; in today's developed countries the primary nutrition problem for the majority of the population is obesity, not lack of food. Yet in low-income countries the nutritional status of both children and adults can have a substantial effect on the incomes of individuals and on the rate of economic growth. In addition, the nutritional status of poor children remains a policy concern in almost all developed countries. This article reviews recent research on the factors that affect the nutritional status of children and adults, and the causal impact of child and adult nutrition on income and on other economic outcomes. It focuses on developing countries, where nutritional problems are the most severe and thus their consequences are the largest. For recent studies of nutrition in developed countries, see Kenkel and...
Malnutrition can be defined as the lack of sufficient nutrients for human growth and/or for carrying out daily work and non-work activities. Nutrients can be classified into two broad groups: macronutrients, which are primarily calories and protein; and micronutrients, the vitamins and minerals that are essential for good health. Lack of macronutrients is often caused by insufficient consumption of staple foodstuffs, while lack of micronutrients often reflects an unbalanced diet. The most serious micronutrient deficiencies in developing countries are lack of iron, iodine, vitamin A and zinc. (See Behrman, Alderman and Hoddinott, 2004, and the references therein for further details.)

The nutritional status of children and adults in developing countries (and in developed countries) is primarily determined by consumption of foodstuffs that contain macronutrients and micronutrients and by the incidence of gastro-intestinal diseases that interfere with the body's ability to extract macronutrients and micronutrients from those foodstuffs. By far the most serious manifestation of such diseases is the incidence of diarrhoea among very young children. The consumption of foodstuffs is in turn determined by household income and food and non-food prices, as proposed by standard demand theory. Some countries have programmes that provide households with food rations or food coupons (stamps) that can be used to purchase food items, which effectively loosens households' budget constraints. The incidence of gastro-intestinal diseases is mainly due to three factors: exposure to infectious diseases, the health knowledge of both children and adults, and the availability (and prices) of medicines and medical care services. A final consideration is the allocation of foodstuffs and medical care within the household, which is likely to depend on the relative bargaining power of key household members; in particular, several studies have shown that children are better nourished in households in which their mothers have a relatively high level of bargaining power (see Strauss and Thomas, 1998, for references).

Many economists, nutritionists and other researchers have attempted to identify the most important causes of malnutrition among children in developing countries. This research is motivated in part by estimates indicating that about 30 per cent of the children in those countries are seriously underweight (de Onis et al., 2004) and about 1.7 million children die every year from malnutrition and diarrhoea (WHO, 2003). Careful empirical studies of children's nutritional status in developing countries have provided credible evidence that the following factors have strong causal effects: mother's education; mother's health knowledge; infant breastfeeding; household income; potable water; and modern toilet facilities. Several specific policy interventions have also been shown to have a strong positive impact on child nutrition: oral rehydration therapy (ORT) for children with diarrhoea; monitoring of child growth; programmes that provide health and nutrition information to mothers; and fortification of commonly purchased food items (such as salt and sugar) with selected micronutrients (see World Bank, 2004, and Filmer, 2003, for detailed references).

The factors that determine the nutritional status of adults in developing countries have received less attention from economists and other researchers, primarily because in almost all cases the impact of poor nutrition on adults is thought to be less harmful than the impact of poor nutrition on children. Higher incomes, higher education levels and availability of health care services all have positive impacts on...
adult health and nutrition. Yet these impacts are not necessarily very strong; for example, the income elasticity of calorie consumption is quite low (Strauss and Thomas, 1998), although it is somewhat higher for the poorest households. Similarly, Haddad et al. (2003) found that the income elasticity of the rate of child malnutrition is less than one in 11 of the 12 countries they analysed. While the results summarized in the previous two paragraphs are intuitively plausible, they can be challenged because formidable econometric problems confound attempts to estimate the determinants of the nutritional status of both children and adults. Several recent studies have carefully attempted to overcome problems of simultaneity bias (for example, food intakes, income and medical treatments are all jointly endogenous), but attenuation bias due to measurement error in the explanatory variables has received less attention. The most convincing studies are those based on either panel data or randomized experiments.

Impact of poor nutrition on socioeconomic outcomes

The impacts of poor nutritional status on important socioeconomic outcomes vary according to the age of the individual when he or she is malnourished. It is useful to consider separately the following three age ranges: from birth to about five years (before children are enrolled in primary school), from six years to the early teenage years (when most children are enrolled in school and not working), and from the late teenage years through retirement age (the working-age years).

Empirical evidence suggests that poor nutrition in the first few years of life can have substantial negative consequences for educational outcomes and, eventually, for adult income (see World Bank, 2004, and Glewwe, 2005, for recent reviews). For example, Glewwe, Jacoby and King (2001) show that children in the Philippines who were malnourished during the first two years of their lives start school at a relatively late age and learn less per year while in school. The precise mechanisms are not completely clear, but it is likely that inadequate nutrition during the first years of life affects the physical development of the brain in ways that cannot be easily reversed. For example, iodine deficiency impairs the development of the central nervous system. The reduction in skills obtained from schooling due to poor nutrition in the preschool years almost certainly has large negative impacts on children's incomes when they become adults, and back-of-an-envelope calculations suggest that the benefits (in terms of life cycle income) of programmes to reduce malnutrition among very young children are much higher than the costs (see Glewwe, Jacoby and King, 2001, for an example of such calculations).

Many nutrition programmes in both developed and developing countries are designed to provide nutritious breakfasts and lunches to children on the days they are in school. In developing countries, there is little research on the impact of these programmes on educational outcomes. Almost all of the existing literature suffers from serious estimation problems and/or small sample sizes (see Glewwe, 2005, for a detailed discussion). While it may seem obvious that providing breakfasts and/or lunches to students would increase their learning, parents may reduce the amount of food provided at home in response to provision of meals at school; surprisingly, Jacoby (2002) found no evidence that parents respond in this way. Perhaps the best evidence on the impact of the nutritional status of the learning of school age children is a recent randomized study of Kenyan pre-schools. Vermeersch and Kremer (2005) provide evidence of a positive impact of school feeding programme on learning, although only in schools with more experienced teachers. Further research is needed on the impact on education
outcomes of child nutrition during their years in school. It may be that improvements in schooling outcomes from school feeding programmes are primarily due to increases in daily attendance brought about by those programmes, as opposed to higher nutritional status among children who participate in those programmes.

Finally, many economists have examined the role of nutrition during adulthood on concurrent labour productivity and labour income. Robert Fogel has studied this phenomenon in the United States and Europe in the 18th and 19th centuries (see Fogel, 1999), but the historical data are too incomplete to resolve a host of econometric issues in a convincing way. Some economists have developed ‘efficiency wage’ models in which low nutrition among adults can lead to involuntary unemployment. Strauss and Thomas (1998) provide a recent review of the empirical evidence on the relationship between adult nutrition, labour productivity and income. There is strong evidence that, Ceteris paribus, better-nourished adults (as measured by body mass index) are more productive workers. (There is also evidence that taller workers are relatively more productive, but height is primarily determined by nutritional status during childhood.) Yet Swamy (1997) and others have presented strong evidence that the estimated magnitudes of the effect of current nutritional status on worker productivity are far too small to be a cause of unemployment in developing countries.

Much has been learned in recent years about the relationship between nutrition and economic and social outcomes in developing countries, but even more remains to be learned. The evidence to date suggests that the most effective, and most cost-effective, nutrition programmes are those that are targeted to children during their first two years of life, for whom the main benefits are a higher rate of survival into adulthood and an increase in life cycle income brought about by higher levels of education. The most convincing studies are based on either panel data or randomized trials, but such data are available for only a handful of countries. Indeed, the Cebu Longitudinal Health and Nutrition Survey, which covers only one region of the Philippines, is the data source for many of the most convincing studies based on panel data. While randomized trials, such as Gertler's (2004) assessment of the impact of Mexico's Progresa programme on children's nutritional status, can be a very effective method for assessing programme and policy impacts, one must wait many years before long-term impacts can be measured. Very little is known about the impact of poor nutrition among school-age children on academic performance and, ultimately, adult income, and the same is true of the impact of policies and programmes designed to improve the nutritional status of adults. A very recent policy option that deserves careful study is the development and provision of genetically modified foodstuffs that contain higher levels of essential nutrients. An example of this is ‘golden rice’ that has been fortified with vitamin A. To provide useful information for policymakers, economists' research efforts in the area of nutrition should not be devoted to developing theoretical models but instead should focus on empirical studies that make careful use of panel data and data from randomized trials. This will require new data collection efforts, but the cost of such data collection is very small compared with the potential benefits.

nutrition and public policy in advanced economies

Janet Currie
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

This article discusses the measurement of nutritional status of populations and examines two classes of tools that policymakers in advanced economies can use to improve nutrition: targeted food and nutrition programmes, and regulation of the food industry. It presents an overview of the economic rationale for providing nutrition programmes (rather than cash assistance), as well as an analysis of some of the difficulties of providing aid in kind – one of the chief difficulties is low take-up of programme benefits by eligible citizens. The overview of regulations suggests that measures aimed at improving nutrition information may be especially attractive.

Article

Measures of nutritional status such as height, body mass index and the prevalence of nutrient-deficiency diseases are now accepted indicators of well-being. Economic development changes nutritional threats to well-being as populations move from scarcity to abundance. Fogel (1994) links the decline of malnutrition to economic growth, and highlights improvements in nutrition as an engine of growth. Cutler, Glaeser and Shapiro (2003) highlight technological change as a factor in reducing the cost of the production and distribution of food: the average household in the United States spent one-third of its income on food in 1960, but spends less than half that amount on food today.

As a result, public policymakers now struggle against a rising tide of obesity and related diseases such as type 2 diabetes using policy tools that were formulated largely to combat the effects of scarcity. The incidence of type 2 diabetes has doubled since 1995 in the United States, where 30 per cent of adults...
over the age of 20 are obese. Even in countries like France, which historically had little obesity, rates are increasing rapidly (World Health Organization, 2005). Surprisingly, many people in the United States are both overweight and consuming diets that are deficient in fibre, calcium, potassium, magnesium and vitamin E. This juxtaposition suggests that an excess of calories and a deficit of nutrients may in fact be closely related and reflect poor food choices rather than food scarcity.

This article considers the difficulties involved in tracking the nutritional status of populations and examines two classes of tools that policymakers in advanced economies can use to improve nutrition: targeted food and nutrition programmes and regulation of the food industry.

Measuring nutrition

Tracking the nutritional status of a population over a long period of time is difficult. Much of Fogel's work relies on the records of army veterans, largely because the veterans represent a large group for whom anthropometric measures are available. Birth weight is also available in many populations over long periods of time (cf. Currie and Moretti, 2007).

Going beyond anthropometric measures is generally expensive. Data on food consumption is often collected using food diaries, in which subjects are asked to record everything that they ate (and the amount that they ate) over some specified period such as a day or a week. These entries must then be converted into data about the number of calories from various sources. Clearly, there is likely to be a great deal of measurement error in this type of data, so large sample sizes are needed to uncover any systematic relationships between food intakes and outcomes.

A few data sets such as the National Health and Nutrition Examination Survey (NHANES) in the United States collect information about the levels of specific nutrients using blood and urine tests as well as food diaries. This information is collected as part of a complete physical examination conducted in a mobile clinic. Each wave takes several years to collect, as the mobile examination units travel to interview sites around the country. The expense of collecting the data means that the survey is mounted approximately once a decade. The long intervals between surveys raise additional problems because best practices in terms of ways to measure nutritional status often change between the surveys. Hence, while one can use the NHANES to track changes in body mass index over time, it is difficult to use these data to examine changes in the prevalence of specific nutritional deficiencies.

A fourth source of information about nutrition comes from health surveillance data. Doctors are often required to report the prevalence of specific conditions in their practices to central health agencies. These central agencies in turn can determine how many cases of something like iron deficiency anemia occur in a given population. One suspects that such surveillance systems will tend to underestimate the extent of nutritional deficiencies to the extent that people go untreated, or doctors fail to meet reporting requirements.

Finally, developed countries often produce statistics about the number of people suffering from ‘hunger’. It is important to realize that in advanced economies hunger is a social construct that is not directly related to measures of actual nutritional deficiency. In 1968, a group of physicians issued ‘Hunger in America’, a landmark report documenting appalling levels of malnutrition among poor children. Outright malnutrition is now extremely rare in the developed world. In the United States, people are now classified as hungry if they respond affirmatively to a series of questions in the current population survey. These questions ask whether households are worried about having the money to pay
for food, whether there are times that households go without food because they lack money to pay for it, and whether specific household members go without food. These ‘food insecurity’ questions are inexpensive to ask and can be asked more frequently and consistently than the direct measures of nutritional status can be collected in more episodic surveys.

However, once poverty is controlled for, food insecurity is predictive of poorer nutritional outcomes among older household members, but not among children (Bhattacharya, Currie and Haider, 2004). To say that food insecurity is not a direct measure of nutritional deficiency does not mean that it is unimportant. Food insecurity has been linked to higher levels of hyperactivity, absenteeism, aggression and tardiness as well as impaired academic functioning among children, although these linkages may not be causal.

**Targeted food and nutrition programmes**

Most advanced economies prefer income support to targeted food and nutrition programmes as a way of improving the nutrition (and overall well-being) of their poorest citizens. In contrast, the United States has an array of food and nutrition programmes targeted to specific low-income groups. School meal (or milk) programmes are an exception, in that they are widespread in advanced economies. Apparently the paternalism involved in creating a feeding programme is acceptable when dealing with children, but not (in many countries) when dealing with adults.

Apart from paternalism, economists have developed an array of rationales for providing benefits (including food) in kind, rather than in cash. One common rationale for government intervention in kind is that malnourished citizens create negative externalities for other citizens, through the psychological distress of those who interact with them, burdens on social programmes and health care systems, or their own inability to work.

A second set of arguments has to do with informational asymmetries. Since the government cannot perfectly identify those who need help, it must create schemes that will encourage self-selection. Such schemes often involve penalizing recipients through stigma or through the imposition of non-trivial transactions costs (see Blackorby and Donaldson, 1988; Besley and Coate, 1991; 1995).

A final rationale is more dynamic: the government fears that cash aid will not be spent as intended, and that recipients will return again and again. The problem is that the government cannot credibly commit to cut off starving people, even if the needy person has squandered past aid (Bruce and Waldman, 1991).

These models shed some light on the question of why in-kind programmes are set up as they are, with often substantial barriers to entry and consequent lack of take-up by the neediest people (see Currie, 2006b, for a discussion of the take-up of these programmes, and of factors that affect it).

A complete survey of the literature assessing US in-kind food and nutrition programmes is beyond the scope of this article, but see Currie (2006a, ch. 3) for more details about the programmes discussed here and evidence regarding their effectiveness. These programmes take various forms and target various groups. The largest and most studied include the Food Stamp Program (FSP), the Supplemental Nutrition Program for Women, Infants, and Children (WIC) and the National School Lunch Program (NSLP). These three programmes have adopted very different approaches to improving nutrition in disadvantaged families.

The NSLP (and the smaller School Breakfast programme) provide free or reduced-price meals
conforming to certain nutritional guidelines directly to their target population. The programme is available in most US government-sponsored schools and serves approximately 27 million lunches every day at a cost of about six billion dollars annually. The FSP provides electronic debit cards that can be redeemed for food with few restrictions on the types of foods which can be purchased. The programme serves about 20 million households at a cost of roughly 19 billion dollars. WIC offers coupons that may be redeemed only for specific types of food (often specific brands), to women, infants, and children under five who are certified to be at nutritional risk. WIC also involves a significant nutrition education component, which is largely absent from the other two programmes. This programme serves about eight million people each month, at a cost of approximately four billion dollars.

WIC packages are tailored to the nutritional needs of each of the target groups. The programme has been credited with virtually eliminating iron deficiency anemia among infants and young children and with improving birth weight and birth outcomes among the most disadvantaged mothers in an extremely cost-effective manner. There is less research available about WIC's effects on young children. In the past, WIC promoted bottle over breast-feeding by giving mothers free infant formula. Ongoing strenuous efforts are being made to promote breast-feeding and give nursing mothers food packages of equal value to those received by mothers getting formula.

The near-unanimous consensus regarding the positive effects of WIC on infant outcomes has been disturbed in recent years by those who argue that there may be unobserved factors that are correlated both with positive infant health outcomes and with WIC participation. While this is true in theory, careful analyses of selection in the WIC programme suggest that it is the most disadvantaged eligible women who participate, and it is unlikely that they have other positive unobserved characteristics that are driving the findings – that is, selection is probably leading to underestimates of the effects of WIC. At some points WIC has also generated controversy by enrolling more infants than the government estimated to be eligible. A National Academy of Sciences report on the subject found, however, that the number of those eligible was underestimated, and that the programme fell a long way short of full take-up (National Research Council, 2003). The fact that many eligible people do not participate in food and nutrition programmes remains a far more significant problem than participation by ineligible people.

FSP benefits are available to all households with incomes less than 130 per cent of the poverty threshold. FSP benefits can be used to purchase virtually any foods at almost all grocery stores. Since the benefits are generally less than the household's food budget, economic theory suggests that the benefit should be treated in the same way as a cash transfer. But several food stamp ‘cash-out’ experiments in which treatment households were given cash instead of food stamps while control households continued to receive food stamps suggested that the cash-out reduced spending on food. However, Whitmore (2002) re-analysed data from one such experiment and found that only households whose benefits exceeded their food budgets initially reduced spending in response to the cash-out. Thus it appears that the FSP may in fact be no different from a cash transfer. It is thus worth asking whether the FSP plays any role other than serving as an indirect cash safety net that is available to the many US households that do not qualify for any other form of assistance. Given that virtually any type of food can be purchased, the FSP should not be expected to have much impact on the quality of the diet, other than via relaxation of the budget constraint. Evidence that people buy and sell stamps (often doing both within a month) further suggests that FSP benefits are treated like cash.

Studies of the FSP shed a good deal of light on the question of take-up and again suggest that lack of participation by eligible people is a greater problem than participation by those who are ineligible.
Enrolments in the FSP grew rapidly in the early 1990s following the expansion of the federal Medicaid programme. Households could sign up for Medicaid and the FSP at the same office, so households that were attracted by Medicaid also signed up for FSP. Conversely, the 1996 welfare reform in the United States was accompanied by a decline in FSP participation even among those who remained eligible. Those who lost eligibility for cash benefits were no longer automatically eligible for the FSP and the fact that people were now required to go through enrolment procedures for the FSP and to repeat those procedures every three to six months drove many eligible people away. These examples suggest that transactions costs are an important deterrent to enrolment in means-tested transfer programmes.

The NLSP operates in a way that is similar to school meal programmes in many other countries. In the United States the poorest children are eligible for free meals, while slightly better off children are eligible for reduced-price meals, and other children can purchase school meals at ‘full price’. The meals are subject to US government dietary guidelines, which were revised in 1994 to limit the amount of fat and sodium.

Evaluations suggest that the NLSP has successfully raised the consumption of important nutrients. At the same time, meals have been roundly criticized for being high in calories, fat and sodium. Still, the evidence suggests that many American children have extremely unhealthy diets which are improved somewhat through participation in the NLSP.

Like other food and nutrition programmes, the NLSP has been criticized for serving too many ineligible children. The US government conducted several studies of this issue, experimenting with different ways to tighten controls on eligibility. In every case, ‘reforms’ were more likely to discourage eligible children from applying than they were to reduce programme use by ineligible children (see Neuberger and Greenstein, 2003). As a result of these policy experiments, the US government adopted several measures designed to make it easier for poor families to document and maintain eligibility when these programmes were re-authorized in 2004.

**Regulation**

Traditionally, regulation of the food industry has aimed to ensure the safety of the food supply. However, regulation has been increasingly used as a tool to improve the quality of the diet. Governments in advanced economies have mandated the inclusion of important nutrients such as iodine in salt (which has eliminated goitre), vitamin D in milk (which has helped to eliminate rickets), and folic acid in flour (which has greatly reduced the incidence of neural tube birth defects). Increasingly, regulation is being targeted at the information available to consumers, through labelling and advertising.

There is a good deal of evidence that consumers respond to food labels. Ippolito and Mathios (1990) examine the effect of a US government decision to allow cereal makers to advertise the link between fibre and cancer reduction. The change led to increased advertisement of fibre content, as well as other content information, and to increases in the consumption of high-fibre cereals. Ippolito and Mathios (1995) found that consumption of fat had been declining secularly, but that it declined more rapidly after manufacturers were allowed to advertise health claims associated with low-fat products.

It is however, unclear whether food labels have allowed consumers to make food choices that are healthier overall. Marketing studies suggest that few consumers consult labels assiduously and that many are unaware of the nutritional contents of items in their food baskets. Moreover, food-away-from-
home constitutes a large and growing fraction of total consumption and is largely exempt from labelling regulations. Low socio-economic status households have higher propensities to suffer from nutrition related disorders and are also least likely to use labels. However, some labelling requirements have encouraged manufacturers to reformulate their products in ways that will benefit all consumers, whether or not they read labels. For example, a recent US requirement that manufacturers label ‘transfats’ has led many producers of products such as crackers to substitute transfats with less harmful fats.

Governments have also acted directly in the limitation of the consumption of unhealthy foods. Many US school districts have removed ‘junk food’ and soft drinks from vending machines, and federal legislation that would require this of all school districts has been introduced. France and the United Kingdom have taken similar measures nationally and the UK is going further by banning burgers and processed sausages in schools and requiring two servings of fruit and/or vegetables per day. The UK also banned the use of celebrities to advertise junk food during children's television programming and the use of film tie-in advertisements in 2006 (Guardian, 2006). Several studies indicate that the majority of food advertising directed at children is for relatively unhealthy foods, and a recent report from the National Academy of Sciences (Institute of Medicine, 2006) concluded that children's preferences are significantly swayed by such advertising, and called for either voluntary or regulatory controls on the advertising of food to children.

Given our increasing knowledge about the links between poor food choices and future health, and the rising social costs of providing health care for nutrition-related conditions such as diabetes, additional future regulation is likely. Government intervention can be viewed as a way of reducing the externalities created by poor individual choices, which in turn may be encouraged by food producers who do not bear the social costs created by their products. Economists can contribute to this important public health debate by analysing the costs and benefits of regulation.

offer curve or reciprocal demand curve

Harvey Gram

S.; monotonicity; offer curve; reciprocal demand curve; recontracting; stability of equilibrium; substitution effects; tatonnement; trading curve; uniqueness of equilibrium; Walras's Law

Article
The offer curve made its first appearance in Alfred Marshall's *Pure Theory of Foreign Trade* (1879), a privately printed paper consisting of the second and third chapters (chosen by Henry Sidgwick) of a four chapter manuscript. Almost 50 years passed before Marshall's analysis became generally available under his own name as Appendix J to *Money, Credit and Commerce* (1923). Thus, it was mainly through the writings of Edgeworth (1894) and others who had read Marshall's original contribution (see Whitaker, 1975, p. 114n), that the offer curve came to be known.

Newman (1965, p. 104) notes the objections raised by Edgeworth (1924) and Wicksell (1925) to the name *offer curve* which was coined by W.E. Johnson (1913) and used by Bowley (1924). They were concerned that *offer curve* might suggest an asymmetry between supply and demand where, in fact, there was none. The alternative name, *reciprocal demand curve*, or *trading curve* (Newman, 1965, pp. 89 ff.), avoids any such suggestion.

Marshall commented that his 'International Trade curves … were set to a definite tune, that called by [John Stuart] Mill' (Pigou, 1925, p. 451). It was Mill who had written that

> supply and demand are but another expression for reciprocal demand; and to say that value will adjust itself so as to equalize demand with supply, is in fact to say that it will adjust itself so as to equalize demand on one side with the demand of the other. (Mill, 1852, p. 604)

Mill's purpose was to close Ricardo's trade model by finding prices such that 'demand will be exactly sufficient to carry off the supply' (Mill 1844, p. 238). Edgeworth, though giving high praise to Mill's mature statement of his equation of international demand, thought little of Mill's exact solution; and Marshall commented only 'that the special example which [Mill] has chosen does not illustrate the general problem in question' (Whitaker, 1975, p. 148). Chipman has argued, however, that Mill, in effect, solved a problem in what would now be called *homogeneous programming*. In claiming Mill's result to be a 'genuine and correct proof of the existence of equilibrium … [pre-dating the next such proof] by eighty years', Chipman remarks of Mill's law of international value, or *reciprocal demand*, that in 'its astonishing simplicity, it must stand as one of the great achievements of the human intellect' (Chipman, 1965, Part 1, pp. 491 and 486, respectively).

Modern uses of the offer curve in trade theory and other areas (see Cass, Okuno and Zilcha, 1980; Cass, 1980; Grandmont, 1985) have a greater affinity with Mill's analysis of a general equilibrium of supply and demand than with Marshall's original argument. That argument had three parts. The first is directly relevant to modern theory and concerns what would now be called the *income and substitution effects* of relative price changes. The second part deals with *increasing returns in production*, a phenomenon whose formulation and implications for traditional theory remain controversial. And finally, there is the problem of the *adjustment mechanism*, a part of Marshall's theory which, though highly regarded (Whitaker, 1975, p. 115; Kemp, 1964, p. 60), has been almost completely eclipsed by a Walrasian inspired 'stability' analysis. What follows is accordingly divided into three sections,
following a brief discussion of the formal basis for the offer curve as it exists in modern theory.

**General equilibrium**

The traditional offer curve arises in the context of a two-country general equilibrium model. Each country has an endowment of resources and a technology for transforming the associated factor service flows into flows of output of two tradable commodities. Resources are owned by the country's consumers, each of whom has a preference ordering which is continuous, convex, and monotonic. Under constant or decreasing returns to scale, resources and technology generate a *convex* production possibilities set (although some degree of increasing returns to scale is not inconsistent with convexity). The assumptions on preferences guarantee that the set of points ranked 'at least as good as' any given point is also *convex*, its boundary defining an indifference curve. If consumers have identical preferences and factor endowments, community indifference curves are simply radial expansions of individual indifference curves (cf. Chipman, 1965, part 2, pp. 690–8).

Geometrical derivations of the offer curve utilize techniques introduced by Leontief (1933), Lerner (1932; 1934), and Meade (1952). Implicit in the derivation is the solution to a pair of problems in constrained optimization. At given commodity prices, $P_j, j=1, 2$, outputs, $Y^k_j$, in each country $k=A, B$, are such that the value of production, $\Sigma j P_j Y^k_j$ is a maximum, subject to resource constraints which define the production possibilities sets. Simultaneously, for given factor supplies, $F^k_i, i=1, 2$ (assuming two factors for simplicity), rental rates or factor prices, $W^k_i$, are such that cost of production, $\Sigma i W^k_i K^k_i$, is a minimum, subject to price constraints which state that equilibrium profits are nowhere positive. Duality theory establishes an equality between maximum value and minimum cost. Because consumers own all resources, total cost is equal to total income, and so consumption choices, $X^k_j$ satisfy Walras's Law: $\Sigma j P_j X^k_j = \Sigma j P_j Y^k_j$.

Given $P_1$ and $P_2$, there may or may not exist a solution or set of solutions, $(Y^k_1 - X^k_1, Y^k_2 - X^k_2), k=A, B$. If $Y^k_1 - X^k_1$ is positive (negative), Walras's Law ensures that $Y^k_2 - X^k_2$ is negative (positive): country $k$ offers an excess supply of good 1 (good 2) in order to satisfy its excess demand for good 2 (good 1). If both prices are positive, $Y^k_1 - X^k_1=0$ implies $Y^k_2 - X^k_2=0$; while if one price is zero and satiation is ruled out, the corresponding excess demand will be unbounded. In Figure 1, the offer curves therefore occupy quadrants II and IV, passing through the origin and approaching the axes asymptotically.

Figure 1
At a given price ratio, measured by the (absolute) slope of a straight line through the origin, the solution for excess supply and excess demand in each country is unique in Figure 1 and therefore (trivially) convex-valued. The solutions are also upper semicontinuous (Chipman, 1965, part 2, p. 717). These two conditions are the basis for the idea of ‘connectedness’ or ‘continuity’ of the offer curve. They follow from the postulates on preferences: continuity, convexity, and monotonicity (where the last can be replaced by the assumption that outputs are strictly positive). The importance of the postulates turns on the fact that when the set of offers by each country, at a given price vector, is closed, convex, and upper semicontinuous, it can be shown that an equilibrium price vector exists. Mill found a unique equilibrium for Ricardo’s trade model by assuming (implicitly) unitary price and income elasticities of demand for the two commodities in each country (Chipman, 1965, part 1, pp. 483–91). The offer curves in Figure 1 intersect three times, indicating three
isolated equilibrium price vectors, \( OE_1, OE_2, \) and \( OE_3 \). Perpendiculars from \( E_1, E_2, \) and \( E_3 \) to the axes mark off the matching reciprocal demands of each country.

Income and substitution effects

The shape of each curve in Figure 1 reflects the income and substitution effects of relative price changes. Consider country \( A \). When \( P_1/P_2 \) is zero output of good 1 is zero and demand is unbounded so that the offer curve shoots off to the right in quadrant IV. As \( P_1/P_2 \) increases, convexity of the production possibilities set ensures that \( Y_1^A \) increases and \( Y_2^A \) decreases (unless both remain constant at a vertex). Assuming hypothetically that country \( A \) is confined to a given, convex-to-the-origin community indifference curve, \( X_1^A \) decreases and \( X_2^A \) increases (unless both remain constant at a ‘corner’ of the curve). These two substitution effects, one in production and one in consumption, reduce excess demand for good 1 (and excess supply of good 2) in quadrant IV, while raising excess supply of good 1 (and excess demand for good 2) in quadrant II. Note, however, that excess supply of good 1 reaches a maximum at \( a \) in quadrant II, while the same is true for good 2 at \( a' \) in quadrant IV. The reason for this is the income effect of the relative price change. In quadrant IV, a higher \( P_1/P_2 \) reduces the real purchasing power of country \( A \) which is an importer of good 1. If both goods are normal, the reduction in \( X_1^A \) associated with substitution is reinforced while the increase in \( X_2^A \) is offset. In quadrant II, the reverse is true. Country \( A \), as an exporter of good 1, gains from an increase in the relative price of good 1. Now the income effect is pushing against the substitution effect in determining \( X_1^A \) and reinforcing it in determining \( X_2^A \). Along the offer curve between \( a \) and \( a' \) substitution effects in production and consumption dominate the income effect. Beyond those critical points, the income effect is dominant in the sense that the excess supply of a commodity is lower when its relative price is higher.

Marshall’s explanation of the critical point \( a \) is somewhat different. The independent variable in his analysis is the quantity of imports rather than the relative price ratio. In Marshall’s normal class, an increase in imports in the neighbourhood of the origin results in an increase in receipts and, for this reason, the volume of exports which can be produced at normal profits increases. Receipts from imports pay the cost of exports. The slope of the offer curve increases (in absolute value) from the origin to point \( a \) because demand for imports is elastic. Beyond point \( a \) import demand turns inelastic, receipts fall off, and so the volume of exports which can be produced at normal profits declines. Marshall referred to this situation as Class I.

A final aspect of the income effect of relative price changes concerns changes in the distribution of purchasing power among consumers within each country, a problem which can only be addressed if consumers have different resource endowments. Assume therefore that country \( A \) and country \( B \) in Figure 1 are, in fact, two groups of consumers within a single country. Aggregate excess demand for good 1 and excess supply of good 2 are positive for price vectors flatter than \( OE_1 \) and for vectors intermediate between \( OE_2 \) and \( OE_3 \), and negative for vectors intermediate between \( OE_1 \) and \( OE_2 \) and steeper than \( OE_3 \). An offer curve defined for the two groups of consumers would therefore pass through the origin three times, tying itself in a bow. Its slope at the origin has three isolated values given by the slopes of \( OE_1 \), \( OE_2 \), and \( OE_3 \) (cf. Johnson, 1959; 1960). A pair of such curves, constructed for two countries, each composed of two differentiated groups of consumers, would intersect at various points in quadrants II and IV. This indicates the possibility of trade pattern reversals as the relative price ratio takes on different equilibrium values.

The one proposition that Marshall insisted upon as ‘the only law to which the curves must conform under all circumstances’ is violated by offer curves which form loops through the origin. This was his Proposition VI to the effect that country \( A \)’s offer curve ‘cannot in any case be cut more than once by a horizontal line. Similarly [country \( B \)’s curve] cannot in any case be cut more than once by a vertical line’ (Whitaker, 1975, p. 140). Marshall’s argument, however, had nothing to do with the income redistribution effects which, upon aggregation of consumer groups (as above), countries (see Chipman, 1965, part 2, p. 217), or generations (see Cass, Okuno and Zilcha, 1980) pp. 25–6), can result in offer curves exhibiting the floral patterns first noted by Johnson (1959; 1960). Rather he was concerned with the problem of increasing returns.

Increasing returns

Marshall put increasing returns under the heading of ‘problems of Exceptional Class II’ (Whitaker, 1975, p. 144). Where an increase in the production of exports leads to the introduction of extensive economies, a reduction in the volume of exports to a level previously experienced would not require as large a volume of imports to cover their costs of production as had previously been the case (assuming implicitly an elastic demand for imports). Thus, a movement along the offer curve would simultaneously shift the curve towards the export axis. Moreover, ‘if time was allowed for the development of economies of production on a large scale, time ought to be allowed for the general increase of demand’ (Pigou, 1925, p. 49). In that event, a given volume of imports would yield higher receipts thereby shifting the offer curve away from the import axis.

Marshall’s long period offer curve does not show any maximum level of exports, as does every static curve constructed on the basis of given resources and technology. Moreover, the
slope of the long period curve can decrease (in absolute value) as a consequence of technological change. It was in this context that Marshall denied that any given volume of imports would cover the costs of more than one volume of exports. His Proposition VI claimed that economies of scale would never be sufficient to lower the total cost of a larger volume of exports below that of a smaller volume previously produced. Marshall had made the same assumption in the first edition of his Principles, but dropped it subsequently (Whitaker, 1975, p. 116).

Modern discussions of the offer curve in the presence of increasing returns are concerned with technological externalities rather than with irreversible economies of large-scale production. A firm's output may depend on the output of the industry to which it belongs. Output in one industry, or the level of employment of particular factors in that industry, may have external effects on the output of another industry. Theoretical questions then arise concerning the convexity of the production possibilities set, the relationship between opportunity cost and relative price, and whether or not production occurs at a limit point of the feasible set. What the models have in common with Marshall's discussion is that the associated offer curves are no longer convex-valued functions of the relative price ratio. Marshall indicated this by drawing offer curves with several inflexion points. In modern treatments of external economies in production, offer curves typically have the shape indicated in Figure 2. Curvature at the origin is opposite to that indicated in Figure 1, changing abruptly at points of complete specialization. (The latter may or may not correspond to the critical points in Figure 1 where excess supply reaches a maximum.)

Figure 2
The curves in Figure 2 have three intersections indicating three equilibrium trades. (These may be reduced to two by drawing curves which are mutually tangent at the origin indicating equal pre-trade price ratios which, in Figure 1, would be sufficient to rule out an equilibrium with positive trade.) There is nothing in principle to prevent all three points from falling along a single ray. The resulting indeterminacy in the volume and direction of trade is the main distinguishing feature of trade models with external economies in production. Chacholiades (1978, pp. 197–9) has considered the problem in some detail, arguing that, in general, a country benefits from specialization in the production of the commodity subject to external economies. If this is the same commodity in each country, then, depending on the pattern of demand, one country may lose from trade. This suggests an even sharper conflict of interest than is evident in Figure 1 where a country is clearly better off in that equilibrium in which its exports are smallest and its imports are largest.

Stability

Stability of equilibrium is defined in relationship to a process of adjustment which determines the movement of prices and/or quantities when the system is out of equilibrium. A distinction has been drawn between processes which focus on price changes and those which focus on quantity changes. A frequently considered case is that in which prices respond to differences between hypothetical supply and demand (those quantities which would prevail on each side of the market if the current price were an equilibrium price). Transactions, however, only take place in equilibrium. This is a recontracting process and its convergence to an equilibrium of supply and demand is often referred to as the Walrasian tâtonnement or ‘groping’ process. Walras, in fact, referred to tâtonnement in connection with the problem of bringing a set of interrelated markets into equilibrium sequentially, and, as such, it...
was problematical since ‘few prices will lie quiet at equilibrium while others are brought to heel, and the whole thing may turn out to be like the labour of Sisyphus’ (Newman, 1965, p. 103).

The offer curves in Figure 1 can be used to illustrate the stability of a recontracting process. Consider a price ratio, \( P_1/P_2 \), slightly greater than the (absolute) slope of \( OE_1 \). Hypothetical exports of good 1 by country \( A \) exceed hypothetical imports by country 2, while the opposite is true for good 2. If \( P_1 \) falls and \( P_2 \) rises in this situation, \( P_1/P_2 \) falls back towards \( OE_1 \). The opposite is true for price ratios slightly lower than the (absolute) slope of \( OE_1 \). Thus, \( E_1 \) is a stable point. Note that, as prices move, the four substitution effects (in production and consumption in both countries) contribute towards reducing the initial divergence between supply and demand for each good. The same is true of part of the income effect. As the price ratio falls towards \( OE_1 \), for example, country \( A \) is made worse off and country \( B \) is made better off. As importers, country \( A \) demands less of good 2 and country \( B \) demands more of good 1 (assuming that the goods are normal), and this reinforces the substitution effects. But, as exporters, country \( A \) demands less of good 1 while country \( B \) demands more of good 2, thereby exacerbating the initial excess supply (of good 1) and excess demand (for good 2). At stable points, such as \( E_1 \) and \( E_3 \), exporters’ income effects are not strong enough to swamp importer’s income effects plus all substitution effects. At \( E_2 \), however, a slight increase in the relative price of good 1 would be associated with a hypothetical excess demand for good 1 and excess supply of good 2. The recontracting hypothesis would therefore result in a further increase in \( P_1/P_2 \), reflecting the fact that the initial increase has generated exporters’ income effects which swamp all other income and substitution effects (cf. Caves and Jones, 1985, pp. 492–4).

A variation on the above analysis allows trade to take place out of equilibrium but assumes that demand for imports is always satisfied. A disequilibrium exchange ray, such as \( Oe \) in Figure 1, cuts the two offer curves in distinct points. Perpendiculars to the axes from these points indicate excess supply of good 1, which causes inventories to rise, and excess demand for good 2, which causes inventories to fall. If \( P_1 \) then falls and \( P_2 \) rises, \( P_1/P_2 \) once again falls back toward \( OE_1 \). During the process, however, country \( A \) must be selling assets to country \( B \) in order for the trade flow to be financed. If the consequence of this is to alter the position and shape of the offer curves, a more complete and undoubtedly more complex analysis of the convergence to equilibrium would be required (cf. Jones, 1961, p. 203). Marshall’s discussion of the adjustment mechanism is concerned neither with a recontracting process nor with inconsistent trades ‘financed’ by changes in inventories. In this theory, profits in export industries are abnormally high at points between a country’s offer curve and the axis measuring its imports. On the other side of the curve, profits in exports are abnormally low. Marshall’s adjustment mechanism is summed up as follows:

\[
\text{when the terms on which a country's foreign trade is conducted are such as to afford a rate of profits higher than the rate current in other industries, the competition of traders to obtain these higher profits will lead to an increase in the exportation of her wares: and vice versa when the rate of profits in the foreign trade [is] exceptionally low.} \quad (Whitaker, 1975, p. 151)
\]

This adjustment in the production of exports (imports and the domestic consumption of exports held constant) appears to have been meant by Marshall to reflect a concomitant change in the production of non-traded goods (Marshall, 1923, pp. 354–5n). Thus, at points off the offer curves

\[
\text{production is changing in both countries, [and so] the dimensions of the Edgeworth box must be changing, as are also the shapes of the offer curves. The extreme subtlety of the Marshallian conception becomes more apparent the further one probes into it.} \quad (Chipman, 1965, Part 2, p. 723)
\]

One can only conclude that efforts to formalize Marshall’s ‘dynamics’ (Samuelson, 1947, pp. 266–8; Kemp, 1964, pp. 66–9; Amano, 1968, pp. 326–39) are but valiant attempts to come to terms with an approach to equilibrium which itself moves in an unspecified manner as a consequence of not being attained initially.

**Conclusion**

Not surprisingly, that part of Marshall’s *Pure Theory of Foreign Trade* which is most evident in modern discussions of the offer curve concerns the income and substitution effects which are central to the theory of supply and demand equilibrium. His treatment of increasing returns and his discussion of the adjustment process raise dynamic considerations associated with changes in technology and with changes in the structure of productive capacity. It is just such changes which present the equilibrium theory of supply and demand with some of its greatest difficulties.

Ohlin was born on 23 April 1899 in Klippan, Sweden. He took a degree in mathematics, statistics and economics at the University of Lund in 1917, a degree in economics under Heckscher at the Stockholm School of Business Administration in 1919, an AM degree under Taussig and Williams at Harvard in 1923, and a Ph.D. degree under Cassel at the University of Stockholm in 1924. Ohlin taught at the University of Copenhagen (1925–30) and, as Heckscher's successor, at the Stockholm School of Business Administration (1930–65). He was a visiting professor at the University of California at Berkeley in 1937 and at Columbia and Oxford in 1947. For the League of Nations Ohlin prepared a report on the world depression in 1931 and for the Swedish government a report on unemployment in 1934. He was a member of the Swedish parliament (1938–70), a member of the Cabinet (1944–45), the leader of the Liberal Party (1944–67); he died on 3 August 1979 in Stockholm.

Trade theory

Ohlin is best known for, and received the 1977 Nobel Prize for, his modernization of the theory of international trade. The modernization was long overdue: discredited in general economic theory after 1870, the labour theory of value was still surviving in the province of international-trade theory half a
century later.

Ohlin's teacher at Stockholm was Gustav Cassel, and his point of departure was Cassel's (1918) version of a Walrasian general equilibrium of a closed economy with perfect mobility of goods and factors. Unlike Walras, Cassel assumed the factor endowments of all households to be fixed. Household income would then be the sum of the products of factor price and all factor endowments of that household. Like Walras, Cassel assumed the input–output coefficients of all goods to be fixed. The competitive price of a good would then be the sum of the products of factor price and all input–output coefficients of that good.

Facing such household income and such competitive goods prices, every household would reveal its preference. Goods–market equilibrium would require industry supply and such household demand to be equal for every good. Industry demand for a factor would be the sum of the products of such industry goods supplies and all input–output coefficients of that factor. Factor-market equilibrium would require household supply and such industry demand to be equal for every factor.

The ultimate determinants of all quantities and relative prices in such a general equilibrium were, first, factor endowments; second, technology in the form of the input–output coefficients; and, third, preferences. Inspired by his other teacher at Stockholm, Eli Filip Heckscher (1919), Ohlin (1924; 1933) set out to modify the Cassel model to fit interregional and international trade.

As his first modification Ohlin visualized an economy composed of regions within which factor mobility was perfect but between which it was imperfect or, as a first approximation, non-existent. In the absence of goods trade, isolation would be complete, and such regions would simply constitute a system of miniature Casselian closed economies. Between them relative prices could differ because factor endowments, technology, or preferences differed. As another first approximation, Ohlin assumed regions to differ solely in their factor endowments, not in their technology or preferences. Finally, Ohlin unfroze Cassel's fixed input–output coefficients, thus making room for factor substitution. With such assumptions he had the ingredients to what later became known as the 'strong' Heckscher–Ohlin theorem. In the simple case of two factors, two goods and two regions the theorem becomes very tractable. In isolation each region would have a relatively low-priced and a relatively high-priced good. Since nothing else than factor endowments differed between regions, the low-priced good would be low-priced because it required relatively much of that region's relatively abundant, hence low-priced, factor. That good will be a candidate for export once we remove isolation. The high-priced good would be high-priced because it required relatively much of that region's relatively scarce, hence high-priced, factor. That good will be a candidate for import once we remove isolation; but we are not removing it yet. As we know, under profit maximization, pure competition, and factor substitution the physical marginal productivity of either factor in terms of either good will equal the real price of that factor in terms of that good.

Now remove isolation and let goods be traded. Export would expand a region's demand for its abundant factor and import reduce the demand for its scarce factor. Thus trade would raise the price of the abundant factor, reduce the price of the scarce one, and encourage substitution between them: either good would use less abundant factor per unit of scarce factor than in isolation. The abundant factor would then have a higher physical marginal productivity and a higher real price in terms of either good than in isolation. Vice versa for the scarce factor. Does all this mean that trade would eventually equalize real factor prices in terms of either good between regions – although no factor ever crossed the border? Yes, in the absence of transportation costs and in the absence of specialization. One reason for specialization would be increasing returns to scale. Specialization would leave a region with an
unproduced good. Where nothing is produced, no factor can have a marginal productivity. In terms of
the unproduced good, then, physical marginal productivity could no longer equal real factor price, and
the theorem would fail. So it would in case of transportation costs or in case regions differed, not in
factor endowments but in technology or preferences. And so it might if there were more than two
factors, goods, or regions.

Few theorems have been as fruitful, that is, few inspired as much later work, theoretical and empirical,
as the Heckscher–Ohlin theorem. Neither Heckscher nor Ohlin applied present-day rigour. To
Heckscher factor-price equalization would be complete; to Ohlin – more aware of the many
qualifications – incomplete. The theorem was first taken up, baptized, and rigourized by Stolper and
Samuelson (1941), who examined a scarce factor's case for protectionism but found ‘the definiteness of
the Heckscher–Ohlin theorem [beginning] to fade’ with more than two factors. More groundwork was
done by Samuelson (1948; 1949). Using his domestic US input–output table with many goods but only
two factors, Leontief (1953; 1956) found the capital–labour ratio to be lower in US exports than in US
import-competing goods. If the Heckscher–Ohlin theorem were true, then, capital would have to be the
scarce and labour the abundant US factor. This Leontief paradox did not make the theorem go away but
stimulated new contributions. A good guide to them is the third part of Chipman's (1966) survey of the
theory of international trade.

Ohlin's second modification of Cassel saw international trade as a special case of interregional trade.
What was special about nations?
First, national differences in factor endowments, technology, and preferences might be rooted in
differences in climate, language, cultural, and legal institutions. Of international movements of factors,
labour as well as capital, and such obstacles to them Ohlin gave a full account. His account of
international capital movements found an early and specific expression (1929) in his discussion with
Keynes of the mechanism of the reparation payments imposed upon Germany by the Versailles Treaty.
Still influenced by Marshallian tradition, Keynes saw a drastic worsening of Germany's terms of trade as
a necessary condition for such payments. To Ohlin reparations were nothing but huge international
transfers of ‘buying power’. Against an uncomprehending 1929 Keynes, Ohlin advocated the view of a
1936 Keynes, that is, the income mechanism would do; no price mechanism was needed.
Second, nations were special in having their own currency and monetary authorities. In a two-country
world such separate currencies would add a new unknown, that is, the price of one currency in terms of
the other – the exchange rate. Fortunately there would also be a new equation, that is, the equilibrium
condition that in a pure-trade model the balance of trade would be zero or that in a trade cum lending
and borrowing model the balance of payments would be zero.

Macroeconomic theory

Less well known to the English-speaking world is Ohlin's macroeconomic theory: its most important
work (1934) was never fully translated. Here, Ohlin was inspired by Wicksell and Lindahl.
Wicksell (1893) had restated Böhm-Bawerk mathematically and (1898) wondered how a Böhm-Bawerk
‘natural’ rate of interest was related to the rate of interest observed in markets where the supply of
money met the demand for it. If such a ‘money’ rate of interest were lower than the natural rate of
interest, entrepreneurs would be induced – and the money supply correspondingly expanded – to pay a
higher money wage rate. Physically speaking, nothing would come of this, for when labour spent the higher money wage rate, prices would rise correspondingly and unexpectedly leave the real wage rate unchanged. There would be a cumulative process of inflation expected by nobody.

Wicksell's answer was made possible by a method fundamentally new in three respects. Wicksell's method was a macroeconomic, dynamic disequilibrium method based upon adaptive expectations whose disappointment constituted the motive force of the system. But Wicksell had applied his method to a model with price as the only variable. Using Wicksell's method and inspired by Lindahl's (1930) refinement of it, Ohlin (1933; 1934) added physical output as an additional variable. Two years ahead of Keynes, Ohlin used three Keynesian tools, that is, the propensity to consume, liquidity preference and the multiplier, and one non-Keynesian tool, that is, the accelerator. The four tools would interact as follows in Ohlin's feedback mechanism. Let consumption demand be stimulated. As a result physical output would rise, generating new income. The propensity to consume would link physical consumption to the level of physical output and thus establish a consumption feedback. The accelerator would link physical investment to the growth of physical output and thus establish an investment feedback. As did the Wicksellian one, Ohlin's two feedbacks unfolded in a cumulative process along a time axis as a succession of disequilibria: expectations and plans were for ever being revised in the light of new experience. By contrast, Keynes used only the consumption feedback and telescoped it into an instant static equilibrium along an output axis.

Ohlin's relation to Keynesian economics was discussed by Steiger (1976), Patinkin (1978), and Brems (1978). Forty-one years apart Ohlin expressed his own view on the matter in (1937) and (1978). Ohlin's (1934) analysis appeared in a report on unemployment requested by the Swedish government, and his policy conclusions were quite specific. In times of excess capacity the government should undertake investment projects – say highway construction or the electrification of state railroads – which would not compete with private investment and which should be allowed to generate fiscal deficits. Tax financing would reduce consumption and thus defeat the purpose of public works. Ohlin wrote the government budget constraint: deficits might be financed by expanding either the bond or the money supply. Sale of government bonds would depress bond prices and thus discourage private investment, again defeating the purpose of public works. That left central-bank discounting of treasury bills as the only way which would not deprive private investment of finance. Thus financed, public works would generate income. Such income generation would be magnified by the multiplier and the accelerator. Except for a nine-page algebraic two-country Cassel general equilibrium, banished to an appendix, Ohlin used neither algebra nor diagrams. But in all his work his style was accurate, cautious and lucid, often enlivened by relevant statistical and historical illustrations.

Oil price shocks are often followed by economic downturns. Both theory and evidence are consistent with the interpretation that this effect results from the disruption of the pattern of spending by consumers and firms on items whose utilization is sensitive to energy prices and supplies.

Keywords

oil and the macroeconomy; real business cycles; inflation

Article

Nine out of ten of the US recessions since the Second World War were preceded by an upward spike in oil prices. One way to inquire whether this might be just a coincidence is with a statistical regression of real GDP growth rates (quoted at a quarterly rate) on lagged changes in GDP growth rates and lagged logarithmic changes in nominal oil prices. The results from an ordinary least squares (OLS) estimation of this relation for $t=1949:II$ to $1980:IV$ are as follows (standard errors in parentheses):

$$y_t = 1.14 + 0.20 y_{t-1} + 0.05 y_{t-2} - 0.10 y_{t-3} - 0.19 y_{t-4} - 0.004 o_{t-1} - 0.027 o_{t-2} - 0.034 o_{t-3} - 0.065 o_{t-4}$$

The coefficient on the fourth lag of oil prices ($o_{t-4}$) is negative and highly statistically significant ($t$-statistic=−2.4), and an $F$-test leads to a rejection of the null hypothesis that the coefficients on lagged oil prices are all zero with a $p$-value of 0.005. Quite a few studies have tested and rejected the hypothesis that the relation between oil prices and output could just be a statistical coincidence, including Rasche and Tatom (1977; 1981), Hamilton (1983), Burbidge and Harrison (1984), Santini (1985; 1992), Gisser and Goodwin (1986), Rotemberg and Woodford (1996), Daniel (1997), Raymond and Rich (1997), Carruth, Hooker, and Oswald (1998), and Hamilton (1993).

Another possibility is that the correlation between oil prices and output results from common dependence on some third factor or factors that are the true cause of both the increase in oil prices and the subsequent recession. For example, something about the last stages of an economic expansion may often produce a surge in oil prices just before output is about to turn down, so that both the oil price increase and the subsequent recession result from the same business cycle dynamics. This is difficult to reconcile with the fact that, at least for the early post-war period, oil price changes could not be predicted from earlier movements in other macro variables (Hamilton, 1983), and that most of the oil spikes can be attributed to exogenous events such as military conflicts (Hamilton, 1985). However, Barsky and Kilian (2002; 2004) have recently developed challenges to
Predicted size of effects

Economic theory suggests that it is the real oil price rather than the nominal price that should matter for economic decisions. It does not make much difference in summarizing the size of any given shock whether one uses the nominal price or the real price of oil, since in most of the shocks discussed here the move in nominal prices is an order of magnitude larger than the change in overall prices during that quarter. However, particularly in the early part of the sample, the nominal oil price would stay frozen for years and then adjust suddenly. To the extent that there is a difference between using nominal and real prices as the explanatory variable in such regressions, the real price results from the confluence of two forces: events such as the Suez crisis, which accounts for almost all of the movement in the nominal price between 1955 and 1965, and the quarter-to-quarter change in inflation, which is completely endogenous with respect to the economy and whose consequences for future output are likely to be quite different from those of an oil shock. In so far as the statistical exogeneity of the right-hand variables is important for interpreting the regression, many researchers have for this reason used the nominal oil price change rather than the real oil price change as the explanatory variable.

One simple framework for thinking about what the effects of energy supply disruptions should be comes from examining a production function relating the output $Y$ produced by a particular firm to its inputs of labor $N$, capital $K$, and energy $E$:

$$Y = F(N, K, E).$$

Suppose that output is sold for a nominal price $P$ dollars per unit, labour is paid nominal wage $W$, energy's nominal price is $Q$, and capital is rented at nominal rate $r$. The profits of the firm are given by

$$PY - WN - rK - QE.$$

A price-taking profit-maximizing firm would purchase energy up to the point where the marginal product of energy is equal to its relative price,

$$F_E(N, K, E) = Q / P,$$

where $F_E(N, K, E)$ denotes the partial derivative of $F(\cdot)$ with respect to $E$. If we multiply both sides of the above equation by $E$ and divide by $Y$, we find

$$\frac{\partial \ln F}{\partial \ln E} = \frac{QE}{PY}.$$

In other words, the elasticity of output with respect to a given change in energy use can be inferred from the dollar share of energy expenditures in total output.

This dollar share for the economy as a whole is fairly small. For example, in 2000 the United States consumed about 7.2 billion barrels of oil. At a price of $30 a barrel, that represents only 2.2 per cent of a $9.8 trillion nominal GDP. With the rapid
price increases of 2003–5, that share has risen to 3.8 per cent of GDP. Table 1 reports Hamilton’s (2003) values for the size of the supply disruptions associated with the five most important oil shocks, calculated from the magnitude of the drop in production in the affected countries. Kilian (2005) has more modest estimates based on his inference that production might have fallen even in the absence of the indicated events, and neither Hamilton’s nor Kilian’s figures take into account the fact that typically production increased in other parts of the world to make up part of the gap. Even using the ten per cent figure and a four per cent crude oil share, however, such shocks would by the above calculation be predicted to reduce GDP by only 0.4 per cent. Table 1 also reports the amount by which US real GDP declined between the date of the oil shock and the trough of the subsequent recession, which trough usually was reached a little over a year after the oil shock. Since the US economy would grow 3.4 per cent during a typical year, these numbers imply declines of real GDP relative to trend in excess of four per cent, an order of magnitude greater than predicted by the factor share argument. Furthermore, Bohi (1991) failed to find statistically significant evidence that industries with greater energy factor shares suffered more than others in response to the oil shocks of the 1970s.

One would arrive at a similar prediction if one thought of the oil shock as an exogenous change in the price of oil rather than a decrease in the quantity supplied. Faced with an increase in fuel costs, one option a given consumer would always have would be to keep on buying as much gas as before and just pay the higher price, decreasing other expenditures as needed. The value of what is lost by such behaviour is given by

\[
\frac{E \cdot \Delta Q}{PY} = \frac{QE}{PY} \cdot \frac{\Delta Q}{Q},
\]

in other words, the percentage change in oil prices \( \Delta Q/Q \) is again multiplied by energy’s value share \( QE/PY \). This actually places an upper bound on the value of what the consumer loses, because, in so far as the consumer opts to reduce \( E \) rather than hold \( E \) fixed, it must be because the latter strategy is in fact an inferior option.

If these oil shocks did contribute to economic downturns, this would have to be attributed to the movements they induced in other factors of production rather than to the value of the lost energy input per se. Some modest adjustments of other factors would be anticipated in a frictionless neoclassical model, but these appear to be small. Kim and Loungani’s (1992) real business cycle analysis suggested that oil price shocks could explain only a modest component of the variance of US output growth.

One modification that can make a difference is to replace the assumption of perfect competition with mark-up pricing. Rotemberg and Woodford (1996) showed that this can induce a response of labour utilization to an oil price shock that greatly amplifies the effects, with simulations in which a ten per cent increase in energy prices could lead to a 2.5 per cent drop in output six quarters later.

Another important margin is the capital utilization rate, as emphasized by Finn (2000), who was able to arrive at similar quantitative effects as Rotemberg and Woodford even under the assumption of perfect competition.

Other mechanisms
Another explanation offered for the correlation between energy prices and output has to do with the role of monetary policy. Barsky and Kilian (2002; 2004) argued that a monetary expansion was the cause of much of the 1973–4 oil price increase, and that this monetary expansion also set the stage for a subsequent decline in output. Bernanke, Gertler and Watson (1997) took the view that the oil shocks were exogenous, but the Federal Reserve responded to them by raising interest rates in order to control inflation, with this monetary contraction itself the principal cause of the downturns. Hamilton and Herrera (2004) argued that the Bernanke, Gertler and Watson conclusion was due primarily to the fact that these authors omitted the biggest effects of oil shocks corresponding to the coefficients on $o_{t-3}$ and $o_{t-4}$ in the regression above. Leduc and Sill (2004) added sticky prices to a theoretical model generalizing the approach considered by Finn (2000), and concluded that monetary policy makes only a modest contribution. More empirically oriented studies also concluding that the oil shocks were more important than any monetary contraction include Dotsey and Reid (1992), Hoover and Perez (1994), Ferederer (1996), Brown and Yücel (1999), and Davis and Haltiwanger (2001).

A different class of explanations emphasizes the frictions in reallocating labour or capital across different sectors that may be differentially affected by an oil shock. For example, one common consequence of an oil price shock is a sudden drop in demand for certain kinds of cars, which leads to lower capacity utilization at affected plants (Bresnahan and Ramey, 1993). Because labour and capital cannot move costlessly to alternative productive activities, the result is idle resources that can significantly multiply the effects described above. Manufacturing of transportation equipment is one of the industries most affected by oil shocks in the United States but has one of the lowest energy intensities, and thus is part of the reason that Bohi (1991) found no connection between energy intensity and output decline. Lee and Ni (2002) found that oil price shocks tend to reduce supply in oil-intensive industries but reduce demand in other industries such as autos. Davis and Haltiwanger (2001) found oil shocks reduce employment the most in industries that are more capital intensive, more energy intensive, and have greater product durability. Keane and Prasad (1996) documented significant differences across industries in the effects of oil shocks on workers’ wages.

Hamilton (1988) and Atkeson and Kehoe (1999) provided theoretical analyses of the way in which technological costs of adjusting capital or labour can result in magnification of the disruptive effects of oil shocks. One of the key predictions of such models is that, unlike the factor share stories, the response of output to oil prices would not be log-linear. When oil prices go up, consumers may postpone their car purchases, but when oil prices go down, they do not go out and buy a second car. In fact, it is a theoretical possibility that, as a result of the output that is lost from trying to reallocate capital and labour, the short-run effect of an oil price decrease would actually be a decline rather than an increase in output.

**Linearity**

If one estimates a log-linear relation between GDP growth and lagged oil prices, the statistical significance of the relation falls as one adds more data (Hooker, 1996), suggesting at a minimum that a linear relation is either mis-specified or unstable. For example, when the regression described above is re-estimated with data through 2005:II, the result is

\[
\begin{align*}
\gamma_t &= 0.69 + 0.28 \gamma_{t-1} + 0.13 \gamma_{t-2} - 0.07 \gamma_{t-3} - 0.12 \gamma_{t-4} + 0.003 \gamma_{t-1} - 0.006 \gamma_{t-2} - 0.002 \gamma_{t-3} - 0.015 \gamma_{t-4} \\
&\quad \text{(0.07) (0.07) (0.07) (0.006) (0.006) (0.006) (0.006) (0.006)}
\end{align*}
\]

Although the $t$-statistic on $o_{t-4}$ remains statistically significant with a $p$-value of 0.02, an $F$-test of the null hypothesis that all four coefficients on lagged oil prices are zero would be accepted with a $p$-value of 0.11. The size of the effect is substantially smaller as well – whereas the 1949–80 regression would predict that GDP growth would be 2.9 per cent slower (at an annual rate) four quarters after a ten per cent oil price hike, the 1949–2005 regression would predict only 0.7 per cent slower growth. A number of authors have concluded that this instability is due to the nonlinearity of the relationship, with a linear relationship breaking down empirically when the huge oil price drops of 1985 failed to produce an economic boom. Loungani (1986) and Davis (1987a; 1987b) were the first to report evidence of nonlinearity of these relations, which they interpreted as implying that the effects of oil shocks resulted from sectoral shifts with costly reallocation of resources. Mork (1989) estimated separate coefficients on oil price increases and decreases, and found that the latter were statistically insignificantly
oil and the macroeconomy: The New Palgrave Dictionary of Economics

To the extent that the oil shocks are operating through an effect on demand for items such as less fuel-efficient cars, the influence would depend not just on the size of the oil price increase but also the context in which it occurred. Lee, Ni and Ratti (1995) found that much better forecasts of GDP growth were obtained if one divided the oil price increase by the standard deviation of recent price volatility. Hamilton (2003) used a flexible parametric model to investigate the nature of this nonlinearity, and found support for the Lee, Ni and Ratti formulation as well as an alternative that looks at how much the oil price might exceed its previous three-year peak; if it does not exceed the previous three-year peak, no oil shock is said to have occurred. An OLS regression of quarterly GDP growth (quoted at a quarterly rate) on lags of this net oil price measure for 1949:II to 2005:II results in the following estimates:

\[
\gamma_t = 0.87 + 0.24 \gamma_{t-1} + 0.11 \gamma_{t-2} - 0.08 \gamma_{t-3} - 0.13 \gamma_{t-4} - 0.009 \sigma^t - 0.014 \sigma^t_{t-2} - 0.009 \sigma^t_{t-3} - 0.031 \sigma^t_{t-4}.
\]

Here an \(F\)-test of the null hypothesis that all coefficients are zero is rejected with a \(p\)-value of 0.006, and a ten per cent increase in oil prices above their previous three-year high is predicted to reduce quarterly GDP growth (quoted at an annual rate) by 1.4 per cent.

Similar evidence of nonlinearity, with oil price increases reducing real output growth, has also been reported for a number of other countries by Mork, Olsen and Mysen (1994), Cuñado and Pérez de Gracia (2003), and Jimenez-Rodriguez and Sanchez (2005).

Other factors and consequences

As noted by Kilian (2005), civil unrest in Venezuela in December 2002 led to a drop in production of 2.3 million barrels a day, representing 3.4 per cent of world production at the time. The net oil price series \(\sigma^t\) reflected a surge in crude oil prices 20 per cent above their previous three-year high. Nevertheless, there was no discernible drop in GDP. Another surge in \(\sigma^t\) of 18 per cent occurred in 2004:III, accompanied by a 1.3 per cent increase in world production, and a third surge of 21 per cent in 2005:I, accompanied by a 0.2 per cent increase in production, with no recession as of the time of this writing (August 2005). It is clear from the last two examples in particular that demand increases rather than supply reductions have been the primary factor driving oil prices over recent years. In so far as these demand increases resulted from global income growth, one wouldn't expect to see the sharp drop in consumer spending on other key items that accompanied the episodes in Table 1.

At a minimum, the failure of a recession to result as of the time of this writing from the oil price increases of 2003–5 suggests that there is not simply a mechanical relation, even a nonlinear one, between oil prices and output. The experience is consistent with the claim that the key mechanism whereby oil shocks affect the economy is through a disruption in spending by consumers and firms on other goods and that, if this disruption fails to occur, the effects on the economy are indeed governed by the factor share argument.

Another potential macroeconomic effect of oil price shocks is on the inflation rate. The long-run inflation rate is governed by monetary policy, so ultimately this is a question about how the central bank responds to the oil shock. Hooker (2002) found evidence that oil shocks made a substantial contribution to US core inflation before 1981 but have made little contribution since, consistent with the conclusion of Clarida, Galí and Gertler (2000) that US monetary policy has become significantly more devoted to curtailing inflation.

Article
Okun was born in Jersey City, New Jersey, on 28 November 1928. He died suddenly in Washington, DC, on 23 March 1980.

Okun received his BA, ranked first in his college class, in 1949 and his Ph.D. in economics in 1956, both from Columbia University. He started teaching at Yale as Instructor in 1952, and advanced up the ladder to the rank of Professor in 1963. From September 1961 to January 1969 Okun was, except for two academic years 1962–4, on leave from Yale at the President's Council of Economic Advisers (CEA) in Washington, first as a staff member, then as a Council Member 1964–8, and finally as Chairman 1968–9. When Administrations changed in 1969, Okun joined the Brookings Institution as a Senior Fellow, an appointment he held the rest of his life.

Prior to his public service in the 1960s Okun was not well known outside Yale. Those who knew him personally appreciated his extraordinary talents and virtues. He was a great and generous teacher, both in the classroom and out. His open-door office was the place for students and colleagues to get things straight, confusions dispelled, errors corrected, models repaired. A thinker of natural integrity and inexhaustible curiosity, he pursued matters in depth, unsatisfied until logic was tight and facts fell into place. His teachings of policy-oriented macroeconomics created an oral tradition that many beneficiaries remember with deep gratitude. But little of it was published, because Art Okun was unduly modest and perfectionist about putting his wisdom into print.

At the CEA Okun found another metier, macroeconomic analysis directly related to the policy issues of the day. It began when President Kennedy's Council, of which one member was from Yale, enlisted Okun as a consultant. The Council wanted to convince the President, his White House staff, the Congress and the public that reduction of unemployment from seven per cent to four per cent would
yield economy-wide benefits much greater than moving from 93 to 96 per cent employment superficially suggested. Okun was asked to estimate the gains of real Gross National Product associated with unemployment reduction. The answer became famous as Okun's Law, one of the most reliable empirical regularities of macroeconomics. Okun found that a reduction of one percentage point of unemployment was associated with a gain of three per cent in real GNP. His research, later published (1962), also provided a methodology for estimating potential GNP, the real output the economy can produce at a full-employment or 'natural' rate of unemployment, and the ‘Gap’ between actual and potential output.

These concepts are central to estimates of the ‘high-employment’ or ‘structural’ federal budget deficits implied by tax and spending policies, as distinguished from actual deficits, which depend also on the performance of the economy as indicated by the Gap. The entire apparatus was displayed in the 1962 Economic Report of the President, and was a mainstay of subsequent Reports for 20 years. Okun himself was a major contributor to all the Reports 1962–70.

Okun was the Council's principal forecaster and estimator of the consequences of alternative policies. As he won the confidence of Council chairmen, White House staff, presidents, and even Treasury secretaries, he became the obvious choice for President Johnson to appoint Council Member and then Chairman. The period 1966–9 was difficult for the CEA and for Okun personally. The four per cent unemployment target had been achieved in 1965, with negligible cost in higher inflation. Then came the acceleration of Vietnam spending, overheating the economy and lifting the inflation rate three percentage points by 1969. At the beginning of 1966 Gardner Ackley, CEA Chairman, and Okun urged President Johnson to ask Congress to raise taxes. He would not do so until too late, and even then the temporary income surtax of 1968 had disappointingly small effects. When Okun left the government in 1969, the unemployment–inflation nexus became the foremost problem on his research agenda for the rest of his career.

From 1969 much of his energy and leadership went into his brainchild, the Brookings Panel on Economic Activity, which enlisted able economists from Brookings and elsewhere for research on the major macroeconomic developments and policies of the times. The papers are published in Brookings Papers on Economic Activity, which under the painstaking editorship of Okun and George Perry quickly became one of the most admired professional journals in economics. The editors put the contents of every issue in perspective with their analytical summaries of the papers and discussions.

Okun had nearly completed a major treatise on macroeconomics (1981) when he died; it was edited and finished by his colleagues at Brookings. The book is a culmination of his thinking and writing over many years, his search for a coherent model of an advanced capitalist economy in a democratic society, based on his understanding of how businesses, workers and consumers behave and relate to one another. Okun did not believe that the economists’ favourite paradigm, purely competitive markets cleared by flexible prices – Adam Smith's ‘invisible hand’ – provided realistic foundations for macroeconomics. He was impressed by the informal reciprocal expectations and obligations that characterize repeated dealings between sellers and customers or employers and workers. A creative phrase-maker, Okun called this web of implicit contracts the ‘invisible handshake’. His ‘customer markets’ are in many ways efficient substitutes for price-cleared auction markets, but they are also the source of endemic macroeconomic difficulties.

Okun saw no easy resolution of the cruel dilemma policymakers face in the trade-off between unemployment and inflation. All too often, and especially in the 1970s, fiscal and monetary demand
management could achieve acceptable outcomes in one of these two dimensions only at the cost of unacceptable results in the other. Okun had no use for the monetarist view that inflation could be easily prevented or conquered if only the central bank mustered sufficient will and wisdom. Nor did he share the simplistic view of some theorists of various schools that inflations are neutral and innocuous, devoid of real consequences. He advocated structural anti-inflation policies, including wage and price guideposts strengthened by tax-based incentives for compliance, to diminish the unemployment costs of anti-inflationary monetary and fiscal measures (1978).

The intellectual climate of professional macroeconomics was inhospitable to Prices and Quantities when it was published. ‘New classical’ models relying on ‘invisible hand’ micro-foundations were the dominant fashion. They are theoretically appealing but have trouble explaining the commonly observed facts of business fluctuations. No one knew those facts better than Okun, whose last published paper (1980) is a masterful litany of the many ways new classical business cycle theories fail to fit them. Fashions change and controversies fade. Okun's macroeconomics will be an important component of whatever new synthesis emerges from contemporary debate.

Arthur Okun was not only an effective adviser and participant in the making of economic policy; he was also a scholar and scientist of political economy – the ancient name for our discipline suggests a broader scope of inquiry and concern that most economists essay today. Okun's reflections on the role of the academic policy adviser in government and on the politics and economics of macroeconomic management, published shortly after he returned to private life, are the most thoughtful of the genre (1970).

For his Godkin Lectures at Harvard (1975) Okun chose the broadest and most basic question of political economy: how democratic societies do, can, and should balance the ethical desirability of mitigating inequalities of well-being against the practical utility of the inequalities arising in free markets as incentives for efficient economic performance. Okun coined the metaphor ‘leaky bucket’ for losses in aggregate wealth incident to government interventions to transfer wealth from rich to poor. Citizens will disagree on the tolerable degree of leakage, he says, but both liberals and conservatives should face the trade-offs realistically. They should be able to agree on measures to plug leaks, exploiting opportunities to diminish inequality without impairing incentives (even if such reforms are not Pareto optimal). Okun suggests an agenda of such opportunities, focusing on measures to assure greater equality of opportunity. The book has already become a classic. In its erudition, logic, lucidity, and wisdom, and above all in its humanity, it truly reflects the qualities of its author.

Okun's Law

Jesús Crespo Cuaresma
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Okun's law describes the empirical relationship between changes in unemployment and output at the macroeconomic level and has been regarded since its discovery by Arthur Okun (1962) as a building block of traditional macroeconomic models. This article discusses the interpretation of this relationship and summarizes recent developments in the econometric specification of Okun's law.

Keywords

aggregate demand; demand and supply shocks; Okun's coefficient; Okun's law; output gap; Phillips curve; production functions; unemployment

Article

The term ‘Okun's law’ refers to the empirical relationship between changes in unemployment and output. It is a basic building block of traditional macroeconomic models, where the aggregate supply function is derived from combining Okun's law with the Phillips curve.

In Okun's original contribution (Okun, 1962), the empirical relationship between unemployment and output is introduced in the context of the quantification of potential output and the measurement of the social costs of unemployment in terms of forgone production.

Okun (1962) presents estimates for the United States which are based on three alternative econometric specifications aimed at quantifying empirically the relationship between unemployment and output growth: (a) regressing (quarterly) changes in the unemployment rate on (quarterly) percentage changes in production (as proxied by Gross National Product, or GNP), (b) regressing the unemployment rate on percentage deviations from potential output, defined as the exponential trend in GNP and (c) regressing the (logarithmized) employment rate on a linear time trend and (logarithmized) GNP. The effect of output changes on unemployment is quantified by the estimated parameter associated with the output variable in each of these regressions, whose inverse is usually known as ‘Okun's coefficient’. The results
in Okun's contribution indicate that there exists roughly a three-to-one link between unemployment and output changes, in the sense that an increase/decrease of three percentage points in output (or the output gap, depending on the specification) is associated with a decrease/increase of one percentage point in unemployment. This rule of thumb is proposed as a ‘subjectively weighted average’ (Okun, 1962, p. 100) of the estimates obtained from the three specifications. Estimations based on data including the post-oil crisis period, which can be found in most modern macroeconomic textbooks, tend to reveal an Okun's coefficient that is closer to two than to three.

Okun's arguments (see, for example, Okun, 1962, p. 99) suggest that the link found between unemployment and output is not to be understood as a *ceteris paribus* relationship, but rather as capturing also the effects of simultaneous changes in labour force, hours worked and productivity (see also Friedman and Wachter, 1974). Okun argues that a reduction in the unemployment rate would induce an increase in the labour force by persuading discouraged workers to seek work actively, and also presents estimates of the increase in hours worked per employed person caused by rising output. The analysis carried out in Okun's contribution, based on data for the United States in 1960, assigns approximately 56 per cent of the change in output to the effect of changes in total labour input measured in hours worked, while the rest is attributed to productivity increases. Prachowny (1993) approaches the quantification of the link between unemployment and output by proposing a specification based on a fairly general production function, where the independent effects of changes in unemployment, hours worked, capacity utilization and labour force on output can be estimated separately. In this setting, Okun's empirical specifications would be appropriate only if certain parameter restrictions on the production function are satisfied. Prachowny (1993) therefore proposes labelling Okun's law ‘Okun's theory’ and testing these restrictions directly on the data. The estimates of the direct effect of unemployment on output obtained using this specification are correspondingly smaller than in the original contribution by Okun, although the econometric modelling strategy used (based on estimating the production function in gap form and in first differences) is not without criticism. Attfield and Silverstone (1997) reconsider this approach using cointegration techniques and find estimates that are comparable with the original values in Okun (1962).

Obviously, the relationship observed between changes in output and changes in the unemployment rate is determined by the nature of the shocks hitting the economy. The usual interpretation of the relationship summarized by Okun's law refers to arguments based on shocks to aggregate demand. Blanchard and Quah (1989) emphasize the importance of identifying demand and supply shocks in order to estimate and interpret Okun's coefficient. Using a dynamic system formed by the unemployment rate and output growth, Blanchard and Quah (1989) assess the issue by isolating supply and demand shocks and interpreting the responses of these two variables to each type of shock. The results suggest that the implied Okun's coefficient for demand shocks is slightly above two, while there is no such systematic short-run relationship between unemployment and output changes following a supply shock. While many macroeconomic textbooks tend to emphasize that the relationship between short-run changes in output and unemployment is a robust and reliable empirical regularity, much of the literature dealing with Okun's law is aimed at evaluating the robustness of this link across countries (Kaufman, 1988; Moosa, 1997; Lee, 2000), in time (Sheehan and Zahn, 1980; Gordon, 1984; Evans, 1989), across econometric specifications (Weber, 1995; Lee, 2000) and across states of the business cycle – recessions...
versus expansions – (Lee, 2000; Crespo Cuaresma, 2003). The results of this branch of literature point towards the existence of asymmetric, country-specific Okun's coefficients, with a higher elasticity of unemployment to output changes in recessions than in expansions, and a lower elasticity in continental European countries compared with Canada, the United States and the United Kingdom. The estimates of Okun's coefficient appear to be sensitive to the specification and de-trending method used for retrieving the cyclical component of output and the unemployment rate. Furthermore, this empirical literature usually reports evidence of structural instability, with a break in Okun's coefficient taking place in the 1970s.

In several countries economic transition was accompanied by the emergence of ‘oligarchs’ – businessmen who amassed fortunes and used them to influence economic policies. At their height in 2003, a few oligarchs controlled much of Russia's economy, as did a similar elite in Ukraine. Oligarchs seem to run their empires more efficiently than other domestic owners. While the relative weight of their firms in the economy is huge, it is not excessive by the standards of the global economy where most of them are operating. Policymakers should therefore focus on ‘political antitrust’ to prevent state capture and subversion of institutions.

An oligarchy, as discussed in Plato's Republic and Statesman and Aristotle's Politics, is a form of government by a small group. Interestingly, while in Plato's works, oligarchy is used as a neutral term, and may include both aristocracy and plutocracy, Aristotle already provides the term with a negative connotation, defining oligarchy (similar to Plato's plutocracy) as a deviant form of the rule by a few (while aristocracy remains the correct one).

In its current meaning in transition economies, the term ‘oligarch’ denotes a businessman who controls sufficient resources to influence national politics. (The lists of oligarchs include only men; the richest Russian businesswoman, Moscow mayor's wife Elena Baturina, ranked outside the top 25 wealthiest Russians in 2004; she entered the Forbes billionaires list (Figure 1) only in 2005 but remained the only woman in the list, ranked 27 out of 34 in 2006 (Forbes, 2004–6). Such businessmen have played a substantial role in almost all transition countries, although most of the discussion of the role of oligarchs in transition has concerned Russia and Ukraine. The reason for this is also similar to the ideas of Plato and Aristotle, who classified oligarchy as an intermediate form of government between dictatorship/monarchy and democracy. On the one hand, EU accession countries in Central and Eastern Europe have succeeded in building accountable and democratic governments, thus limiting the role of oligarchs. On the other hand, members of the Commonwealth of Independent States (except Russia and Ukraine) have seen the concentration of power in the hands of a single politician rather than a group of rich businessmen. Also, Russian oligarchs have been more prominent than those in Ukraine, in terms of both their wealth (due to Russia's resource richness) and their substantial impact on politics. Actually, in the Forbes 2005 and 2006 lists the total wealth of all non-Russian billionaires from transition countries (including China but excluding Hong Kong) was less than that of the single richest Russian. Not surprisingly, Russian oligarchs have been studied in far more detail. This is why this article concentrates on the case study of Russia even though most issues are relevant to Ukraine and other transition countries. (See Aslund, 2006, for a study of Ukrainian oligarchs; Gorodnichenko and Grigorenko, 2005, provide a quantitative analysis.)

http://www.dictionaryofeconomics.com.proxy.library.cuny.edu/article?id=pde2008_0000056&goto=B&result_number=1241
It is not clear who first used the term ‘oligarch’ to describe the newly emerged class of Russian tycoons. Kommersant (2003) refers to a pro-market politician Boris Nemtsov (then a governor of Nizhny Novgorod region, later to become a deputy prime minister) and a journalist, Alexander Privalov (then Izvestiya daily and Expert weekly), both introducing the term in 1994–5. It is also clear that the Russian elite's thinking of oligarchs has been affected by Jack London's The Iron Heel (1908), an anti-utopia on the rise of an oligarchy of robber barons, which was widely publicized in Soviet times.

Who are the oligarchs?

There is no complete list of Russian oligarchs. Given the multi-layered and non-transparent ownership structure of Russian companies, compiling such a list would be extremely difficult. On the other hand, any such list has to be constantly updated: there is substantial vertical mobility among Russia's richest. For example, out of seven or eight business groups that dominated President Yeltsin's Russia in the 1990s, two were destroyed by the 1998 crisis (SBS and Inkombank), one took a hit but survived to be later sold to fellow billionaires

Source: Forbes (2002–6)
Oligarchs: The New Palgrave Dictionary of Economics

(Roskredit-cum-Metalloinvest), two have their leaders (Berezovsky and Gusinsky) in exile, and one (Khodorkovsky) in prison. Other problems are related to the vagueness of the
definition of oligarchs. First, there are different views on how to measure tycoons’ power rather than wealth (this is especially important for a comparison between oligarchs and US
robber barons). Second, it is not clear whether to count public officials and CEOs of large public companies as oligarchs. In what follows, we stick to the definition of oligarchs as
private owners, although certain CEOs of state-owned firms and family members of some government officials do resemble oligarchs in many respects.

The first list of oligarchs probably belongs to Boris Berezovsky (by all accounts, an oligarch himself) who, in his 1996 interview in the *Financial Times*, named seven bankers who
controlled about 50 per cent of the productive assets of the Russian economy. Since then there have been numerous lists, some even endorsed by the oligarchs themselves. Still, all the
oligarch rankings identify similar sets of individuals. Table 1 presents a list that was constructed based on a study of ownership concentration in a substantial subset of Russian
economy by the World Bank’s 2004 *Country Economic Memorandum* (CEM) for Russia (see Guriev and Rachinsky, 2005, for a detailed description of the data-set and the project).
The study refers to summer 2003 – the oligarchs’ heyday. While this study has its limitations, it makes it possible to reach some conclusions on who the Russian oligarchs are, and
why they matter.

How important are the oligarchs?

First, the oligarchs do control a substantial part of Russian economy. In the CEM sample, they account for about 40 per cent of sales and employment – more than all other private owners combined, or more than federal and regional governments combined. (As of June 2006, quite a few of these oligarchs have seen their assets nationalized, so a more relevant figure would be 30 per cent.)

Cross-country comparisons of wealth concentration are usually based on the share of stock market capitalization controlled by a given number (often ten) of families. Certainly, it is not a perfect metric – after all, it doesn't include firms not listed on stock markets, and emerging markets are likely to provide at best an imperfect measure of value. But we are not aware of comparable data-sets on non-listed firms, so we have to rely on the data on the share of the stock market owned by the top ten families. By that measure, ownership concentration in modern Russia is higher than in any other country for which the data are available. The top ten families or ownership groups (a subset of Table 1) owned 60.2 per cent of Russia's stock market in June 2003. This percentage is much higher than in any country in Continental Europe, where the share of the ten largest families is less than 35 per cent in small countries and less than 30 per cent in all large countries. In the United States and the United Kingdom, this share is in single-digit percentages. (A less rigorous approach is to look at the Forbes billionaires lists. Even though Russian companies are significantly undervalued relative to their OECD counterparts, Forbes, 2004, lists 26 billionaires in Russia; only the United States and Germany have more. The 26 Russian billionaires are worth $81 billion, or 19 per cent of Russia's annual GDP. The 26 richest US citizens are worth four per cent of US GDP; the total wealth of all US billionaires is less than seven per cent of US GDP.) In the East Asian countries before the 1997 crisis, the highest shares of the ten largest families were in Indonesia (58 per cent), Philippines (52 per cent), Thailand (43 per cent) and Korea (37 per cent). The numbers for Indonesia and Philippines include the

Sources: Employment and sales are from World Bank (2004) and Guriev and Rachinsky (2005). The percentages in parentheses are the shares of employment/sales of the World Bank's sample, which in turn covers a substantial share of the economy (yet, as some industries are not represented, the list misses a couple of important candidates, such as Alexander Lebedev of National Reserve Corporation). Wealth is the market value of the oligarchs' stakes in spring 2004, calculated by authors using Forbes (2004) and stock market data. Wealth includes stakes of all the partners identified by the survey. Each entry lists the leading shareholder(s) in a respective business group, the name of the holding company or the flagship asset, and one or two major sectors. Several individuals per group are reported only when there is equal or near equal partnership. Ranking is based on employment in the sample and may therefore be different from the actual, as the sample disproportionately covers assets of different oligarchs. Employment and sales are based on official firm-level data for 2001. The exchange rate was 29 roubles to the US dollar.

RSPP=Russian Union of Industrialists and Entrepreneur, the leading lobbying organization for Russian business. Among other things, RSPP represented the private sector in multiple meetings with President Putin, including the first one where the 2000 pact was allegedly concluded. B=RSPP Bureau membership (in total, the RSPP Bureau includes the President and 24 members); we also list the RSPP committees/taskforces the particular oligarchs are in charge of (in total there are 17 committees/taskforces in the RSPP).

bSome RSPP committee chairs have retired from active business. Eremeev was an Interros executive prior to the appointment at RSPP. Hoffman discusses Berezovsky rather than Abramovich. In 2000–3, Abramovich took over most of Berezovsky's assets in Russia as Berezovsky went into exile. Kiselev was Metalloinvest Board Chairman at the time of appointment at RSPP. Mamut was MDM Board Chairman at the time of appointment at RSPP. Yurgens was a Sistema executive prior to the appointment at RSPP.

cKhodorkovsky remained a Bureau member and a Committee Chair for a while even after he was imprisoned, indicted and even convicted.

How important are the oligarchs?
holdings of the Suharto and Marcos families, each controlling 17 per cent of total market capitalization in the respective countries. In Russia, the personal wealth of ex-President Yeltsin and President Putin is considered to be very modest.

What do oligarchs control?

Each group in Table 1 controls assets in multiple provinces of Russia and even other countries, and in several industries. Mostly, the oligarchs’ conglomerates are horizontally and vertically integrated. (Only Abramovitch, Deripaska, MDM group, and Potanin control major assets in unrelated industries, but even in their empires a single industry accounts for most of the conglomerate’s value.) Oligarchs do dominate the largest industrial sectors, in particular natural resources (especially oil and metals) and automotive. The only large sectors not controlled by oligarchs are natural gas, energy, and manufacture of machinery. The gas and energy sectors are dominated by federally owned monopolies Gazprom and RAO UES; machinery production is a diverse sector which is populated by defence equipment suppliers (controlled by the federal government), oligarch firms and smaller firms controlled by non-oligarch private domestic owners.

Do oligarchs exercise excessive market power in the sectors that they control? The sectors controlled by oligarchs are indeed those with the highest concentration ratios in Russia (Guriev and Rachinsky, 2005). However, these are also tradable goods sectors that are subject to global competition. For example, consider the ten sectors where oligarchs control more than 20 per cent of total sales. Except for ore and automotives, all these sectors sell to the global market: they export 30 to 90 per cent of their output; indeed, these sectors account for half of total Russian exports. The first exception, ore production, is mostly owned by oligarchs’ vertically integrated conglomerates, where ore is an input. The second exception, the automotive sector, is a classic example of interest group politics. Russian cars are not internationally competitive, and the industry has always relied on protection. Such protection was usually granted, especially in the period in the 1990s when the largest carmaker’s CEO, Vladimir Kadannikov, served as the first deputy prime minister in charge of economic policy. Yet, even with high import duties and support for domestic producers through generous tax write-offs and subsidies, import penetration was 25 per cent and rising. As of 2000, Oleg Deripaska consolidated his control over the second largest car producer and almost all of the bus and truck production, and the lobbying for stronger protection reached new heights. Indeed, one of the main reasons Russia is not yet a member of the World Trade Organization is that the WTO requires lowering import duties for cars, and Russia’s automotive lobby launched an aggressive (and a very successful) anti-WTO campaign. The lobbyists managed to install increasingly high tariffs on both used and new imported cars.

The large industries where oligarchs play a large role are also those with substantial economies of scale. Indeed, these are exactly the sectors where large business empires originated in many countries in the late 19th century and the early 20th century, including the United States, Japan and Sweden. But, except for the automotive sector, there seems little reason for concern that Russia’s oligarchs have excessive market power. Although their conglomerates are large by Russian standards, they are certainly not excessive by global standards. Some oligarchs are important global players in their industries (especially in oil and metals), but none is a dominant market leader. Thus, there is no basis, on efficiency grounds, for antitrust policies aimed at breaking up the oligarchs’ companies. Instead, it is more important that Russian competition policy assure a level playing field for all owners without regard to their size and political influence.

How did the oligarchs gain control?

A common belief is that the oligarchs owe their fortunes to the ‘loans-for-shares’ auctions held in mid-1990s, which are widely regarded as the most scandalous episode of Russian privatization. In the classical loans-for-shares scenario, the government appointed a commercial banker to run an auction that would allocate a controlling stake of a large natural resource enterprise in exchange for a loan to the federal government that the latter never intended to repay. Not surprisingly, the auctioneer always awarded the stake to himself for a nominal bid (usually, slightly above a very low reserve price) by excluding all outside bidders. The scheme was designed to consolidate the bankers’ support for Yeltsin’s re-election campaign in 1996.

The conventional loans-for-shares story fits Abramovich (in 1995–7, a junior partner of Berezovsky), Khodorkovsky, and especially Potanin. The other two winners were the oil sector insiders Alekperov and Bogdanov, who obtained stakes in firms they already controlled. However, most of those listed in Table 1 did not become oligarchs through the loans-for-shares programme. Some of the 22 largest owners tried to participate in the loans-for-shares programme and even offered more competitive bids, but were excluded by those in charge of respective auctions; some even raised their concerns in public.

Most of the individuals listed in Table 1 are relatively young: nine of them are in their thirties, and 13 are in their forties. (Both mean and median individuals in Table 1 are 44 years old. Russian oligarchs are much younger than their American counterparts. In the Forbes list, the average age of the 25 richest Americans is 64 years; the average age of all 262 US billionaires is the same.) The older oligarchs have typically come from Soviet-era nomenklatura. Prior to transition, they were either managing their respective enterprises or working in government agencies supervising those enterprises. When Soviet-era enterprises were privatized, they successfully converted their de facto control into ownership rights. The younger entrepreneurs started from scratch in the late 1980s, building their initial wealth during President Gorbachev’s partial reforms when the coexistence of regulated and quasi-market prices created huge opportunities for arbitrage. In 1992, as price liberalization and privatization began, most of them owned trading companies and/or banks. Thus, when
privatization of industrial enterprises occurred, they had the financial capital available to purchase ownership in privatization auctions. Some of these entrepreneurs were neither industry nor government insiders; yet, they converted Soviet manufacturing enterprises into successful modern capitalist firms. Of course, a cynic might note that such companies are near the bottom of the list in Table 1 in terms of size, while the loans-for-shares winners dominate the top of the list.

Oligarchs’ dilemmas

Whatever the source of individual oligarchs’ wealth, the Russian public still deems it illegitimate, believing that the oligarchs obtained their initial wealth through connections and furthered it by securing preferential treatment through exerting political influence. (In a July 2003 poll by ROMIR, an independent Russian research and polling agency, 88 per cent responded that all large fortunes were amassed in an illegal way, 77 per cent said that privatization results should be partially or fully reconsidered, and 57 per cent agreed that the government should launch criminal investigations against the wealthy; Vedomosti, 2003.) This has created a fundamental problem for Russia's transition: promoting democratic values (that is, respecting the median voter's opinion) may undermine liberal values (private property rights in a substantial part of the economy). This conflict has created a window of opportunity for such a pragmatic politician as President Vladimir Putin, who has managed to play oligarchs and voters off against each other to consolidate his own political power. Curbing the oligarchs’ political influence was an essential part of Vladimir Putin’s presidential campaign in 2000. In his open letter to voters, he promised to treat the oligarchs in the same way as other entrepreneurs; a few days later he announced that all interest groups would be kept at an ‘equal distance’ from his government. In the first meeting with the leading oligarchs on 28 July 2000, President Putin offered them the following pact. As long as the oligarchs paid taxes and did not use their political power (at least not against Putin), Putin would respect their property rights and refrain from revisiting privatization. This pact defined the ground rules of oligarchs’ interaction with central and regional government during Putin's first term (2000–4). Although the pact could have never been written, even the general public was well aware of its existence. A poll by FOM (2000), an independent non-profit Russian polling organization, a week after the meeting showed that 57 per cent Russians knew about it.

Putin's threat to prosecute any oligarch who deviated from the pact was based on the median voter's support for expropriating the oligarchs. Putin carried out his threat in 2003, when the prominent oligarch Mikhail Khodorkovsky, the majority owner of the Yukos oil company, deviated from the pact by openly criticizing corruption in Putin's administration and supporting opposition parties and independent media. He and his partners were soon arrested or forced into exile, and their stakes in Yukos expropriated. It is not clear why Khodorkovsky did not stick to the pact. Perhaps he thought that supporting opposition parties rather than challenging Putin himself was not a violation. Almost certainly, he did not expect Putin to respond so decisively.

The expropriation of the Yukos shareholders certainly involved serious costs for Russian economy – the investment climate worsened and capital flight increased substantially. However, Putin clearly demonstrated that his priority was to establish his credibility even if this damaged his economic agenda. The Yukos affair has clarified the rules of the game between oligarchs and the Kremlin. Oligarchs have learned the risks associated with violating the pact, and so in the future they will be less likely to interfere in national politics. The Yukos affair effectively shifted the bargaining power from oligarchs to bureaucrats. Although outright expropriation of oligarchs will probably remain just a threat, their cash flows will be milked more intensively by bureaucrats in the form of kickbacks, donations to pet projects, and direct bribes (for a discussion of this ‘contract’ between bureaucrats and the entrepreneurs as a ‘viability insurance contract’, see Ickes, 2005). This will in turn undermine oligarchs’ property rights and incentives to invest. To sustain economic growth, Putin has to constrain rent-seeking by his own bureaucrats. This task is certainly not an easy one, given that democratic checks and balances are very weak. Moreover, neither government nor the oligarchs are interested in the development of democracy and civil society. (Actually, oligarchs may also benefit from imperfect property rights protection as there are economies of scale in private rent-seeking; see Glaeser, Scheinkman and Shleifer, 2003; Rajan and Zingales, 2003; Sonin, 2003.) Bureaucrats do not like to cede their control, while oligarchs are afraid of the median voter's redistributive agenda.

The potential exit strategy for any individual Russian oligarch is to sell a large stake to a reputable foreign investor. Indeed, expropriating foreigners is harder for the state because they are more popular than oligarchs, and because of pressures from foreign governments. However, timing the exit properly is a complex problem. Selling too early would bring too little as the assets are initially undervalued. Delaying the sale in order to restructure the company and improve its transparency would raise the price, but would also increase the risk of expropriation by the Russian government. This expropriation may also occur through a seemingly market-based transaction. For example, the government can use public funds to pay the oligarch the market value of his assets in exchange for (hidden) substantial side payments to selected government officials or their pet projects. Given the threat of complete expropriation, this is an offer the oligarch cannot refuse.

Economic performance of the oligarchs

Do oligarchs create value or strip assets? Do they improve the performance of the firms they control or injure their performance? Most oligarchic groups are horizontally or vertically integrated and are run by active majority owners, so the usual ‘conglomerate discount’ diseconomies of scale are unlikely to apply. A more important problem is, of course, the political risk of expropriation that shortens time horizons and reduces the incentives to invest.

On the other side, several arguments suggest that Russia's oligarchs might improve firm performance. First, the oligarchs’ performance might be superior because they have
oligarchs: The New Palgrave Dictionary of Economics

Successfully overcome the separation of ownership and control. An oligarch who owns a very large majority share should have strong incentives to restructure companies and to seek to improve the value of this asset, rather than for diverting cash flows and stripping the assets. Even if a firm was originally privatized to dispersed shareholders, its ownership structure was quickly consolidated through dilution and, in some cases, outright expropriation of outside investors, including government and foreigners. The current champions of transparency, Mikhail Khodorkovsky and Vladimir Potanin (now chairing Russia's National Council for Corporate Governance), kept expropriating outside investors until as recently as 1999. In our sample, oligarchs do control large stakes in their firms. In an average firm where the largest owner is the oligarch, he controls 79 per cent; in the case of non-oligarch private domestic owners, the corresponding figure is only 74 per cent. The difference is statistically significant but not necessarily economically important. The average degree of control exercised by smaller owners over their companies is also very high. Poor protection of minority shareholders rights has resulted in consolidation of control within most Russian companies. As a result, smaller owners are not investors that hold small stakes in large companies; rather, they hold large stakes in small companies.

Second, vertical integration can mitigate the risk of hold-up problems, where in a situation of relatively few buyers and sellers each party must be concerned that the other will attempt to renegotiate and seize a greater share of the joint surplus. Many oligarch empires have been built to overcome such hold-up problems: for example, all Russian major oil companies are vertically integrated; most steel producers own sources of coal and ore; some companies own ports, fleets of railroad cars and even railroad track. Third, in a situation with underdeveloped financial markets, external finance is costly; larger oligarch-run firms can benefit from their access to internal finance. They can create an internal financial market to finance expansion (see Khanna and Yafeh, 2005, for the discussion of these two benefits for business groups in developing countries). Fourth, Russia lacks a clear rule of law, and the larger conglomerates are certainly more effective than small firms in influencing judicial and political decisions and protecting their property from the predatory ‘grabbing hand’ of federal and local governments.

There is still no convincing test of whether and how oligarchs affect the performance of their firms. Constructing such a test is a significant challenge. Preliminary results (Guriev and Rachinsky, 2005) show that in terms of total factor productivity growth (with industry, region and size controlled for) oligarchs’ firms do perform almost as well as foreign firms and better than other Russian-owned firms. Yet more empirical work is needed to control for endogeneity of oligarch ownership, and to study the long-term effects. In addition, more work is needed to produce a quantitative evaluation of the oligarchs’ effect on social welfare.

Oligarchs and Russia’s future

While ownership concentration in Russia is higher than in other countries today, it does not seem unprecedented in historical perspective. Owners of Korean chaebols, Japanese zaibatsu, Sweden’s and Italy’s largest family controlled firms, and US ‘robber barons’ exercised a similar share of economic and political power. Also, in many of these countries the oligarchs’ wealth was accumulated with substantial support from the state (in direct subsidies, tax breaks, land grants, subsidized credit, and so forth) and was deemed illegitimate by a substantial share of the public at some points in history. Yet these countries have managed to build functioning market economies, although it took much longer for some of them to create functioning democracies. Therefore, it is not clear whether and how soon Russia will succeed in establishing legitimacy of private property rights and whether this will be accompanied by a transition to a sustainable democracy.

Article

No article entitled ‘oligopoly’ appeared in any edition of Palgrave's Dictionary of Political Economy. It is true that the simplest case of oligopoly, that is, duopoly, was considered more than a century and a half ago, by Cournot; but such an analysis was motivated by purely theoretical interests. The fact is that only in the 20th century and especially after the Second World War did this market form become important in economic reality, as a result of two processes of economic change: the process of concentration and the process of differentiation. In those branches where the former process has asserted itself – for example, steel, basic chemical products, cement, electricity – concentrated oligopoly with relatively homogeneous products has emerged; where the latter process has prevailed, we find differentiated oligopoly; in those branches where both processes have taken place simultaneously, then mixed oligopoly has emerged. In both processes innovations have played a major role, with the proviso that in the process of concentration innovations have given rise to economies of scale, whereas in the process of differentiation the most important role has been that of technological innovations implying economies of specialization; in this case, technological innovations are combined with commercial innovations. In fact, differentiated oligopoly can be found mainly in those activities in which quality competition, commercial services and advertising have had a particularly relevant role – non-durable consumer goods, such as textiles, tyres, canned foods, soft drinks and cigarettes are often produced in conditions of differentiated oligopoly.

In the past, when the standard of living of the masses of consumers was not much above the subsistence level, there was not much scope for the factors just mentioned. With the gradual increase of per capita
income, consumers’ preferences have acquired an increasing space. At the same time the possibility of advertising has been greatly enhanced by particular innovations – modern means of transportation and the so-called mass media, among which radio and television play a special role. Mixed oligopoly (concentration cum differentiation) is typical of several industries producing consumer durables such as automobiles, typewriters, refrigerators, radio and television sets, computers; mixed oligopoly can be found in several important service sectors such as banking and insurance. In addition a large number of non-durable consumers’ goods and services – including commercial services – constitute the area where differentiated oligopoly prevails; it is well to point out that as a rule there is no difference between imperfect competition and differentiated oligopoly. Analytically, the former can be seen, as a rule, as a first and the latter as a second approximation; this standpoint becomes natural if we recognize that the imperfect markets are composed by a ‘chain of oligopolistic groups’.

After careful reflection, we are bound to admit that in modern industry and in services, oligopoly, in its three varieties, is the rule and competition the exception – to be found in certain industries producing sufficiently homogeneous non-durable goods and in subsidiary activities. Competition, on the other hand, is the rule in most agricultural and mineral raw materials traded in international markets.

1. According to the traditional (neoclassical) conception, markets in competitive conditions are formed by a great number of firms, each of which is so small as to be unable to influence prices. Each firm, then, is bound to accept the market price and pushes output up to the point at which marginal cost – which, after a point, cannot but be increasing – equals price. In fact, the increasing marginal cost, that is, diminishing returns both in the short and in the long run are a necessary feature of traditional theory. In monopoly equilibrium is reached when the decreasing marginal income equals marginal cost. Indeed, according to that theory, only two market forms are worth consideration – competition and monopoly – the former being the rule, the second the exception. (The analytical tools to be used for imperfect competition are those worked out for monopoly.)

The whole analysis is statical and thus presupposes given technology. To work out theoretical models consistent with dynamic analysis, we have to go back to the classical concept of competition, where freedom of entry and not the number and size of firms is crucial. If we adopt this concept, it is easy to shift from competition to non-competitive market forms, by considering obstacles of various relevance to entry. Clearly, when in a given market the obstacles to entry are serious, firms operating in that market are likely to be few; this, however, is to be seen, not as a preliminary datum, but as the likely (not necessary) result of the existence of those obstacles.

When the obstacles to entry are of little importance, then a super-normal profit will attract new firms: supply will increase and the price will fall, so that super-normal profit will tend to disappear: such a profit can persist when obstacles to entry are important.

Having chosen this approach, in a first approximation we have to distinguish, in price analysis, between agriculture and mining, on the one hand, where obstacles to entry as a rule are modest, and industry and services, on the other, where those obstacles are often considerable. Again, in the first approximation, we can state, with Ricardo, that in primary activities in the short run prices depend on demand and supply, whereas in the long run they depend on costs. If we refer to the short run and intend to work out an analysis susceptible of empirical verification, we realize that ‘demand’ can be variously interpreted; in the case of raw materials traded in the international markets, demand can best be represented by an index of world industrial production. In industry and services, instead, in the short run prices depend principally on changes in direct costs and, in the long run, on changes in total costs per unit.
The reason for this sharp difference as regards short-run variations of prices is as follows. In primary activities firms, owing to the relative freedom of entry, have no outstanding market power and cannot influence prices, which vary according to the variations of aggregate demand and aggregate supply. In the other activities, however, prices are to a non-negligible extent controlled by firms and, in particular, by those that act as price leaders. Starting from a price that is accepted by all firms – that is, from an ‘equilibrium price’ – the firms acting as leaders will modify it when the conditions of equilibrium change. There are, then, two analytical problems, conceptually different but strictly interrelated: the problem of price determination and that of price variations. In traditional terms, the former problem belongs to the area of statical analysis, the latter to that of dynamics. We can accept such a distinction provided that it implies no cleavage, that is, provided that we can pass without discontinuities from the analysis of price determination to that of price variations.

The problem of price determination implies the analysis of the equilibrium, which includes: the size of the market (that is, the position in a Cartesian diagram of the demand curve, a concept that becomes relevant when firms are no more conceived as atoms); the shape of the demand curve (that is, the elasticity of demand); technology, salaries and other administrative expenses; taxes; and the prices of durable and those of variable means of production. This is not the place to present a formal solution of the problem of price determination. Suffice it to say that the concept of entry-preventing price and elimination price are important analytical tools to be used in the construction of a theoretical model of price determination. Once the price reaches the level acceptable to all firms – the equilibrium level – each firm is in a position to calculate the markup, that is, the ratio between price and cost or, more precisely, direct cost. When the equilibrium conditions change, the price is to be changed. Normally this occurs without a price war, since such wars are costly and major firms are willing to undertake them if only the expected gains (net of risks) are higher than expected costs, an occurrence that does not appear to be frequent.

The analytical steps, then, are two: the first is to understand how the equilibrium price is arrived at; the second is to understand how it varies when the equilibrium conditions change. If in the first step the concepts of entry-preventing and elimination prices are essential, in the second step it is the ‘full cost principle’ that plays the key role. Empirical enquiries have consistently shown that this principle is generally followed by managers operating in non-agricultural activities. Yet for a long period it has been considered only as a rough rule of thumb, without theoretical relevance. Probably the reasons are twofold. The first is that it contradicts the received doctrine, which is founded on marginal analysis and which, as a condition of equilibrium, assumes a rising marginal cost – the full cost principle, instead, which is based on the markup on direct costs, assumes the marginal cost to be constant and therefore equal to direct cost. The second reason is that that principle has been described as if it were a criterion to determine the price, not to modify it, but it can have a meaning only in the second case. Thus, Hall and Hitch (1939), in their pioneer empirical enquiry, report that ‘prime (or “direct”) cost per unit is taken as the base, a percentage addition is made to cover overheads•…•and a further conventional addition•…•is made for profit’. However, it is evident from this statement that the crucial theoretical problem is to explain the height of the two percentage additions – that can be unified into one percentage. Thus, given the cost elements, we have to explain the conditions that limit the discretionary powers of managers in choosing a given percentage and not another, that is, we have to explain the equilibrium conditions. Only after having explained the equilibrium price can the markup acquire a meaning. In other words, the full cost principle is theoretically meaningless as regards the problem of price determination and
becomes meaningful as regards the problem of price variations: in fact, barring price wars, the markup appears to be the quickest and most rational way for firms, and particularly for price leaders, to arrive at a new equilibrium price when the equilibrium conditions vary.

The further question is to understand why direct cost and not total unit cost is taken as the term of reference to modify the price in the short run – say, year by year or even in shorter periods. The reason is that the changes in the prices of variable factors affect without much delay all firms, though not necessarily in the same proportions, whereas the changes in the other equilibrium conditions – size of the market, elasticity of demand, technology, salaries and other overhead costs – affect the firms at different degrees and in different times. These changes either affect prices in relatively long periods or do not affect them at all – substantial increases in overhead costs can be offset, not by price increases, but through productivity increases. To be sure, when these are insufficient, the increases in overhead costs can push some of the firms out of the market; this can also be the outcome of unfavourable changes in market conditions.

Changes in direct costs, then, tend to be shifted to prices in the short run. But even for this category of changes a sort of hierarchy is necessary: changes in the prices of raw materials (including the sources of energy) tend to be fully shifted on prices of finished products in both directions, since those changes tend very quickly to affect all firms. This is not so for changes in wage cost per unit, since this cost is given by the ratio between wages and productivity. Now, wage changes – if we except the areas of the so-called submerged economy – affect in a relatively short run all firms, whereas productivity increases due to organizational innovations and to technological changes determined by previous investment tend to take place at different rates in the different firms (declines in productivity are exceptional): only those changes in wage cost per unit of output have to be shifted onto prices that are common in both the upward and the downward direction. However, under contemporary conditions the shift in the downward direction will be more limited than that in the upward direction, since it is unlikely that the prices of finished industrial products in international markets will generally decrease; and it is international competition that, in industry, will limit the market power of the firms of a given country. Briefly, in the short run, the shift of changes in total direct costs will tend to be not only partial but also asymmetrical.

In the case of industrial products, then, short-run variations in prices depend on the variations of direct costs: demand does affect prices, but, as a rule, only in the long run and not in the same direction, as is the case in the short-run variations of prices under competitive conditions, but in the opposite direction, since the long-run expansion of demand makes the entry of new firms easier and opens the possibility of exploiting economies of scale. Thus, an expansion of demand tends, *ceteris paribus*, to reduce and not to raise the price. In the short run demand increases have no significant direct effect on prices of industrial goods; they can have an indirect effect, that is, via the prices of raw materials, when demand pressure is so strong as to affect not only finished products but also raw materials. As for finished products, demand pressure tend to affect not prices but (consistently with the Keynesian conception) the level of activity.

2. If we pass from partial to general analysis and adopt the framework of a Sraffian model, we are bound to distinguish between basic and non-basic (‘luxury’) products. If we decide to consider not only competitive but also non-competitive markets, we have to drop either the assumption of a unique rate of profit or the assumption of a unique wage rate (for a given type of labour). In any case, prices enter into the conditions of simple reproduction. The conditions of expanded reproduction, that is, of accumulation – to use the Marxian expression – imply, in addition, that at least a share of the surplus be employed
productively, that is, invested – the velocity of accumulation being determined by that basic product that has got the lowest surplus. It is important to point out that technological progress is essential not only in the case of accumulation but also in the case of simple reproduction, since mineral products tend gradually to exhaust themselves; it is essential also in the case of a growth proportional to the increase of population, not only due to the reason just mentioned, but also due to the necessity of offsetting the tendency of diminishing returns in agriculture.

3. If we adopt a Sraffian model of general analysis, the study of the effects of technological changes meets with several problems, certainly serious, but, in principle, not insurmountable; in fact, some important steps in this direction have already been made by Sraffa himself. That study, instead, seems to be precluded if we adopt a Walrasian model of general equilibrium that implies a strictly static framework, in which all firms operate in conditions of diminishing returns, that is, of increasing marginal costs. Now, barring special cases, increasing returns are to be related to changes in the methods of production, even in the short run: increases in the productivity of labour can take place as a consequence of quick readjustments of the labour force and of innovating investment carried out in previous periods. A long series of empirical observations – among which may be mentioned Dunlop's 1938 article on the movement of real wages, the 'Verdoorn Law' and 'Okun's Law' – show that increasing, not diminishing, returns dominate modern economies and, in particular, non-agricultural activities. Thus, to admit that it is not perfect but imperfect competition and oligopoly that is the rule seems to be the only way to reconcile theoretical models and empirical enquiries in both partial and general analysis.

4. In the short run technical progress takes mainly the form of increases in productivity of means of production and, in particular of labour; in the long run one has also to consider the production of new goods, that in the short run represent a tiny fraction of the total. The diversification of output, which in fact conditions the growth of all firms, can assume either a prevailingly commercial character, in the case where the goods are already in the market, or also a technological character, if the goods or the process through which they are produced are new. In its turn, the expansion of demand represents the condition for the introduction of two important types of technological innovations – that is, new goods and new processes implying the exploitation of economies of scale – which, after all, is nothing but another way to re-propose the Smithian proposition according to which 'the division of labour is limited by the extent of the market'.

For the sake of simplicity, we limit ourselves to considering, as the index of technical progress both for the short and the long run, the increase in productivity of labour. The basic consequence of this increase is, at the aggregate level, a systematic divergence between the average variations of nominal incomes and the average variations of prices, with the fall of the relative prices of those goods produced in the most dynamic industries. Referring to average variations, the said divergence can take four different forms:

Nominal incomes Prices

(a) falling falling more rapidly
(b) constant falling
(c) rising constant
(d) rising rising more slowly

Cases of falling prices – (a) and (b) – were frequent in the 19th century, when the process of
concentration and that differentiation in industry and services had not proceeded far enough and
competition was still the rule in those sectors. In the 20th century case (a) occurred during the first four
years of the Great Depression; but, in sharp contrast to what was normally occurring in the 19th century,
the level of activity in industry and services fell much more than prices, whereas in agriculture the prices
fell violently, but the level of activity remained approximately constant. The comparison with the great
depression of the 19th century – which occurred in the years 1873–9 – is illuminating.
Putting aside services, which offer a picture similar to that of industry, the percentage changes in prices
and production of agriculture and industry during the two great depressions (I and II) were as follows:

<table>
<thead>
<tr>
<th></th>
<th>United Kingdom</th>
<th>United States</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Prices</strong></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Agriculture I</td>
<td>−18 +3</td>
<td>+31 +4</td>
</tr>
<tr>
<td>II</td>
<td>−44 0</td>
<td>−54 +2</td>
</tr>
<tr>
<td>Industry I</td>
<td>−29 −5</td>
<td>−33 −5</td>
</tr>
<tr>
<td>II</td>
<td>−21 −16</td>
<td>−23 −48</td>
</tr>
</tbody>
</table>

If we except the period of the great depression of the 20th century, which was in all senses an
exceptional event, with productivity varying in a very irregular fashion, in the 20th century cases (c) and
(d) – rising nominal incomes with constant prices or prices rising more closely – were the rule. Now, it
is not indifferent that the fruits of technical progress have one type of consequence or the other on prices
and incomes.

When prices of all goods fall, the means of production (Sraffa's basic products) become cheaper and this
stimulates the expansion of all firms, including those that do not introduce innovations. On the other
hand, when prices fall demand increases automatically in real terms.

Let us now consider what happens when productivity rises but prices do not fall. If, in such
circumstances, nominal incomes do not rise, the whole increase in productivity tends to translate itself
into a decreasing level of employment; to have at least a stable level of employment, nominal incomes
should rise in proportion to the increase in productivity; and this is not an automatic process. It is
unlikely that wages and salaries rise if there is not a systematic action of trade unions, unless the process
of differentiation and the consequent increasing fragmentation in the labour market have become so
widespread as to favour wage increases even without a generalized pressure of trade unions. On their
side, non-labour incomes will increase only if investment or government expenditure increases, or both.
Investment can increase only if new investment opportunities arise, due to technical innovations,
whereas government expenditure can increase as a political decision. On the other hand, with stable
prices, the firms that do not introduce innovations cannot receive the stimulus arising from the means of
production becoming cheaper. As a result, the process of growth tends to become more and more
unbalanced, unless a general expansion of demand – originated by innovations and/or by government –
takes the place of the stimulus afforded by an overall fall in prices.

In short, owing to the obstacles to entry, in most non-agriculture activities the ‘competitive mechanism’
for the distribution of the fruits of technical progress (falling prices, stable nominal incomes) has been
more and more substituted by the ‘oligopolistic mechanism’ (stable prices and increasing nominal
incomes). In the new conditions, the process of growth requires increasing intervention of public
powers, but not necessarily in the form of increasing public expenditure. That intervention can consist of
taxation (to afford incentives or to put brakes), or can support the prices and the incomes of those activities, like agriculture, least affected by those two processes, or can promote the source of technological innovation, that is, scientific research, or – to give another important example – can create conditions favourable to development of small firms, not only with fiscal and credit incentives, but also by supplying real services – especially commercial and technical assistance. All these measures of public powers can push up the growth of the volume of investment to the velocity required to avoid an increase of unemployment or gradually to reduce it to the frictional level.

If the countervailing influences of public interventions process are not strong enough, in the new conditions the process of growth tends to become more unbalanced not only from the standpoint of the different industries (since those that do not carry out innovations directly have no more the stimulus determined by the declining prices of the means of production they use), but also from the point of view of income distribution. In fact, the downward price rigidity tends to create special margins in certain industries or in certain firms. These rising margins do not necessarily become above-normal profits; they can become, too, above-normal wages or salaries, depending on the relative strength of the opposing parties. Instead of the above-normal incomes, the advantages for workers can also take the form of a greater stability of employment; similarly, the advantages of capitalists can take the form, rather than of above-normal profits, of more stable profits.

5. It seems that in recent times the process of differentiation has become more important than the process of concentration and the economies of specialization seem to have become more important than the economies of scale. This new development in industry has been promoted by at least three changes: (1) the growth of electronics and allied industries; (2) the reaction of increasing masses of workers in advanced countries against the monotony of assembly lines and other methods of mass production; (3) the growing differentiation in consumer preferences originated by the increasing per capita income. In services, differentiation has always been important and in recent times has become even more important; at the same time, services become the most important section of the economy in the so-called post-industrial societies. Considering the declining relative weight of agriculture and mining in advanced societies, we have to conclude that the area of flexible prices tends to shrink and that of rigid prices to expand – I mean flexibility or rigidity in the downward direction. In particular, the area of rigid prices tending to expand refers more and more to services and less and less to industry; this phenomenon, that has important consequences also on the overall behaviour of prices, up to now has received very little attention.

It remains true, however, that the increasing rigidity of prices of goods and services determines the need for an increase in demand large enough to avoid a decline in employment, if population grows. Now, with the diffusion of high education, with the space for a rapidly increasing number of goods opened up by the increasing per capita income, in recent times the potentialities of development have increased. But such potentialities can remain unexploited if they are left to spontaneous market forces; given the rate of interest, all depends on investment stimulated by technological innovations that promise to be profitable and that can be devised and carried out by private firms without the support or the stimulus afforded by public powers. If those investments are not enough to promote an increase of demand capable of generating an increase in income at least equal to that in productivity, unemployment gradually grows. It is well to emphasize that the main obstacles to a policy of economic growth arise not by diminishing returns, but either from the side of the public deficit, if the increasing supply of bonds pushes up the rate of interest; or from the side of the foreign deficit, which pushes up the value of
foreign currencies, giving rise to a special kind of inflationary pressure. Such problems are aggravated by the fact that the two deficits, to some extent, reinforce each other: for instance, large firms tend to borrow abroad, owing to the high internal rate of interest. But these are matters that go beyond the limits of our theme.

Olson, Mancur (1932–1998)

Joe A. Oppenheimer

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Mancur Olson was one of the small group of economists in the 20th century who laid the foundation of rational choice theorizing about non-market behaviour. He demonstrated self-interested individuals have a great incentive to free ride rather than to contribute to the supply of a public good. He also showed how self-interested group behaviour explained why nations tend to stagnate after periods of growth. Utilizing the notion of profit seeking political entrepreneurs, he argued the benefits of democratic systems were to contain the extractive costs imposed by government and to extend the time horizons for property rights.

Article

Along with a handful of other economists of the 20th century (Kenneth Arrow, James Buchanan, Anthony Downs, and John von Neumann), Mancur Olson laid the foundation for the adoption of rational choice theorizing about non-market behaviour in the social sciences. His work (1965) on the relationship between the rational choice of individuals and the performance of groups had a revolutionary impact on the fields of sociology and political science. In 1967 he left his first academic job at Princeton University to become Deputy Assistant Secretary of the US Department of Health, Education and Welfare. From there he went to the University of Maryland, where he held the position of Distinguished Professor of Economics, co-founded the University of Maryland's Center for Collective Choice, and
founded the Institute for Research on the Informal Sector (IRIS).

Mancur Olson was born in January 1932 to a Norwegian-American farming family in North Dakota's Red River Valley. The valley contained some of the richest farmland in the state; the family grew mainly flax and did quite well. Neither his parents nor other members of that generation in the Olson family were educated beyond high school, but his father and his uncle were intellectually curious and questioning of society's arrangements. Mancur grew up on the farm and, as the eldest of three sons, he was permitted to be party to the adults' conversations about farming and social problems.

Throughout his life he recalled those early discussions regarding the shared interests of farmers in getting a fair price for their crops, the difficulties in their meeting other common concerns and the many references to the ability of the Scandinavian countries to overcome narrow interests to achieve both social justice and economic growth. He noted these as the part of his inheritance that motivated his lifelong research interests in the problems of collective action, social justice and economic prosperity.

Mancur went to college at North Dakota State University on an Air Force Reserve Officer Training Corps (ROTC) scholarship. There he studied agricultural economics and had the good fortune to be mentored by Rainer Schickle (the father of the American composer, Peter Schickle). He won a Rhodes scholarship and went to Oxford, only to discover that Oxford dons could not imagine that a graduate (1954) from North Dakota's Agricultural College could qualify for entry into their graduate programme of Philosophy, Politics and Economics. So, unlike most of the other Americans coming from more prestigious institutions, he was required to get a second BA from Oxford before going on for an M.Phil. At Oxford he met his lifelong companion and wife, Allison, who was also getting her M.Phil. (in history). The Olsons left Oxford together for the environs of Boston, where Allison had a job at Smith College and Mancur was to get a Ph.D. at Harvard. Two barriers were created. First, Mancur's chosen advisors, first Kenneth Galbraith and then also Otto Eckstein, left for Washington to work in the Kennedy administration. Further, Air Force officials discovered that Mancur had yet to do his service for his North Dakota Air Force ROTC contract, and they required him to leave Harvard to do military service. That service was performed between Rand, Brookings and the Air Force Academy for two years, after which he was able to finish his work again at Harvard under the tutelage of Thomas Schelling. During this time their family grew and eventually Allison and Mancur had four children: Elicka, born in 1963, a veterinarian; Severn, born in 1967, a civil servant; Sander, born in 1969, a journalist; and Garth, who died in infancy.

Olson's major contribution to economics and to the social sciences more broadly was in the analysis of 'non-market' economics. He focused both on how individual non-market behaviour and political institutions (broadly understood) affected socio-political and economic outcomes. Many of his most important findings are encapsulated in his three major books The Logic of Collective Action (LCA) (1965), The Rise and Decline of Nations: Economic Growth, Stagflation, and Social Rigidities (RD) (1982), and Power and Prosperity: Outgrowing Communist and Capitalist Dictatorships (PP) (posthumous, 2001).

His first book, LCA, grew out of his dissertation, and focused on the non-Paretian outcomes one can expect from unorganized groups of individuals in their efforts to secure costly public goods (that is, goods where consumers cannot be excluded and consumption by one does not diminish consumption by another) such as air quality and peace. LCA built on the findings of William Baumol (1967) and Paul Samuelson (1954) who had shown that suboptimality was to be expected from rational self-interested behaviour regarding public goods. Olson expanded their arguments and generalized them by noting that
the satisfying of virtually all shared interests is a form of public good, thereby selling the argument to the non-economist. The crux of the observation is simple: self-interested individuals have a great incentive to free ride rather than to contribute to the supply of a public good. Individuals will, after all, receive the good if others supply it. In LCA, Olson also tried to develop an argument that the size of the group was central to the analysis, but this was later shown to be erroneous (Frohlich and Oppenheimer, 1970; Hardin, 1982). The work spawned a paradigm shift in the study of group behaviour in both political science and sociology.

In RD, Olson built on LCA (and also the 1962 work of Buchanan and Tullock, who argued that one could evaluate constitutional rules by the externalities imposed upon losing subsets of the population by the extraction of resources for redistribution to the winners). In RD Olson argued that narrow-interested lobbying groups, designed to extract rewards from the general population via governmental action, clung to stable political systems much like barnacles to a ship's hull. Such extractive interests were shown to be more harmful the narrower the interests they represented. Newer political systems, built on cataclysmic changes in a society, were likely to be relatively free of such encumbrances and hence would lead to less wasteful extraction. Therefore, their economies would be more likely to exhibit substantial and sustained growth than would those associated with more established, stable political systems. He expanded the analysis (1990) to consider the comparative efficiency of the Scandinavian political systems' foundation on a coalition of a very few, very broad political interests. These welfare states were contrasted with welfare states in other industrialized countries built on a patchwork quilt of narrow, coalesced social-interest groups.

Coupled with Downs's 1957 work *An Economic Theory of Democracy*, LCA also sparked a reconsideration of political leaders as entrepreneurs (Salisbury, 1969; Frohlich, Oppenheimer and Young, 1971) as a way of solving the collective action problem. In the 1990s Olson himself began to mine the profit motive as a tool to understand the motivational characteristics of political leaders, and to reconsider the social gains from democracy. By assuming politics was necessarily based on coercive taxes, he considered the evolution of political systems as a hypothetical history from roving bandits to stationary bandits and then to kleptocratic political leaders constrained by the rules of succession and, more generally, competition. Roving bandits would take what they could. Stationary bandits, who controlled an area (for example, 'war lords' and mafiosi) would find it worth their while to ensure the prosperity of the population they exploited. Rules of succession, such as those that underlie monarchies, were shown to change the time horizon for maximizing the extractive behaviour of the kleptocrat, thereby giving incentives to investments that had longer time horizons. Using the finding that narrower interests impose greater costs on society than wider ones, Olson (1993) and McGuire and Olson (1996) showed the general gain from democratic (majoritarian) systems to be the decrease in imposed external costs by the winning kleptocrats, as well as the extension of the time horizons for property rights. His last book, PP, built upon his kleptocratic entrepreneurial arguments and their relation to the time horizon of politicians. Long-term property and other rights were seen to be a key to the development of more complex financial markets that underlie modern economic development.

Olson's heritage is extraordinarily wide: the general interest in 'social dilemmas' grew directly out of his work via the translation of LCA into the language of n person game theory. His sure-handed encouragement of young scholars interested in non-market economics helped foster the multidisciplinary adoption of rational choice theoretic tools in the social sciences in general.

Oncken, August (1844–1911) were a German historian of economic thought who made significant contributions to the study of the Physiocrats and the work of François Quesnay. His work, particularly in his later years, focused on the history of economic thought and the development of economic ideas from the 18th to the early 20th century.

Oncken was born in Heidelberg on 10 April 1844 and died in Schwerin (Mecklenburg) on 10 July 1911. After studies in Munich, Heidelberg and Berlin, Oncken first became a landowner in Oldenburg. His scholarly interest in physiocracy was a life-long interest in agriculture. He began his academic career as university lecturer in economics and statistics at the Vienna School of Agriculture. In 1878, after a brief interlude at the Aachen Institute of Technology he accepted an appointment as professor of economics at the University of Bern, where he taught a wide range of courses until his retirement (because of failing eyesight) at the end of 1909.

As a general economist, Oncken has little claim to our attention. He never had a correct understanding of things like, say, diminishing returns, and he remained an unsophisticated advocate of protection, particularly for agriculture (1901a), applauding Henry Carey as the greatest living economist (1874). As an historian of economic thought, however, he was one of the leading lights between 1870 and 1920. In his earliest historical paper (1874) Oncken criticized Adam Smith, in the spirit of German economics of that time, for his ‘materialism’ and his radical ‘laissez faire’ doctrines. In his latest historical paper (1877) he confessed that these criticisms did not survive a careful reading of the original sources. Instead he now stressed the similarities between those two giants of moral philosophy.

In Bern, Oncken's interests shifted to the Physiocrats. The result was a series of masterpieces of archival detective work and historical interpretation. It begins with a paper on the relationship between the Physiocrats and their disciples in Bern (1886a). In the following monograph (1886b), Oncken traces the maxim ‘laissez faire’ to d'Argenson (and not to Boisguillebert, as Stephan Bauer states in the Encyclopaedia of the Social Sciences) and further back to the time of Colbert, while ‘laissez passer’ was later added by de Gournay in a conversation with Mirabeau. In this context, Oncken puts forth the startling conjecture (not reiterated in (1902)) that the Tableau Economique was originally printed in support of a bid by Quesnay for the premier ministership.
Oncken's edition of Quesnay's writings (1888) became fundamental for all further work in this field. The sought-for completeness, however, eluded Oncken, because his very publication set off a renewed search of archives, culminating in Bauer's discovery of an early (but still not the first) version of the *Tableau Economique* (published by the British Economic Association) and of the article ‘Hommes’ in 1890. A further article, ‘Impôts’, was later published by Schelle. On the other hand, Oncken's collection includes non-economic writings not available in the 1958 edition, as well as the basic biographical sources. A first, hand-written draft of the *Tableau* was later reproduced in Oncken's *History of Political Economy* (1902).

Oncken himself made use of much of the newly discovered material in a succession of essays on Quesnay's life (1894–6) and the history of physiocracy (1893a, 1893b and 1897a). He was well aware that the time was not ripe for a definitive biography, but for brilliance of historical scholarship Oncken's essays are unsurpassed. It is regrettable that, being available only in German and in inaccessible journals, they are usually not given the credit they deserve.

With respect to the circumstances under which the *Tableau Economique* was first printed, we do not seem to have progressed much beyond Oncken. The story that the most famous single page in the history of economics was typeset and printed by a bored Louis XV with his own hands, Oncken regarded as a fable, mainly because of its incompatibility with the known facts about the King's character. Schelle, however, chose to treat the story, despite its implausibility, as historical fact and his view was still accepted by Jacqueline Hecht in 1958.

Of the *History of Political Economy* (1902), only the first volume appeared, dealing with the time before Adam Smith. The first half, reaching from antiquity to mercantilism, is today of little interest. The second half, treating the Physiocrats and their predecessors, is still a valuable source of historical information about men, books and ideas, making an effective case for Quesnay as the ‘founder’ of economic science.

Oncken later returned to Adam Smith by defending him, not without some polemics, against his detractors of the Schmoller School (1897b, 1898). In another paper (1909), he also pointed out that Smith did not borrow from Ferguson, but had valid reasons for feeling that Ferguson had borrowed from his lecture notes.

Operations research (OR) is both a profession and an academic discipline. It involves the application of advanced analytical methods to improve executive and management decisions. This survey highlights the types of OR models and techniques in common use. It explores the roots of OR and its theoretical and professional evolution, and presents the current trends which shape its future.

Article

Operations research is commonly referred to as OR. In the United Kingdom, where the first formally recognized group of practitioners was formed, it is called ‘operational research’. Other names, such as ‘management science’, ‘operational analysis’ and ‘systems analysis’, are frequently used as synonyms. Definitions of OR abound. The differences among these definitions reflect important dimensions of conflict in philosophy and perception of the field among the members of the various communities identifying themselves as operations researchers. It is instructive, therefore, to examine some of these definitions to identify areas of agreement about the distinctive characteristics of the field as well as those
dimensions which are a cause of tension.
The Operational Research Society of the UK, the oldest OR professional society, developed the following official definition (Dando and Sharp, 1978, p. 940):

Operational Research is the application of the methods of science to the complex problems arising in the direction and management of large systems of men, machines, materials and money in industry, business, government and defense. The distinctive approach is to develop a scientific model of the system, incorporating measurements of factors such as chance and risk, with which to predict and compare outcomes of alternative decisions, strategies or controls. The purpose is to help management determine its policy and actions scientifically.

Its current website suggests that OR is the discipline of ‘applying advanced analytical methods to make better decisions’ (the OR Society). While these definitions see OR as an eclectic, problem-centred approach where scientific methods are employed to help management, definitions proposed in the United States view OR as a science or as a distinctive methodology providing scientific bases for decision-making. The constitution of the Operations Research Society of America (ORSA) referred to OR as ‘the science of operations research’ (House, 1952, p. 28). This view was incorporated in 1982 in the Decision and Management Program of the U.S. National Science Foundation that referred to the emergence of a combined theoretical and empirical science of operational and managerial processes (Little, 1986). The current website of the Institute for Operations Research and Management Science (INFORMS) which has succeeded ORSA, refers to OR as the ‘science of better’.

The scientific view of OR sees its goals as (a) the development of models of operations that represent the causal relationship between controlled variables, uncontrolled variables and system performance, and (b) the development of the computational means for identifying levels of controlled variables in ways that help managers of a system achieve systems outputs as close as possible to the ones they desire. A broader and more proactive variant of the scientific view of OR was proposed in the first major textbook to be published on OR (Churchman, Ackoff and Arnoff, 1957). It suggested that the goal of OR is an overall understanding of optimal solutions to executive-type problems in organizations. This comprehensive goal of OR implies a normative prescriptive role with boundaries emancipated from mere reactive problem-solving.

Examination of the various definitions of OR establishes the following features upon which there is almost general agreement: (a) OR focuses upon executive and management-type decisions in organized systems; (b) a distinct feature of the methodologies used in OR is the development of quantitative models which relate controllable and uncontrollable variables to system performance measures; and (c) the outputs of OR models are solutions, that is, suggested levels of control variables that meet some prescribed restrictions. In addition, OR attempts to identify those solutions that are ‘better’ than others or are ‘best’ given an objective function and the validity of solutions ought to be tested empirically. OR, however, is concerned not only with the derivation of solutions but their relevance to management practice and their implementation.

While OR definitions reflect the ideals and aspirations of many leaders of OR communities, a commonly held view is that OR is a collection of techniques (National Academy of Sciences, 1976). In fact, the
success in practice of some OR techniques, such as linear programming and the proliferation of accessible optimization packages, is responsible for this perception. In part, it is also a reflection of imbalances in the work of OR academics. Examination of the content of OR journals and textbooks, for example, would support such a proposition. Indeed, much of the academic effort since the mid-1980s has focused on articulating the supporting mathematical theories of OR models, the development of alternative models and computational methods with a glaring absence of empirical testing (Denizel, Usdiken and Tuncalp, 2003). This, however, was more a result of a natural progression of the life cycle of the field than a paradigm shift.

Disagreements in the OR communities exist with regard to the following questions. First, what is the level of generality that OR models can attain (that is, what are the prospects of OR becoming a science of operations as opposed to an approach to problem-solving in specific organizational contexts)? Second, what is the degree of comprehensiveness of OR missions, in particular the degree to which a systems approach should characterize OR activities (that is, focus of OR methodologies upon overall effects of a proposed solution on an organization rather than a narrower problem-solving focus)? Third, what is the role of interdisciplinary teamwork in OR?

**OR models and techniques**

Models and computational techniques are key elements in the OR methodology. Models in OR, as opposed to models developed by mathematicians, derive their legitimacy from the real world (as in other sciences) and from their potential uses. Thus one can classify OR models and techniques according to the type of management problems or decision areas they deal with.

Some of the characteristic problem areas that have stimulated OR modeling include:

- Allocation problems
- Inventory problems
- Queuing problems
- Scheduling problems
- Competitive problems
- Renewal and replacement problems
- Search problems
- Revenue management
- Supply chain management
- Financial and marketing engineering
- Data mining

Each of these problem areas is characterized by some typical structures which have stimulated the development of certain classes of mathematical models as well as their supporting mathematical theories. Often, however, a type of mathematical model developed for a specific problem area can be used to model processes with similar structures in other problem areas.

Let us consider, for example, allocation problems. These are the typical economic problems of allocating scarce resources between competing demands so as to maximize net benefits. The allocation, however,
must satisfy some prescribed constraints. The first primitive mathematical programs were formulated by economists late in the 18th century. The typical structure of mathematical programs is the maximization or minimization of an objective function subject to a set of constraints. The properties of the objective function and the special structures of the constraints determine the methods and difficulty of finding optimal values. For example, *linear programming* postulates a system with a linear objective function, linear constraints and non-negative control variables. Thus sub-areas of mathematical programming designate the mathematical structure of the optimization problem at hand: *integer programming* requires integer solutions; *quadratic programming* postulates a quadratic objective function; *stochastic programming* assumes that stochastic parameters describe the objective function; *chance-constrained programming* assumes that the restrictions on a problem are given as probabilities of satisfying each constraint, and so on.

An interesting allocation problem arises in situations with multiple decision units with separate conflicting objectives, when rules for trade-offs or reconciliation of conflict are not given. This problem led to the emergence of *multi-criteria programming*, a technique that postulates several objective functions subject to a set of joint constraints.

As we indicated, while mathematical programming emerged as a means of dealing with allocation problems, its applications cut across most areas of OR endeavour.

*Queuing theory* evolved primarily to help design service policies to deal with congestion and waiting lines. The theory has its roots in probability theory. The application of the theory demonstrates well a problem which characterizes many OR models – limited empirical validity. Indeed, in many practical situations, the probability distributions which characterize arrival and service time depart from those postulated by the basic theory. In such cases problems become analytically intractable and simulation techniques are used.

*Inventory and production control theory* can be divided into the tractable but unrealistic deterministic cases, and the more problematic stochastic cases. The theory has contributed important insights as to the shape of optimal policies, but specific solutions to problems arising in the real world are typically obtained by simulation.

*Simulation* is indeed the most prolific OR technique. It is used in practice especially to model stochastic processes and provide solutions to analytically difficult or intractable problems. A computer model representing the system provides the vehicle for low-cost, fast experimentation with alternative patterns of control variables.

Competitive problems have led to the emergence of *game theory*. While the theory has had some important applications (for example, designing optimal stable policies of inspections associated with international nuclear-testing restrictions), its restrictive assumptions with respect to the rationality of players have limited its usefulness for modelling many competitive business situations. *Gaming* and simulation techniques are often used to improve strategic decisions in competitive situations.

Scheduling problems are typically modelled as *network flow optimization* problems. Two techniques have received great attention and have been employed widely in project planning: the program evaluation and review technique (PERT) and the critical path method (CPM). Network flow optimization is used extensively to deal with many transportation and communication problems.

An important area of OR modelling is the area of Markov and related processes. In a Markov process, knowledge of the present makes the future independent of the past. Markov chains have been used extensively in manpower planning.
Dynamic programming is a method of analysing multi-stage decision processes in which each decision in a sequence depends upon those preceding it as well as exogenous factors. The technique reduces significantly the computational effort by eliminating the need to enumerate and consider the consequences of all possible decision sequences. The method is used in a wide variety of problem areas. In the 1980s revenue management methods combining accurate demand forecasts with intelligent dynamic pricing were developed for and adopted by airlines, and their use spread to other sectors. In the 1990s increasing globalization and the emergence of complex business networks of suppliers and producers created the need for better supply chain management. Advances in computing power, communications and operation research methods created new modelling opportunities responding to the challenge of finding best overall combinations of suppliers, transportation, production, warehousing and inventory. Recent modelling efforts in this domain incorporate ‘game like’ situations in cooperative networks where incentives of different participants may be misaligned. The late 1990s saw the emergence of e-commerce and powerful information technology applications in business generating high volumes of customer data. Large, high-quality data stimulated the development of data mining techniques to use the data to improve business strategies and operations. The proliferation of personal powerful computers created opportunities for the development of OR applications for a variety of business functions. Financial and marketing engineering are examples of OR applications to traditional functional fields of business.

The lack of definite boundaries as to what constitutes OR makes it difficult to determine whether some techniques originating in other fields, but frequently used by OR practitioners, should be designated as OR techniques. Statistical analysis, forecasting methodologies and evaluation techniques are good examples.

The roots of OR

The beginnings of OR can be traced to the emergence of the executive function and the complex organization brought about by the Industrial Revolution of the 19th century. The mathematical roots of OR can be traced earlier to the work of Quesnay (1759), who formulated primitive mathematical programming models. This fundamental work was followed by the work of Walras (1883), and by the work of von Neumann (1937) and Kantorovich (1939).

The roots of empirical OR can be traced to the scientific management movement. The work of Taylor, Gantt, Emerson and other pioneers of scientific management began around 1885. They proposed that scientific methods of analysis and measurement could and should be used in production management and business decisions. In 1909, Erlang, a Danish mathematician, published his study of traffic congestion in a telephone network, pioneering the modelling of queues. In 1916 Lanchester published his ‘N-square law’, assessing the fighting power of opposing forces. The theory was tested retrospectively against Admiral Nelson’s plan of the battle of Trafalgar.

The appearance of OR as an organized activity is associated with preparation in the UK for the Second World War. In 1936 the British government decided to set up radar stations. The need to study the operational use of radar chains in order to increase their ability to detect aircraft led to the establishment of a study group of scientists called ‘the operational research group’. Their success led to the adoption of OR by other branches of the military. In 1942 an OR section was established by the US Air Force. OR was soon adopted by other branches of the US military. Under the aegis of the US Air Force, a team of
economists and mathematicians began in 1947 to model the military structure and the economy. During this period Dantzig (1963) developed the simplex method of solving linear programs.

The evolution of OR

The diffusion of OR to the industrial world was slow. Only in the early 1950s did the tools and methods of OR begin to be used outside the military. The first important industrial application of OR was the use of linear programming to schedule a petroleum refinery (Charnes and Cooper, 1961).

The Operational Research Club of Britain was formed in 1948, and the Operations Research Society of America (ORSA) was established in 1951. Other national societies for OR soon followed, and in 1957 the International Federation of Operational Research Societies was formed. Books, journals and university programmes specializing in OR proliferated in the 1960s. A gradual process of change in the membership of most OR communities started, bringing a shift towards a higher proportion of university-based members. While the ORSA constitution saw as one of its major missions the establishment and maintenance of professional standards of competence in OR, the evolution of the field caused more emphasis to be placed upon the academic mission of the development of methods and techniques of OR. The tension between practice and theory of OR indeed originated in the 1950s and 1960s. It is interesting to note that this period is viewed by some as the best of times for OR (Miser, 1978) and by others as the worst of times (Churchman, 1979).

The period saw some of the most exciting mathematical developments since the simplex algorithm. Examples are the important paper by Kuhn and Tucker (1951) laying the foundations of nonlinear programming; the paper by Gomory (1958) presenting a systematic computational technique for integer programming; the works of Bellman (1957) developing dynamic programming; the seminal book by Ford Jr and Fulkerson (1962) articulating network flow optimization; and the volume edited by Arrow, Karlin and Scarf (1958) on the mathematical theory of inventory and production processes. Other important developments during the period were the articulation of decision analysis (see, for example, Raiffa, 1968), the development of stochastic programming and chance-constrained programming (see, for example, Charnes and Cooper, 1959) and the development of the dual method (Lemke, 1954) and the linear complementarity algorithm (Lemke, 1965). Yet, despite these developments, Churchman (1979, p. 13) called the period ‘dreary’, lamenting the separation of theoretical developments from application, describing OR modelling as a ‘study of the delights of algorithms; nuances of game theory; fascinating but irrelevant things that can happen in queues’.

The 1980s also saw a breakthrough development in the inventory management field. Roundy (1985; 1986) found a simple heuristic and proved that it yields schedules within two per cent of the optimal solution; this work anticipated also the coordination problems characterizing supply chain management.
The 1990s saw articulation of the general theory of supermodularity and lattice programming pioneered by Veinott, Edmonds and Topkis (see Topkis, 1998). The theory provides fundamental insights to certain classes of optimization problems and issues related to monotone comparative statics, fundamental in economic analysis. The development of polynomial submodular set functions – an unresolved problem remaining – was solved simultaneously by Iwata, Fleischer and Fujishige and Schrijver (see Fleischer, 2000).

The new millennium also saw a breakthrough in graph theory – the characterization of the strong perfect graphs by Chudnovsky, Robertson, Seymour and Thomas (see Cornuéjols, 2003).

Perhaps more important to the future of operations research has been the great progress achieved since the mid-1990s in computational methods. Advances in computing machinery, software improvements and development combined to increase the practical significance of the various OR methods. The increased speed of computation and the huge increases in computer memory capacity have made it possible to solve much larger problems and use entirely different solution strategies (Bixby, 2002). Improved software also allowed also better interface with users, increasing the accessibility of OR methods to a wider population of users.

The scope of OR was enlarged while the cohesiveness of its communities reduced. Fragmentation was identified by many as an explanation of the declining memberships of many OR and management science professional societies. OR appeared to some observers to be ‘in danger of losing its identity as a recognized activity and being assimilated into other fields of endeavor’ (Bonder, 1979, p. 218). Thus, while the power of OR methods and their use increased, the period since the mid-1980s has witnessed some trends which are threatening the identity of OR as a distinct profession.

The future of OR

The apparent divorce of OR theory from practice and empirical testing led some leaders in the OR community to wonder whether ‘the future of OR is past’. The microcomputer revolution has increased the benefit–costs ratios of OR methods and increased the direct access of general business users to OR. OR groups and practitioners, however, have lost some of their unique advantages as gatekeepers to the application of OR methods. Much of the diffusion of OR methods to the industry is now accomplished through the sales of packaged programs, and is marketed through demonstration CDs. Many users of OR methods in business do not consider themselves OR practitioners. Thus, the dispersion of OR practice in business has resulted in a loss of professional identity (Geoffrion, 1992).

Loss of professional identity reduces the flow of new recruits to the profession and limits the career opportunities of OR professionals. The success of OR methods may, therefore, entail the decline of the profession. The sustainability and health of the profession depends on its ability to adopt new business models that fit the new environment, turning threats to opportunities for growth.

opportunity cost

James M. Buchanan
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
choice; opportunity cost; scarcity

Article

The concept of opportunity cost (or alternative cost) expresses the basic relationship between scarcity and choice. If no object or activity that is valued by anyone is scarce, all demands for all persons and in all periods can be satisfied. There is no need to choose among separately valued options; there is no need for social coordination processes that will effectively determine which demands have priority. In this fantasized setting without scarcity, there are no opportunities or alternatives that are missed, forgone, or sacrificed.

Once scarcity is introduced, all demands cannot be met. Unless there are ‘natural’ constraints that predetermine the allocation of end-objects possessing value (for example, sunshine in Scotland in February), scarcity introduces the necessity of choice, either directly among alternative end-objects or indirectly among institutions or procedural arrangements for social interaction that will, in turn, generate a selection of ultimate end-objects.

Choice implies rejected as well as selected alternatives. Opportunity cost is the evaluation placed on the most highly valued of the rejected alternatives or opportunities. It is that value that is given up or sacrificed in order to secure the higher value that selection of the chosen object embodies.

Opportunity cost and choice

Opportunity cost is the anticipated value of ‘that which might be’ if choice were made differently. Note that it is not the value of ‘that which might have been’ without the qualifying reference to choice. In the absence of choice, it may be sometimes meaningful to discuss values of events that might have occurred but did not. It is not meaningful to define these values as opportunity costs, since the alternative scenario does not represent a lost or sacrificed opportunity. Once this basic relationship between choice and opportunity cost is acknowledged, several implications follow.
First, if choice is made among separately valued options, someone must do the choosing. That is to say, a chooser is required, a person who decides. From this the second implication emerges. The value placed on the option that is not chosen, the opportunity cost, must be that value that exists in the mind of the individual who chooses. It can find no other location. Hence, cost must be borne exclusively by the chooser; it can be shifted to no one else. A third necessary consequence is that opportunity cost must be subjective. It is within the mind of the chooser, and it cannot be objectified or measured by anyone external to the chooser. It cannot be readily translated into a resource, commodity, or money dimension. Fourth, opportunity cost exists only at the moment of decision when choice is made. It vanishes immediately thereafter. From this it follows that cost can never be realized; that which is rejected can never be enjoyed.

The most important consequence of the relationship between choice and opportunity cost is the ex ante or forward-looking property that cost must carry in this setting. Opportunity cost, the value placed on the rejected option by the chooser, is the obstacle to choice; it is that which must be considered, evaluated, and ultimately rejected before the preferred option is chosen. Opportunity cost in any particular choice is, of course, influenced by prior choices that have been made, but, with respect to this choice itself, opportunity cost is choice-influencing rather than choice-influenced.

Other notions of cost

The distinction between opportunity cost and other conceptions or notions of cost is best explained in this choice-influencing and choice-influenced classification. Once a choice is made, consequences follow, and these consequences may, indeed, involve utility losses, either to the person who has made initial choice or to others. In a certain sense it may seem useful to refer to these losses, whether anticipated or realized, as costs, but it must be recognized that these choice-determined costs, as such, cannot, by definition, influence choice itself.

A single example may clarify this point. A person chooses to purchase an automobile through an instalment loan payment plan, extending over a three-year period. The opportunity cost that informs and influences the choice is the value that the purchaser places on the rejected alternative, in that case the anticipated value of the objects which might be purchased with the payments required under the loan. Having considered the potential value of this alternative, and chosen to proceed with the purchase, the consequences of meeting the loan schedule follow. Monthly payments must be made, and it is common language usage to refer to these payments as ‘costs’ of the automobile. The individual will clearly suffer a sense of utility loss as the payments come due and must be paid. As choice-influencing elements, however, these ‘costs’ are irrelevant. The fact that, in a utility dimension, post-choice consequences can never be capitalized is a source of major confusion.

Economists recognize the distinction being made here in one sense. With the familiar statement that ‘sunk costs are irrelevant’, economists acknowledge that the consequences of choices cannot influence choice itself. On the other hand, by their formalized constructions of cost schedules and cost functions, which necessarily imply measurability and objectifiability of costs, economists divorce cost from the choice process.

Essentially the same results hold for accountants, who normally measure estimated costs strictly in the ex post or choice-influenced sense. Those ‘costs’ estimated by accountants can never accurately reflect the value of lost or sacrificed opportunities. Numerical estimates could be introduced in working plans
for alternative courses of action prior to decision, but such estimates of opportunity costs would be the accountant's measure of the values for projects not undertaken rather than the value of commitments made under the project chosen.

As suggested, choice-influencing opportunity costs exist only for the person who makes choice. By definition, opportunity costs cannot 'spill over' to others. There may, of course, be consequences of a person's choice that impose utility losses on other persons, and it is sometime useful to refer to these losses as 'external costs'. The point to be emphasized is that these external costs are obstacles to choice, and hence a measure of forgone opportunities, only if the individual who chooses takes them into account and places his own anticipated utility evaluation on them.

Opportunity cost and welfare norms

The source of greatest confusion in the analysis and application of opportunity cost theory lies in the attempted extension of the results of idealized market interaction processes to the definition of rules or norms for decision makers in non-market settings. In full market equilibrium, the separate choices made by many buyers and sellers generate results that may be formally described in terms of relationships between prices and costs. Under certain specified conditions, prices are brought into equality with marginal costs through the working of the competitive process. Further, the general equilibrium states described by these equalities are shown to meet certain efficiency norms.

Prices may be observed; they are objectively measurable. A condition for market equilibrium is equalization of prices over all relevant exchanges for all units of a commodity of service. From this equalization it may seem to follow that marginal costs, which must be brought into equality with price as a condition for the equilibrium of each trader, are also objectively measurable. From this the inference is drawn that, if marginal costs are then measured, 'efficiency' in resource use can be established independently of the competitive process itself through the device of forcing decision makers to bring prices into equality with marginal costs.

The whole logic is a tissue of confusion based on a misunderstanding of opportunity cost. The equalization of marginal opportunity cost with price for each trader is brought about by the adjustments made by each trader along the relevant quantity dimension. The fact that the marginal opportunity costs for all traders are all brought into equalization with the relevant uniform price implies only that traders retain the ability to adjust quantities of goods until this condition is met. There is no implication to the effect that marginal opportunity costs are equalized in some objectively meaningful sense independently of the quantity adjustment to price.

Consider an idealized market for a good that is observed to be trading at a uniform price of $1 per unit. The numeraire value of the anticipated lost opportunity is $1 for each trader. But it is only as quantity is adjusted that the trader can bring the numeraire value of his subjectively experienced and anticipated utility sacrifice into equality with the objectively set price that he confronts. The anticipated value of that which is given up in taking a course of action is no more objectifiable and measurable than the anticipated value of the course of action itself. The two sides of choice are equivalent in all respects. Independently of market choice, there is no means through which marginal opportunity costs can be brought into equality with prices. Hence, any ‘rule’ that directs ‘managers’ in non-market settings to use cost as the basis for setting price is and must remain without content. There is, however, a second equally important criticism of the welfare rule that opportunity cost reasoning identifies, quite apart from
the measurability question. Even if the first criticism is ignored, and it is assumed that marginal opportunity cost can, in some fashion, be measured, instructions to ‘managers’ to use cost to set price must rely on ‘managers’ to behave, personally, as robots rather than rational utility-maximizing individuals. Why should a ‘manager’ be expected to follow the rule? Would he not be expected to behave so that marginal cost, that which he faces personally, be brought into equality with the anticipated value of the benefit side of choice? The fact that the ‘manager’ remains in a non-market setting insures that he cannot be the responsible bearer of the utility gains and losses that his choices generate. His own, privately sensed, gains and losses, evaluated either prior to or after choice, must be categorically different from those anticipated for principals before choice and enjoyed and/or suffered by principals after choice.

Opportunity cost and the choice among institutions

As noted earlier, in the absence of ‘natural’ constraints that predetermine allocation, the introduction of scarcity introduces the necessity of choice, either directly among ultimate ‘goods’ or indirectly among rules, institutions, and procedures that will operate so as to make final allocative determinations. Opportunity cost in the second of these choice-settings remains to be examined. In a sense, the use of institutionalized procedures to generate allocations of scarce resources may eliminate ‘choice’ in the familiar meaning used above and is akin in this respect to the ‘natural’ constraints noted. Results may emerge from the operation of some institutional process without any person or group of persons ‘choosing’ among end-state alternatives, and, hence, without any subjectively-experienced opportunity cost. Despite the absence of this important bridge between cost and choice in the ordinary sense, however, values may be placed on the ‘might have beens’ that would have emerged under differing allocations. The patterns of these estimated value losses, over a sequence of institution-determined allocations, may enter, importantly, in a rational choice calculus involving the higher-level choice among alternative institutional procedures for allocation. In this higher-level choice, opportunity cost again appears as the negative side of choice even if ‘choice’ in the standard usage of the term is not involved in the making of allocations, taken singly.

Consider the following extreme example. There are two mutually exclusive thermostat settings for a building, High and Low. An institution is in being that uses an unbiased coin to ‘choose’ between these two settings each day. It is meaningful for an individual to discuss the potential value to be anticipated if the setting is High rather than Low, even if the individual does not make the selection, individually or as a member of a collective. The setting that is ‘chosen’ by the coin flip has consequences for individual utility and these consequences may be anticipated in advance of the actual ‘choice’. So long as the institutional procedure remains in effect, however, with respect to a single day's selection, the anticipated value lost by one setting of the thermostat rather than the other cannot represent opportunity cost.

Suppose, now, that instead of the unbiased and equally weighted device, the institution in being is one that allows all persons in the building to vote, each morning, on the thermostat setting with the majority option ‘chosen’ for the day. Assume, further, that the group of voters is large, so that the influence of a single person on the expected majoritarian outcome is quite small. It is important to emphasize that, in this procedure, as with the coin toss, no person really ‘chooses’ among the alternative end-states. Each voter confronts the quite different, intra-institutional choice between ‘voting for High’ and ‘voting for...
low’, with the knowledge that any individual has relatively little influence on the outcome. In the choice that he confronts, the voter cannot rationally take into account the anticipated losses from the ultimate alternatives, either for himself or for others, in any full-value sense of the term. The loss anticipated from, say, a Low thermostat setting may be estimated to be valued at $1,000 for the individual. Yet if he considers himself to have an influence on the outcome of the voting choice only in one case out of a thousand, the expected utility value of the anticipated loss will be only $1 in terms of the numeraire. This $1 will then represent the numeraire value of the opportunity cost involved in voting for High.

Since these same results hold, with possibly differing values, for all voters, no one ‘chooses’ in accordance with fully evaluated gains and losses. ‘Choices’ emerge from the institutional procedure without full benefit – cost considerations being made by anyone, taken singly or in aggregation. In the relevant opportunity-cost sense, effective choice is shifted to that among alternative institutions. The results of the ‘choices’ made within an institution over a whole sequence of periods (over many days in our thermostat example) may, of course, become data for the choice comparison among institutions themselves. And, to the extent that the individual, when confronted with a choice among institutions, knows that he is individually responsible for the selection, the whole opportunity cost logic then becomes relevant at the level of institutional or constitutional choice. This result is accomplished, however, only if each person in the relevant community does, in fact, become the chooser among institutional rules. Only if, at some ultimate level of institutional-constitutional choice the Wicksellian unanimity rule becomes operative, hence giving any person potential choice authority, can the opportunity cost of alternatives for choice be expected to enter and to inform individual decisions.

Summary

Opportunity cost is a basic concept in economic theory. In its rudimentary definition as the value of opportunities forgone as a result of choice in the presence of scarcity, the concept is simple, straightforward, and widely understood. In the analysis of choices made by buyers and sellers in the marketplace, the complexities that emerge only in rigorous definition of the concept remain relatively unimportant. But when attempts are made to extend opportunity cost logic to non-market settings, either in the derivation of norms to guide decisions or in application to choice within and among institutions, the observed ambiguity and confusion suggest that even so basic a concept requires analytical clarification.

optimal fiscal and monetary policy (with commitment)

Mikhail Golosov and Aleh Tsyvinski
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

‘Optimal fiscal and monetary policy with commitment’ is a policy of choosing taxes and transfers or monetary instruments to maximize social welfare. ‘Commitment’ refers to ability of a policymaker to make binding policy choices.

Keywords

bonds; commitment; disability insurance; Friedman rule; homotheticity; incentive compatibility; inflation targeting; inflation tax; intermediate good; linear taxation; lump sum taxes; Mirrlees, J.; money; nominal interest rates; optimal fiscal and monetary policy with commitment; optimal interest rate; optimal monetary policy; optimal taxation; output gap; partial equilibrium; Ramsey taxation; separability; sticky prices; tax smoothing; taxation of capital income; taxation of consumption; taxation of income; Taylor rule; time preference; uniform commodity taxation

Article

The Ramsey approach to the optimal taxation

‘Ramsey approach to optimal taxation’ is the solution to the problem of choosing optimal taxes and transfers given that only distortionary tax instruments are available. A starting point of a Ramsey problem is postulating tax instruments. Usually, it is assumed that only linear taxes are allowed. Importantly, lump sum taxation is prohibited. Another assumption crucial to this approach is that all activities of agents are observable. Given the set taxes, a social planner (government) maximizes its objective function given that agents (firms and consumers) are in a competitive equilibrium. Usually, it is assumed that government's objective is to finance an exogenously given level of expenditures. It is important to note that if the lump sum taxes were allowed than the first welfare theorem would hold, and the unconstrained optimum
There are two common approaches to solving Ramsey problems. The first is the *primal* approach, which characterizes a set of allocations that can be implemented as a competitive equilibrium with taxes. By ‘implementation we mean’ the following: for a set of taxes find a set of (consumption and labour) allocations and equilibrium prices such that these allocations are a competitive equilibrium given taxes. Conversely, a set of (consumption and labour) allocations is implementable if it is possible to find taxes and equilibrium prices such that these allocations are a competitive equilibrium given these prices and taxes. Implementation often makes it possible to simplify a Ramsey problem by reformulating a problem of finding optimal taxes as the problem of finding implementable allocations. This reformulation is referred to as the *primal approach* to Ramsey taxation.

**Main lessons of Ramsey taxation: uniform commodity taxation, zero capital tax in the long run, and tax smoothing**

One of the central results of the literature on Ramsey taxation is *uniform commodity taxation* (Atkinson and Stiglitz, 1972). Consider a model with a finite set of consumption goods that can be allocated between government and private consumption. All of these goods are produced with labour. Assume that each consumption good can be taxed at a linear rate. Then, under certain separability and homotheticity assumptions, commodity taxation is uniform, that is, the optimal taxes are equated across consumption goods.

Ramsey taxation provides a compelling argument against taxing capital income in the long run in a model of infinitely lived households. The *Chamley–Judd result* (Chamley 1986; Judd 1985) states that in a steady state there should be no wedge between the intertemporal rate of substitution and the marginal rate of transformation, or, alternatively, that the optimal tax on capital is zero. The intuition for the result is that even a small intertemporal distortion implies increasing taxation of goods in future periods in contrast to the prescription of the uniform commodity taxation. Therefore, distorting the intertemporal margin is very costly for the planner. Jones, Manuelli and Rossi (1997) extend the applicability of the Chamley–Judd result by showing that the return to human capital should not be taxed in the long run.

Chari, Christiano and Kehoe (1994) provide the state-of-the art numerical treatment for optimal Ramsey taxation over the business cycle and conclude that the *ex ante* capital tax rate is approximately zero. There has been a long debate on the optimal composition of taxation and borrowing to finance government expenditures. Barro (1979) considers a partial equilibrium economy and argues that it is optimal to smooth distortions from taxation over time, a policy referred as *tax smoothing*. The implication of this analysis is that optimal taxes should follow a random walk. Lucas and Stokey (1983) consider an optimal policy in a general equilibrium economy without capital, and show that, if government has access to state-contingent bonds, optimal taxes inherit the stochastic process of the shocks to government purchases. Chari, Christiano and Kehoe (1994) extend this analysis to an economy with capital and show the Lucas and Stokey results remain valid in that set-up with or without state contingent debt, as long as the government can use taxes on capital to effectively vary the *ex post* after-tax rate of return on bonds. Finally, Aiyagari et al. (2002) show that, if *ex post* taxation of returns is impossible, the optimal taxes follow a process similar to a random walk. They also show the conditions under which the tax smoothing hypothesis is valid.
The Mirrlees approach to optimal taxation

The Mirrlees approach to optimal taxation is built on a different foundation from Ramsey taxation. Rather than stating an ad hoc restricted set of tax instruments as in Ramsey taxation, Mirrlees (1971) assumed that an informational friction endogenously restricted the set of taxes that implement the optimal allocation. This set-up allows arbitrary nonlinear taxes, including lump-sum taxes. The informational friction posed in those models is unobservability of agents’ skills: only labour income of agents can be observed. Therefore, from a given level of labour income it cannot be determined whether a high-skill agent provides a low amount of labour or effort, or whether a low-skill agent works a prescribed amount. The objective of the social planner (government) is to maximize ex ante, before the realization of the shocks, utility of an agent. This objective can be interpreted as either insurance against adverse shocks or as ex post redistribution across agents of various skills. An informational friction imposes incentive compatibility constraints on the planner's problem: allocations of consumption and effective labour must be selected such that an agent chooses not to misrepresent its type. In summary, the objective of the Mirrlees approach is to find the optimal incentive–insurance trade-off: how to provide the best insurance against adverse events (low realizations of skills) while providing incentives for the agents to reveal their types (provide high amount of labour).

Main lessons of the Mirrlees approach in a static framework

Theoretical results providing general characterization of the optimal taxes in the static Mirrlees environment are limited. The central result is that the consumption–leisure margin of an agent with the highest skill is undistorted, implying that the marginal income tax at the top of the distribution should be optimally set equal to zero. Saez (2001) is a state-of-the art treatment of the static Mirrlees model in which he derives a link between the optimal tax formulas and elasticities of income. Mirrlees (1971) was also able to establish broad conditions that would ensure that the optimal marginal tax rate on labour income was between zero and 100 per cent.

Main lessons of dynamic Mirrlees literature: distorted intertemporal margin

Recent literature starting with Golosov, Kocherlakota, and Tsyvinski (2003) and Werning (2001) extends the static Mirrlees (1971) framework to dynamic settings. Golosov, Kocherlakota, and Tsyvinski (2003) consider an environment with general dynamic stochastically evolving skills. An example of a large unobservable skill shock is disability that is often difficult to observe (classical example is back pain or mental illness). Golosov, Kocherlakota, and Tsyvinski (2003) show for arbitrary evolution of skills that, as long as the probability of agent's skill changing is positive, any optimal allocation includes a positive intertemporal wedge: a marginal rate of substitution across periods is lower than marginal rate of transformation. The reason for this is that this wedge improves the intertemporal provision of incentives by implicitly discouraging savings. This result holds even away from the steady state and sharply contrasts with the Chamley–Judd result that stems from the exogenous restriction on tax
instruments. Golosov, Kocherlakota, and Tsyvinski (2003) and Werning (2001) show that in a case of constant types a version of uniform commodity taxation holds and the intertemporal margin is not distorted.

Implementation of dynamic Mirrlees models is more complicated than implementation of either static Mirrlees models, which are implemented with an income tax, or Ramsey models of linear taxation. By ‘implementation’ we mean finding tax instruments such that the optimal allocation is a competitive equilibrium with taxes. One possible implementation is a direct mechanism that mandates consumption and labour menus for each date. However, such a mechanism can include taxes and transfers never used in practice. Three types of implementations have been proposed. In Albanesi and Sleet (2006), wealth summarizes agents’ past histories of shocks that are assumed to be i.i.d. and allows us to define a recursive tax system that depends only on current wealth and effective labour. Golosov and Tsyvinski (2006) implement an optimal disability insurance system with asset-tested transfers that are paid to agents with wealth below a certain limit. Kocherlakota (2005) allows for a general process for skill shocks and derives an implementation with linear taxes on wealth and arbitrarily nonlinear taxes on the history of effective labour.

Optimal monetary policy

The theory of the optimal monetary policy is closely related to the theory of optimal taxation. Phelps (1973) argues that the inflation tax is similar to any other tax, and therefore should be used to finance government expenditures. Although intuitively appealing, this argument is misleading. Chari, Christiano and Kehoe (1996) extend the Ramsey approach to analyse optimal fiscal and monetary policy jointly in several monetary models, and find that typically it is optimal to set the nominal interest rate to be equal to zero. Such a policy is called a ‘Friedman rule’, after Milton Friedman, who was one of the first proponents of zero nominal interest rates (Friedman, 1969). To understand intuition for the optimality of Friedman rule, it is useful to think about the distinctive the features that distinguish money from other goods and assets. In most models money plays a special role of providing liquidity services to households that cannot be obtained by using other assets such as bonds. Inefficiency arises if the rates of return on bonds and money are different, since by holding money balances households lose the interest rate. When a nominal interest rate is equal to zero, which in a deterministic economy implies that inflation is negative, with nominal prices declining with the rate of households’ time preferences, the real rates of return on money and bonds are equalized and this inefficiency is eliminated.

The optimality of the Friedman rule stands in a direct contrast with Phelps’ arguments for use of the inflationary tax together with other distortionary taxes such as taxes on consumption or labour income. The reason for this is that money, unlike consumption or leisure, is not valued by households directly but only indirectly, as long as it facilitates transactions and provides liquidity. Therefore, it is more appropriate to think of money as an intermediate good in acquiring final goods consumed by households. Diamond and Mirrlees (1971) established very general results about the undesirability of distortion of the intermediate goods sector, which in monetary models implies that the inflationary tax should not be used despite the distortions caused by taxes on the final goods and services.

The intuition developed above is valid under the assumption that nominal prices are fully flexible, and firms adjust to them immediately in response to changes in market conditions. However, even casual
observation suggests that many prices remain unchanged over long periods of time, and Bils and Klenow (2004) document inflexibility of prices for a wide variety of goods. Inflexible or sticky prices lead to additional inefficiencies in the economy that could be mitigated by monetary policy. For example, an economy-wide shock, such as an aggregate productivity shock or change in government spending, may call for readjustment of real prices. If adjustment of nominal prices is sluggish, the central bank can increase welfare by adjusting nominal interest rates and affecting real prices.

It is important to recognize that the government is also able to affect real (after-tax) prices using fiscal instruments instead. In fact, Correia, Nicolini and Teles (2002) show that, if fiscal policy is sufficiently flexible and can respond to aggregate shocks quickly, then the Friedman rule continues to be optimal even with sticky prices, with fiscal instruments being preferred to monetary ones. In current practice, however, it appears that it takes a long time to enact changes in tax rates, while monetary policy can be adjusted quickly. Schmitt-Grohe and Uribe (2004) show that, as long as tax levels are fixed or the government is not able to levy some of the taxes on goods or firms' profits, then the optimal interest rate is positive and variable.

Most of the applied literature on the monetary policy is based on the joint assumption of sticky prices and inflexible fiscal policy. Woodford (2003) provides a comprehensive study of the optimal policy in such settings. This analysis examines how central bank response should depend on the type of the shock affecting the economy, the degree of additional imperfections in the economy, and the choice of policies that would rule out indeterminacy of equilibria. Two common policy recommendations for central banks share many of the features of the optimal policy responses in this analysis. One of such recommendations – a Taylor rule (see Taylor, 1993) – calls for the interest rates to be increased in response to an increase in the output gap (the difference between actual and a target level of GDP) or inflation. Another recommendation, inflation forecast targeting, requires that the central bank commits to adjust interest rate to ensure that the projected future path of inflation or other target variables does not deviate from the pre-specified targets.

In addition to the analysis set out above, several new, conceptually different approaches to the analysis of monetary policy have emerged in the recent years. For example, da Costa and Werning (2005) re-examine optimal monetary policy with flexible prices in Mirrleesian settings and confirm the optimality of the Friedman rule there. Seminal work by Kiyotaki and Wright (1989) has given rise to a large search-theoretic literature seeking to understand the fundamental reasons that money differs from other goods and assets in the economy. Lagos and Wright (2005) provide a framework for the analysis of optimal monetary policy in such settings.

optimal fiscal and monetary policy (without commitment)

Mikhail Golosov and Aleh Tsyvinski
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

‘Optimal fiscal and monetary policy’ is a policy of choosing taxes and transfers or monetary instruments to maximize social welfare. ‘Absence of commitment’ refers to inability of a policymaker to make binding policy choices.

Keywords

bonds; central bank; commitment; dimensionality; Friedman rule; infinite-horizon models; inflation; inflationary bias; inflationary cap; Markov-perfect equilibria; nominal interest rates; optimal fiscal policy without commitment; optimal monetary policy without commitment; output gap; Ramsey taxation; rational expectations; sustainable equilibrium; taxation of capital; Taylor rule; time consistency of monetary and fiscal policy

Article

Most of the results of optimal taxation literature in the Ramsey framework are derived under the assumption of commitment. *Commitment* is usually defined as ability of a government to bind future policy choices. This assumption is restrictive. A government, even a benevolent one, may choose to change its policies from those promised at an earlier date. The first formalization of the notion of time inconsistency is due to Kydland and Prescott (1977), who showed how timing of government policy may change economic outcomes. Furthermore, equilibrium without commitment can lead to lower welfare for society than when a government can bind its future choices.

An example that clarifies the notion of time inconsistency in fiscal policy is taxation of capital. A classical result due to Chamley (1986) and Judd (1985) states that capital should be taxed at zero in the long run. One of the main assumptions underlying this result is that a government can commit to a sequence of capital taxes. However, a benevolent government will choose to deviate from the prescribed sequence of taxes. The reason is that, once capital is accumulated, it is sunk, and taxing capital is no
Optimal fiscal and monetary policy (without commitment): The New Palgrave Dictionary of Economics

longer distortionary. A benevolent government would choose high capital taxes once capital is accumulated.

The reasoning above leads to the necessity of the analysis of time inconsistent policy as a game between a policymaker (government) and a continuum of economic agents (consumers). A formalization of such a game and an equilibrium concept is due to Chari and Kehoe (1990). They formulate a general equilibrium infinite-horizon model in which private agents are competitive, and the government maximizes the welfare of the agents. They define an equilibrium concept – sustainable equilibrium – which is a sequence of history-contingent policies that satisfy certain optimality criteria for the government and private agents.

Recent developments in solving for the set of sustainable government policies use the techniques of the analysis of repeated games due to Abreu (1986) and Abreu, Pearce and Stachetti (1990). Phelan and Stachetti (2001) extend these methods to analyse the equilibria of the Ramsey model of capital taxation. Their contribution is to provide a method in which the behaviour of consumers is summarized as a solution to the competitive equilibrium, thus significantly reducing the dimensionality of the problem. They provide a characterization of the whole set of sustainable equilibria of the game. Their methods are especially relevant for the environments in which the punishment to the deviator is difficult to characterize analytically.

Benhabib and Rusticchini (1997) and Marcet and Marimon (1994) provide an alternative method to solve policy games without commitment. They use the techniques of optimal control in which they explicitly impose additional constraints on the standard optimal tax problem such that a government does not deviate from the prescribed sequence of taxes. Their methods, while easier to use than those of Abreu (1986), Abreu, Pearce and Stachetti (1990) and Phelan and Stachetti (2001), are efficient only if the worst punishment to the deviating government can be easily determined.

Klein, Krusell and Rios-Rull (2004) numerically solve for equilibria where reputational mechanisms are not operative and characterize Markov-perfect equilibria of the dynamic game between successive governments in the context of optimal Ramsey taxation. For a calibrated economy, they find that the government still refrains from taxing at confiscatory rates.

Optimal monetary policy without commitment

The problem of time consistency also arises in monetary economics. Kydland and Prescott (1977) and Barro and Gordon (1983) analyse a reduced form economy with a trade-off between inflation and unemployment. Consider an economy where the growth rate of nominal wages is being set one period in advance. The government can decrease unemployment by having setting the inflation rate higher than the wage rate, thus reducing the real wage; but inflation is socially costly. Suppose that a monetary authority chooses the inflation rate after nominal wages were set in the economy to maximize social welfare. Such a rate would equalize the marginal benefits of reducing unemployment and the marginal costs of increasing inflation. But now consider wage determination in a rational-expectations equilibrium. In anticipation of the government's policy, agents will choose a positive growth rate of wages to avoid losses from inflation. Therefore, in equilibrium the monetary authority is not able to affect unemployment, but there is a positive rate of inflation. This outcome is inefficient since by committing not to inflate ex ante the monetary authority could achieve the same level of unemployment.
but with zero inflation. Therefore, the lack of commitment by the monetary authority will lead to inflationary bias, or an inefficiently high level of inflation.

Similar effects are present in many other monetary models. For example, Calvo (1978) shows time inconsistency of the optimal policy in a general equilibrium model. Chang (1998) considers a version of Calvo's model to find the optimal monetary policy without commitment. Similar to Phelan and Stacchetti (2001), he uses tools of repeated game theory to describe the best equilibrium in the game between the central bank and a large group of agents.

A substantial amount of work has been done in finding the ways to overcome time consistency problems. One of the first practical proposals is Rogoff's (1985) suggestion to appoint a 'conservative' central banker, whose private valuation of the costs of inflation is higher than the social valuation. Such a banker has less temptation to inflate, and the inflationary bias will be reduced.

Pre-specifying the rules of conduct for monetary policy reduces the discretionary actions a central bank can undertake and improves time consistency. For example, the commonly advocated Taylor rule prescribes that the central bank sets nominal interest rates as a linear function of inflation and the output gap with fixed coefficients (see, for example, Woodford, 2003). On the other hand, it may be desirable to leave some discretion to the central bank, particularly if it has access to information about economic conditions which is impossible or impractical to incorporate into predetermined rules. Athey, Atkeson and Kehoe (2005) consider an example of such an economy where the central bank has private information about the state of the economy, which is unavailable to others. They show that the optimal policy in such settings is an inflationary cap that allows discretion to the central bank as long as the inflation rate is below a certain bound.

Following Lucas and Stokey's (1983) analysis, substantial work has been done in determining conditions under which the government can eliminate the time consistency problem by optimally choosing debt of various maturities. Lucas and Stokey themselves point out the fundamental difficulty with this approach in monetary economies since, as long as the government holds a positive amount of nominal debt, it is tempted to inflate in order to reduce its real value. Two recent papers describe some of the conditions under which this problem can be overcome. Alvarez, Kehoe and Neumeyer (2004) consider several monetary models and show that if it is optimal to set nominal interest rates at zero (that is, the optimal monetary policy with commitment is to follow the Friedman rule), then the time consistency problem can be solved. By issuing a mixture of nominal and real (indexed) bonds in such a way that the present value of the nominal claims is zero, the temptation for inflation can be removed. Persson, Persson and Svensson (2006) consider a model where the Friedman rule is not optimal, but they still are able to characterize the optimal maturity structure of nominal and indexed bonds that achieve the social optimum with commitment even with time-inconsistent government.

optimal tariffs

Nuno Limão

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Optimal tariffs allow a country to exploit its market power in international trade. A country can improve its terms of trade by unilaterally restricting its exports if it faces a downward-sloping demand for them or restricting its imports if it faces an upward-sloping foreign export supply. This argument against unilateral free trade is over 150 years old but it remains central to modern theories that explain trade agreements and their rules. This, along with recent evidence that prior to such agreements countries exploit their market power in trade, shows that optimal tariffs may be an important positive theory of protection.

Article

A country that faces a downward-sloping demand for its exports has market power and therefore, as a monopolist, can benefit from restricting its export supply. When a country's exporters are perfectly competitive, the government can coordinate this restriction via an export tax, which increases the world price for its exports and so improves its terms of trade. Analogously, a country facing an upward-sloping export supply has market power in imports and can benefit from restricting them via a tariff. Generally, the optimal tariff is defined as the rate that unilaterally maximizes a country's welfare and is given by the inverse elasticity of foreign export supply, as determined by optimal monopsony pricing.

The terms-of-trade argument against unilateral free trade is over 150 years old, yet it remains one of the hardest to refute theoretically. The reason is simple. A country's atomistic consumers impose an
externality on each other since, by increasing import demand, they raise the equilibrium price for all. The optimal instrument to correct an externality must target it at the source (Bhagwati and Ramaswami, 1963), and the optimal tariff does this by reducing import demand. This quantity reduction entails a cost but, for a sufficiently small tariff, it is more than offset by the improved terms of trade. This is one of the only cases when, in the absence of retaliation, the tariff is a first-best instrument. However, if a tariff improves a country's terms of trade, it worsens those of its trading partner, who is therefore likely to retaliate. The typical trade war outcome is to leave both worse off relative to free trade, which explains many economists' opposition to optimal tariffs as a normative theory. The trade war outcome points to the benefits from reciprocal tariff reductions and as such the terms-of-trade argument remains central to modern theories of trade agreements and their rules. This, along with recent evidence that prior to such agreements countries exploit their market power in trade, shows that optimal tariffs may be an important positive theory of protection rather than an irrelevant normative one.

Informal derivation and applications

The standard derivation of the optimal tariff focuses on a standard neoclassical economy with no domestic externalities and available lump-sum transfers to address any resulting redistribution issues (see Graaf, 1949–50). A Pareto optimum for the closed economy requires the domestic marginal rate of substitution between any two goods i and j to equal their marginal rates of transformation, which in a competitive economy is done via the domestic relative prices, that is, \( MRS_{ij} = \frac{p_i}{p_j} = MRT_{ij} \). An open economy can exchange goods at the prevailing world prices, which can be thought of as having access to a new technology or foreign rate of transformation. Now efficient production requires the domestic \( MRT_{ij} \) to equal the marginal foreign rate of transformation (MFRT). Optimal ad valorem tariffs, \( t_i \), imposed on the world prices, \( \pi_i \), ensure that this additional condition for efficiency is met, by introducing a wedge such that the relative price faced by domestic producers is equal to \( MFRT_{ij} \), that is, \( \frac{p_i}{p_j} = \frac{\pi_i(1 + t_i)}{\pi_j(1 + t_j)} \). The final step is to determine the \( MFRT_{ij} \), which simply reflects the relative marginal cost of these goods in the world market. The marginal cost for the importer is \( \pi_i + a_i \), the price paid for the unit plus the marginal change in price(s) it causes, \( a_i = \sum_k m_k \partial \pi_k / \partial m_i \). Therefore the optimal \textit{ad valorem} tariff rates are determined by

\[
\frac{\pi_i(1 + t_i)}{\pi_j(1 + t_j)} = \frac{\pi_i(1 + a_i)}{\pi_j(1 + a_j)}
\]

for all \( i \) and \( j \),

which is satisfied by any tax structure such that
When all cross-price elasticities are zero, \( a_i/\pi_i \) is simply the inverse of the foreign export supply for \( i \), \( 1/\varepsilon_i \), and we obtain the standard formula, \( t_i = 1/\varepsilon_i \). Otherwise \( t_i \) also includes the cross-elasticities, as \( a_i \) captures the weighted sum of marginal world price changes in all goods due to the increase in demand for \( i \).

Since the cross-effects in \( a_i \) can be negative the optimal tariff may be zero or even a subsidy on any or all goods. However, that can't be the case with only one import and one export good, \( i = m \) and \( e \), as is easily shown if their cross-elasticity is zero. To see this, note that with two goods we can attain the same outcome with either a tariff or an export tax (Lerner, 1936), which simultaneously accounts for market power in imports and exports. Solving (1) with \( t_e = 0 \) we have the import tariff rate

\[
t_m = \frac{1/\varepsilon_m + 1/\varepsilon_e}{1 - 1/\varepsilon_e},
\]

which is positive given the positively defined elasticities of foreign export supply, \( \varepsilon_m \), and foreign import demand, \( \varepsilon_e \), and \( 1/\varepsilon_e < 1 \).

The result extends in several ways under perfect competition settings. If a domestic distortion exists, and is addressed by a first-best instrument, then the rate in (2) is generally still optimal. Graaf (1949–50) shows this for external (dis)economies in production, for example. The equivalence of tariffs and quantity restrictions, that is, quotas, under certainty implies that quotas can be used to the same effect provided that their rents accrue to the country that imposes them (but the welfare and trade volume outcomes of tariff and quota wars differ, as shown by Rodriguez, 1974). Kemp (1966) and Jones (1967) derive the optimal tax structure when capital is mobile and a country has market power in goods and factors trade. Similarly to (2) the optimal tariffs on goods take into account their effect on the price of capital and vice versa.

Tariffs can also affect a country's terms of trade under imperfect competition. However, there are fewer general results in these settings, even in the simpler cases of zero cross-price elasticities. Nonetheless, a few points are worth noting. First, if a country has a monopoly importer or exporter (for example, an agricultural marketing board or a cartel of oil exporters such as OPEC) then there is no first best role for a trade tax – a monopolist would already optimally restrict quantities. A tariff may still be necessary to internalize effects from any cross-elasticities, as Gros (1987) shows for a monopolistic competition model. Second, under imperfect competition a tariff can affect a country's terms of trade even if it has an infinitesimally small share of the world's expenditure. For example, if imposing a small \emph{ad valorem} tariff reduces the import demand elasticity, then it also improves the welfare of a small importer facing a
monopoly exporter (Katrak, 1977; Brander and Spencer, 1984). However, when the country is small the tariff is generally not the first best instrument.

**Early contributions and current relevance as a positive theory**

There have been four important waves in the development and application of the optimal tariffs idea. They were each about 40 to 50 years apart, and at least three appear to be linked to important policy events.

Several early advances in trade theory arose during the debate over the repeal of British import duties imposed by the Corn Laws of 1815. Robert Torrens, a famous classical economist, initially supported the repeal but eventually turned against unilateral free trade as he understood that countries may gain from tariffs through an improvement in their terms of trade. This basic idea and the intuition for it are found in Torrens (1833; 1844) and Mill (1844). However, a country will actually gain only if the terms-of-trade benefit offsets the cost from lower import volume; in a second phase of development, Edgeworth (1894) shows that this is the case unless the foreign country's offer curve is perfectly elastic, while Bickerdike (1906; 1907) develops the first optimal tariff formula, similar to (3).

Renewed interest in the topic came after the Smoot Hawley Tariff Act of 1930, which raised US average tariffs to about 50 per cent and triggered a cycle of tariff retaliation. The key contributions by Kaldor (1940), Scitovsky (1942) and Johnson (1953–4) focus on the outcomes when countries retaliate. Johnson (1953–4) shows the outcome of a tariff war using tariff reaction curves that summarize a country's best response. He confirms that two symmetric countries prefer free trade to a trade war; but otherwise one of them may be better off under a trade war.

The latest developments in the topic also came in the wake of important economic events. Mayer (1981) examines the possible tariff outcomes under the tariff cutting formulas used in the 1973–9 multilateral trade negotiations under the General Agreement on Tariffs and Trade (GATT). Since then numerous authors have relied on the tariff war equilibrium as the threat point for the theoretical analysis of multilateral and bilateral trade agreements. Notably, Bagwell and Staiger (1999; 2002) argue that the purpose of the GATT and its successor, the World Trade Organization, is to allow countries to reciprocally lower protection in a way that eliminates the terms-of-trade component of tariffs, and show that such an economic theory of GATT can explain several of its key rules.

Despite the success of the terms-of-trade motive for tariffs in explaining important features of trade agreements, its power as a positive theory of trade protection is often questioned for two reasons. First, governments do not set tariffs to maximize social welfare. Although governments often set tariffs to redistribute income across interest groups, this does not imply that tariffs will not reflect market power. For example, Johnson (1950) derives the revenue-maximizing tariff rate, which does not maximize welfare but is nonetheless increasing in a country's market power since a given tariff rate yields higher revenue, under a less elastic export supply. Moreover, recent micro-founded political economy models predict that a large country's unilateral tariff reflects its market power, even if the government places no weight on social welfare (Grossman and Helpman, 1995). Thus, even if the primary objective of the government is a political economy one, its tariffs can reflect market power since this allows it to achieve that objective at a lower cost as it captures some income from its trading partners via improved terms of trade.
The second critique is the argument that most countries cannot affect their terms of trade and so it is not an important determinant of protection. Critics concede that certain commodity exporters do have some market power and have at times exerted it (for example, OPEC's oil restrictions or export taxes by marketing boards). But evidence of market power in exports appears to go beyond these obvious cases since aggregate estimates of $\varepsilon_e$ in (3) are often found to be low, sometimes close to unity. Nonetheless, there are considerable difficulties in estimating and interpreting such aggregate elasticities, which are often estimated only for countries already setting their tariffs cooperatively. Therefore cross-country comparisons of average tariffs and these aggregate elasticities cannot provide much insight into the empirical importance of the terms-of-trade motive.

There is also growing evidence of market power in imports since when countries change their exchange rates or tariffs part of the effect is absorbed by the foreign exporters (cf. Kreinin, 1961). Broda, Limão and Weinstein (2006) provide compelling evidence that countries have and exploit their market power. They estimate inverse foreign export supply elasticities by good and country, and find that even small countries have some market power, which is increasing in country size and degree of good differentiation. They then examine tariffs for countries that are not setting them cooperatively and find that they are set higher in goods with higher inverse elasticities. They conclude that market power is an economically and statistically important determinant of tariffs.

In sum, optimal tariffs are evolving from a curious normative theory to a positive one. The broad applicability of the terms-of-trade motive for tariffs; its theoretical success in explaining important rules of trade agreements; and the recent evidence that countries exploit their market power, all indicate this will remain a key concept in economics.

optimal taxation

Louis Kaplow
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Optimal taxation concerns how various forms of taxation should be designed to maximize social welfare. The task requires an integrated consideration of the revenue-raising and distributive objectives of taxation. The central instrument in developed economies is the labour income tax, the analysis of which was pioneered by Mirrlees (1971). Subsequently, Atkinson and Stiglitz (1976) showed how commodity taxes should be set in the presence of an optimal income tax, the results differing qualitatively from, and in important respects displacing, the teachings derived from Ramsey's (1927) seminal analysis of the pure commodity tax problem.

Article

Optimal taxation concerns the question of how various forms of taxation should be designed in order to maximize a standard social welfare function subject to a revenue constraint. The task requires an integrated consideration of the revenue-raising and distributive objectives of taxation. The central instrument in developed economies is the labour income tax. Mirrlees (1971) pioneered the analysis of this challenging problem. Subsequently, Atkinson and Stiglitz (1976) showed how commodity taxes should be set in the presence of an optimal income tax. The results are qualitatively different from —
and in important respects displace – prior teachings that originate in Ramsey's (1927) analysis of the pure commodity tax problem. In addition to setting particular taxes optimally, it is also necessary to choose optimally among tax systems.

**Income Taxation**

**Model**

The standard optimal income tax model involves a one-period setting in which individuals’ only choice variable is their degree of labour effort $l$. There is a single composite consumption good $c$. An individual’s utility is given by $u(l, c)$, where $u_c > 0$ and $u_l < 0$. An individual’s consumption is given by

$$c = w l - T(w l),$$

where $w$ is the individual’s wage rate and $T$ is the tax-transfer function.

The motivation for redistributive taxation is that individuals differ, in particular in their wages, that is, their earning abilities. The distribution of abilities will be denoted $F(w)$, with density $f(w)$. Individuals’ wage rates are taken to be exogenous. Their pre-tax earnings $w l$ are the product of their wage rate and level of labour effort. More broadly, one can interpret labour effort as including not only hours of work but also intensity and not only productive effort but also investments in human capital.

Taxes and transfers, $T(w l)$, at any income level may be positive or negative. The (uniform) level of the transfer received by an individual earning no income, that is, $-T(0)$, is sometimes referred to as the grant $g$. Taxes may be interpreted broadly, to include sales taxes or value-added tax (VAT) payments in addition to income taxes. Transfers include those through the tax system in addition to welfare programmes. The inclusion of transfers is important both practically, since they are in fact significant, and conceptually, since otherwise redistribution would be limited to transfers between the rich and the middle class, once the poor were exempted from the tax system.

Taxes and transfers are taken to be a function of individuals’ incomes, assumed to be observable, and it is this dependence of taxes on income that is the source of distortion. If taxes could instead depend directly on individuals’ abilities, $w$, individualized lump-sum taxes would be feasible and redistribution could be accomplished without distorting labour supply. Ability, however, is assumed to be unobservable.

The government’s problem is to choose $T(w l)$ to maximize social welfare, which can be stated as

$$\int W(u(c(w), l(w))) f(w) dw,$$

(2)
where $c$ and $l$ are each expressed as functions of $w$ to refer to the levels of consumption achieved and labour effort chosen by an individual of ability $w$. If $W$ is linear, the welfare function is utilitarian, whereas if $W$ is strictly concave, additional weight is given to inequality in utility levels (not just levels of marginal utilities). This maximization is subject to a revenue constraint and to constraints regarding individuals’ behaviour. The former is

$$\int T(wl(w))t(w)dw = R,$$

(3)

where $R$ is an exogenously given revenue requirement. Here, revenue is to be interpreted as expenditures on public goods that should be understood as implicit in individuals’ utility functions; because these expenditures are taken to be fixed, they need not be modelled explicitly. Regarding the latter constraints, individuals are assumed to respond to the given tax schedule optimally, which determines the functions $c(w)$ and $l(w)$.

Mirrlees’s (1971) original exposition has been followed by subsequent elaborations, much of which is synthesized and extended in Atkinson and Stiglitz (1980), Stiglitz (1987), Tuomala (1990), and Salanié (2003). Because the problem is formidable, the present discussion will be confined to stating basic results, such as are embodied in first-order conditions and produced by simulations.

**Linear income tax**

Substantial illumination with greatly reduced complexity is provided by first examining a linear income tax,

$$T(wl) = twl - g,$$

(4)

where $t$ is the (constant, income-independent) marginal tax rate and $g$, as previously noted, is the uniform per-capita grant. Because of the presence of the grant $g$, a linear income tax can be highly redistributive (consider setting $t$ at 100 per cent and $g$ equal to mean income net of any per capita revenue requirement – in the absence of incentive constraints) or not at all redistributive ($t$ may be 0 per cent and $g$ equal to the negative of the per capita revenue requirement). Foreshadowing discussion of the nonlinear income tax, the degree of redistribution is more directly related to the levels of $t$ and $g$ than to
the shape (deviation from linearity) of the tax schedule.
To derive the optimal linear income tax, the government's maximization problem can be written in Lagrangian form as choosing \( t \) and \( g \) to maximize

\[
\int \left[ W(u(1-t)w) + g, l(w)) + \lambda(tw - g - R) \right] f(w) \, dw,
\]

(5)

where \( \lambda \) is the shadow price of revenue, referring to the constraint (3), and expression (4) is substituted into expression (1) so that consumption is expressed in terms of the specific linear tax system under consideration. Following Atkinson and Stiglitz (1980) and Stiglitz (1987), the first-order condition for the optimal tax rate can usefully be expressed as

\[
\frac{t}{1-t} = -\frac{\text{cov}(\alpha(w), y(w))}{\int y(w) \varepsilon(w) f(w) \, dw}.
\]

(6)

where \( y(w)=wl(w) \), income earned by individuals of ability \( w \); \( \varepsilon(w) \) is the compensated elasticity of labour effort of individuals of ability \( w \); and \( \alpha(w) \) is the net social marginal valuation of income, evaluated in dollars, of individuals of ability \( w \):

\[
\alpha(w) = \frac{W' u_{\varepsilon}(w)}{\lambda} + tw\left( \frac{\partial l(w)}{\partial g} \right).
\]

(7)

The numerator of the first term on the right side of expression (7) indicates how much additional (lump-sum) income to an individual of ability \( w \) contributes to social welfare (\( u_c \) indicates how much utility rises per dollar and \( W' \) indicates the extent to which social welfare increases per unit of utility) and this product is converted to a dollar value by dividing by the shadow price of government revenue. The second term takes into account the income effect, namely, that giving additional lump-sum income to an individual of ability \( w \) will reduce labour effort (\( \partial l(w)/\partial g<0 \)), which in turn reduces government tax collections by \( tw \) per unit reduction in \( l(w) \).

Expression (6) indicates how various factors affect the optimal level of a linear income tax. Beginning
with the numerator on the right side, a higher (in magnitude) covariance between $\alpha$ and $y$ favours a higher tax rate. In the present setting, $\alpha (w)$ will (under assumptions ordinarily postulated) be falling with income. Note that a larger covariance does not involve a closer (negative) correlation but rather a higher dispersion (standard deviation) of $\alpha$ and of $y$. The dispersion of $\alpha$ will tend to be greater the more concave (egalitarian) is the welfare function $W$ and the more concave is utility as a function of consumption (that is, the greater the rate at which marginal utility falls with income). Income, $y$, will have a higher dispersion (again, under standard assumptions) when the distribution of underlying abilities is more unequal. In sum, more egalitarian social preferences, more rapidly declining marginal utility of consumption, and higher underlying inequality each contribute to a higher optimal tax rate.

The denominator indicates that a higher compensated labour supply elasticity favours a lower tax rate. The other terms in the integrand indicate that, ceteris paribus, the labour supply elasticity matters more with regard to high-income individuals and at ability levels where there are more individuals (typically the middle of the income distribution) because of the greater sacrifice in revenue.

The foregoing exposition is incomplete in not emphasizing the various respects in which income effects are relevant (they influence $\alpha$ and also $\lambda$) and in ignoring that the values on the right side of expression (6) are endogenous. Especially for the latter reason, the literature has relied heavily on simulations.

The most-reported optimal linear income taxation simulations are those of Stern (1976). For his preferred case — an elasticity of substitution between consumption and labour of 0.4, a government revenue requirement of 20 per cent of national income, and a social marginal valuation of income that decreases roughly with the square of income — he finds that the optimal tax rate is 54 per cent and that individuals’ lump-sum grant equals 34 per cent of average income. To illustrate the benefits of redistribution, he finds that a scheme that uses a lower tax rate, just high enough to finance government programmes (that is, with a grant of zero), produces a level of social welfare that is lower by an amount equivalent to approximately 5 per cent of national income. If there is very little weight on equality, the optimal tax rate is only 25 per cent, whereas if there is extreme weight on equality, the optimal tax rate is 87 per cent. Returning to his central case, an extremely low labour supply elasticity implies an optimal tax rate of 79 per cent, and an elasticity as high as had been used in some earlier literature implies an optimal tax rate of 35 per cent. In the absence of the need to finance government expenditures, the optimal tax rate is 48 per cent, and if government expenditures are twice as high, the optimal tax rate is 60 per cent.

### Nonlinear income tax

Mirrlees (1971) and subsequent investigators employ control-theoretic techniques to address the more general formulation of the optimal nonlinear income taxation problem, which requires choosing an entire tax schedule $T (w^l)$ rather than a single tax rate. In this maximization, the constraints regarding individuals’ maximizing behaviour entail that no individual of any type $w$ will prefer the choice specified for any other type $w^\circ$. This approach is related to the use of the revelation principle in work on mechanism design, and in similar spirit many researchers following Stiglitz (1982) and others analyse a simpler, discrete variant of the problem, often involving two types, in which the binding incentive constraint is usually that the high-ability type not have an incentive to mimic the low-ability type in...
optimal taxation: The New Palgrave Dictionary of Economics

order to pay less tax.
The analysis of the continuous case can be summarized in a first-order condition for the optimal marginal income tax rate at any income level $y^*$, where $w^*$ and $l^*$ correspond to the ability level and degree of labour effort supplied by the type of individual who would earn $y^*$. Making the simplifying assumptions that utility is separable between consumption and labour effort and that marginal utility $u_c$ is constant, the condition can be expressed as

$$\frac{T'(w^*l^*)}{1 - T'(w^*l^*)} = \frac{1 - F(w^*)}{\xi^* w^* f(w^*)} \int_{w^*}^{\infty} \left(1 - \frac{W'(u(w))/u_c}{\lambda} \right) f(w) \, dw$$

where $\xi^* = 1/(1 + l^* u_l/u_l)$ — which, when marginal utility is constant as assumed here, equals $\epsilon/(1 + \epsilon)$, where $\epsilon$ again is the elasticity of labour supply. For derivations of related expressions, see, for example, Auerbach and Hines (2002), Atkinson and Stiglitz (1980), Dahan and Strawczynski (2000), Diamond (1998), Saez (2001), and Stiglitz (1987). Note that this formulation (like those in recent literature) includes $1 - F(w^*)$ in both the numerator and the denominator on the right side. The motivation is that, in the first term, $(1 - F(w^*)) / f(w^*)$ is purely a property of the distribution of $w$, and, in the second term, because the numerator is an integral from $w^*$ to $\infty$, the term as a whole gives an average value for the expression in parentheses in the integrand. Both aspects aid intuition, as will be seen in the discussion to follow.

Expression (8), being a first-order condition, should be interpreted by reference to an adjustment that slightly raises the marginal tax rate at income level $y^*$ (say, in a small interval from $y^*$ to $y^* + \delta$), leaving all other marginal tax rates unaltered. There are two effects of such a change. First, individuals at that income level face a higher marginal rate, which will distort their labour effort, a cost. Second, all individuals above income level $y^*$ will pay more tax, but these individuals face no new marginal distortion. That is, the higher marginal rate at $y^*$ is inframarginal for them. Since those thus giving up income are an above-average-income slice of the population (it is the part of the population with income above $y^*$), there tends to be a redistributive gain.

The right side of expression (8) can readily be interpreted in terms of this perturbation (although it should be kept in mind that this interpretation omits, inter alia, income effects and the endogeneity of variables). Begin with the first term. Revenue is collected from all individuals with incomes above $y^*$, which is to say all ability types above $w^*$; hence the $1 - F(w^*)$ in the numerator. This factor favours marginal tax rates that fall with income. As there are fewer individuals who face the inframarginal tax, the core benefit of a higher marginal rate declines. In the extreme, if there is a highest known type in the income distribution, the optimal marginal rate at the top would be zero because $1 - F$ would be zero: a higher rate collects no revenue but distorts the behaviour of the top individual. However, when there is
no highest type, known with certainty in advance, this result is inapplicable. Furthermore, with a known highest type, simulations suggest that zero is not a good approximation of the optimal marginal tax rate even quite close to the top of the income distribution, so the zero-rate-at-the-top result is of little practical importance.

To continue with the first term, raising the marginal rate at a particular point distorts only the behaviour of the marginal type, which explains the $f(w^*)$ in the denominator. For standard distributions, this factor is rising initially and then falling, which favours falling marginal rates at the bottom of the income distribution and rising rates at the top. The denominator also contains weights of $\xi^*$, indicating the extent of the distortion, and $w^*$, indicating how much productivity is lost per unit of reduction in labour effort. The elasticity is often taken to be constant, although some empirical evidence on the elasticity of taxable income supports a rising elasticity due to the greater ability of higher-income individuals to avoid taxes. This consideration may favour marginal rates that fall with income. Finally, $w^*$ is rising, which also favours falling marginal rates: The greater is the wage (ability level), the greater is the revenue loss from a given decline in labour effort.

The second term applies a social weighting to the revenue that is collected. The expression in parentheses in the integrand in the numerator is the difference between the marginal dollar that is raised and the dollar equivalent of the loss in welfare that occurs on account of individuals above $w^*$ paying more tax. As in the interpretation of expression (7), $u_c$ is the marginal utility of consumption to such individuals, $w^*$ indicates the impact of this change in utility on social welfare, and division by $\lambda$, the shadow price on the revenue constraint, converts this welfare measure into dollars. This integral is divided by $1 - F(w^*)$, which as noted makes the second term an average for the affected population.

This term tends to favour marginal rates that rise with income. The greater is $w$, the lower is $w^*$ (unless the welfare function is utilitarian, in which case this is constant) and the lower would be the marginal utility of income $u_c$ (had we not abstracted from this effect in the simplifying assumptions). Hence, at a higher $w^*$ the average value of the term subtracted in the integrand is smaller, making the entire term larger. Note further that, if social welfare or utility is reasonably concave, $w^* u_c$ will approach zero at high levels of income, at which point this term will be nearly constant in $w^*$. That is, the term favours rising marginal tax rates when income is low or moderate, but has little effect on the pattern of marginal tax rates near the top of the income distribution.

Because of difficulties in determining the shape of the optimal income tax schedule by mere inspection of the first-order condition (8), analysts beginning with Mirrlees (1971) have used simulations to help join the theoretical analysis with empirical estimates of labour supply elasticities and of the distribution of skills or income in order to provide further illumination. Tuomala (1990) offers a useful survey and set of calculations. In all the cases he reports, marginal tax rates fall as income increases, except at very low levels of income. Mirrlees's (1971) original calculations had displayed a similar tendency, but subsequent researchers had questioned the extent to which this result may have depended on the social preferences he stipulated or the arguably high labour supply response he assumed. Later work, however, suggests that a greater social preference for equality or a lower labour supply response tends to increase the level of optimal marginal tax rates but does not generally result in a substantially different shape. This phenomenon is also illustrated by Slemrod et al. (1994), who examine the optimal two-bracket income tax. In all of their simulations, the optimal upper-bracket marginal rate is lower than the lower-
bracket rate; indeed, this gap widens as the social preference for equality increases because of the additional value of raising the lower-bracket rate in generating funds to increase the grant, which is of greatest relative benefit to the lowest-income individuals.

Subsequent work further explores the circumstances in which optimal marginal tax rates might rise with income. Kanbur and Tuomala (1994) find that, when inequality in individuals’ abilities (wages) is significantly greater than previously assumed (but at levels they suggest to be empirically plausible), optimal marginal tax rates do increase with income over a substantial range, although for upper-income individuals optimal marginal rates still fall with income. Diamond (1998) examines a Pareto distribution of skills (instead of the commonly used lognormal distribution), under which the \((1 - F) / f\) component of expression (8) rises more rapidly at the top of the distribution, and finds that optimal marginal tax rates are rising at the top. However, Dahan and Strawczynski’s (2000) simulations indicate that Diamond’s result was driven in large part by his additional assumption that preferences were quasi-linear, thus removing income effects. (Nevertheless, their diagrams do suggest that, consistent with Diamond’s claim, moving from a lognormal to a Pareto distribution favours higher rates — still falling, but notably less rapidly — at the top of the income distribution.) Saez (2001), using income distribution data in the United States from 1992 and 1993, finds that the shape of the distribution of \((1 - F) / w_f\) is such that optimal rates should fall substantially well into the middle of the income distribution, to an income of approximately $75,000, rise until approximately $200,000, and then be essentially flat thereafter.

An additional result from the simulations is that, at the optimum, a nontrivial fraction of the population does not work, and this fraction is larger when social preferences favour greater redistribution and when the labour supply elasticity is higher. This outcome should hardly be surprising because, as the analysis of expression (8) and the simulations suggest, high marginal rates tend to be optimal at the bottom of the income distribution, along with a sizable grant. Relatedly, little productivity and thus little tax revenue is sacrificed when those with very low abilities are induced not to work (whereas substantial revenue is raised from the rest of the population, for whom marginal tax rates on the first dollars of income are inframarginal).

Extensions

Given the central importance of income taxation to the revenue and distributive objectives of government, further exploration of various aspects of the problem should be a high research priority. A number of features have received some, although generally quite limited, attention. For broader discussions and further references, see Atkinson and Stiglitz (1980), Stiglitz (1987), Tuomala (1990), Salanié (2003), and Kaplow (2008).

A critical assumption in optimal income tax analysis is that earning ability is unobservable so that income, a signal of ability, is taxed instead, which is the source of distortion. Hence, it is worth considering the possibilities for basing taxation more directly on ability. To some degree, hours may be observable, and ability (wages) can thus be inferred. But in many occupations (notably, self-employment) hours are difficult to observe, and both hours and wages are manipulable, such as by extending reported hours and lowering the reported wage. Another approach would be to measure proxies of earning ability, such as through testing. Unfortunately, skills measurable by testing explain...
only some of the variance in earning ability, and, if taxes were to be based on test results or other ability measures, individuals would adjust their performance and thereby distort the measurement. A third technique — one sometimes employed — is to adjust taxes and transfers for observable personal attributes, such as physical disability, age or family composition.

In general, tax and transfer schedules could be made a function of various imperfect signals of ability (or of other pertinent differences, such as in utility functions). For each value of the signal, there would in essence be a different tax schedule, governed by the first-order condition (8); each of these tax schedules would, however, be linked in a common optimization by the shadow price $\lambda$. One might view models like those of Akerlof (1978), in which he assumes that a subset of the lowest-ability group can be identified perfectly (‘tagged’), and Stern (1982), in which he examines the usefulness of a noisy signal of ability in a two-type model, as special cases of this more general formulation.

There exist myriad additional complications. One is that income may be a noisy signal of ability, whether because of variations in occupations (for a given ability, one job may pay more to compensate for specific disamenities) or in preferences (an individual may earn more not because of greater ability but rather due to a higher marginal utility of consumption or a lower marginal disutility of labour effort). Another possibility is that individuals may have preferences concerning redistribution itself, perhaps due to altruism or envy. Other topics that have been explored include liquidity constraints, general equilibrium effects of taxation on the distribution of pre-tax wages, uncertainty, interactions with non-tax distortions, and human capital.

**Commodity taxation**

**Commodity taxation with income taxation**

To examine optimal commodity taxation with labour income taxation, the foregoing model can be modified as follows. In place of consumption $c$, individuals choose commodity vectors $x$ and, as before, labour effort $l$ to maximize the utility function $u(x, l)$. On the left side of individuals’ budget constraints (1), $c$ is replaced by $\rho x$, where $\rho$ is the consumer price vector equal to $p + \tau$: the sum of a producer price vector (taken to be constant and equal to production costs) and a vector of commodity taxes (which, if negative, are subsidies).

Atkinson and Stiglitz (1976) demonstrate that, when the income tax is set optimally, commodity taxes should be undifferentiated, that is, $\tau = 0$, when utility is weakly separable in labour (on which more in a moment). Alternatively, other levels of $\tau$ are similarly optimal as long as the ratio of any two consumer prices equals the ratio of producer prices, with the difference in consumer price level being offset by an adjustment to the income tax schedule. (For example, if all commodity taxes are ten per cent rather than zero, the income tax schedule may be reduced so that, at all levels of pre-tax income $wl$, disposable income is ten per cent higher.) Subsequent work extends this uniformity result to examine cases in which the income tax need not be optimal and to assess various partial reforms, one result being that any proportionate reduction in non-uniform commodity taxes can generate a Pareto improvement (see Kaplow, 2006; also Konishi, 1995; Laroque, 2005).

The intuition behind the uniformity result is that, despite the second-best setting (due to the inherently distortionary character of a redistributive labour income tax), there is nothing to be gained — except
distortion of consumption — by differentiating commodity taxes when the utility function is weakly separable in labour. When that assumption is relaxed, one has the qualification — due originally to Corlett and Hague (1953) in a Ramsey setting — that complements to leisure (labour) should be taxed (subsidized). For example, taxing beach attendance or the purchase of novels may make leisure less attractive, encouraging labour effort and thereby reducing the distortion due to the income tax. Other qualifications, including with regard to preferences that depend on ability, other preference heterogeneity, and administrative and enforcement concerns, are catalogued in Kaplow (2008).

The Ramsey problem: commodity taxation alone

The foregoing analysis is usefully contrasted with that of Ramsey (1927), who considered how to set commodity taxes on a population of identical individuals to meet a revenue requirement. The familiar result is that commodity taxes should be inversely proportional to the elasticity of demand, with refinements for demand interdependencies. Introducing nonidentical individuals leads to modifications reflecting distributive concerns that entail higher taxes than otherwise on luxuries and lower taxes on necessities. See generally Atkinson and Stiglitz (1976, 1980), Auerbach and Hines (2002), Salanié (2003), and Stiglitz (1987).

As initially emphasized in Atkinson and Stiglitz (1976) and elaborated in Stiglitz (1987) and Kaplow (2008), however, neither prescription is apt if there is also an income tax. In the original Ramsey model in which all individuals are identical and thus there are no distributive concerns, the optimal tax obviously would be a uniform lump-sum extraction (a limiting case of an income tax), which, it should be noted, neither requires information about individuals’ types nor is distributively objectionable in this setting. When differences in earning ability are admitted, the optimal tax is a nonlinear income tax, and in typical cases the lump-sum component involves a uniform lump-sum subsidy. Nevertheless, optimal commodity taxation still is not guided either by the familiar inverse-elasticity rule or by the general preference for harsher treatment of luxuries than of necessities. As noted, in the basic case optimal differentiation is nil regardless of the demand elasticity or how demand changes with income, and qualifications such as that favouring taxation (subsidization) of leisure complements (substitutes) are largely unrelated to the level of the own-elasticity of demand for a commodity or its income elasticity.

Applications

Optimal commodity taxation is, in an important sense, a building block for the analysis of many other important problems. For example, Atkinson and Stiglitz (1976) explain how the analysis of optimal capital taxation can be assimilated into the framework, for it involves nonuniform taxation of consumption in different time periods, which may be interpreted in terms of the model simply as differently indexed commodities. Hence, in the basic case, the optimal tax on capital is zero.

Furthermore, as discussed by Kaplow (2004, 2008), other types of government policy may be analysed in a similar fashion. Allowing for externalities, the no-differential-tax prescription may be interpreted as requiring that consumer price ratios equal not producer price ratios but instead ratios of full social costs; hence, first-best Pigouvian taxes and subsidies (that is, set equal to marginal external effects) are optimal despite second-best concerns about distortionary income taxation and distributive effects. For public
By contrast, much prior and ongoing work examines these problems and others in a Ramsey-like setting. As Stiglitz (1987) observes, this course may be appropriate for developing economies in which income taxation is largely infeasible, but not for developed economies with an income tax.

Optimal tax systems

Most optimal taxation analysis simply assumes that certain tax instruments are available and others are not. Mirrlees (1971), Atkinson and Stiglitz (1980), and Slemrod (1990), however, emphasize the importance of motivating the presumed set of available instruments by administrative and enforcement concerns that indicate what actually is feasible. Ideally, these concerns would not be stipulated but rather would be made endogenous. Often, feasibility is a matter of degree, and one must choose among various imperfect systems, the quality of each being determined by policy choices regarding administration and enforcement and also by how the instrument is used.

To illustrate these trade-offs, note that a nonlinear income tax may be a more fine-tuned redistributive instrument than a linear income tax but is subject to additional types of manipulations that are costly to regulate. Likewise, if nonuniform commodity taxation is employed, there exist incentives to reclassify commodities. More comprehensive tax bases may avoid unnecessary distortions but be more costly to administer. The extent of evasion under any system may depend on the level of tax rates and on what other taxes are in place.

Greater attention to the choice among tax systems seems warranted. Whether or not to have a 20 per cent VAT, relying far less on income taxes, is probably a more important decision than how to set commodity tax differentials in light of subtle qualifications to the uniformity result. System choices are likely to be particularly important for developing countries, where fewer options are feasible and the available instruments are changing over time and in ways that are influenced by other government policies.

Article

An exchange economy consists of a group of people, each of whom has preferences concerning what commodities he or she likes, and initial holdings of the various commodities available. Operating under whatever institutional rules permit freedom of contract, the society redistributes the initial holdings among itself so as to achieve a distribution that is in some sense a solution to the exchange problem. But in what sense? Over the years three common meanings of solution have emerged, each with ever greater clarity. In order of increasing structural content rather than historical origin they are: (a) optimality in the sense of Edgeworth (1881) and Pareto (1909), or for brevity EP-optimality; (b) core solutions, which originated wholly with Edgeworth (1881) but had to wait until the advent of game theory before they were properly understood; and (c) competitive equilibria, which owe most to Walras (1874). Diverse as they are these three concepts are linked by a common thread, that each agent's objective is to seek the greatest satisfaction possible within the constraints that bind him.

If the roles of objectives and constraints are interchanged in (a), (b) and (c) we obtain three new concepts of solution, which are in effect mirror images of the earlier ideas. Thus corresponding to EP-optimality there is (a)' efficiency in the sense of Allais (1943, pp. 610–16, 637–44) and Scitovsky (1942), or in brief AS-efficiency. Corresponding to the core is the idea (b)' of a compensated core (for which see below), and corresponding to competitive equilibria is the concept (c)' of compensated equilibria due to Arrow and Hahn (1971, p. 108), although the closely related quasi-equilibria were defined earlier by Debreu (1962).

(Curiously enough, the passage in Scitovsky (1941–2) that gives his definition of (a)' was omitted from the reprinted version in his collected essays (1964). Very clear accounts of his approach may however be found in Samuelson (1956) and Graaff (1957), while Allais has published many further...
elaborations of his ideas, for example in Allais (1978). Those ideas were clearly at work in the pioneering paper by Debreu (1951), where he used them to overcome the problem ‘that no meaningful metrics exists in the satisfaction space, [that is, that utility is not cardinally measurable]’ (1951, p. 273). Later, Debreu’s proof of the Second Fundamental Theorem of Welfare Economics (the ‘pricing-out’ of EP-optima) in Chapter 6 of (1959) also depended quite explicitly on the use of AS-efficiency.) The interrelations between competitive and compensated equilibria are well recognized (see for example cost minimization and utility maximization) and concern such matters as the existence of locally cheaper points, which in turn necessarily imply market valuations of commodity bundles. The analogous interrelations between EP-optimality and AS-efficiency, and between cores and compensated cores, do not involve market phenomena and perhaps as a consequence are not so well known.

1 Preliminaries

We need appropriate language and notation, and some general assumptions. The exchange economy consists of \( m \) agents, indexed by \( h \), and \( n \) goods, indexed by \( i \). Each agent has a preference relation \( \preceq \) that is defined over some subset of the non-negative orthant of \( \mathbb{R}^n \) and whose meaning is ‘at least as good as’. It is assumed to be composed of two disjoint sub-relations, strict preferences \( \succ \) and indifference \( \sim \). Completeness and convexity of preferences are never assumed, and only partial transitivity is required, in the sense that the two cases \( z^1_k \succ k z^2_k \) and \( z^1_k > k z^3_k \) and \( z^1_k > k z^2_k \) and \( z^2_k \sim k z^3_k \) are each assumed to lead to the conclusion \( z^1_k \succ k z^3_k \). In particular, \( \sim \) need not be transitive.

A distribution (or allocation) \( Z \) is any \( m \times n \) matrix of the individual holdings \( z^h_i \), so that \( Z^0 \) is the distribution of initial holdings \( z^0_h \) or the endowment. If two distributions \( Z^1 \) and \( Z^2 \) are such that \( z^1_k \succ k z^2_k \) for every agent \( h \), then we write \( Z^1 \succ Z^2 \) and say that \( Z^1 \) is better than \( Z^2 \). Similarly, \( Z^1 \succeq Z^2 \) means that \( z^1_k \succeq k z^2_k \) for every \( h \); we say that \( Z^1 \) meets \( Z^2 \). If \( Z^1 \) meets \( Z^2 \) and the number of agents \( k \) for whom \( z^1_k \sim k z^2_k \) is at least 1 and not \( m \), then we write \( Z^1 \succeq Z^2 \).

An agent’s holdings are written \( z_h = (z^1_h, z^2_h, \ldots, z^m_h) \). The symbolic expression \( \Sigma Z \) means the commodity vector \( z = \Sigma z_h \) (all summations here are over the index \( h \) for agents). In particular, \( \Sigma Z^0 = z^0 \), the vector of total endowments of each good; \( O \) is the vector with zero amounts of every good. \( Z^1 \prec Z^2 \) means \( z^1_h < z^2_h \) for every \( h \), that is, \( \Sigma z^1_j \) is less in every component (good) than \( \Sigma z^2_j \); \( Z^1 \) is then less than \( Z^2 \). Similarly, \( Z^1 \leq Z^2 \) means that \( \Sigma z^1_j \) is not greater than \( \Sigma z^2_j \) in any component. If \( Z^1 \leq Z^2 \) and the number of goods \( j \) for which \( \Sigma z^1_{h_j} = \Sigma z^2_{h_j} \) is at least 1 and not \( n \), we write \( Z^1 < Z^2 \).

The notation \( Z^1 \succ Z^2 \) means \( (z^1 - z^2) < O \). In an exchange economy it is natural to assume \( z^0 \succ O \). A distribution \( Z \) is feasible if \( \Sigma Z = z^0 \), the use of= here rather than \( \leq \) implying that free disposal is not assumed; quantities have to be conserved during exchange.

The assumptions made in this section will be maintained throughout.
Purely for simplicity the definition of EP-optimality given by Arrow–Hahn (1971, p. 91) is used here, generalized to allow for incompleteness of preferences but specialized to an exchange economy. For compactness, that exchange economy will always be denoted $E(\succsim_0 Z^0)$.

**Definition 1 (D1):** A distribution $Z^1$ is **EP-optimal** for $E(\succsim_0 Z^0)$ if: (a) it is feasible; and (b) there is no other feasible distribution $Z$ that is better than $Z^1$.

Notice that D1 depends only on the totals $z^0$ and not on their distribution $Z^0$. Applying a weaker meaning of being better, namely: that $Z \succ Z^1$, produces a smaller set of allocations that can withstand such tests, the **strongly EP-optimal allocations**. Proofs of the interrelations between this more usual type of EP-optimality and the strong AS-efficiency defined below are similar to those given here, but with more complication, much as the theory of non-negative matrices is basically similar to but more complicated than the theory of positive matrices.

The following definition of AS-efficiency is implicit in the original works of Allais and Scitovsky.

**Definition 2 (D2):** A distribution $Z^2$ is **AS-efficient** for $E(\succsim_0 Z^0)$ if: (c) it is feasible; and (d) there is no other distribution $Z$ which meets $Z^2$ and is less than $Z^0$.

Again, D2 depends only on $z^0$ and not on $Z^0$, since ‘less than $Z^0$’ actually involves only $z^0$. As before, a weaker meaning of being less, namely: that $Z \prec Z^2$, produces a smaller set of allocations that can withstand such tests, the **strongly AS-efficient allocations**.

The first special assumption asserts a kind of monotonicity of preference for the society considered as a whole.

**Assumption 1 (A1):** For any $Z$ and any commodity vector $s \succ \succ \mathbf{0}$ there exists $Z^s$ such that $\sum Z^s = \sum Z + s$ and $Z^s \succ \succ Z$.

**Theorem 1:** Assume A1. If $Z^1$ is EP-optimal then it is AS-efficient.

**Proof:** This and all other proofs are by contraposition. If $Z^1$ is not AS-efficient, there exists $Z$ such that $Z \succeq Z^1$ and $\sum Z \prec \prec Z^0$. So there is a vector of surpluses in every commodity, i.e. $s = (z^0 - \sum Z) \succ \succ \mathbf{0}$. Hence from A1 there is $Z^s$ such that $\sum Z^s = \sum Z + s = z^0$ and $Z^s \succ \succ Z$. But then $Z^s \succ \succ Z \succeq Z^1$ implies $Z^s \succ \succ Z^1$, and $Z^s$ is feasible. So $Z^1$ is not EP-optimal.

The second special assumption does not involve the topology of $R^n$ but nevertheless plays the role of a continuity condition on preferences.

**Assumption 2 (A2):** For any agent $h$, $Z^1_h \succ n Z^2_h$ implies the existence of $\mu_h \in (0, 1)$ such that $\lambda Z^1_k \succeq \lambda Z^2_k$ for all $\lambda \in [\mu_h, 1)$.

**Theorem 2:** Assume A2. If $Z^2$ is AS-efficient then it is EP-optimal

**Proof:** If not, there exists $Z$ such that $\sum Z = z^0$ and $Z \succ Z^2$. From A2 there exists for each $z_h$ in $Z$ some $\mu_h \in (0, 1)$ such that $\lambda Z^1_k \succeq \lambda Z^2_k$ for all $\lambda \in [\mu_h, 1)$. Put $\mu$ equal to the maximum of these $\mu_h$, so that $\mu < 1$ and write $\mu Z$ for the $m \times n$ matrix of the $\mu_z h$. Then $\mu Z \succeq Z^2$. But by construction and the fact that $z^0 \succ \succ \mathbf{0}$, $\sum u Z = u \sum Z \prec \prec \sum Z = z^0$. So $Z^2$ is not AS-efficient.
### 3 Cores and compensated cores

The language and notation of Section 1 need modification to cope with cores. A *coalition* $C$ is any non-empty subset of the $m$ agents in the economy, and $|C|$ denotes its cardinality, so that $1 \leq |C| \leq m$. A *distribution over* $C$ is the $|C| \times n$ matrix $Z_C$ whose rows are the $n$-vectors $z_k$ for $k \in C$. The notation $\Sigma Z_C$ means the sum over the $|C|$ rows of $Z_C$, and for any $Z^0$ and any $C$ we write $Z_C^0 = \Sigma Z_C^0$, the total endowments available to the coalition $C$. Given any distribution $Z$ for the whole economy and any coalition $C$, the $C$-section of $Z$ is the distribution $Z_C$ over $C$.

The notion and language of Section 1 for preferential and quantitative relations between distributions will be applied freely to $C$-sections. But rather than writing $Z \succ Z'$ etc., the simpler notation $Z_C \succ Z_C'$ will be used. Just as in Section 2 with EP-optimality and AS-efficiency, stronger concepts of core and compensated core could be defined and corresponding results proved for them; but that is not done here.

**Definition 3 (D3):** A distribution $Z_1$ is in the *core* of $Z$ if: (i) it is feasible; and (ii) there is no coalition $C$ and no distribution $Z_C$ over $C$ such that (a) $\Sigma Z_C = Z_C^0$ and (b) $Z_C$ is better than the $C$-section $Z_1^C$ of $Z$.

D1 is the special case of D3 in which the only coalition allowed is the whole society, and similarly for D2 and D4, which is given next.

**Definition 4 (D4):** A distribution $Z_2$ is in the *compensated core* of $Z$ if: (iii) it is feasible; and (iv) there is no coalition $C$ and no distribution $Z_C$ over $C$ such that (c) $Z_C$ meets $Z_2^C$ and (d) $\Sigma Z_C < Z_2^C$.

The rationale for D4 is clearly similar to that for D2. Equally clearly, it is the appropriate ‘mirrored’ version of the core, in which objectives and constraints are interchanged. For example, it is easy to show that any compensated equilibrium of $E(\succeq C, Z^0)$ is in its compensated core. A much deeper result, for an exchange economy with a continuum of agents, is a ‘compensated’ version of the core equivalence theorem of Aumann (1964), namely: the set of the compensated equilibria is precisely the compensated core (Newman, 1982). Moreover, the assumptions and proof needed for this result are significantly simpler than in the classic paper of Aumann; in particular, only a non-topological separating hyperplane theorem is needed.

Since a coalition can be of any size, from one agent to every agent, the monotonicity of preference for the society as a whole asserted by A1 is quite inadequate to prove interrelations between cores and compensated cores. Instead, we use a more standard monotonicity assumption:

**Assumption 3 (A3):** For any agent $h$, $Z_h^1 \succeq Z_h^2$ implies $Z_h^1 \succ Z_h^2$.

**Theorem 3:** Assume A3. If $Z^1$ is in the core of $E(\succeq C, Z^0)$ then it is in its compensated core.

**Proof:** If not there is a coalition $C$ and a distribution $Z_C$ over $C$ such that $Z_C \geq Z_C^1$ and $\Sigma Z_C < Z_C^0$. So for $C$ there is a vector $s_C$ of surpluses in every commodity, that is, $s_C = \left( Z_C^0 - \Sigma Z_C^3 \right) \succ 0$. 

Now form a new distribution $Z^*_C$ over $C$ by adding the vector $\left( \left[ C \right]^{-1} \right)_S \succ \mathbf{0}$ to each $z_k$ for $k \in C$, and denote the result by $Z^*_C$. Since $Z^*_k \succ z_k$ from A3 $Z^*_C \succ k^2 z_k$. Then $Z^*_C \succ z_C \succeq Z^1_C$ so that $Z^*_C \succ Z^1_C$.

Moreover, by construction, $\Sigma Z^*_C = Z^0_C$. Hence $Z^1$ is not in the core.

Theorem 4: Assume A2. If $Z^2$ is in the compensated core of $E(\succeq z, Z^0)$ then it is in its core.

Proof: If not, there exists a coalition $C$ and a distribution $Z_C$ over $C$ such that $\Sigma Z_C = Z^0_C$ and $Z_C \succ Z^2_C$. The proof then proceeds as in Theorem 2.

4 Conclusion

There is remarkable symmetry between the solution concepts (a) and (b) on the one hand, and (a)' and (b)' on the other. However, there is a major asymmetry. The concepts (a) and (b) implicitly give each member of the society a positive weight, that is, each person ‘counts’ for something. Hence, as Edgeworth first observed (1881, p. 23), it is easy to show that a distribution is (strongly) EP-optimal if and only if it maximizes the satisfaction of any agent picked at random, given both the total endowments and the levels of satisfaction of the remaining $(m-1)$ agents.

The corresponding statement for strong AS-efficiency is not so obvious. Suppose (and this is Scitovsky’s original argument) that we fix the levels of satisfaction of everyone in the society and the total amounts of all but one commodity chosen at random, say $z_i$. Then it is tempting to say that a distribution is AS-efficient if and only if it minimizes the usage of $z_i$. The trouble with this is that, in the situation prevailing $z_i$ just might be a commodity that nobody wants. So it is not scarce, its shadow price is zero, and there is no point in trying to economize on its use. Unlike the case with persons, we cannot be sure that a commodity chosen at random will carry positive weight.

The obvious way of dealing with this point is to put sufficient structure on the problem to make $z_i$ always desired. But then it ceases to be an arbitrary commodity, unless all commodities are always so desired; and that is a strong assumption indeed.

Exactly the same difficulty arises of course with efficient production programmes, if they are defined as allocations that maximize the output of an arbitrary product $\forall j$ given the supplies of all the factors and the quantities of all products other than $\forall j$. This is really not surprising, since such ‘Pareto-efficiency’ is the analogue in a production economy of AS-efficiency in an exchange economy.

optimum quantity of money

Timothy S. Fuerst
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The optimum quantity of money is a normative monetary policy conclusion drawn from the long-run properties of a theoretical model. Most famously associated with Milton Friedman, the optimum calls for a zero nominal rate of interest and thus a steady state of price deflation at the long-run real rate of interest. Although this policy prescription has played a minor role in monetary policy implementation, it has had an enormous influence in monetary theory.

Article

The optimum quantity of money is most famously associated with Milton Friedman (1969). The optimum is a normative policy conclusion drawn from the long-run properties of a theoretical model. Friedman posited an environment that abstracts from all exogenous shocks and nominal price and wage sluggishness. The basic logic is then straightforward. One criterion for Pareto efficiency is that the private cost of a good or service should be equated to the social cost of this good or service. The service in question is the transactions role of money. The social cost of producing fiat money is essentially zero. Since fiat money pays no interest, the private cost of using money is the nominal interest rate. Hence, one criterion for Pareto efficiency is that the nominal interest rate should equal zero. Since long-run real rates are positive, this implies that monetary policy should bring about a steady deflation in the general price level. This famous policy prescription is now commonly called the Friedman rule.

Although most closely associated with Friedman's (1969) bold statement of the policy conclusion, the basic idea of the optimum quantity can be found in Tolley (1957), who argues, on similar efficiency
optimum quantity of money: The New Palgrave Dictionary of Economics
grounds, for paying interest on currency. Friedman (1960) credits Tolley with this suggestion, and further notes that an alternative policy would be a steady deflation. It is curious that Friedman (1960) dismisses the ‘Friedman rule’ deflation as not feasible for practical purposes. Finally, the optimum-quantity result is implicit, but never noted, in Bailey (1956) who examines the welfare cost of inflation but does not consider the welfare gain of deflations.

In practice, the optimum-quantity result has had remarkably little influence on monetary policy implementation. Although many central banks pursue low inflation rates with an eventual goal of price stability, no central bank has advocated a policy that would bring about a steady price deflation. There are likely several reasons, both judgemental and theoretical, that have led to this lack of influence. I will briefly review both types of objections.

One of the first theoretical objections to the optimum-quantity results was made by Phelps (1973), who argued that Friedman's first-best argument ignored the second-best fact that money growth produces seigniorage revenues for a government, and that all forms of taxation produce distortions of some kind. If ‘money’ or ‘liquidity’ is a good like any other, then familiar optimal taxation arguments would suggest that it should be taxed via a steady inflation. This argument seems all the more persuasive given empirical estimates of a fairly low money demand elasticity.

This public finance approach spawned a very large literature. Important contributions include Kimbrough (1986), Guidotti and Vegh (1993), Correia and Teles (1996; 1999), Chari, Christiano and Kehoe (1996), and Mulligan and Sala-i-Martin (1997). These analyses were much more explicit than Friedman (1969) and considered a fully dynamic theoretical environment with no nominal rigidities. A key relationship in all these models is the transactions or shopping function. The time spent by households shopping (s_t) is a function of the form: $s_t = \phi(c_t, m_t)$, where $c_t$ denotes real consumption and $m_t$ denotes real cash balances. The function $\phi$ is assumed to be homogenous of degree $k$, increasing in consumption, and decreasing in real cash balances, the latter effect motivated by the transactions function of money. Money can be thought of as an intermediate good that facilitates consumption purchases. Now suppose a central government needs to finance an exogenous level of spending and can do so only with distortionary taxes on, say, labour income, or the inflation tax on money balances. In this case, is the Friedman rule still optimal?

Most of these papers were supportive of the Friedman rule, concluding that in such a second-best environment the optimal monetary policy is a zero nominal rate. Mulligan and Sala-i-Martin (1997) argued that the result was fragile as it depended on the degree of homogeneity in $\phi$ and the alternative tax instruments available to the government, for example, income taxes against consumption taxes. These conflicting results have been usefully explained in DeFiore and Teles (2003), who demonstrated that the reason for the divergent conclusions is an inappropriate specification of how consumption taxes are entered in the transactions cost function. They consider a more general environment in which the government has access to both consumption and income taxes. They also consider the case where money is costly to produce at a constant marginal cost of $\alpha$. Further, they demonstrate that if $\phi$ is linearly homogenous ($k=1$) then the optimal interest rate is equal to $\alpha$. This is a modified Friedman rule in that the private cost and social cost of money are set equal to each other, and is analogous to the Diamond and Mirrlees (1971) optimal taxation result: intermediate goods should not be taxed when consumption taxes are available and the technology is constant returns to scale ($k=1$). If $\phi$ is not linearly...
homogeneous, then the optimal policy involves a tax (or subsidy) on money proportional to $\alpha$. Since money is essentially costless to produce ($\alpha = 0$) the optimal nominal interest rate is zero. DeFiore and Teles (2003) thus conclude that the Friedman rule is the optimal second-best policy for all homogeneous transactions technologies. Hence, the Phelps (1973) objection appears to be settled in Friedman's favour. A second theoretical objection to the optimum-quantity result is that, in a world with nominal rigidities, a steady general price deflation would produce unwanted relative price movements since not all nominal prices would be adjusted simultaneously. Strictly speaking this is not a theoretical objection to Friedman (1969), as he assumed a world with perfectly flexible nominal prices and wages. But if one believes that nominal rigidities are important, and that they matter even in the long run, then this is a relevant objection to the Friedman rule. For example, in the dynamic new Keynesian (DNK) class of models (for example, Woodford, 2003) the assumed nominal rigidities have permanent effects so that any departure from price stability causes permanent movements in relative prices. Hence, these models typically suggest that optimal policy is a stable price level, and that a Friedman-rule deflation would be suboptimal. These DNK models typically abstract from the nominal interest rate distortions that are at the heart of the optimum-quantity result. A model that combined the DNK nominal rigidities with the nominal rate distortion would presumably result in a long-run optimal nominal interest rate somewhere between zero and the steady-state real rate.

The principle judgemental objection to the Friedman rule is historical. The instances in US history in which deflations occurred are associated with severe recessions, most famously in the 1929–33 period. A related judgemental concern deals with the zero bound. If the central bank's principal tool to stimulate the economy is a reduction in the nominal rate of interest, then the zero nominal rate prescribed by the Friedman rule apparently leaves no additional ammunition in the monetary policy arsenal (as nominal rates cannot be negative). This nervousness about the Friedman rule was enhanced by the experience of Japan during the 1990s. The Japanese economy performed poorly at a time in which general prices were falling and the short-term nominal rate was zero.

Since central banks have not followed Friedman's (1969) proposal to set the nominal rate to zero, a natural issue is to quantify the welfare costs of being away from Friedman's optimum quantity of money. Following in the footsteps of Bailey (1956), Lucas (2000) uses a theoretical environment similar to that of Correia and Teles (1996; 1999) to address this question. The welfare cost is approximately the area underneath the money demand curve between the optimal zero nominal rate and the interest rate under question. Lucas reports that the welfare cost of a four per cent nominal rate is between 0.2 per cent and one per cent of annual income, the difference depending upon the assumed behaviour of money demand as the nominal rate approaches zero. Since a zero nominal rate has not been observed in the United States in the post-Second World War period, the data cannot determine which estimate is more accurate. But either estimate suggests a fairly modest welfare cost.

Studies analysing the optimality of the Friedman rule have been reignited by the new class of search-theoretic monetary models. These models are micro-based, replacing the function $\phi$ in DeFiore and Teles (2003) with a search-based trading environment in which money improves the chances of successfully finding a suitable partner with whom to trade. In an innovative paper, Lagos and Wright (2005) use a search-theoretic environment to address the optimality of the Friedman rule and the welfare consequences of deviating from it. In search models of money the buyer and seller engage in a
bargaining game to determine the transactions price at a given meeting. The buyer is carrying money and has thus postponed previous consumption. If sellers have some bargaining power, then there is a hold-up problem because part of the gain associated with the holding of money is received by the seller. This bargaining distortion leads the buyers to economize on money holdings so that they are below the socially efficient level. Lagos and Wright (2005) demonstrate that the optimal policy in this search environment is the Friedman rule (a similar conclusion is reached by Shi, 1997). But more interestingly, the welfare cost of being away from the Friedman rule, at say a four per cent nominal rate, is significantly higher than calculated by Lucas (2000). This arises because the positive nominal rate exacerbates an already suboptimal level of real balances arising from the hold-up problem. The search models of money have rekindled interest in the optimality of the Friedman rule at just the time when DeFiore and Teles (2003) appear to have settled the issue in the aggregative monetary models. The coming years will probably see further work on the Friedman rule from this search-theoretic perspective. A key issue is the nature of the bargaining process that arises at trading opportunities. These recent developments testify to the continued prominence of the optimum quantity of money in monetary theory, if not practice. The lasting contribution of the theory is to introduce explicit, utility-based welfare analysis into monetary economics.

Article

In 1973, Black, Scholes and Merton developed a method for the valuation of a European option based on the idea of perfect replication of its payoff. Their approach demonstrates how to act in an uncertain environment so that relevant risks are controlled. Around the same time, trading of options on common stocks started in the Chicago Board Options Exchange. Theory met practice and an exciting and fruitful journey started on the crossroads of economics, finance and mathematics. Its impact was phenomenal in both academia and industry. New areas of research were created, and numerous educational and training activities were established. The derivatives market grew at an unprecedented rate and influenced the development of other markets. Complex mathematical modelling and technical sophistication, predominant elements in theory and applications in engineering and natural sciences, now entered the theory and practice of finance. This was not the first time that stochastic modelling touched finance. At the beginning of the 20th century, in his pioneering doctoral work, Bachelier (1900) proposed a
stochastic model, based on normality assumptions on their returns, for stock prices. In many aspects, however, his work was ahead of its time and had no impact for years to come.

What was the Black, Scholes and Merton option valuation approach? A European call option is a contract that gives its owner the right to buy the underlying stock at a given price, $K$ and a given maturity, $T$. Their model, powerful and simple, assumed a liquid market environment consisting of a non-defaultable bond and a stock. The bond yields constant interest rate $r$, while the stock price, $S_t$, is modelled as a log-normal diffusion process having constant mean rate of return, $\mu$, and volatility parameter, $\sigma$. Applying Ito's formula – a fundamental result of modern stochastic calculus – they were able to build a dynamic self-financing portfolio, $(\alpha_t, \beta_t)$, $0 \leq t \leq T$, that replicates the option payoff, that is, for which $\alpha_T + \beta_T = (S_T - K)^+$. For all $t$, the option price, $\nu_t$, is, then, given by the current portfolio value, $\nu_t = \alpha_t + \beta_t$. Stochastic and differential arguments yield the price process representation $\nu_t = C(S_t, t)$, with the function $C$ satisfying the partial differential equation

$$C_t + \frac{1}{2}\sigma^2 S^2 C_{SS} + rSC_S = rC$$

(1)

and the terminal condition $C(S_T, T) = (S_T - K)^+$. The components of the replicating portfolio turn out to be $\alpha_t = S_tC_S(S_t, t)$ and $\beta_t = C(S_t, t) - \alpha_t$ representing the amounts invested, respectively, in the stock and bond.

The construction of the price and hedging policies, as well as the specification of various sensitivity indices (greeks), thus amount to solving linear partial differential equations, a relatively easy task given the existing technical body in mathematical analysis.

The industry rapidly adopted the Black and Scholes model as a standard for the valuation of simple (vanilla) options. Soon after, more complex products were created and traded, like options on fixed-income securities, currencies, indices and commodities. Gradually, the options market experienced great growth and its liquidity reached very high levels (for a concise exposition see, for example, Musiela and Rutkowski, 2005).

In parallel, substantial advances in research took place. In 1979, Harrison and Kreps laid the foundations for the development of the risk-neutral pricing theory. They created a direct link between derivative valuation and martingale theory. For a finite number of traded securities and under general assumptions on their price processes and related payoffs, they established that the price of a replicable contingent claim corresponds to the expected value, calculated under the risk-neutral probability of the (discounted) claim's payoff. These results were further developed and presented by Harrison and Pliska (1981). In the years that followed, the theory was extended and a model-independent approach for pricing and risk management emerged. In a generic derivatives model, the (discounted) prices of primary assets are represented by a vector-valued semi-martingale $S_S = (S_S^1, \ldots, S_S^m)$, defined in a probability space $(\Omega, \mathcal{F}, (\mathcal{F}_t), \mathbb{P})$ where $\mathbb{P}$ is the historical measure. The (discounted) payoff, $C_T$, is taken to be an $\mathbb{F}$-T-
measurable random variable. The derivative price, discounted under the same numeraire as $S$ and $C_T$, is given by the conditional expectation

$$V_t(C_T) = E_Q(C_T | \mathcal{F}_t).$$

(2)

The pricing measure $Q$ is equivalent to $\mathbb{P}$ and, under it, the (discounted) price processes become martingales, that is, $E_Q(S_s | \mathcal{F}_t) = S_t$, $t \leq s \leq T$. The derivative prices, themselves martingales under $Q$, are linear with respect to their payoffs, time and numeraire consistent and independent of their holder's risk preferences.

Fundamental questions in risk-neutral valuation are related to existence and uniqueness of the derivative price. Uniqueness turns out to be equivalent to the replicability of all claims in the market. Such a market is classified as complete. Stochastic integration theory was used to establish that market completeness is equivalent to uniqueness of the risk-neutral martingale measure $Q$. In this case, the price is given by (2) and, thus, exists and is unique. If, however, the market is not complete there is multiplicity of equivalent martingale measures. In this case, perfect replication is abandoned and absence of arbitrage becomes the key requirement for price specification and model choice. In an arbitrage-free model, a judicious choice of the pricing measure is made and the price is still represented as in (2). In many aspects, market completeness and absence of arbitrage are complementary concepts. Their relationship has been extensively studied with the use of martingale theory and functional analysis. Important results in this direction are formulated in the First and Second Fundamental Theorems of Asset Pricing (see, among others, Bjork, 2004; Delbaen and Schachermayer, 2006).

The risk-neutral valuation theory, built on a surprising fit between stochastic calculus and quantitative needs, revolutionized the derivatives industry. But its impact did not stop there. Because the theory provides a universal approach to price and manage risks, the option pricing methodology has been applied in an array of applications. Indeed, corporate and non-corporate agreements have been analysed from an options perspective. Option techniques have also been applied to the valuation of pension funds, government loan guarantees and insurance plans. In a different direction, applications of the theory resulted in a substantial growth of the fields of real options and decision analysis. Complex issues related, for example, to operational efficiency, financial flexibility, contracting, and initiation and execution of research and development projects were revisited and analysed using derivative valuation arguments (see the review article of Merton, 1998).

Since the 1970s, theoretical developments, technological advances, modelling innovations and creation of new derivatives products have been proceeding at a remarkable rate. During this period, theory and practice have been shaping each other in a unique challenging and intense interaction. The rest of the article is, mainly, dedicated to this dimension.

Theory and practice in derivatives markets
The Black and Scholes model included various assumptions that are not valid in practice. Interest rates and volatilities are not constant, trading is not continuous, defaults occur and information is not complete. How did academic research and industry reality react to and handle these issues? Albeit there are very distinct priorities, needs and goals, shortcomings of the theory not only did not limit its applicability but prompted a remarkable progress between the theoretical and the applied worlds. Models were developed and innovative computational techniques were invented, and used in practice, for new complex products (exotics). Progress did not occur simultaneously. While theory developed mostly in bursts, practice continued the use of basic models which often involved self-contradictory assumptions. However, despite internal modelling inconsistencies, industry applications offered valuable intuition and feedback to the abstract theoretical developments.

The first revisited assumption was that the (short) interest rate is constant. Models of stochastic interest rates started appearing, and a major breakthrough occurred in 1992 with the work of Heath, Jarrow and Morton. Moving away from modelling directly the short rate, their novel approach was focused on the dynamics of the entire (instantaneous and continuously compounded) forward curve \( f(t, T) \), defined by

\[
f(t, T) = - \frac{\partial}{\partial T} \ln B(t, T)
\]

where \( B(t, T) \) represents the price, at time \( t \), of a zero-coupon discount bond with maturity \( T \). To facilitate the analysis of the forward curve, Musiela (1993) introduced an alternative parametrization, namely, \( r(t, x) = f(t, t + x) \), which exhibited the importance of infinite dimensional diffusions and stochastic partial differential equations in finance. This helped to find answers to a number of practical questions related to the yield curve dynamics. Indeed, the issue of consistency between the yield curve construction and its evolution was resolved. Additionally, the support of the yield curve distribution has been studied and the mean reversion, or, more mathematically, stationarity of the entire yield curve dynamics has been addressed.

Clearly, the infinite dimensional analysis was useful in a study of the dynamics of the forward rates for all maturities. There was, however, still a problem that needed to be looked at, namely, that the forward rates \( f(t, T) \) are not traded in the market, and the Libor and swap rates are together with options on them. Moreover, information contained in these option prices should be taken into account in the specification of the yield curve dynamics. Because the market trades caps and swaptions in terms of their Black and Scholes volatilities, it would be advantageous to develop a term structure model that is consistent with such practice, a task seen by many academics at that time, as impossible for its apparent internal inconsistency.

In a series of papers by Miltersen, Sandmann, Sondermann, Brace, Gatarek, Musiela, Rutkowski and Jamshidian (see Part II of Musiela and Rutkowski, 2005, for a detailed exposition of these works), a new modelling framework for term structure dynamics was put in place. The so-called Libor, also known as BGM (Brace–Gatarek–Musiela), and swap market models resolved the outstanding issue of the link between the traded instruments and the mathematical description of their dynamics. In essence, they provided a model-independent framework for the analysis of the interest rates dynamics when coupled
Options (new perspectives)

The New Palgrave Dictionary of Economics

with the advances – taking place in parallel – in the modelling of volatility smile dynamics. The latter
issue is discussed next.

The Black and Scholes model assumes constant volatility and hence, within this model, a call option
with arbitrary strike is priced with the same volatility. However, call options of different strikes are
priced differently by the market which ‘allocates’ into the Black and Scholes formula a strike-dependent
volatility generating the so-called volatility smile. This is clearly inconsistent with the assumption of the
model. It turns out, however, that a complete collection of call prices, for all strikes and maturities,
uniquely determines the one-dimensional distributions of the underlying forward price process, under a
probability measure which should be interpreted as a forward measure to the option maturity. In a series
of papers, Dupire (1993) shows how to construct martingale diffusions with a given set of one-
dimensional distributions, demonstrating, once more, that the market practice is theoretically sound and
internally consistent when analysed from the perspective of the appropriate model. The Black and
Scholes model is used only to convert the quoted volatility into a price and it is no longer used for the
pricing of vanilla options. Moreover, there are many ways of constructing martingales with a given set
of one-dimensional marginals, and the question is not so much how to construct one but, rather, which
one to choose and under which criteria. The important message here is that, again, one can now look at
the problem in a completely model-independent way, provided all objects – namely, the underlying
assets, the associated probability measures and the relevant market information – are correctly
interpreted.

Obviously, the theory and practice, at least in the equity, foreign exchange and interest rates derivatives
markets, have moved to a different level and reached a certain degree of maturity. Of course, important
challenges remain but experience since the 1970s defines clearly a path to follow.

Current challenges and perspectives

Credit risk

A fundamental assumption of the Black and Scholes model is that the underlying securities do not
default. However, default is a realistic element of financial contracts and very relevant to any firm's
performance. Credit-linked instruments have, by now, become a central feature in derivatives markets.
These are financial products that pay their holders amounts contingent on the occurrence of a default
event ranging from bankruptcy of a firm to failure to honour a financial agreement. Examples include,
among others, credit default swaps (CDS), credit default obligations (CDO) and tranches of indices.
Their market has grown more than eightfold in recent years and, undoubtedly, credit risk is, today, one
of the most active and challenging areas in quantitative finance.

There are various issues that make the problems in credit risk difficult, from both the modelling and the
implementation point of view. The first challenge is how to model the time of default. In academic
research, there are two well-established approaches, the structural and the reduced. In the structural
models, it is postulated that uncertainty related to default is exclusively generated by the firm's value.
Modelling default, then, amounts to building a good model for the company's assets and determining
when the latter will fall below existing liabilities. However, such default times are, typically, predictable
which is not only unrealistic, but, also, difficult to implement due to limited public information about the
firm's prospects. In the other extreme, the reduced-form models, the default time is associated with a
point process with an exogenously given stochastic jump intensity. The intensity essentially measures the instantaneous likelihood of default. Reduced models are more tractable for pricing and calibration but the default times are completely sudden (totally inaccessible), a non-realistic feature. Recently, efforts have been made to bridge the two approaches by incorporating the limited information the investors might have about the firm’s value. This information-based approach is gradually emerging but a number of modelling and technical serious issues remain to be tackled. See, among others, Bielecki and Rutkowski (2002) and Schönbucher (2003).

Even though the above models are theoretically sound, their practical implementation is so difficult that it makes them, effectively, inapplicable. The main problem stems from the high dimensionality and inability to develop computational methods that track ‘name by name’ the valuation outputs. For this reason, the focus in the industry has shifted to an alternative direction centred on modelling the joint distribution of default times. An important development in this direction is the use of a copula function, a concept introduced in statistics by Sklar (1959). The aim is to define the joint distribution of a family of random variables when their individual marginal distributions are known. Such marginal distributions may be, frequently, recovered from the market, as is the case with CDS that yield implicit information on the underlying name’s default time. Today, the most widely used copula is the one-factor Gaussian one, proposed by Li (2000). Its popularity lies in the ability to obtain the sensitivity, and thus information on hedging, of the derivative price in a name by name correspondence.

Model specification

As has been mentioned earlier, the theory has long departed from perfect replication, and practice never relied on it. Absence of arbitrage is the underlying pricing criterion in the derivatives market. However, a plethora of pricing issues and model specifications arise every day. Derivatives markets have been growing very rapidly, and high liquidity in vanilla options on a large number of underlyings including, among others, single stocks and equity indices, interest rates, foreign exchange and commodities, has been achieved. The users benefit from competitive prices, quoted at very tight spreads, for the protection they need. This, in itself, brings another challenge to the providers of such services and products, namely, the models that are currently under development need to reflect this liquidity before they can be used for the pricing of less liquid products. This process is known in the industry as model calibration. To a large extent, one can assume that the market gives the prices for simple derivatives like calls and puts and, hence, pricing considerations dissolve. However, more exotic options need to be priced and this must be done in a way consistent with the basic products (vanilla).

To provide some intuition, consider the case of the so-called first generation exotic, namely, a down and out call option. This is a barrier option that reduces to a simple call option when the likelihood of crossing the barrier is very small. Consequently, a model to price such an option must return the market price of a call in such a scenario. Call prices will be liquid for all strikes up until a certain maturity, say, 18 months or two years for currency options. However, there may be a need to price products with embedded currency options of very long maturity, like up to 50 years in dollar–yen exchange rate. In this case, a suitable model needs to be developed that accommodates short- and long-term issues. On one hand, the model must fit the short-dated foreign exchange (FX) calls and puts. On the other, it has to be consistent with the interest rates volatilities and must capture correctly the dependence structure
between the dollar and yen interest rates curves, their volatilities and the spot FX.

A standard approach for solving such problems consists of writing a continuous-time model and trying to fit it to the liquid prices. This task is often very difficult to complete. Indeed, as more market information must be put into a model, the more complicated the model gets, the more difficult and time consuming the calibration procedure becomes, and the more time it takes to produce accurate prices and stable sensitivity reports. To a large extent, model calibration is identical to the specification of one-dimensional distributions of the underlying process. Model specification, on the other hand, can be identified with the specification of an infinite dimensional copula function defining the joint distribution of the entire path, given the marginal distributions that can be deduced from the call prices. At this point, it is important to recall that, often, option payoffs depend solely on a finite dimensional distribution of the underlying process. Consequently, the need to specify the continuous-time dynamics remains valid only if one wants to link the concept of price with perfect replication of the payoff, a requirement that is, in any case, not met in practice.

Seen from this perspective, a new modelling path emerges, namely, one can take the marginals as given by the call prices and choose a copula function in such a way that the joint distribution is consistent with an arbitrage-free model. For example, if one wants to price a forward start option, the distributions of the underlying asset at two different dates are given. Then, only the joint distribution needs to be specified but in such a way that the martingale property is preserved. Clearly, there is an infinite number of ways to build such a martingale, and the choice should be based on additional information – for example, not on the smile as seen today but on the assumptions one might want to make about the smile dynamics.

**Risk measures**

As was previously discussed, absence of arbitrage is the fundamental ingredient in derivative pricing. Absence of perfect replication remains, however, a major issue and dictates the creation of financial reserves. To this effect, regulatory policies have been in place for few years now. These requirements prompted the axiomatic analysis of the so-called risk measures, which are nonlinear indices yielding the capital requirement of financial positions. The theory of coherent risk measures was proposed by Artzner et al. (1999). A popular risk measure is the ‘value at risk’, which, despite its widespread use, neither promotes diversification nor measures large losses accurately. Since the mid-1990s a substantial research effort has been invested in further developing the theory. Relaxing a scaling assumption in the coherent case has led to the development of convex risk measures. The next step has been the axiomatic construction of dynamic risk measures that are time consistent, an indispensable property of any pricing system.

options

Robert C. Merton
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

An option is a security whose owner has a right to buy (sell) it at a specified price on a specified date (or, with an American-type option, on or before the specified date). Trading of options on common stock began in 1973 and has since spread to other commodities. Option pricing theory provides a unified theory for the pricing of corporate liabilities. Of its more recent extensions, perhaps the most significant is its application in the evaluation of operating or ‘real’ options in the capital budgeting decision problem.

Article

A ‘European-type call (put) option’ is a security that gives its owner the right to buy (sell) a specified quantity of a financial or real asset at a specified price, the ‘exercise price’, on a specified date, the ‘expiration date’. An American-type option provides that its owner can exercise the option on or before the expiration date. If an option is not exercised on or before the expiration date, it expires and becomes worthless.

Options and forward or futures contracts are fundamentally different securities. Both provide for the purchase (or sale) of the underlying asset at a future date. A long position in a forward contract obliges its holder to make an unconditional purchase of the asset at the forward price. In contrast, the holder of a call option can choose whether or not to purchase the asset at the exercise price. Thus, a forward contract can have a negative value whereas an option contract never can.

The first organized market for trading options was the Chicago Board Options Exchange (CBOE) which
began trading options on common stocks in 1973. The initial success of the CBOE was followed by an expansion in markets to include options on fixed-income securities, currencies, stock and bond indices, and a variety of commodities. Although these markets represent an increasingly larger component of total financial market trading, options are still relatively specialized financial securities. Option pricing theory has, nevertheless, become one of the cornerstones of financial economic theory. This central role for options analysis derives from the fact that option-like structures pervade virtually every part of the field. Black and Scholes (1973) provide an early example: shares of stock in a firm financed in part by debt have a payoff structure which is equivalent to a call option on the firm's assets where the exercise price is the face value of the debt and the expiration date is the maturity date of the debt. Option pricing theory can thus be used to price levered equity and, therefore, corporate debt with default risk.

Identification of similar isomorphic relations between options and other financial instruments has led to pricing models for seniority, call provisions and sinking fund arrangements on debt; bonds convertible into stock, commodities, or different currencies; floor and ceiling arrangements on interest rates; stock and debt warrants; rights and stand-by agreements. In short, option pricing theory provides a unified theory for the pricing of corporate liabilities.

The option-pricing methodology has been applied to the evaluation of noncorporate financial arrangements including government loan guarantees, pension fund insurance and deposit insurance. It has also been used to evaluate a variety of employee compensation packages including stock options, guaranteed wage floors, and even tenure for university faculty. Perhaps the most significant among the more recent extensions of option analysis is its application in the evaluation of operating or 'real' options in the capital budgeting decision problem. For example, a production facility which can use various inputs and produce various outputs provides the firm with operating options that it would not have with a specialized facility which uses a fixed set of inputs and produces a single type of output. Option-pricing theory provides the means of valuing these production options for comparison with the larger initial cost or lower operating efficiency of the more flexible facility. Similarly, the choice among technologies with various mixes of fixed and variable costs can be treated as evaluating the various options to change production levels, including abandonment of the project. Research and development projects can be evaluated by viewing them as options to enter new markets, expand market share or reduce production costs.

As these examples suggest, option analysis is especially well suited to the task of evaluating the 'flexibility' components of projects. These, corporate strategists often claim, are precisely the components whose values are not properly measured by traditional capital-budgeting techniques. Hence, option-pricing theory holds for the promise of providing quantitative assessments for capital budgeting projects that heretofore were largely evaluated qualitatively. Survey articles by Smith (1976) and Mason and Merton (1985) provide detailed discussion of these developments in option analysis along the extensive bibliographies.

The lineage of modern option pricing theory began in 1900 with the Sorbonne thesis, ‘Theory of Speculation’, by the French mathematician Louis Bachelier. The work is rather remarkable because, in analysis the problem of option pricing, Bachelier derives much of the mathematics of probability diffusions; this, five years before Einstein's famous discovery of the theory of Brownian motion. Although, from today's perspective, the economics and mathematics of Bachelier's work are flawed, the connection of his research with the subsequent path of attempts to describe an equilibrium theory of...
option pricing is unmistakable. It was not, however, until nearly 75 years later with the publication of the seminal Black and Scholes article (1973), that the field reached a sense of closure on the subject and the explosion in research on option pricing applications began.

As with Bachelier and later researchers, Black and Scholes assume that the dynamics for the price of the asset underlying the option can be described by a diffusion process with a continuous sample path. The breakthrough nature of the Black–Scholes analysis derives from their fundamental insight that the dynamics trading strategy in the underlying asset and a default-free bond can be used to hedge against the risk of either a long or short position in the option. Having derived such a strategy, Black and Scholes determine the equilibrium option price from the equilibrium condition that portfolios with no risk must have the same returns as a default-free bond. Using the mathematics of Ito stochastic integrals, Merton (1973, 1977) formally proves that with continuous trading, the Black–Scholes dynamic portfolio will hedge all the risk of an option position held until price exercise or expiration, and therefore, that the Black–Scholes option price is necessary to rule out arbitrage.

Along the lines of the derivation for general contingent claims pricing in Merton (1977), a sketch of the arbitrage proof for the Black–Scholes price of a European call option on a nondividend-paying stock in a constant interest rate environment is as follows.

Assume that the dynamics of the stock price, $V(t)$, can be described by a diffusion process with a stochastic differential equation representation given by:

$$dV = \alpha V dt + \sigma V dz$$

where $\alpha$ is the instantaneous expected return on the stock; $\sigma^2$ is the instantaneous variance per unit time of the return, which is a function of $V$ and $t$; $dz$ is a standard Wiener process. Let $F[V, t]$ satisfy the linear partial

$$0 = \frac{1}{2} \sigma^2 V^2 F_{11} + rVF_1 - rF + F_2$$

where subscripts denote the partial derivatives and $r$ is the interest rate. Let $F$ be such that it satisfies the boundary conditions:

$$F / V \leq 1; \quad F(0, t) = 0; \quad F[V, T] = \max[0, V - E].$$
Note from (3) that the value of $F$ on these boundaries are identical to the payoff structure on a European call option with exercise price $E$ and expiration date $T$. From standard mathematics, the solution to (2) and (3) exists and is unique.

Consider the continuous-time portfolio strategy which allocates the fraction $w(t) \equiv F_1 [V, t] V(t) / P(t)$ to the stock and $1-w(t)$ to the bond, where $P(t)$ is the value of the portfolio at time $t$. Other than the initial investment in the portfolio at there are no contributions or from the portfolio until it is liquidated at $t = T$.

The prescription for the portfolio strategy for each time $t$ depends only on the first derivative of the solution to (2)–(3) and the current values of the stock and the portfolio. It follows from the prescribed allocation $w(t)$ that the dynamics for the value of the portfolio can be written as:

$$\begin{align*}
dP & = w(t)P \, dV / V + \left[ 1 - w(t) \right] rP \, dt = F_1 \, dV + r[P - F_1 V] \, dt.
\end{align*}
$$

(4)

As a solution to (2), $F$ is twice-continuously differentiable. Hence, we can use Ito's Lemma to express the stochastic process for $F$ as:

$$dF = \left[ \frac{1}{2} \sigma^2 V^2 F_{11} + \alpha V F_1 + F_2 \right] dt + F_1 \sigma V \, dz$$

(5)

where $F$ is evaluated at $V = V(t)$ at each point in time $t$. But, $F$ satisfies (2). Hence, we can rewrite (5) as:

$$dF = F_1 \, dV + r[F - F_1 V] \, dt.$$  

(6)

Define $Q(t)$ to be the difference between the value of the portfolio and the value of the function $F[V, t]$ evaluated at $V = V(t)$. From (4) and (6), we have that $dQ = rQ \, dt$ which is a nonstochastic differential equation with solution $Q(t) = Q(0) \exp[rt]$ and $Q(0) = P(0) - F[V(0), 0]$. Hence, if the initial investment in the portfolio is chosen so that $P(0) = F[V(0), 0]$ then $Q(t) \equiv 0$ and $P(t) = F[V(t), t]$ for all $t$.

Thus, we have constructed a dynamic portfolio strategy in the stock and a default-free bond that exactly replicates the payoff structure of a call option on the stock. The solution of (2) and (3) for $F$ and its first
The New Palgrave Dictionary of Economics

derivative $F_1$ provides the ‘blueprint’ for that construction. The standard no-arbitrage condition for equilibrium prices holds that two securities with identical payoff structures must have the same price. It follows, therefore, that the equilibrium price of the call option at time $t$ must equal the Black–Scholes price, $F[V(t), t]$. The extraordinary impact of the Black–Scholes analysis on financial economic research and practice can in large part be explained by three critical elements: (1) the relatively weak assumptions for its valid application; (2) the variables and parameters required as inputs are either directly observable or relatively easy to estimate, and there is computational ease in solving for the price; (3) the generality of the methodology in adapting it to the pricing of other options and option-like securities. Although framed in an arbitrage type of analysis, the derivation does not depend on the existence of an option on the stock. Hence, the Black–Scholes trading strategy and price function provide the means and the cost for an investor to create synthetically an option when such an option is not available as a traded security. The findings that the equilibrium option price is a twice continuously differentiable function of the stock price and that its dynamics follow an Ito process are derived results, not assumptions. The striking feature of (2) and (3) is not the variables and parameters that are needed for determining the option price but rather, those not needed. Specifically, determination of the option price and the replicating portfolio strategy does not require estimates of either the expected return on the stock, $\alpha$ or investor risk preferences and endowments. In contrast to most equilibrium models, the pricing of the option does not depend on price and joint distributional information for all available securities. The only such information required is about the underlying stock and default-free bond. Indeed, the only variable or parameter required in the Black–Scholes pricing function that is not directly observable is the variance rate function, $\sigma^2$. This observation has stimulated a considerable research effort on variance-rate estimation in both the academic and practising financial communities. With some notable exceptions, equations (2) and (3) cannot be solved analytically for a closed-form solution. However, powerful computational methods have been developed to provide high-speed numerical solutions of these equations for both the option price and its first derivative. As in the original Black and Scholes article, the derivation here focuses on the pricing of a European call option. Their methodology is, however, easily applied to the pricing of other securities with payoff structures contingent on the price of the underlying stock. Consider, for example, the determination of the equilibrium price for a European put option with exercise price $E$ and expiration date $T$. Suppose that in the original derivation we change the boundary conditions specified for $F$ in (3) so as to match the payoff structure of the put option on these boundaries. That is, we now require that $F$ satisfy $F \leq E; F[0, t] = E \exp[-r(T - t)]; F[V, T] = \max[0, E - V]$. Once $F$ and its derivative are specified, the development of the replicating portfolio proceeds in identical fashion to show that $P(t) = F[V(t), t]$. With the revised boundary conditions, the portfolio payoff structure will match that of the put option at exercise or expiration. Thus, $F[V(t), t]$ is the equilibrium put option price. As shown in Merton (1977), the same procedure can be used to determine the equilibrium price for a security with a general contingent payoff structure, $G[V(T)]$, by changing the boundary conditions in (3) so that $F[V, T] = G[V]$. A particularly important application of this procedure is in the determination of pure state-contingent prices. Let $\pi[V, t; E, T]$ denote the solution of (2) subject to the boundary conditions:
\begin{align*}
\pi / V & \leq 1; \quad \pi[0, t; E, T] = 0; \quad \pi[V, T; E, T] = \delta(E - V)
\end{align*}

where \( \delta(x) \) is the Dirac delta function with the properties that

\( \delta(x) = 0 \text{ for } x \neq 0 \)

and \( \delta(0) \) is infinite in such a way that

\begin{align*}
\int_{a}^{b} \delta(x) \, dx &= 1 \text{ for } a < 0 < b.
\end{align*}

By inspection of this payoff structure, it is evident that this security is the natural generalization of Arrow–Debreu pure state securities to an environment where there is a continuum of states defined by the price of the stock and time. That is loosely, \( \pi[V, t; E, T] \, dE \) is the price of a security which pays $1 if \( V(T) = E \) at time \( T \) and $0, otherwise.

As is well known from the Green's functions method of solving differential equations, the solution to equation (2) subject to the boundary condition \( F[V, T] = G[V] \) can be written as:

\begin{align*}
F[V, t] &= \int_{0}^{\infty} G[E] \, \pi[V, t; E, T] \, dE. \\
(7)
\end{align*}

Thus, just as with the standard Arrow–Debreu model, once the set of all pure state-contingent prices, \( \{ \pi \} \) are derived, the equilibrium price of any contingent payoff structure can be determined by mere summation or quadrature.

To underscore the central importance of call option pricing in the general theory of contingent claims pricing, consider a portfolio containing long and short positions in call options with the same expiration date \( T \) where each 'unit' contains a long position in an option with exercise price \( E - \varepsilon \), a long position in an option with exercise price \( E + \varepsilon \), and a short position in two options with exercise price \( E \). If one takes a position in \( 1/\varepsilon^2 \) units of this portfolio, the payoff structure at time \( T \) with \( V(T) = V \) is given by:
\[
\{\max\{0, V + \varepsilon - E\} - 2\max\{0, V - E\} + \max\{0, V - \varepsilon - E\}\} / \varepsilon^2.
\]

(8)

The limit of (8) as \(\varepsilon \to 0\) is \(\delta(E - V)\) which is the payoff structure to a pure contingent-state security. If \(F[V, t; E, T]\) is the solution to (2) and (3), then it follows from (8) that:

\[
\pi[V, t; E, T] = \lim_{\varepsilon \to 0} \{F[V, t; E - \varepsilon, T] - 2F[V, t; E, T] + F[V, t; E + \varepsilon, T]\} / \varepsilon^2 = \frac{\partial^2 F[V, t; E, T]}{\partial E^2}.
\]

(9)

Hence, once the call-option pricing function has been determined, the pure state-contingent prices can be derived from (9).

For further discussion of options, see especially the January/March 1976 issue of the *Journal of Financial Economics*; the October 1978 issue of the *Journal of Business*; and the excellent book by Cox and Rubinstein (1985).

An ordering (also called a complete preordering or a weak ordering) is a binary relation which is reflexive, transitive and complete, that is, it is a preordering that is complete.

A binary relation $R$ defined on a set $S$ is a set of ordered pairs of elements of $S$, that is, a subset of the Cartesian product of $S$ with itself, $S \times S$. One writes $xRy$ (or $(x, y) \in R$) to mean that $x \in S$ stands in relation $R$ to $y \in S$. An ordering is a binary relation, $R$, which satisfies three properties: (i) reflexivity: for all $x \in S$, $xRx$; (ii) transitivity: for $x, y, z \in S$, if $xRy$ and $yRz$, then $xRz$; and (iii) completeness for all $x, y \in S$, $xRy$ or $yRx$, where ‘or’ is used in its non-exclusive sense.

A simple example results from letting $S$ be the real line and $R$ the greater than or equal to relation so that $xRy$ if and only if $x \geq y$. The most common use of orderings in economics is in preference theory where $S$ is a commodity space and $R$ stands for ‘at least as desirable as’. Every ordering can be separated into its symmetric and asymmetric factors, respectively, as follows:

$xRy$ if and only if $xRy$ and $yRx$.

and

$xPy$ if and only if $xRy$ and not $yRx$. 

Keywords

choice; compensation criteria; happiness; interpersonal utility comparisons; ordering; preference orderings; preferences; transitivity; utility measurement; welfare economics; well-being
In the case of preference theory, these correspond to indifference and strict preference relations. In consumer theory orderings first appeared in the work of Wold (1943–4). In an attempt to put utility theory on a more solid foundation, Wold posited the existence of an ordering with certain properties and demonstrated that this could be represented by a continuous real-valued function, thus making absolutely clear that this was an ordinal concept. Perhaps the most innovative and useful aspect of Wold's argument was an insightful definition of a continuous ordering. (An ordering is continuous if the sets \( x | x R y, y \in S \) and \( x | y R y, y \in S \) are closed.)

The first modern treatment of the subject appears in Arrow (1951). Agents as well as society as a whole are characterized by their orderings over spaces of alternative. That the choices of society be consistent with an ordering, and understanding the implications of that requirement, has been particularly important in welfare economics. For example, various compensation criteria have been shown to fail transitivity (see Gorman, 1955) and hence be unsuitable for public decision-making. In addition, by representing agents and society by their orderings, Arrow made the first step toward unravelling a long-standing confusion between the measurability of utility on the one hand and interpersonal comparability on the other. This step was critical if social decision-making was to rest on solid ground; for an accessible discussion of these issues see Blackorby, Donaldson and Weymark (1984).

It is common in economics to represent agents by their preference orderings. This leads to a set of complicated and somewhat unresolved issues: what are the relationships among the notions of preference, choice and happiness or well-being. Either a preference ordering or the choices of an individual may be viewed as a primitive and they may or may not be mutually consistent; the issues at stake can, however, be characterized quite precisely. The relationship between either of these and some notion of happiness or well-being is much less clear; for a good introduction to these problems see Sen and Williams (1982).

Oresme, Nicholas (1325–1382)

Barry Gordon

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Aquinas, St. Thomas; Biel, G.; Buridan de Bethune, J.; debasement; Langenstein, H. von; money as standard of value; Oresme, N.; William of Ockham

Article

A noted mathematician and physicist and Bishop of Lisieux (1377–82), Oresme was a close friend and adviser of Charles V of France. Because of the frequent currency debasements of his era, he contributed a most influential treatise on money, *Tractatus de origine natura jure, et mutationibus monetarum* (c1360). Other works by Oresme of interest to economists are his commentaries on Aristotle's politics, economics, and ethics.

Oresme's tract on money owes much to the ideas of Jean Buridan de Bethune, who was Rector of the University of Paris (c1327) and may have taught Oresme. Another to take up Buridan's line of monetary thought was Heinrich von Langenstein (1325–97), a German theologian who taught at both Paris and Vienna. In the next century, the doctrines of Buridan and Oresme were developed by Gabriel Biel (1430–95), a founder of the University of Tübingen and its first professor of theology (from 1484). Biel wrote the outstanding *Tractatus de Potentate et Utilate Monetarum*.

Each of the foregoing Schoolmen wrote in the nominalist tradition deriving from the Oxford philosopher William of Ockham (1285–1347), a tradition that stands in opposition to St Thomas Aquinas on money as on much else. The nominalists question the Thomistic understanding of money as a standard of value established by the Prince (that is, by the ruler of the state). In their view, the Prince's right with respect to setting the standard is a limited right.

According to Oresme and the other nominalists, who are reacting against the princely practice of debasement, a particular currency is likely to be an effective medium of exchange only if the nominated values of the units of that currency are acceptable to the citizens who are the users of the medium. They add that the users of the money are the real owners of it, and so have the right to be consulted by the Prince concerning appropriate arrangements.

Such ideas were revolutionary in terms of much earlier Western thought. One notable aspect of the
revolution is the shifting of the grounds for thinking about money. Earlier scholastic discussion had concentrated on the morality of individual transactions but here the operation of a monetary system as a whole begins to come into view.

Organization of the Petroleum Exporting Countries (OPEC)

James L. Smith
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Since the 1960s, the Organization of the Petroleum Exporting Countries (OPEC) has dominated the world oil market by exercising physical control over a large portion of the world's oil reserves. Coordinated production restraint among OPEC members has artificially limited the supply of oil and succeeded in pushing oil prices far above the competitive level. Despite its past success, OPEC faces three basic problems that, in the long run, tend to undermine all cartels: coordination failures, opportunistic cheating, and the entry of competing producers who manage to find and bring alternative supplies to the market.

Keywords

Article

The Organization of the Petroleum Exporting Countries (OPEC), an international cartel of oil-producing states, affects the price of nearly all crude oil traded in the world economy and has done so since the early 1970s. Founded in 1960, OPEC initially consisted of five member states (Iran, Iraq, Kuwait, Saudi Arabia and Venezuela) which together accounted for 38 per cent of total world production of crude oil. The founders sought to coordinate national petroleum policies and forge a more united front in dealings with the multinational oil companies that operated within their borders. Although membership has grown to 12, OPEC's share of global crude oil production still amounts to only about 44 per cent. Coordinated restraints on output (especially since 1973) have deliberately held OPEC's market share in check.

During its first decade (1960–70), OPEC's principal objective was to secure for its members a larger share of the profits derived from the production and sale of their oil – the stated goal being to raise government take from 50 per cent to 80 per cent of total profit. Beginning with the so-called Teheran–Tripoli Agreements of 1970–71, OPEC turned to what has become its main purpose: manipulating the level of world oil prices by restricting productive capacity and output. Initially, this was attempted without assigning individual production quotas to the respective members. Only after the downturn in world oil prices that began in 1982 did OPEC introduce a formal system of production allocations – which remained in force as of 2007. The members meet at regular intervals (and sometimes on an emergency basis) to review market conditions and adjust individual production ceilings as needed to maintain a target price. Adelman (1995) and Parra (2004) describe the intriguing economic and political challenges faced by the members of OPEC in dealing with the market and with each other.

There is no question that OPEC members have restricted production in ways that are unrelated to the physical scarcity of oil. Even though OPEC's proved oil reserves in 2007 were double those of 1973, the cartel initiated sharp output cuts that by 1985 had removed nearly half of their previous production from the market, as shown in Figure 1. Not until 2005 did OPEC production regain (barely) the level of 1973. Over that same period, worldwide consumption of crude oil grew by 50 per cent and production from non-OPEC producers (who faced much higher marginal costs) managed to increase by 70 per cent.

Figure 1
Economic models of OPEC behaviour

Early economic analyses of OPEC behaviour questioned whether the output reductions might reflect competitive or other forms of non-cooperative conduct (for example, oligopoly),
as opposed to outright collusion. Mead (1979) and Johany (1980) proposed a ‘property rights’ explanation that linked the production cuts to the wave of nationalizations that swept through the global oil industry in the early 1970s. Property rights in oil reserves were transferred, via nationalizations, from the multinational corporations (with higher presumed discount rates) to OPEC states (with lower presumed discount rates and therefore greater patience in extracting the oil). However, this explanation is belied by the fact that, throughout the 1960s, these same host governments had repeatedly exhorted the multinational companies to increase, not decrease, their rates of production (Adelman, 1982).

Teece (1982) and Crémer and Salehi-Isfahani (1980) advanced the idea that the limited domestic revenue needs (‘absorptive capacity’) of some OPEC members imposed an indirect restriction on production. The higher the price, the lower the volume of oil exports required to achieve a requisite amount of revenue. The result would be a backward-bending supply curve that links lower oil output to higher prices in a manner that implies no coordination among OPEC members. One problem with this argument, as Adelman (1982) pointed out, is that the absorptive capacities of OPEC members seemed to increase faster than export revenues. Griffin's (1985) subsequent empirical tests found little statistical support for the target revenue hypothesis.

Distinguishing between the various models of OPEC behaviour has been complicated by the fact that cooperative and non-cooperative models share many similar predictions. Thus, the same body of evidence has been interpreted in ways that are consistent with a variety of competing models. By focusing on one aspect of producer behaviour (short-run reactions to cost shocks) that more clearly distinguishes between models, Smith (2005) found a degree of parallelism among OPEC producers that can be accounted for only as the result of cooperative behaviour, not competition or mere interdependence among producers, as in the Cournot oligopoly or Stackelberg dominant-firm models.

Future challenges facing OPEC

Levenstein and Suslow (2006) identify three critical problems that any cartel must solve if it is to endure: coordination, cheating and entry. In the case of OPEC, the last of these has been the easiest. OPEC is protected by barriers to entry that stem from ownership and control of low-cost oil reserves. Roughly 75 per cent of the world's proved reserves of crude oil are located in OPEC nations. Additional reserves are discovered and developed each year, but this process has become increasingly difficult and expensive – even more so outside OPEC than within. Thus, production of crude oil from non-OPEC sources does expand when the cartel cuts production and pushes prices up, but the scope for this is limited and will remain so.

The problem of cheating has been more difficult for OPEC. Any system of output restraints is vulnerable to the free-rider problem. Although OPEC as a whole may benefit by restricting total output, individual members are tempted to produce beyond their assigned quotas. Cartel membership is most beneficial to those members who do not cut production. Without a system to detect and punish cheating, the cartel is hampered by a Prisoner's Dilemma in which the dominant strategy for most, if not all, members is to ignore their assigned quotas.

It is common, as in Gately (2004), to distinguish between ‘core’ (low cost, high compliance) and ‘non-core’ (high cost, low compliance) members of OPEC. In fact, compliance with the quota by members of both groups has been sporadic, as shown in Figure 2. Since the inception of the formal quota system in 1983, total OPEC production of crude oil through 2005 has exceeded the ceiling by four per cent on average, but on numerous occasions the excess has run to 15 per cent or more. In general, full compliance has been achieved only during episodes (like 2005–6) when the production ceiling itself tested the limits of each member’s available production capacity, such that cheating was not feasible.

Figure 2

The third problem – coordination among members – presents further difficulties. Due to economic and demographic heterogeneity, the interests of individual OPEC members do not naturally align behind a single ‘correct’ price or production target. In part this is due to the fact that OPEC has limited means by which to redistribute earnings among members. Therefore, any given set of quotas determines not only the overall profit of OPEC but also the individual revenues that accrue to each member. Moreover, coordination requires agreement not only about how aggregate output is parcelled out to individual members, but also about the amount of oil to be produced by OPEC in total. Members with low-cost, long-lived reserves may be more reluctant to have OPEC pursue severe output cuts since too-high prices would induce technological development and new forms of energy (or energy
conservation) that will eventually compete with OPEC. Members that possess smaller reserves and shorter horizons are less affected by this and may prefer deeper production cuts.

Internal divisions between ‘price hawks’ and ‘price doves’ have been observed previously and will likely surface within OPEC again.

In terms of longevity, OPEC is already far beyond the mean lifetime (five years) of contemporary international cartels (Levenstein and Suslow, 2006). In terms of economic impact, it is sufficient to note that crude oil is among the most valuable commodities exchanged in international trade, with total daily receipts in 2007 in excess of $1 billion. Thus, by exerting even a small impact on the market price, the cartel effects an enormous transfer of wealth between consumers and producers of crude oil, and creates a substantial allocative inefficiency of the type that arises whenever the price of a product deviates from its marginal cost. As of 2007, no one has attempted to reckon the full magnitude of welfare losses that may be associated with OPEC’s manipulation of the world oil market.

A Venetian monk, Ortes left his cloister on the entreaties of his mother after his father’s death, but remained in holy orders and was ever a strenuous defender of the clergy. It is with this purpose that he wrote his Errori popolari intorno al-l’Economia nazionale, his Lettere sulla religione and his treatise Dei Fide-commessi a famiglie e a chiese, with the scope of upholding the existence of clerical property in Mortmain.

In his Economia nazionale (vols xxi, xxii, and xxiii, of Custodi’s Scrittori classici italiani di economia politica, Milan, 1802–1816) Ortes endeavours to demonstrate that as the wealth of a nation is determined by the (previous) wants of its members, the riches of one of them cannot increase unless at the expense of another one; the bulk of existing riches is in each nation measured by its wants, and cannot by any means whatever exceed this measure. (Discorso preliminare)

From this rather startling proposition, Ortes, who certainly was an original thinker, deduces the condemnation of the principles on which mercantilism was based.

Money is only a sign of wealth, and must never be considered as being wealth itself. The error of those who mistake money for wealth, proceeds from a confusion between the equivalent of a thing and the thing itself, or between two equivalents which they consider as identical things, although they are not. (ch. ix)
Ortes, Giammaria (1713–1790) : The New Palgrave Dictionary of Economics

In his *Riflessioni sulla popolazione* (Venice, 1790, and vol. xxiv of Custodi) Ortes controverts the prevailing opinion that an increase of population must necessarily increase the wealth of a nation, and maintains that ‘in any nation whatever the population is compelled to keep within fixed limits, which are invariably determined by the necessity of providing for its subsistence’ (*Prefazione*). In his very first chapter he asserts that, if natural instincts were allowed full play, population would increase in a *geometrical* progression (doubling every 30 years), and calculates that a group of 7 persons composed of three old people, two young men and two young women of 20, would be the ancestors at the end of 150 years of 224 living persons.

Sheer violence keeps down the numbers of animals within the necessary limits, but among men, ‘generation is limited by reason’ (ch. iii), especially by voluntary celibacy, which affords Ortes an occasion of extolling the provident discipline of the Roman Catholic Church. Ortes is a harbinger of Malthus; first by his law of the geometrical increase of population, and secondly by the influence which he ascribes to human reason as a prudential check against over-population.

Ortes was a fervent mathematical student, and expresses himself in algebraical formulae in his *Calcolo sopra il Valore delle Opinionum umane* (vol. xxiv, Custodi). In the same work he illustrates his meaning by curves, which, if not actually traced, are at least minutely described.

**Edward Cannan**

Ortes is undoubtedly the most eminent of the Venetian economists of the 18th century; his genius, original and sometimes paradoxical, is often opposed to the general tendency of the ideas of his time, and though his researches are occasionally faulty in their method, he has left a deep impress on the history of economic theory. He regards economic laws as immutable, like those of nature; he maintains this in opposition to the opinion usually accepted in his time, which regarded economics only in relation to special interests. Perhaps it is this idea which leads him to distrust the action of the state, considering it is not adapted to promote the wealth of a country.

While Ortes applied a mathematical method to economics, his arguments are based throughout on abstract theory, disregarding the study both of facts and of history as not appertaining to economic science. This detracts from the value of his labours. Still his works are of weight in the history of economic theory. He did not adopt the doctrines of the Physiocrats, and he also recognizes the importance of division of labour, and the important place taken by production in economic theory. Contrary to the prevailing ideas of his day, Ortes upholds universal free exchange.

output fall – transformational recession

Barry W. Ickes
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

A significant decline in GDP has been a common feature in transition economies. This sharp drop in output has been seen as a surprise and puzzle to many observers. Understanding the nature of the output fall is crucial to understanding transition. Analysis is complicated by measurement issues associated with moving from plan to the market. Theoretical models of the output fall are examined, including those that see the output fall as a natural consequence of the legacies of the Soviet-type economic system.

Article

A significant output decline has been a common feature in transition economies. To some extent this is a surprise: transition represents the removal of (highly significant) distortions. See, for example, Blanchard (1997, p. v): ‘The fact that the transition came with an often large initial decrease in output should be seen as a puzzle. After all, the previous economic system was characterized by a myriad of distortions. One might have expected that removing most of them would lead to a large increase, not a decrease, in output.’ Or as Svejnar (2000, p. 8) notes, ‘The depth and length of the early transition depression was unexpected.’ Similarly, Robert Mundell has written:

The first and most obvious conclusion is that output contracted by a cumulative percentage never before experienced in the history of capitalist economies (at least in peacetime). Early denials that the contractions were occurring have proved to be incorrect. We observe that cumulative contractions over the 1990–4 period ranged widely, from a low of 18% to a high of more than 80%. (Mundell, 1997, pp. 97–8)

Hence, a simple neoclassical argument would predict that output would rise rather than fall as the transition starts. Yet output fell in each transition economy, and quite significantly. The officially reported cumulative output decline for 26 transition economies from 1989 to 1995 was 41 per cent. Of this, the average decline in central Europe was 28 per cent and in the former Soviet Union it was 54 per cent (Fischer and Sahay, 2000, Table 1). By comparison, output in the United States during the Great Depression declined by 34 per cent. The ubiquitous nature of the output fall thus represents an important puzzle for transition economics, and understanding the causes and nature of the output fall is crucial. Analysis of the output fall is complicated by important measurement issues. In the change of economic systems from plan to market, the valuation of goods and services changes dramatically. This makes it important to distinguish official measures of the output fall from welfare-based measures.

Stylized facts

It is useful to begin with some stylized facts about the output fall. Official GDP measures of output are given in Figures 1 and 2. It is evident from these figures that in all transition economies output follows a U-shaped pattern. This represents another interesting puzzle. A theory based on the chaotic nature of the collapse of planning might predict that output would collapse at the start of transition, but would rise from that point. The pattern displayed by the transition economies, on the other hand, suggests that the peak output fall occurs with a lag of several years. So an additional part of the puzzle is to explain why the output fall intensifies in the early transition.

Figure 1
Official GDP growth in central and eastern Europe. Source: International Monetary Fund Dataset.

Figure 2
Measured output fell in all transition economies. Generally, the declines are larger in the former Soviet Union (FSU) than in central and eastern European economies (CEEs). For example, using 1989 as the starting point, the falls in Poland (15 per cent), Hungary (18 per cent), and the Czech Republic (21 per cent) were relatively moderate compared with Russia, where from 1991 GDP fell by 40 per cent. Later reformers appear to have larger falls: Ukraine has had a very significant fall in output. (There is, however, a puzzle concerning the output path of Uzbekistan. The output fall was smaller there than in any former Soviet republic, yet it reformed the least. For an analysis, see Zettelmeyer, 1998.)

If we look at industrial output, rather than GDP, the observed declines would be even larger: about 40–50 per cent in central Europe and 50–60 per cent in the FSU. The reason, of course, is that most of the negative value added under planning was in industry, so we would expect a larger contraction there.

The decline in investment, especially in inventories and housing, was even greater than the decrease in GDP. This is especially true for defence. Hence, consumption has fallen less than GDP. In a sense, this is not a surprise as investment is more volatile than output in market economies. Yet transition as an economic process involves restructuring, and this does require investment. The fact that investment absorbed so much of the shock means that the resumption of growth was delayed even further. But it also means that living standards have not fallen as much as GDP. This is important for considering the welfare effects of the output decline.
Measurement issues

Perhaps the output fall is overestimated. (Aslund, 2002, p. 121, considers the output fall to be a myth.) There are many problems with interpreting official data in the context of transition, especially with respect to living standards: too many, indeed, to discuss here. Tracing output dynamics in the transition is complicated by the measurement issues that arise as the economic environment changes from central planning to market forces. Hence, an important issue in understanding the output fall is to gauge the extent to which it is a statistical rather than a real phenomenon.

Some observers (Aslund, 2002; Campos and Coricelli, 2002) argue that the size of the output fall is overstated because of the growth in the size of the shadow economy in early transition. It is argued that the hidden economy grew substantially during the transition period. Hence, actual production fell by less than measured output. The factual basis of this claim is controversial, however. It is also suspect theoretically. The biggest incentive to growth in the second economy is price controls. Hence, price liberalization should result in an immediate drop in the size of the shadow economy. The countervailing pressure could come from tax incentives, but it is hard to believe that this force is stronger than the impact of price controls.

The typical evidence cited in support of the proposition that the hidden economy grew in transition is that measured output fell by more than electricity production. Estimates based on comparing electricity consumption and GDP assume that the elasticity is close to unity. But this elasticity is well below unity in market economies during recessions, so employing the unit elasticity assumption amounts to assuming away the phenomenon to be measured. In Finland, for example, real GDP fell by about 11 per cent from 1990 to 1993 while electricity consumption rose by 5.5 per cent (Statistics Finland). By the logic of the advocates of the power consumption thesis we are led to conclude that the hidden economy exploded in size over these three years. For example, if the hidden economy initially was five per cent of total output, then for electricity consumption to rise with no change in intensity of use the hidden economy would have had to grow by 319 per cent! This seems hard to believe. A more likely explanation is the decline in capacity utilization that occurs in recessions causes kilowatt hours of electricity per unit of GDP to increase.

Moreover, as shown by Alexeev and Pyle (2003) the frequently cited estimates of Johnson, Kaufmann and Shleifer (1997) assumed no growth in the size of the shadow economy of the Soviet Union from the late 1970s to the collapse of the system. (The same error is made by Aslund, 2002, p. 122.) This assumption is rejected by all observers of the Soviet economy. Hence, these empirical estimates of the growth in the shadow economy are based on too small an estimate of its initial size.

A second measurement problem in assessing the output fall arises because of the inadequacy of the inherited statistical system to cope with a market economy. Command economies, by their nature, focused on population statistics with regard to output. This is natural in a planned economy where the output produced was the result of a central plan. Indeed, the very nature of command required the planners to coordinate output, hence the statistical system needed to record what each enterprise produced. (Of course, in practice, this was difficult, as discussed in command economy.) The demise of the planning system weakened the authority of central statistical systems. More importantly, new entry became increasingly important in market economies, and the inherited statistical systems are not organized effectively to capture this.

It is also argued that under command systems enterprises had an incentive to overstate output in order to achieve bonuses, while firms in market economies want to hide output in order to avoid taxes (for example, Shleifer and Treisman, 2004). It is thus argued that much output is simply missed by the change in the incentive to report. While it is certainly the case that firms have an incentive to hide output – especially when the financial system is undeveloped so they cannot seek external finance – the incentive to over-report under planning is less clear. Enterprises in planned economies were subject to the notorious ratchet effect. Higher production today meant higher output targets in the future – essentially a highly progressive dynamic tax system. The typical response to the ratchet effect was to produce only as much as needed to satisfy the plan. Hence, it is not at all clear that enterprises over-reported output in the command system.

A more important reason to question the magnitude of the output fall is the contraction in value-destroying activities. Because prices were distorted in planned economies, a portion of economic activity actually destroyed value at market prices. The contraction in these activities represents an increase in welfare, and correctly measured represents an increase in national income as well. The problem is that at the prices that prevailed in command economies this output appeared to be valuable; hence the contraction is measured as a fall in output.

There are two aspects to this decline. First, the separation of domestic from world prices means that activities that produce value added at domestic prices could destroy value at world prices. Given the underpricing of raw materials and overpricing of industrial goods characteristic of planned economies, this was more than a theoretical possibility. External liberalization then leads to a contraction of these activities (McKinnon, 1991). The second aspect is that domestic prices were similarly distorted so that domestic price liberalization has a similar effect. This is discussed below.

To the extent that a reduction of value-destroying activity occurs at the same time as output falls, it is clear that movements in measured output are not consistent with movements in welfare. Indeed, if a greater measured output fall is associated with a faster removal of value-destroying activities, then it is likely that welfare is enhanced by the output fall. In this case the output fall is associated with more reform and quicker removal of welfare destroying activities. (This also means that output recovery could mean a resurgence of value-destroying activities, in which case the upward-sloping part of the U shape is welfare decreasing. Unlikely, but it might be relevant for Belarus under President Lukashenko.) Of course, for this to be the case there must be a serious distortion in national income measurements. To the extent that output measurements use base-weighted prices this is possible.
It is difficult to measure the extent to which the output fall is overstated by the contraction of value destroying activities. For example Aslund (2002, p. 126) estimates that about 20 per cent of GDP was value destroying in the last years of Communism. He uses, as an indicator, the decline in the share of industry in GDP. Soviet-type economies were over-industrialized, and liberalization led to sectoral shifts as services, which were previously undersupplied, expanded. Moreover, shifts in relative prices, discussed below, also lead to a reduction in the share of value added produced by industry. Thus, one cannot infer value destruction from the change in industrial shares. The general problem is that output may be falling for various reasons so one cannot consider all of the contraction to be previously value destroying. One valuable indicator of the importance of value destruction is given by the comparison of the contraction in industrial output with the rise in consumption that occurred in transition economies. In Russia, for example, industrial output contracted by roughly 35 per cent from January 1992 to January 1994. Real disposable income, on the other hand, increased by almost 70 per cent in the same period (albeit from depressed levels). The fact that real disposable income was growing at the same time as industrial output was contracting suggests that the cessation of value-destroying activity was an important process, and that some of the output fall may be overstated.

A related problem is the shift in preferences. Gaddy and Ickes (2003) argue that a specific index number problem leads to an overstatement of the output fall – the camellia effect. The argument is easily understood in terms of an analogy. Consider a flower shop that specializes in the sale of extremely rare camellias. Cultivating these plants is inordinately expensive, but this activity is profitable because the shop has a customer willing to pay very high prices for camellias. Now suppose this customer passes away. The shop can no longer sell rare camellias at a price that covers the cost of production. So camellia cultivation ceases. Resources that were previously devoted to camellia production will now be used for something else, say, roses. Profits at the flower shop fall because camellias were very profitable as long as their special customer lived. But given that there is no longer a market for rare camellias (while there is a market for roses, everyone is better off with rose cultivation than if they continued to cultivate camellias as if nothing had changed.) In the Soviet regime defence output was demanded despite the enormous cost. It had value as long as the Communist Party had command over resources. The special customer of Soviet times made it ‘valuable’ to produce defence output. When the Soviet system collapsed, so did the special customer. Output thus fell – valued at Soviet prices – because at those prices defence output was valued far above cost. After the fall this output is not valued sufficiently and production declines. This is an output fall, but welfare is certainly higher with lower defence production given that the Communist Party is no longer the measure of value.

To see this, suppose that we have two final goods, \((x_1, x_2)\), and that the pre-transition production bundle is \((x_1^A, x_2^A)\), where good 2 is defence output, and \(A\) represents planners’ preferences. The post-transition allocation is \((x_1^B, x_2^B)\), and reflects social preferences. We might consider, for example, that at point A there is large military production and little civilian production, reflecting planners’ preferences \((U_P)\). The new production bundle is at point B, based on society’s preferences. Note that using pre-transition prices to value output, GDP is \(\gamma^A = \sum_i p_i^A x_i^A\).

Now suppose that liberalization causes the production bundle to move to point F in Figure 3. This is the most pessimistic outcome – demand for \(x_2\) declines with almost no increase in \(x_1\). Measured in real terms, at the old prices, output falls approximately by the distance AF in units of \(x_2\), or \(\sum_i p_i^A x_i^F - \sum_i p_i^A x_i^A\). But this greatly overestimates the welfare change, because it places a high value on the output that has fallen in valuation.

**Figure 3**

The camellia effect
Although output has fallen precipitously at planners’ prices, measured at the new prices welfare has clearly increased. The minimum expenditure to achieve the old welfare level \( e(p^g, \tilde{u}^R) \) is less than the cost of purchasing bundle \( F \) at the new prices. It is evident that welfare is higher at point \( F \) than at point \( A \). Output has risen at the new prices but has fallen at the old prices.

From Figure 3 we can also distinguish the fall in output due to coordination-type failure and that due to measurement. If resources are fully utilized we would be at point \( B \). Hence \( \sum_i p_i^g x_i^g - \sum_i p_i^g x_i^F \equiv \Omega \) measures the fall in output due to coordination-type failure. The measured fall in output, could be larger or smaller than this. The key point, however, is that the measured fall does not measure \( \Omega \) at all.

Notice that, if the resources devoted to defence production are highly specialized, then there may be great inertia in response to the demand shift. It may be very hard to find alternative uses for these inputs. Output may remain depressed for quite a while. There may also be interesting behavioural issues to think about. A Russian defence enterprise director may expect that the government will soon restore orders and that cuts were temporary. This would lead to inertia in shifting to new activities. Both of these inertial forces could prolong the decline in output.

The importance of the camellia effect for thinking about the output decline is especially important in comparative terms. The camellia effect explains why transitional recessions are observed. But the size of this drop will be proportional to the share of ‘camellias’ in GDP, and this clearly differs across the post-Communist world. (Even for the former Soviet
The differences are dramatic, as Russia had a much larger than average share of Soviet defence industry; see Gaddy, 1996.) In a country like Russia the size of the defence sector was especially large. This exacerbates the size of the output drop that is due to transitional factors. To measure the pure transition effect we should compare what would have been produced under central planning had planners’ preferences not determined production decisions with what happened during transition. Ignoring the camellia effect mixes the two sources of output fall.

Theories of the output fall

Theories of the output fall in transition generally fall into one of two classes. The first class of theories treats this phenomenon as a sign of inefficiency. The output fall is thus welfare decreasing. The second class treats the output fall as a natural feature of liberalization but does not consider the fall to be welfare reducing. (One could also consider the specific negative shocks that have caused output disruptions. For central Europe there is the breakup of Council for Mutual Economic Assistance (CMEA) trade plus the end of subsidized energy from the Soviet Union. For the former Soviet Union there is the disruption in trade caused by the breakup of a common economic space into 15 independent countries. For Russia, there is the decline in oil prices. The importance of movements in the oil price for Soviet and Russian output has been emphasized by Gaddy and Ickes, 2005. The power of this explanation has been fortified by the close timing of the recovery of Russian output with the increase in oil prices starting in the later 1990s.)

A basic framework for thinking about the output fall is the reallocation problem. Consider an economy with two sectors, state (S) and private (P). Initially all labour is employed in the state sector. It is assumed that labour productivity in the private sector ($\beta$) exceeds that in the state sector ($\alpha$), $\alpha < \beta$. The reallocation process occurs as labour moves from the state to the private sector. Per-capita output, $y_t$, is thus given by

$$y_t = \alpha \frac{L^S_t}{L_t} + \beta \frac{L^S_t - L^S_t}{L_t},$$

it is immediately apparent that rather than decline, output will increase monotonically in the transition. Hence, to obtain an output fall some unemployment of resources is necessary. If the private sector cannot absorb all the labour released from the state sector then labour will be unemployed, $L^U_t$. In that case per-capita output is given by

$$y_t = \alpha \frac{L^S_t}{L_t} + \beta \frac{L^S_t - L^S_t - L^U_t}{L_t}.$$

This simple framework suggests that to produce an output fall some rigidity or friction is required that prevents smooth reallocation of the labour released from the state sector. The essence of transition suggests that this will be likely. In addition to the normal culprits such as wage rigidity, institutional features play a critical role. For example, prior to the privatization of state sector assets, capital is immobile between sectors. This naturally limits the absorption rate of the private sector. Hence, the exit rate from unemployment will depend on the rate of growth of the private sector. What is important to understand are the determinants of the exit rates from these states. Notice that the growth of the private sector may depend on what is happening in the other sectors. This dependence can occur for several reasons. First, following Aghion and Blanchard (1994), unemployment can cause fiscal deficits which must be financed at the expense of the private sector, limiting its growth. Second, the growth of the private sector may depend on the rate at which complementary resources are released from the state sector. This is especially true for the most basic of resources for production, space. Until privatization of fixed capital takes place it is difficult for new private enterprises to obtain space for production, let alone to lease equipment.

At the most basic level, unemployment can be due to rigidity in real wages. But it is hard to understand how this can explain the output falls that were actually observed, as real wages fell in most transition economies once prices were liberalized. Hence the need for more fully developed theories.

Double marginalization
Li (1999) develops a theory of the output fall in transition based on double marginalization. The basic idea is that the dismantling of central planning or centralized organization of production permits monopolistic and vertically interdependent enterprises to pursue their own monopoly profits by restricting output and intermediate trade to the detriment of the economy as a whole. The basic idea is that the collapse of planning institutions removes constraints on intermediate producers’ activities. Intermediate producers now have monopoly power, so they raise prices. This happens all along the supply chain, and results in an increase in the cost of producing final output. So there is less final output available and government output falls. The essential reason is that the enterprises do not consider the consequences of their price increases for the profits of the other enterprises. Since there is less left over for consumers, it is equivalent to a decrease in real wages, and hence labour supply falls.

The essential idea of the double marginalization theory is that output falls because liberalization precedes the development of competition. Entry is a process that takes time. Hence, the theory would predict that output falls would be greater in economies that are less able to ‘import’ competition through opening the economy. This roughly fits the picture of larger output falls in the FSU than in the CEEs. But the theory also predicts that the output fall should be largest when liberalization first takes place, since that is when market power is most potent. The effect of double marginalization should wane over time. This is harder to reconcile with the paths of output in Figures 1 and 2.

The double marginalization model also predicts that each enterprise will face a contraction in demand and an increase in input prices relative to wage rate. The contraction in demand is attributable to the following factors in this model: the decline in real wage rate, the decline in the government’s real income and the decline in input demand. The increase in input prices relative to wage rate is attributable in this model to monopoly pricing by a ‘web of monopolies’. The more complex is the web of inter-industry production, the greater the propagation of the price shock. Hence, complexity magnifies any intermediate price markup throughout the economy, resulting in higher input prices relative to wage rate. The sharp increase in input costs is indicative of a sharp supply contraction. This prediction is also consistent with empirical observations.

**Disorganization**

Blanchard and Kremer (1997) (see also Blanchard, 1997) have developed a model of disorganization that has had great impact. Their argument is that the output fall is a result of the chaos that surrounds the elimination of central planning. They focus on three mechanisms (hold-up problems, coordination, and uncertainty problems) that are greatly magnified as the result of missing institutions likely to be important at the start of transition. The basic idea is that the collapse of planning causes performance to decline during the period when alternative market mechanisms have not yet developed.

The basic idea can be understood in terms of a simple example presented by Blanchard and Kremer. Consider a vertical chain of production. Assume that each step is carried out by a different enterprise. A unit of a primary good is needed at the first step. At the end of the n steps one unit of the final good results, and we normalize the price of this good to unity. The value of the intermediate output, at each step, is zero. The supplier of the primary input has an alternative use, which is c. This could be much lower than one. It is a private opportunity that could be exporting the good, or selling it for a less fabricated use. Under planning the relations in the chain were directed from above. With liberalization alternative activities may be considered.

The end of planning thus leads to n bargaining problems. Each unit must bargain with a supplier and a customer. They assume that there is Nash bargaining at each step, so that the surplus is split given the symmetry of the situation. To see what happens start with the last step. The value of the surplus in the last stage (bargaining between the final producer and the last intermediate producer) is 1. This follows because the value of the good at stage n is still zero. So the last intermediate producer gets one half of the surplus. Similar bargaining takes place at all the upstream stages. At the n−1 stage there is one half to split … Continue in this fashion and it follows that the first intermediate producer gets \( \left( \frac{1}{2} \right)^n \). The surplus available to split at the first stage is \( \left( \frac{1}{2} \right)^n - c \), since the first producer must purchase the primary input to produce. It is thus clear that unless \( c < \left( \frac{1}{2} \right)^n \) the raw material will be diverted and production will cease. Moreover, c does not need to be all that large to trigger defection that results in a fall in output that could be as large as \( 1 - \left( \frac{1}{2} \right)^n \). Thus rather meagre private opportunities can cause a rather large fall in output.

Blanchard and Kremer interpret c as the level of complexity of production. As n increases, the likelihood of defection increases exponentially. This is a hold-up problem. Each producer in the chain must produce before bargaining with the next in line. This suggests that the problem would go away if each of the producers could sign an enforceable contract before production takes place. As long as \( c < \frac{1}{2} \), defection could be avoided and production could take place, if the intermediate producers could sign a contract to split the 1−c before production. The problem is thus one of asset specificity and incomplete contracts. Eliminating the ministry before institutions that support contracts are developed is the source of the problem. Vertical integration could help, but this requires ownership to be specified, another problem early in transition. The notion that producers in transition could suffer from this problem is not far-fetched. (It is interesting to compare this outcome with the double marginalization case. Notice that in that case the raw materials producer has market power and thus a higher share of the surplus than is the case in the bargaining problem. This makes production in the state sector more likely. Of course, what is not explained is why the producer is able to extract monopoly rents in a situation of bilateral monopoly.)

Blanchard and Kremer consider other examples based on incomplete information. A state-owned enterprise must negotiate with many suppliers that may have outside options. Each of the suppliers produces a key input without which production is impossible. With uncertainty over the magnitude of outside options a state-owned enterprise must guess how much
to pay for the inputs. When outside opportunities are low the possibility that the state-owned enterprise offers too low a price is negligible. But as these outside opportunities rise this probability increases. Even if it is still efficient to sell to the state-owned enterprise because of uncertainty over the size of these options, the price offered may be too low and production falls. The interesting feature of this model is that it produces a U-shaped output path. The key assumptions are technological complementarities and inefficient bargaining.

A coordination example can also be constructed. Suppose that the firm needs \( n \) workers (it could be supplying firms, but this is easier), and the technology is Leontief. If all workers stay, the firm produces one unit of output per worker. If a worker leaves, a replacement is hired with output per worker equal to \( \gamma < 1 \). Here again \( n \) measures the degree of complexity, while \( \gamma \) is an inverse measure of the specificity of the production process or job-specific human capital.

Each worker has an alternative opportunity given by \( c \), distributed on \([0, \bar{c}]\), where \( \bar{c} \) represents the maximum outside opportunity, which is of course a function of the state of the transition. Draws from this distribution are independent across workers. The distribution is known, but the specific realization is private information. This could be thought of as alternative employment, perhaps in a Western multinational. The firm pays a common wage, \( w \), to all workers, equal to output per worker. This simplifies the analysis, but is probably not crucial.

The key assumption of the model is that workers must decide whether to take up the alternative before they know the decision of the other workers. This creates the coordination problem. Workers are risk neutral, so that all we need to look at is expected output. There are thus two potential outcomes: (a) all workers stay, output per worker and thus the wage are equal to unity, or; (b) one or more workers leave, output per worker and the wage are equal to \( \gamma \).

The decision problem for the agents boils down to determining some threshold level of outside opportunities, \( c^* \), such that if \( c < c^* \), workers stay and vice versa. If a worker leaves he receives \( c \). If he stays his expected earnings will depend on what the other \( n-1 \) workers do. Assume symmetry so that the other workers will have the same \( c^* \). Then the probability that they all stay is \( (F(c^*)^{n-1}) \), where \( F(c) \) is the distribution function such that \( F(0) = 0 \) and \( F(\bar{c}) = 1 \). Expected output per worker is then equal to \( (F(c^*)^{n-1}) + \gamma [1 - (F(c^*)^{n-1})] \).

The key point is that there may be multiple equilibria, depending on the level of outside opportunities. If alternative opportunities are very low, workers always stay in the firm, and output equals 1. As outside opportunities increase there are two equilibria; in one of these output falls close to \( \gamma \). With very high outside opportunities production in the state sector ceases. Note the problem here is coordination, not uncertainty. If the outside opportunity were common knowledge, with \( \gamma < c < \bar{c} \) there would still be two equilibria.

The essential feature of the disorganization model is that central planning is replaced before the infrastructure of markets is created. The lack of central organization leads to disorganization, and the development of outside opportunities makes this problem more severe. Over time, market infrastructure develops and disorganization problems are lessened.

Roland and Verdier (1999) develop a related model of disorganization, focusing on search frictions rather than bargaining problems. In their model liberalization means that enterprises can search for new suppliers and customers. There are good matches and bad matches. If too many bad clients are searching the productivity of potential matches may fall. What is critical in their model is that relationship-specific investments take place only after long-term matches are formed. If search continues this will not happen, investment demand will fall, and output can fall.

Investment specificity is crucial in this model. Without it output would not fall even with bad matches, since the partners could produce this period and keep on searching. It is the asset specificity that introduces the cost of bad matches.

The Roland–Verdier model is interesting from a theoretical point of view, but one may wonder how relevant it really is for explaining the output fall. The problem is that the initial output fall was associated with very little search for new suppliers. The predominant behaviour was a relationship-conservatism. Agents tried to maintain their relationships as much as possible. Networks of suppliers already had relationship-specific investments. The problem is that they had no customers who would purchase the goods at a price that covered their new costs.

A more subtle, but equally important explanation of the output fall focuses on the micro distortions due to Soviet pricing rules. Ericson (1999) has analysed this problem. His focus is on structural problems with Soviet pricing – the arbitrariness and non-uniformity of producers’ prices across users of the product within standard commodity aggregates. Ericson shows that Soviet pricing rules hid inefficiency and waste, creating an illusion of capacity and output that wasn’t there. The advantage of this theory is that it can explain why prices exploded when output fell. His argument is that post-Soviet ‘stagflation’ is, to some extent, a consequence of the irrational structure of production hidden in apparently consistent (adjusted) input–output (I–O) matrices and economic statistics.

Soviet pricing rules contained three systematic distortions: (a) basic factors were seriously undervalued (land was free, and capital-in-place virtually so); (b) raw materials and natural resources were undervalued; and (c) highly processed goods – in particular investment products and services – were seriously overvalued. These distortions in the principles of economic valuation used in centrally planned economies systematically hide tremendous waste, exaggerating both net outputs and net income (economic value) produced, while understating the productivity of that most seriously mismeasured factor of production, capital. This implies that the size of the apparent initial collapse in industrial production is evidently exaggerated, even if one ignores new economic activity generated in the wake of the reforms. However, the wasteful production structure can also spur a continuing and deepening collapse, as it is not economically viable in a market environment.

Ericson shows that embedding these distortions in the input–output tables that are used to create national income statistics results in lower prices for inputs than for final uses, and
generates an understatement of the share of gross output used in the production process. Thus, it leads to an overstatement of the share of net output. Furthermore, these distortions cannot be revealed by any consistent input–output framework derived from the ‘value’ of transactions between sectors; the methodology itself imposes a consistency that hides those distortions. This means that the true nature of the system cannot be revealed until price liberalization takes place. Until then, intersectoral relationships are hidden. This is what creates the ‘circus mirror’ effect discussed by Gaddy and Ickes (2002). (A circus mirror distorts size and shape. Soviet pricing rules had the same effect, making value added look larger and intermediate input use look smaller). Just as an individual may look taller and thinner in a circus mirror, the Soviet-type economy appeared more productive under Soviet pricing rules. Liberalization revealed the true nature of the economy.

Ericson shows that for the case of Russia the 1991 input–output coefficients were substantially understated, hiding significant materials input use and waste, and hence obscuring much of the inherited inefficiency in the industrial structure. This inefficiency became of consequence for producers when liberalization released them from ministerial tutelage and constraints, and made them primarily responsible for covering their own costs. Because enterprises are initially constrained by existing technological structures, the first impact of liberalization is typically seen in the move to raise prices to cover their full material costs and to compensate for any increases. This led to increases in industrial prices that far exceeded the general rate of inflation, raising the real price of industrial output and consequently real materials costs. As in the double marginalization theory, price increases in the intermediate sector propagate through the economy and result in less final output. But the impulse is different. Ericson's theory does not require any market power on the part of intermediate producers. Price increases are solely due to price liberalization itself in the context of Soviet pricing. Of course, at those increased real prices, demand for many products, now not supported by plan requirements, falls dramatically; producers find they are unable to sell at higher prices and hence unable to recover the full costs of production. Yet they continued to operate and ship output to traditional users of their product.

Ericson's theory is thus consistent with several important aspects of the output fall that are hard to explain in other models. First, his theory explains why the output fall is associated with a rise in the price level. Second, it is consistent with higher wholesale price inflation than consumer price inflation. Third, it is consistent with the explosion of inter-enterprise arrears. Supply and disorganization type theories make no prediction with regard to overall inflation and they are inconsistent with the latter two observations.

**Empirical analysis**

Most empirical analyses of the output fall has been focused on assessing the role of policies (primarily, stabilization and liberalization) and initial conditions in determining the size of the fall in output. This literature is too large to summarize here (a good summary is Campos and Coricelli, 2002), but a few points can be made. First, results are very dependent on how policies, especially the speed and extent of liberalization, are measured, and how initial conditions are proxied. Measures of liberalization that rely on expert evaluation are subject to performance bias: that is, the liberalization score that is assessed is often inferred from economic performance. The set of initial conditions that are important include the degree of over-industrialization, repressed inflation, dependence on CMEA trade, distance from Frankfurt, years spent under Communism, initial income, and the rate of urbanization. Depending on the set used results can differ dramatically.

One of the most comprehensive studies of the impact of policies versus initial conditions is by Berg et al. (1999). They use a sample of 26 transition economies and use a general to specific modelling approach that allows for differential effects of policies and initial conditions and for time-dependent effects of initial conditions. They find that structural reforms are more important than either policies or initial conditions in explaining the cross-country variation in performance. Initial conditions play the dominant role in explaining the output fall, while structural reforms explain the recovery. The most important initial conditions appear to be the degree of over-industrialization and trade dependency.

**Conclusion**

Although the size of the output fall indicated by official measures is clearly overstated, the fact that output and incomes did fall in the aftermath of liberalization is not disputed. Moreover, the fact that output followed a U-shaped pattern has had important consequences for transition. Not least of these is the negative effect it had on the political support for many economic reformers. The output decline made it politically difficult to stick with reforms. Hence, the output declines may have altered the course of policy reform in transition. Ironically, it seems that reform reversals were often associated with longer output declines.

overlapping generations model of general equilibrium

John Geanakoplos
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The OLG model of Allais and Samuelson retains the methodological assumptions of agent optimization and market clearing from the Arrow–Debreu model, yet its equilibrium set has different properties: Pareto inefficiency, multiplicity, positive valuation of money, and a golden rule equilibrium in which the rate of interest is equal to population growth (independent of impatience). These properties are shown to derive not from market incompleteness, but from lack of market clearing ‘at infinity’: they can be eliminated with land or uniform impatience. The OLG model is used to analyse bubbles, social security, demographic effects on stock returns, the foundations of monetary theory, Keynesian vs. real business cycle macromodels, and classical vs. neoclassical disputes.

Article

The consumption loan model that Paul Samuelson introduced in 1958 to analyse the rate of interest, with or without the social contrivance of money, has developed into what is without doubt the most important and influential paradigm in neoclassical general equilibrium theory outside of the Arrow–Debreu economy. Earlier Maurice Allais (1947) had presented similar ideas which unfortunately did not then receive the attention they deserved. A vast literature in public finance and macroeconomics is based on the model, including studies of the national debt, social security, the incidence of taxation and bequests on the accumulation of capital, the Phillips curve, the business cycle, and the foundations of monetary theory. In this article I give a hint of these myriad applications only in so far as they illuminate the general theory. My main concern is with the relationship between the Samuelson model and the Arrow–Debreu model.

Allais’s and Samuelson’s innovation was in postulating a demographic structure in which generations overlap, indefinitely into the future; up until then it had been customary to regard all agents as contemporaneous. In the simplest possible example, in which each generation lives for two periods, endowed with a perishable commodity when young and nothing when old, Samuelson noticed a great surprise. Although each agent could be made better off if he gave half his youthful birthright to his predecessor, receiving in turn half from his successor, in the marketplace there would be no trade at all. A father can benefit from his son’s resources, but has nothing to offer in return. This failure of the market stirred a long and confused controversy. Samuelson himself attributed the suboptimality to a lack of double coincidence of wants. He suggested the social contrivance of money as a solution. Abba Lerner suggested changing the definition of optimality. Others, following Samuelson’s hints about the financial intermediation role of money, sought to explain the...
consumption loan model by the incompleteness of markets. It has only gradually become clear that the ‘Samuelson suboptimality paradox’ has nothing to do with the absence of markets or financial intermediation. Exactly the same equilibrium allocation would be reached if all the agents, dead and unborn, met (in spirit) before the beginning of time and traded all consumption goods, dated from all time periods, simultaneously under the usual conditions of perfect intermediation. Indeed, in the early 20th century Irving Fisher (1907; 1930) implicitly argued that any sequential economy without uncertainty, but with a functioning loan market, could be equivalently described as if all markets met once with trade conducted at present value prices.

Over the years Samuelson's consumption loan example, infused with Arrow–Debreu methods, has been developed into a full-blown general equilibrium model with many agents, and multiple kinds of commodities and production. It is equally faithful to the neoclassical methodological assumptions of agent optimization, market clearing, price taking, and rational expectations as the Arrow–Debreu model. This more comprehensive version of Samuelson's original idea is known as the overlapping generations (OLG) model of general equilibrium.

Despite the methodological similarities between the OLG model and the Arrow–Debreu model, there is a profound difference in their equilibria. The OLG equilibria may be Pareto suboptimal. Money may have positive value. There are robust OLG economies with a continuum of equilibria. Indeed, the more commodities per period, the higher the dimension of multiplicity may be. Finally, the core of an OLG economy may be empty. None of this could happen in any Arrow–Debreu economy.

The puzzle is: why? One looks in vain for an externality, or one of the other conventional pathologies of an Arrow–Debreu economy. It is evident that the simple fact that generations overlap cannot be an explanation, since by judicious choice of utility functions one can build that into the Arrow–Debreu model. It cannot be simply that the time horizon is infinite, as we shall see, since there are classes of infinite horizon economies whose equilibria behave very much like Arrow–Debreu equilibria. It is the combination, that generations overlap indefinitely, which is somehow crucial. In Section 4 I explain how.

Note that in the Arrow–Debreu economy the number of commodities, and hence of time periods, is finite. One is tempted to think that, if the end of the world is put far enough off into the future, it could hardly matter to behaviour today. But recalling the extreme rationality hypotheses of the Arrow–Debreu model, it should not be surprising that such a cataclysmic event, no matter how long delayed, could exercise a strong influence on behaviour. Indeed, the OLG model proves that it does. One can think of other examples. Social security, based on the pay-as-you-go principle in the United States in which the young make payments directly to the old, depends crucially on people thinking that there might always be a future generation. Otherwise the last generation of young will not contribute; foreseeing that, neither will the second-to-last generation of young contribute, nor, working backward, will any generation contribute. Another similar example comes from game theory, in which cooperation depends on an infinite horizon. On the whole, it seems at least as realistic to suppose that everyone believes the world is immortal as to suppose that everyone believes in a definite date by which it will end. (In fact, it is enough that people believe, for every $T$, that there is positive probability the world lasts past $T$.)

In Section 1, I analyse a simple one-commodity OLG model from the present value general equilibrium perspective. This illustrates the paradoxical nature of OLG equilibria in the most orthodox setting. These paradoxical properties can hold equally for economies with many commodities, as pointed out in Section 4. Section 2 discusses the possibility of equilibrium cycles in a one-commodity, stationary, OLG economy. In Section 3, I describe OLG equilibria from a sequential markets point of view, and show that money can have positive value.

In the simple OLG economy of Section 1 there are two steady-state equilibria, and a continuum of non-stationary equilibria. Out of all of these, only one is Pareto efficient, and it has the property that the real rate of interest is always zero, just equal to the rate of population growth, independent of the impatience of the consumers or the distribution of endowments between youth and old age. This ‘golden rule’ equilibrium seems to violate Fisher's impatience theory of interest.

In Section 5 I add land to the one-commodity model of Section 1. It turns out that now there is a unique steady-state equilibrium that is Pareto efficient and that has a positive rate of interest, greater than the population growth rate, that increases if consumers become more impatient. Land restores Fisher's view of interest. In this setting it is also possible to analyse the effects of social security.

In Section 6 I briefly introduce variations in demography. It is well known that birth rates in the United States oscillated every 20 years over the 20th century. Stock prices have curiously moved in parallel, rising rapidly from 1945 to 1965, falling from 1965 to 1985, and rising ever since. One might therefore expect stock prices to fall as the post-war baby boom generation retires. But some authors have claimed that these parallel fluctuations of stock prices must be coincidental. Otherwise, since demographic changes are known long in advance, rational investors would have anticipated the price fluctuations and changed them. In Section 6 I allow the size of the generations to alternate and confirm that in OLG equilibrium land prices rise and fall with demography, even though the changes are perfectly anticipated.

In Section 7 I show that not just land but also uniform impatience restores the properties of infinite horizon economies to those found in finite Arrow–Debreu economies.
Section 8 takes up the question of comparative statics. If there is a multiplicity of OLG equilibria, what sense can be made of comparative statics? Section 8 summarizes the work showing that, for perfectly anticipated changes, there is only one equilibrium in the multiplicity that is ‘near’ an original ‘regular’ equilibrium. For unanticipated changes, there may be a multidimensional multiplicity. But it is parameterizable. Hence, by always fixing the same variables, a unique prediction can be made for changes in the equilibrium in response to perturbations. In Section 9 we see how this could be used to understand some of the New Classical–Keynesian disputes about macroeconomic policy. Different theories hold different variables fixed in making predictions.

Section 10 considers a neoclassical–classical controversy. Recall the classical economists’ conception of the economic process as a never-ending cycle of reproduction in which the state of physical commodities is always renewed, and in which the rate of interest is determined outside the system of supply and demand. Samuelson attempted to give a completely neoclassical explanation of the rate of interest in just such a setting. It now appears that the market forces of supply and demand are not sufficient to determine the rate of interest in the standard OLG model. In other infinite-horizon models they do.

Section 11 summarizes some work on sunspots in the OLG model. Uncertainty in dynamic models seems likely to be very important in the future. An explanation of the puzzles of OLG equilibria without land is given in Section 4: lack of market clearing ‘at infinity’. By appealing to non-standard analysis, the mathematics of infinite and infinitesimal numbers, it can be shown that there is a ‘finite-like’ Arrow–Debreu economy whose ‘classical equilibria’, those price sequences which need not clear the markets in the last period, are isomorphic to the OLG equilibria. Lack of market clearing is also used to explain the suboptimality and the positive valuation of money.

1 Indeterminacy and suboptimality in a simple OLG model

In this section we analyse the equilibrium set of a one-commodity per period, overlapping generations (OLG) economy, assuming that all agents meet simultaneously in all markets before time begins, just as in the Arrow–Debreu model. Prices are all quoted in present value terms; that is, \( p_t \) is the price an agent would pay when the markets meet (at time \( -\infty \) ) in order to receive one unit of the good at time \( t \). Although this definition of equilibrium is firmly in the Walrasian tradition of agent optimization and market clearing, we discover three surprises. There are robust examples of OLG economies that possess an uncountable multiplicity of equilibria, that are not in the core, or even Pareto optimal. This lack of optimality (in a slightly different model, as we shall see) was pointed out by Samuelson in his seminal (1958) paper. The indeterminacy of equilibrium in the one-commodity case is usually associated first with Gale (1973). In later sections we shall show that these puzzles are robust to an extension of the model to multiple commodities and agents per period, and to a non-stationary environment. We shall add still another puzzle in Section 3, the positive valuation of money, which is also due to Samuelson.

A large part of this section is devoted to developing the notation and price normalization that we shall use throughout. In any Walrasian model the problem of price normalization (the ‘numeraire problem’) arises. Here the most convenient solution in the long run is not at first glance the most transparent.

Consider an overlapping generation (OLG) economy \( E = E_{-\infty, \infty} \) in which discrete time periods \( t \) extend indefinitely into the past and into the future, \( t \in \mathbb{Z} \). Corresponding to each time period there is a single, perishable consumption good \( x_t \). Suppose furthermore that at each date \( t \) one agent is ‘born’ and lives for two periods, with utility

\[
    u^t(\ldots, x_t, x_{t+1}, \ldots) = a^t \log x_t + (1 - a^t) \log x_{t+1}
\]

defined over all vectors

\[
    x = (\ldots, x_{-1}, x_0, x_1, \ldots) \in \mathbb{L} = \mathbb{R}_+^{\mathbb{Z}}.
\]

Thus we identify the set of agents \( A \) with the time periods \( \mathbb{Z} \). Let each agent \( t \in A \) have endowment
\[ e^t = (..., e^t_s, e^t_{t+1}, ...) \in \mathbb{L} \]

which is positive only during the two periods of his life. Note that

\[ \sum_{t \in \mathcal{A}} e^t_s = e^{s-1} + e^s_s \text{ for all } s \in \mathbb{Z}. \]

An equilibrium is defined as a (present value) price vector

\[ \rho = (..., \rho_{-1}, \rho_0, \rho_1, ...) \in \mathbb{L} \]

and allocation

\[ \bar{x} = [x^t = (..., x^t_s, x^t_{t+1}, ...); t \in \mathcal{A}] \]

satisfying \( \bar{x} \) is feasible, that is,

\[ \sum_{t \in \mathcal{A}} x^t_s = \sum_{t \in \mathcal{A}} e^t_s \text{ for all } s \in \mathbb{Z} \tag{1} \]

and

\[ \sum_{s \in \mathbb{Z}} p_s e^t_s < \infty \text{ for all } t \in \mathcal{A} \tag{2} \]

and

\[ x^t \in \arg\max_{x \in \mathbb{L}} \left\{ u^t(x) \left| \sum_{s \in \mathbb{Z}} p_s x_s \leq \sum_{s \in \mathbb{Z}} p_s e^t_s \right. \right\}. \tag{3} \]
The above definition of equilibrium is precisely in the Walrasian tradition, except that it allows for both an infinite number of traders and commodities. All prices are finite, and consumers treat them as parametric in calculating their budgets. The fact that the definition leads to robust examples with a continuum of Pareto-suboptimal equilibria calls for an explanation. We shall give two of them, one at the end of this section, and one in Section 4. Note that condition (2) becomes necessary only when we consider models in which agents have positive endowments in an infinite number of time periods. As usual, the set of (present value) equilibrium price sequences displays a trivial dimension of multiplicity (indeterminacy), since, if \( p \) is an equilibrium, so is \( kp \) for all scalars \( k > 0 \). We can remove this ambiguity by choosing a price normalization \( q_t = p_{t+1} / p_t \) for all \( t \in Z \). The sequence \( q = (\ldots, q_{-1}, q_0, \ldots) \) and allocations \((x^t; t \in A)\) form an equilibrium if (1) above holds together with

\[
x^t \in \arg \max_{x \in \mathcal{L}} \left\{ u^t(x) | x_t + q_{t} x_{t+1} \leq e_{t}^l + q_{t} e_{t+1}^l \right\}.
\]

(4)

Notice that we have taken advantage of the finite lifetimes of the agents to combine (2) and (3) into a single condition (4). We could have normalized prices by choosing a numeraire commodity, and setting its price equal to one, say \( p_0 = 1 \). The normalization we have chosen instead has three advantages as compared with this more obvious system. First, the \( q \) system is time invariant. It does not single out a special period in which a price must be 1; if we relabelled calendar time, then the corresponding relabelling of the \( q_t \) would preserve the equilibrium. In the numeraire normalization, after the calendar shift, prices would have to be renormalized to maintain \( p_0 = 1 \). Second, on account of the monotonicity of preferences, we know that, if the preferences and endowments are uniformly bounded

\[
0 < \underline{a} \leq a^t \leq \overline{a} < 1, \ 0 < \underline{e} \leq e_{t}^l, \ e_{t+1}^l \leq \overline{e} \leq 1 \text{ for all } t \in A
\]

then we can specify uniform a priori bounds \( \underline{k} \) and \( \overline{k} \) such that any equilibrium price vector \( q \) must satisfy \( \underline{k} \leq q_t \leq \overline{k} \) for all \( t \in Z \). Third, it is sometimes convenient to note that each generation's excess demand depends on its own price. We define

\[
[z_{t}^l(q_t), z_{t+1}^l(q_t)] = (x_t^l - e_t^l, x_{t+1}^l - e_{t+1}^l)
\]

for \( x^t \) satisfying (4), as the excess demand of generation \( t \) when young and when old. We can accordingly rewrite equilibrium condition (1) as

\[
z_{t}^{t-1}(q_{t-1}) + z_{t}^t(q_t) = 0 \text{ for all } t \in Z.
\]

(5)

Let us now investigate the equilibria of the above economy when preferences and endowments are perfectly stationary. To be concrete, let

\[
a^t = a \text{ for all } t \in A
\]
and let

$$e_t^t = e, \text{ and } e_{t+1}^t = 1 - e, \text{ for all } t \in A$$

where $e > a > 1/2$. Agents are born with a larger endowment when young than when old, but the aggregate endowment of the economy is constant at 1 in every time period. Furthermore, each agent regards consumption when young as at least as important as consumption when old ($a > 1/2$), but on account of the skewed endowment the marginal utility of consumption at the endowment allocation when young is lower than when old:

$$\frac{a}{e} < \frac{1 - a}{1 - e}.$$ 

If we choose

$$q_t = \bar{q} = \frac{(1 - a)e}{(1 - e)a} > 1$$

for all $t \in \mathbb{Z}$, then we see clearly that at these prices each agent will just consume his endowment; $q = (\ldots, \bar{q}, \bar{q}, \ldots)$ is an equilibrium price vector, with $x^t = e^t$ for all $t \in A$. Note that if we had used the price normalization $p_0 = 1$, the equilibrium prices would be described by

$$(\ldots, p_0, p_1, p_2, \ldots) = (\ldots, 1, \bar{q}, \bar{q}, \ldots)$$

where $p_t \to \infty$ as $t \to \infty$. With $a = 1/2$ and $e = 3/4$, we get $\bar{q} = \frac{3}{4}$ and $p_t = 3t$.

But there are other equilibria as well. Take $q = (\ldots, 1, 1, 1, \ldots)$, and

$$(x^t, x_{t+1}^t) = (a, 1 - a) \text{ for all } t \in A$$

This 'golden rule' Pareto equilibrium dominates the autarkic equilibrium previously calculated. With $a = 1/2$ and $e = 3/4$, we see that $(1/2, 1/2)$ is much better for everyone than $(3/4, 1/4)$. This raises the most important puzzle of overlapping generations economies: why is it that equilibria can fail to be Pareto optimal? We shall discuss this question at length in Section 4.

For now, let us observe one more curious fact. We can define the core of our economy in a manner exactly analogous to the finite commodity and consumer case. We say that a feasible allocation $x = (x^t, t \in A)$ is in the core of the economy $E$ if there is no subset of traders $A' \subset A$, and an allocation $y = (y^t, t \in A')$ for $A'$ such that
overlapping generations model of general equilibrium: The New Palgrave Dictionary of Economics

\[ \sum_{t \in A'} y^t = \sum_{t \in A'} e^t, \]

and

\[ u^t(y^t) > u^t(x^t) \quad \text{for all} \quad t \in A'. \]

A simple argument can be given to show that the core of this economy is empty. For example, the golden rule equilibrium allocation is Pareto optimal, but not in the core. Since \( a < e \), every agent is consuming less when young than his initial endowment. Thus for any \( t_0 \in A \), the coalition \( A' = \{ t \in A | t \geq t_0 \} \) consisting of all agents born at time \( t_0 \) or later can block the golden rule allocation.

Let us continue to investigate the set of equilibria of our simple, stationary economy. Gale (1973) showed that for any \( \bar{q}_0 \), with \( 1 < \bar{q}_0 < \bar{q} \), there is an equilibrium price sequence

\[ q = (\ldots, q_{-1}, q_0, q_1, \ldots) \]

with \( q_0 = \bar{q}_0 \). In other words, there is a whole continuum of equilibria, containing a nontrivial interval of values. Incidentally, it can also be shown that for all such equilibria \( q \), \( q_t \rightarrow \bar{q} \) as \( t \rightarrow \infty \), and \( q_t \rightarrow 1 \) as \( t \rightarrow -\infty \). Moreover, these equilibria, together with the two steady state equilibria, constitute the entire equilibrium set. This raises the second great puzzle of overlapping generations economies. There can be a non-degenerate continuum of equilibria, while in finite commodity and finite agent economies there is typically only a finite number. Thus if we considered the finite truncated economy \( E_{-T,T} \) consisting of those agents born between \(-T\) and \( T \), and no others, then it can easily be seen that there is only a unique equilibrium \( (q_{-T}, \ldots, q_T) = (\bar{q}, \ldots, \bar{q}) \), no matter how large \( T \) is taken. On the other hand, in the overlapping generations economy, there is a continuum of equilibria. Moreover, the differences in these equilibria are not to be seen only at the tails. In the OLQ economy, as \( \bar{q}_0 \) varies from 1 to \( \bar{q} \), the consumption of the young agent at time zero varies from \( a \) to \( e \), and his utility from \( a \log e + (1 - a) \log (1 - e) \) (which for \( e \) near 1 is close to \(-\infty\) ), all the way to \( a \log a + (1 - a) \log (1 - a) \). By pushing the ‘end of the world’ further into the future, one does not approximate the world which does not end. We shall take up this theme again in Section 4.

It is very important to understand that the multiplicity of equilibria is not due to the stationarity of the economy. If we imagined a non-stationary economy with each \( a^t \) near \( a \) and each \( (e^t, e^{t+1}) \) near \( (e, 1-e) \), we would find the same multiplicity. One might hold the opinion that in a steady-state economy one should only pay attention to steady-state equilibria, that is, only to the autarkic and golden rule equilibria. In non-steady-state economies, there is no steady-state equilibrium to stand out among the continuum. One must face up to the multiplicity.

Let us reconsider how one might demonstrate the multiplicity of equilibria, even in a non-stationary economy. This will lead to a first economic explanation of indeterminacy similar to the one originally proposed by Gale. Suppose that in our non-stationary example we find one equilibrium \( \hat{q} = (\ldots, \hat{q}_{-1}, \hat{q}_0, \hat{q}_1, \ldots) \) satisfying:

\[ Z_{t}^{t-1}(\hat{q}_{t-1}) + Z_{t}^{t}(\hat{q}_{t}) = 0 \quad \text{for all} \quad t \in \mathbb{Z}. \]

Let us look for ‘nearby’ equilibria.

We shall say that generation $t$ is expectations sensitive at $\hat{q}_t$ if both $[\partial Z_t^t(\hat{q}_t) / \partial q_t] \neq 0$ and $[\partial Z_{t+1}^t(\hat{q}_t) / \partial q_t] \neq 0$. If the first inequality holds, then the young’s behaviour at time $t$ can be influenced by what they expect to happen at time $t+1$. Similarly, if the second inequality holds, then the behaviour of the old agent at time $t+1$ depends on the price he faced when he was young, at time $t$.

Recalling the logarithmic preferences of our example, it is easy to calculate that the derivatives of excess demands, for any $q_t > 0$, satisfy

$$\frac{\partial Z_t^t(q_t)}{\partial q_t} = a^t q_t^{t+1} \neq 0$$

and

$$\frac{\partial Z_{t+1}^t(q_t)}{\partial q_t} = \frac{- (1 - a^t) q_t^t}{q_t^2} \neq 0.$$

Hence, by applying the implicit function theorem to (1) we know that there is a non-trivial interval $]t-1, t[$ containing $\hat{q}_t-1$ and a function $F_t$ with domain $]t-1, t[$ such that $F_t(\hat{q}_t-1) = \hat{q}_t$, and more generally,

$$Z_{t-1}^t(q_{t-1}) + Z_t^t[F_t(q_{t-1})] = 0 \text{ for all } q_{t-1} \in ]t-1, t[.$$

Similarly there is a non-trivial interval $]t, t+1[$ containing $\hat{q}_t$, and a function $B_t$ with domain $]t, t+1[$ such that $B_t(\hat{q}_t) = \hat{q}_t$, and more generally, $Z_{t}^{t-1}(B_t(q_t)) + Z_t^t(q_t) = 0$, for all $q_t \in ]t, t+1[$. Of course, if $F_t(q_{t-1}) = q_t \in ]t, t+1[$, then $B_t(q_t) = q_{t-1}$.

These forward and backward functions $F_t$ and $B_t$, respectively, hold the key to one understanding of indeterminacy. Choose any relative price $q_0 \in ]l^F, l^G_0[$ between periods 0 and 1. The behaviour of the generation born at 0 is determined, including its behaviour when old at period 1. If $q_0 \neq \hat{q}_0$, and generation 1 continues to expect relative prices $\hat{q}_1$ between 1 and 2, then the period 1 market will not clear. However, it will clear if relative prices $q_1$ adjust so that $q_1 = F_1(q_0)$. Of course, changing relative prices between period 1 and 2 from $\hat{q}_1$ to $q_1$ will upset market clearing at time 2, if generation 2 continues to expect $\hat{q}_2$. But if expectations change to $q_2 = F_2(q_1)$, then again the market at time 2 will clear. In general, once we have chosen $q_t \in ]t, t+1[$, we can take $q_{t+1} = F_{t+1}(q_t)$ to clear the $(t+1)$ market. Similarly, we can work backwards. The change in $q_0$ will cause the period 0 market not to clear, unless the previous relative prices between period −1 and 0 were changed from $\hat{q}_{t-1}$ to $q_{t-1} = B_0(q_0)$. More generally, if we have already chosen $q_t \in ]t, t+1[$, we can set $q_{t-1} = B_t(q_t)$ and still clear the period $t$ market.

Thus we see that it is possible that an arbitrary choice of $q_0 \in ]l^F_0, l^G_0[$ could lead to an equilibrium price sequence $q$. What happens at time 0 is undetermined because it depends on expectations concerning period 1, and also the past. But what can rationally be expected to happen at time 1 depends on what in turn is expected to happen at time 2, and so on.

There is one essential element missing in the above story. Even if $q_t \in ]t, t+1[$, there is no guarantee that $q_{t+1} = F_{t+1}(q_t)$ is an element of $]l^G_{t+1}, l^F_{t+1}[$. Similarly, $q_t \in ]t, t+1[$ does not necessarily imply that $q_{t-1} = B_t(q_t) \in ]l^F_{t-1}, l^G_{t-1}[$. In our steady state example, this can easily be
remedied. Since all generations are alike,

\[ F_t = F_1, \quad B_t = B_0, \quad i_t^F = i_0^F \quad \text{and} \quad i_t^B = i_0^B \quad \text{for all} \quad t \in \mathbb{Z}. \]

One can show that the interval \((1, \overline{a}) \subset i_0^F \cap i_0^B\), and that if \(q_0 \in (1, \overline{a})\), then \(F_1(q_0) \in (1, \overline{a})\), and \(B_0(q_0) \in (1, \overline{a})\). This establishes the indeterminacy we claimed.

In the general case, when there are several commodities and agents per period, and when the economy is non-stationary, a more elaborate argument is needed. Indeed, one wonders, given one equilibrium \(\hat{q}\) for such an economy, whether after a small perturbation to the agents there is any equilibrium at all of the perturbed economy near \(\hat{q}\). We shall take this up in Section 8.

It is worth noting that we can define two more complete markets OLG economies with present value prices. In the economy \(E_{0, \infty}\) only agents born at time \(t \geq 1\) participate. The definition of OLG equilibrium is the same as before, except that now the set of agents is restricted to the participants, and market clearing is only required for \(t \geq 1\). In the \(q\)-normalized form, equilibrium is defined by \(q = (q_1, q_2, \ldots)\) such that

\[ Z_1^1(q_1) = 0Z_t^{t-1}(q_{t-1}) + Z_t^t(q_t) = 0 \quad \forall t \geq 2. \]

It is immediately apparent (with one agent born per period and one good) that \(E_{0, \infty}\) has a unique equilibrium, at which no agent trades and which is Pareto inefficient.

We could also define an economy \(E_{0, \infty}^M\) in which only agents \(t \geq 1\) participate, but where we require (in the normalized price version) that

\[ Z_1^1(q_1) = -MZ_t^{t-1}(q_{t-1}) + Z_t^t(q_t) = 0 \quad \forall t \geq 2. \]

Equilibrium in \(E_{0, \infty}^M\) is as if we gave an outside agent who had no endowment the purchasing power of \(M\) at time 1, and still managed to clear all markets \(t \geq 1\). As long as \(0 \leq M \leq Z_1^0(\overline{a})\), \(E_{0, \infty}^M\) has an equilibrium. Take \(q_0\) solving \(M = Z_1^0(q_0)\), and \(q_t = F_t(q_0)\) and \(q_t = F_t(q_{t-1})\) for \(t \geq 2\). We examine these two models more closely in Section 3.

2 Endogenous cycles

Let us consider another remarkable and suggestive property that one-commodity, stationary OLG economies can exhibit. We shall call the equilibrium \(q = (\ldots, q_{-1}, q_0, q_1, \ldots)\) periodic of period \(n\) if \(q_0, q_1, \ldots, q_{n-1}\) are all distinct, and if for all integers \(i\) and \(j\), \(q_i = q_{i+jn}\). The possibility that a perfectly stationary economy can exhibit cyclical ups and downs, even without any exogenous shocks or uncertainty, is reminiscent of 1930s–1950s business cycle theories. In fact, it is possible to construct a robust one-commodity per period economy which has equilibrium cycles of every order \(n\). Let us see how.

As before, let each generation \(t\) consist of one agent, with endowment \(\varepsilon^t = (\ldots, 0, \varepsilon, 1 - \varepsilon, 0, \ldots)\) positive only in period \(t\) and \(t+1\), and utility \(u'(x)u_1 + u_2(x_{t+1})\). Again, suppose that \(\overline{a} = u_2'(1 - \varepsilon) / u_1'(\varepsilon) > 1\). It is an immediate consequence of the separability of \(u\), that for \(q_t \leq \overline{a}\),
From monotonicity, we know that \( z_t^t(q_t) \rightarrow 0 \) as \( q_t \rightarrow 0 \). Hence it follows that for any \( 0 < q_0 < \bar{q} \), there is a unique \( q_{-1} = B_0(q_0) \) with

\[
Z_t^t(q_t) \leq 0, \quad Z_{t+1}^t(q_t) \geq 0, \quad \frac{\partial Z_{t+1}^t(q_t)}{\partial q_t} < 0.
\]

From the fact that \( Z_0^0(q_0) = -e \) for all \( q_0 \), it also follows that there is some \( \underline{q} \leq \bar{q} \) such that if \( q_0 \in [\frac{\bar{q}}{\underline{q}}, \bar{q}] \), then \( B_0(q_0) \in [\underline{q}, \bar{q}] \).

Now consider the following theorem due to the Russian mathematician Sarkovsky and to the mathematicians Li and Yorke (1975).

**Sarkovsky–Li–Yorke Theorem**: Let \( B: [\underline{q}, \bar{q}] \rightarrow [\underline{q}, \bar{q}] \) be a continuous function from a nontrivial closed interval into itself. Suppose that there exist a three-cycle for \( B \), that is, distinct points \( q_0, q_1, q_2 \) in \( [\underline{q}, \bar{q}] \) with \( q_1 = B(q_0), q_2 = B(q_1), q_0 = B(q_2) \). Then there are cycles for \( B \) of every order \( n \).

Grandmont (1985), following related work of Benhabib and Day (1982) and Benhabib and Nishimura (1985), gave a robust example of a one-commodity, stationary economy \((u_1, u_2, e)\) giving rise to a three-cycle for the function \( B_0 \). Of course a cycle for \( B_0 \) is also a cyclical equilibrium for the economy, hence there are robust examples of economies with cycles of all orders.

**Theorem**: (Benhabib–Day, 1982; Benhabib–Nishimura, 1985; Grandmont, 1985). There exist robust examples of stationary, one-commodity OLG economies with cyclical equilibria of every order \( n \).

This result is extremely suggestive of macroeconomic fluctuations arising for endogenous reasons, even in the absence of any fundamental fluctuations. Note first, however, that all of the cyclical equilibria, except the autarkic one-cycle \((\ldots, \bar{q}, \bar{q}, \bar{q}, \ldots)\), can be shown to be Pareto optimal (see Section 4), while the theory of macroeconomic business cycles is concerned with the welfare losses from cyclical fluctuations. (On the other hand, the fact that cyclical behaviour is not incompatible with optimality is perhaps an important observation for macroeconomics.) More significantly, it must be pointed out that Sarkovsky's theorem is a bit of a mathematical curiosity, depending crucially on one dimension. And of course non-stationary economies, even with one commodity, will typically not have any periodic cycles. By contrast, the multiplicity and suboptimality of non-periodic equilibria that we saw in Section 1 are robust properties that are maintained in OLG economies with multiple commodities and heterogeneity across time. The main contribution of the endogenous business cycle literature is that it establishes the extremely important, suggestive principle that very simple dynamic models can have very complicated ('chaotic') dynamic equilibrium behaviour.

In the next section we turn to another phenomenon that can generally occur in overlapping generations economies, but never in finite horizon models.

### 3 Money and the sequential economy

Money very often has value in an overlapping generations model, but it never does in a finite horizon Arrow–Debreu model. The reason for its absence in the latter model is familiar: money would enable some agents to spend more on goods than they received from sales of their goods. But that would mean in the aggregate that spending on goods would exceed revenue from the sale of goods, contradicting market clearing in goods.

This argument can be given another form. Without uncertainty, Arrow–Debreu equilibrium can be reinterpreted as a sequential equilibrium with contemporaneous prices. But if the number of periods is finite, then in the last period the marginal utility of money to every consumer is zero, hence so is its price. In the second-to-last period nobody will pay to end up holding any money, because in the last period it will be worthless. By induction it will have no value even in the first period.

Evidently both these arguments fail in an infinite horizon setting. There is no last period, so the backward induction argument has no place to begin. And with an infinite number of consumers, aggregate spending and revenue might both be infinite, preventing us from comparing their sizes. On the other hand, there are infinite horizon models where money cannot have value. The difference between the OLG model and these other infinite horizon models will be discussed in Section 7.
Strictly speaking, the overlapping generations model we have discussed so far has been modelled along the lines of Arrow–Debreu: each agent faced only one budget constraint and equilibrium was defined as if all markets met simultaneously at the beginning of time (−∞). In such a model money has no function. However, we can define another model, similar to the first considered by Samuelson, in which agents face a sequence of budget constraints and markets meet sequentially, and where money does have a store-of-value role. Surprisingly, this model turns out to have formally the same properties as the OLG model we have so far considered. To distinguish the two models we shall refer to this latter monetary model as the Samuelson model.

Suppose that we imagine a one-good per period economy in which the markets meet sequentially, according to their dates, and not simultaneously at the beginning of time. Suppose also that there are no assets or promises to trade. In such a setting it is easy to see that there could be no trade at all, since, as Samuelson put it, there is no double coincidence of wants. The old and the young at any date both have the same kind of commodity, so they have no mutually advantageous deal to strike. But as Samuelson pointed out, introducing a durable good called money, which affects no agent's utility, might allow for much beneficial trade. The old at date \( t \) could sell their money to the young for commodities, who in turn could sell their money when old to the next period's young. In this manner new and more efficient equilibria might be created. The ‘social contrivance of money’ is thus connected to both the indeterminacy of equilibrium and the Pareto suboptimality of equilibrium, at least near autarkic equilibria. The puzzle, we have said, is how to explain the positive price of money when it has no marginal utility.

A closer examination of the equilibrium conditions of Samuelson’s sequential monetary equilibrium reveals that, although it appears much more complicated, it reduces to the timeless OLG model we have defined above, but with one difference, namely, that the budget constraint of the generation endowed with money is increased by the value of money. The introduction of the asset money thus ‘completes the markets’ in the sense of Arrow (1953), by which we mean that the equilibrium of the sequential economy can be understood as if it were an economy in which money did not appear and all the markets cleared at the beginning of time (except, as we said, that the incomes of several agents are increased beyond the value of their endowments). The puzzle of how money can have positive value in the Samuelson model can thus be reinterpreted in the OLG model as follows. How is it possible that we can increase the purchasing power of one agent beyond the value of his endowment, without decreasing the purchasing power of any other agent below his, and yet continue to clear all the markets? Before giving a more formal treatment of the foregoing, let me re-emphasize an important point. It has often been said that the paradoxical properties of equilibrium in the sequential Samuelson consumption loan model can be explained on the basis of incomplete markets. Adding money to the model, however, completes the markets, in the precise sense of Arrow–Debreu, but the result is the OLG model in which the puzzles remain.

Let us now formally define the sequential one-commodity Samuelson model with money, \( E_{0, \infty}^{M, S} \). Consider a truncated economy in which there is a new agent ‘born’ at each date \( t \geq 0 \), whose utility depends only on the two goods dated during his lifetime, and whose endowment is positive only in those same commodities. At each date \( t \geq 1 \) there will be two agents alive, a young one and an old one. Let us suppose that trade does not begin until period 1, so that the date 0 generation must consume its endowment when it is young. To this truncation of our earlier model we now add one extra commodity, which we call money. Money is a perfectly durable commodity that affects no agent's utility. Agents are endowed with money \((M_t^t, M_{t+1}^t)\), in addition to their commodity endowments.

A (contemporaneous) price system is defined as a sequence 

\[
(\pi, p) = (\pi_1, \pi_2, \ldots; p_1, p_2, \ldots)
\]

of contemporaneous money prices \( \pi \), and contemporaneous commodity prices \( p \), for each \( t \geq 1 \). The budget set for any agent \( t \geq 1 \) is defined by

\[
\{(m_t, M_t^t, x_t, x_{t+1}) \geq 0 | \pi_t m_t + p_t x_t \leq \pi_t M_t^t + p_t e_t^t \text{ and } \pi_{t+1} M_{t+1}^t + p_{t+1} e_{t+1}^t \}
\]

For agent 0 the budget constraint is
The budget constraints express the principle that in the Samuelson model agents cannot borrow at all, and cannot save, that is, purchase more when old than the value of their old endowment, except by holding over money $m_t$ from when they were young. Let $m_t^t(\pi, p)$ and $m_{t+1}^t(\pi, p)$ be the utility maximizing choices of money holdings by generation $t$ when young and when old. As before, the excess commodity demand is defined by $Z_t^t(\pi, p)$ and $Z_{t+1}^t(\pi, p)$.

To keep things simple, we suppose that agent 0 is endowed with $M_0^0 = M$ units of money when he is old, but all other endowments $M^t$ are zero. Since money is perfectly durable, total money supply in every period is equal to $M$. Equilibrium is defined by a price sequence $(\pi, p)$ such that for all $t \geq 1$,

$$m_t^t(\pi, p) + m_{t+1}^t(\pi, p) = M$$

and $Z_{t-1}^t(\pi, p) + Z_t^t(\pi, p) = 0$.

At first glance this seems a much more complicated system than before.

But elementary arguments show that in equilibrium either $\pi_t = 0$ for all $t$, and there is no intergenerational trade of commodities, or $\pi_t > 0$ for all $t$, or $\pi_t < 0$ for all $t$. In the case where $\pi_t > 0$, no generation will choose to be left with unspent cash when it dies, hence $m_t^{t+1}(\pi, p) = 0$ for all $t$, hence money market clearing is reduced to

$$m_t^t(\pi, p) = M$$

for all $t \geq 1$.

By homogeneity of the budget sets, if $\pi_t > 0$, we might as well assume $\pi_t = 1$ for all $t$. But then the prices $p_t$ become the same as the present value prices from Section 1. From period by period Walras’ Law, we deduce that, if the goods market clears at date $t$, so must the money market. So we never have to mention money market clearing.

Moreover, by taking $q_t = (\pi_t p_{t+1}) / (\pi_{t+1} p_t)$ we can write the commodity excess demands for agent $t \geq 1$ just as in Section 1, by

$$[Z_t^t(q_t), Z_{t+1}^t(q_t)]$$

and they are the same as

$$[Z_t^t(\pi, p), Z_{t+1}^t(\pi, p)]$$

The only agent who behaves differently is agent 0, whose budget set must now be written
overlapping generations model of general equilibrium: The New Palgrave Dictionary of Economics

\[ \mathcal{g}^0(\mu, M) = \{(x_0, x_1) | x_0 = e_0^0, x_1 \leq e_1^0 + \mu M \}, \]

where

\[ \mu = \frac{\pi_1}{\rho_1}. \]

We can then write agent 0's excess demand for goods at time 1 as

\[ z_1^0(\mu, q, M) = z_1^0(\mu M) = \mu M. \]

Thus any sequential Samuelson monetary equilibrium can be described by \((\mu, q), \mu \geq 0\), satisfying

\[ z_1^0(\mu M) + z_1^1(q_1) = 0, \]

and

\[ z_{t-1}^t(q_{t-1}) + z_t^t(q_t) = 0 \text{ for all } t \geq 2. \]

But of course that is precisely the same as the definition of an OLG equilibrium for \(E_{0, \infty}^{\mu M}\) given in Section 1.

4 Understanding OLG economies as lack of market clearing at infinity

In this section we point out that the suboptimality of competitive equilibria, the indeterminacy of non-stationary equilibria, the non-existence of the core, and the positive valuation of money can all occur robustly in possibly non-stationary OLG economies with multiple consumers and \(L > 1\) commodities per period. We also note the important principle that the potential dimension of indeterminacy is related to \(L\). In the two-way infinity model, it is \(2L-1\). In the one-way infinite model without money it is \(L-1\); in the one-way infinity model with money the potential dimension of indeterminacy is \(L\).

None of these properties can occur (robustly) in a finite consumer, finite horizon, Arrow–Debreu model. In what follows we shall suggest that a proper understanding of these phenomena lies in the fact that the OLG model is isomorphic, in a precise sense, to a ‘*-finite’ model in which not all the markets are required to clear.

One of the first explanations offered to account for the differences between the Arrow–Debreu model and the sequential Samuelson model with money centred on the finite lifetimes of the agents and the multiple budget constraints each faced. These impediments to intergenerational trade (for example, the fact that an agent who is ‘old’ at time \(t\) logically cannot trade with an agent who will not be ‘born’ until time \(t+s\)) were held responsible. But as we saw in the last section, without uncertainty the presence of a single asset like money is enough to connect all the markets. Formally, as we saw, the model is identical to what we called the OLG model in which we could imagine all trade taking place simultaneously at the beginning of time, with each agent facing a single budget constraint involving all the commodities. What prevents trade between the old and the unborn is not any defect in the market, but a lack of compatible desires and resources.
Another common explanation for the surprising properties of the OLG model centres on the ‘paradoxes’ of infinity, as suggested by Shell (1971). In finite models, one proves the generic local uniqueness of equilibrium by counting the number of unknown prices, less 1 for homogeneity, and the number of market clearing conditions, less 1 for Walras’ Law, and notes that they are equal. In the OLG model there is an infinity of prices and markets, and who is to say that one infinity is greater than another? We already saw that the backward induction argument against money fails in an infinite horizon setting, where there is no last period. Surely it is right that infinity is at the heart of the problem. But this explanation does not go far enough. In the model considered by Bewley (1972) there is also an infinite number of time periods (but a finite number of consumers). In that model all equilibria are Pareto optimal, and money never has value, even though there is no last time period. The problem of infinity shows that there may be a difference between the Arrow–Debreu model and the OLG model. In itself, however, it does not predict the qualitative features (like the potential dimension of indeterminacy) that characterize OLG equilibria.

Consider now a general OLG model with many consumers and commodities per period. We index utilities \(u^t,h\) by the time of birth \(t\), and the household \(h \in H\), a finite set. Household \((t, h)\) owns initial resources \(e_t^t,h\) when young, an \(L\)-dimensional vector, and resources \(e_{t+1}^t,h\) when old, also an \(L\)-dimensional vector, and nothing else. As before utility \(u^t,h\) depends only on commodities dated either at time \(t\) or \(t+1\). Given prices

\[
q_t = (q_{ta}, q_{tb}) \in \Delta^{2L-1}_{++} = \left\{ q \in \mathbb{R}^{2L}_{++} \mid \sum_{\ell=1}^{2L} (q_{\ell} + q_{L+\ell}) = 2 \right\}
\]

consisting of all the \(2L\) prices at date \(t\) and \(t+1\), each household in generation \(t\) has enough information to calculate the relevant part of its budget set

\[
g_{t,h}^t(q_t) = \left\{ (x_t, x_{t+1}) \in \mathbb{R}^{2L} \mid q_{ta} \cdot x_t + q_{tb} \cdot x_{t+1} = q_{ta} \cdot e_t^t,h + q_{tb} \cdot e_{t+1}^t,h \right\}.
\]

Hence we can write household excess demand \([Z_t^t(q_t), Z_t^{t,h}(q_t)]\) and the aggregate excess demand of generation \(t\) as \([Z_t^t(q_t), Z_{t+1}(q_t)]\), where

\[
Z_{t+s}^t(q_t) = \sum_{h \in H} Z_{t+s}^{t,h}(q_t), s = 0, 1.
\]

Of course we need to put restrictions on the \(q_t\) to ensure their compatibility, since \(q_{tb}\) and \(q_{t+1,ta}\) refer to the same period \(t+1\) prices. But this is easily done by supposing that

\[
q_{tb} = \lambda_t q_{t+1,ta} \text{ for some } \lambda_t > 0, \forall t \in \mathbb{Z}.
\]

Present value OLG prices \(p\) can always be recovered from the normalized prices \(q\) via the recursion

\[
We shall now define three variations of the OLG model and equilibrium, depending on when time starts, and whether or not there is money.

Suppose first that time goes from \(-\infty\) to \(\infty\). We can write the market clearing condition for equilibrium exactly as we did in the one-commodity, one-consumer case, as

\[
q_{t-1}^{t-1} + q_t^t = 0, \quad t \in \mathbb{Z}.
\]

Similarly we can define the one-way infinity economy \(E_{0,\infty}\), in which time begins in period 0, but trade begins in time 1. We simply retain the same market clearing conditions for \(t \geq 2\),

\[
q_{t-1}^{t-1} + q_t^t = 0, \quad t \geq 2
\]

\[
(A')
\]

\[
\sum_{h \in H} z_{1,0}^{0,h} + z_{1,1}^1(q_1) = 0,
\]

(7)

it being understood that \(z_{1,0}^{0,h}\) has been modified to \(z_{1}^{0,h}(q_1)\) because every agent \((0,h)\) is forced to consume his own endowment at time 0, so that he maximizes over his budget set

\[
B_{0,h}(q_1) = \left\{ (x_0, x_1) \in \mathbb{R}_{+}^{2L} | x_0 = e_0^{0,h}, q_1 \cdot x_1 \leq q_1 \cdot e_1^{0,h} \right\}.
\]

Finally, let us define equilibrium in a one-way infinity model with money, \(E_{0,\infty}^M\), when agents \((0,h)\) are endowed with money \(M^h\), in addition to their commodities, by \((\mu, q), \mu \geq 0\), satisfying

\[
\sum_{h \in H} z_{1}^{0,h}(q_1, \mu M^h) + z_{1,1}^1(q_1) = 0,
\]

\[
(A'')
\]
Again it is understood that the agents \((0, h)\) born in time 0 cannot trade in time 0, and they maximize over the budget set

\[
B^{0, h}(q_{1a}, \mu M^h) = \{(x_0, x_1) \in \mathbb{R}^2_{\geq 0}, x_0 = e_0^0 \cdot h, q_{1a} \cdot x_1 \leq q_{1a} \cdot e_1^0 + \mu M^h\}.
\]

These are the natural generalizations of the one-good economies defined in Section 1. (There is one small difference. With many agents born per period we can no longer conclude that if one agent holds a positive amount of money when young, then so must every other agent – no matter when he is born. We shall ignore this complication and allow some agents to hold negative money."

We must now try to understand very generally why there may be many dimensions of OLG equilibria, why they might not be Pareto efficient, and how it is possible that some agents can spend beyond their budgets without upsetting market clearing. Our explanation amounts to ‘lack of market clearing at infinity’. We illustrate this for the case \(E_{0, \infty}\).

Consider the truncated economy \(E_{0,T}\) consisting of all the agents born between periods 0 and \(T\). Market clearing in \(E_{0,T}\) is defined to be identical to that in \(E_{0, \infty}\) for \(t=1\) to \(t=T\). But at \(t=T+1\), we require \(Z^T + 1(q_t) = 0\) in \(E_{0,T}\). This is a perfectly conventional Arrow–Debreu economy, and so necessarily has some competitive equilibria, all of which are Pareto efficient; generically its equilibrium set is a 0-dimensional manifold.

We have already seen in Section 1 what a great deal of difference there is between the economies \(E_{0,T}\) (no matter how large \(T\) is) and \(E_{0, \infty}\). The interesting point is that, by appealing to non-standard analysis, which makes rigorous the mathematics of infinite and infinitesimal numbers, one can easily show that the economy \(E_{0,T}\) for \(T\) an infinite number, inherits any property that holds for all finite \(E_{0,T}\). Thus the paradoxical properties of the economy \(E_{0, \infty}\) do not stem from infinity alone, since the infinite economy \(E_{0,T}\) does not have them. We shall need to modify \(E_{0,T}\) before it corresponds to \(E_{0, \infty}\). Nevertheless, the economies \(E_{0,T}\) do provide some information about \(E_{0, \infty}\).

Theorem: (Balasko–Cass–Shell, 1980; Wilson, 1981). Under mild conditions, at least one equilibrium for \(E_{0, \infty}\) always exists.

To see why this is so, note that \(E_{0,T}\) is well-defined for any finite \(T\). From non-standard analysis we know that the sequence \(E_{0,T}\) for \(T \in \mathbb{N}\) has a unique extension to the infinite integers. Now fix \(T\) at an infinite integer. We know that \(E_{0,T}\) has at least one equilibrium, since \(E_{0,s}\) does for all finite \(s\). But if \(T\) is infinite, \(E_{0,T}\) includes all the finite markets \(t=1,2,\ldots\), so all those must clear at an equilibrium \(q^*\) of \(E_{0,T}\). Taking the standard parts of the prices \(q^*_t\) for the finite \(t\) (and ignoring the infinite \(t\)) gives an equilibrium \(q^*\) for \(E_{0, \infty}\).

To properly appreciate the force of this proof, we shall consider it again, when it might fail, in Section 7, where we deal with infinite lived consumers.

In terms of the existence of equilibrium, \(E_{0, \infty}\) (and similarly \(E_{0, \infty}^M\) and \(E_{-\infty, \infty}\)) behaves no differently from an Arrow–Debreu economy. But the indeterminacy is a different story.

Definition: A classical equilibrium for the economy \(E_{0,T}\) is a price sequence \(q^* = (q_1, \ldots, q_T)\) that clears the markets for \(1 \leq t \leq T\), but at \(t=T+1\), market clearing \(Z^T + 1(q_T) = 0\) is replaced by

\[
Z^T + 1(q_T) \leq \sum_{h \in H} e_{T+1,h}.
\]
Thus in a classical equilibrium there is lack of market clearing at the last period. The aggregate excess demand in that period, however, must be less than the endowment the young of period \( T+1 \) would have had, were they part of the economy. Economies in which market clearing is not required in every market are well understood in economic theory. Note that in a classical equilibrium the agents born at time \( T \) are not rationed at \( T+1 \); their full Walrasian (notional) demands are met, out of the dispossessed endowment of the young. But we do not worry about how this gift from the \( T+1 \) young is obtained. The significance of our classical equilibrium for the OLG models can be summarized in the following theorem from Geanakoplos and Brown (1982):

**Theorem:** (Geanakoplos–Brown, 1982). Fix \( T \) at an infinite integer. The equilibria \( q \) for \( E_{0,\infty} \) correspond exactly to the standard parts of classical equilibria \( q^* \) of \( E_{0,T} \).

The Walrasian equilibria of the economy \( E_{0,\infty} \), which apparently is built on the usual foundations of agent optimization and market clearing, correspond to the ‘classical equilibria’ of another finite-like economy \( E_{0,T} \) in which the markets at \( T+1 \) (‘at infinity’) need not clear. The existence of a classical equilibrium in \( E_{0,T} \), and thus an equilibrium in \( E_{0,\infty} \), is not a problem, because market clearing is a special case of possible non-market clearing, and \( E_{0,T} \), being finite-like, always has market clearing equilibria. Thus even though the number of prices and the number of markets in \( E_{0,\infty} \) are both infinite, by looking at \( E_{0,T} \) it is possible to say which is bigger, and by how much. There are exactly \( L \) more prices than there are markets to clear. From Walras’ Law we know that if all the markets but one clear, that must clear as well. Hence having \( L \) markets that need not clear provides for \( L-1 \) potential dimensions of indeterminacy.

**Corollary:** (Geanakoplos–Brown, 1982). For a generic economy \( E_{0,\infty} \), there are at most \( L-1 \) dimensions of indeterminacy in the equilibrium set.

Though the classical equilibria of \( E_{0,T} \) generically have \( L-1 \) dimensions of indeterminacy, it is by no means true that there must be \( L-1 \) dimensions of visible indeterminacy. If we consider any classical equilibrium \( q^* \) for a generic economy \( E_{0,T} \), then we will be able to arbitrarily perturb some set of \( L-1 \) prices near their \( q^* \) values, and then choose the rest of the prices to clear all the markets up through time \( T \). But which \( L-1 \) prices these are depends on which square submatrix \( N \) (of derivatives of excess demands with respect to prices) is invertible. For example, call the economy \( E_{0,\infty} \) intertemporally separable if each generation \( t \) consists of a single agent whose utility for consumption at date \( t \) is separable from his utility for consumption at date \( t+1 \). Then the \( L-1 \) free parameters must all be chosen at date \( T+1 \) (as part of \( q^*_{T+1} \)), that is, way off at infinity.

**Corollary:** (Geanakoplos–Pollemarchakis, 1984). Intertemporally separable economies \( E_{0,\infty} \) generically have locally unique equilibria (in the product topology). For example, a natural generalization of the example in Section 1 would be to generations consisting of a single Cobb–Douglas consumer of \( L \) goods when young and when old. The corollary shows that this economy has no indeterminacy of equilibrium. Since Cobb–Douglas economies seem so central, one might guess that multi-good OLG economies \( E_{0,\infty} \) do not generate indeterminacy. But that is incorrect. Separability with one agent drastically reduces the effect expectations about future prices can have on the present, because changes in future consumption do not change marginal utilities today. In the separable case, changing all \( L \) prices tomorrow only affects today through the one dimension of income.

Even when the \( L-1 \) degrees of freedom may be chosen at time \( t=1 \), there still may be no visible indeterminacy, if the matrix \( N \) has an inverse (in the non-standard sense) with infinite norm. But when the free \( L-1 \) parameters may be chosen at \( t=1 \) and also the matrix \( N \) has an inverse with finite norm, then all nearby economies must also display \( L-1 \) dimensions of indeterminacy.

**Theorem:** (Kehoe–Levine, 1984; Geanakoplos–Brown, 1982). In the \( E_{0,\infty} \) OLG model there are robust examples of economies with \( L-1 \) dimensions of indeterminacy. In the monetary economy, \( E_{0,\infty}^M \), there are robust examples of economies with \( L \) dimensions of indeterminacy.

Let us now turn our attention to the question of Pareto optimality.

**Definition:** An allocation \( \bar{x} = (x^t, h, 0 \leq t \leq T) \) is classically feasible for the economy \( E_{0,T} \) if \( \sum (t,h) \in A x^t h \leq \sum (t,h) \in A^2 p^t h \), for \( 0 \leq t \leq T+1 \). The classically feasible allocation \( \bar{x} \) for \( E_{0,T} \) is a classic Pareto optimum if there is no other classically feasible allocation \( \bar{y} \) for \( E_{0,T} \) with \( u^t(y^t, h) > u^t(x^t, h) \) for all \( (t,h) \in A \) with \( 0 \leq t \leq T \), with at least one inequality \((0,h)\) representing a non-infinitesimal difference.

**Theorem:** (Geanakoplos–Brown, 1982). The Pareto-optimal allocations \( \bar{x} \) for the OLG economy \( E_{0,\infty} \) are precisely the standard parts of classical Pareto-optimal allocations \( \bar{x}^* \) for \( E_{0,T} \), if \( T \) is fixed at an infinite integer.
The upshot of this theorem is that the effective social endowment includes the commodities $E_{T+1}$ of the generation born at time $s=T+1$, even though they are not part of the economy $E_{0:T}$. Since the socially available resources exceed the aggregate of private endowments, it is no longer a surprise that a Walrasian equilibrium, in which the value of aggregate spending every period must equal the value of aggregate private endowments, is not Pareto optimal.

On the other hand, this does not mean that all equilibria are Pareto suboptimal. If the (present value) equilibrium prices \( p_t \to 0 \), as \( t \to \infty \) (or, more generally, if \( p_{T+1} \) is infinitesimal), then the value of the extra social endowment is infinitesimal, and there are no possible non-infinitesimal improvements. To see this, let \( (p, \bar{x}) \) be an equilibrium in present value prices for the OLG economy $E_{0,\infty}$. Consider the concave–convex programming problem of maximizing the utility of agent \( (0, \bar{h}) \), holding all other utilities of agents \( (t, h) \) with \( 0 \leq t \leq T \) at the levels \( u'/(u') \) they get with \( \bar{x} \), over all possible allocations in $E_{0:T}$ that do not use more resources, even at time $T+1$, than \( \bar{x} \). Clearly \( \bar{x} \) itself is a solution to this problem. But now let us imagine raising the constraints at time $T+1$ from

$$
\sum_{h \in H} x_{T+1}^{h} \to \sum_{h \in H} (E_{T+1}^{h} + E_{T+1}^{h+1}).
$$

What is the rate of change of the utility \( u^0, \bar{h} \)? From standard concave programming theorems, for the first infinitesimal additions to period $T+1$ resources, the rate of change of \( u^0, \bar{h} \) is on the order of \( p_{T+1} \), assuming \( p_1 \) is normalized to equal the marginal utility of consumption for agent \( (0, \bar{h}) \) at date 1. Additional resources bring decreasing benefits. This shows that if \( p_{T+1} \) is infinitesimal, then there are no possible non-infinitesimal improvements with a finite amount of extra resources.

An important example of \( p_t \to 0 \) occurs when the prices are summable, as they are when they decline geometrically to zero. Thus in a stationary equilibrium with a positive real interest rate, equilibrium must be Pareto efficient. Another proof of efficiency in the case of geometric present value prices is to observe that then the present value of the aggregate endowment must be finite, so the standard proof of Pareto efficiency in a finite horizon model goes through.

If \( p_t \) increases geometrically to infinity, then it is evident that equilibrium cannot be Pareto efficient. Thus, in a stationary equilibrium with a negative real interest rate, equilibrium must be Pareto inefficient.

When \( p_t \to 0 \) but also does not increase exponentially to infinity, the calculation becomes much more delicate. An infinitesimal increase \( \varepsilon \) in resources at time $T+1$ can be used to increase utility of \( (0, \bar{h}) \) on the order of \( p_{T+1} \varepsilon \), which is still infinitesimal if \( p_{T+1} \) is non-infinitesimal but finite. As the increases \( \varepsilon \) get larger, this rate of change could drop quickly, as higher derivatives come into play (assuming that agents have strictly concave utilities), leaving infinitesimal (and thus invisible) increases in utility even with a finite increase in resources. Second derivatives, and their uniformity, come into play. But this subtle case has been brilliantly dealt with:

*Theorem:* (Cass, 1972; Benveniste–Gale, 1975; Balasko–Shell, 1980; Okuno–Zilcha, 1980). *If agents have uniformly strictly concave utilities, and if the aggregate endowment is uniformly bounded away from 0 and \( \infty \), then the equilibrium \( (p, \bar{x}) \) with present value prices \( p \) for an OLG economy \( E_{0,\infty} \) is Pareto optimal if and only if \( \sum_{t=0}^{\infty} 1 / \| p_t \| = \infty \).*

Note that in this theorem it is the present value prices that play the crucial role. It follows immediately from this theorem that the golden rule equilibrium \( Q = (...) +, 1, 1, 1, (...) \) for the simple one good, stationary economy of Section 1 is Pareto optimal, since the corresponding present value price sequence is also \( (...) +, 1, 1, 1, (...) \). In fact, a moment's reflection shows that any periodic, non-autarkic equilibrium must also be periodic in the present value prices \( p \). Hence, as we have said before, but without a proof, the cyclical equilibria of Section 2 are all Pareto optimal.

Having explained the indeterminacy and Pareto suboptimality of equilibria for \( E_{0,\infty} \) in terms of lack of market clearing at infinity, let us re-examine the monetary equilibria of OLG economies \( E_{0,\infty}^M \), where \( M = (M^h; \ h \in H) \) is the stock of money holdings by the agents \( (0, h) \) at time 0.

The next theorem shows that any monetary equilibrium allocation of \( E_{0,\infty}^M \) corresponds to the standard part of a non-monetary economy \( E_{0:T}(z) \) obtained from \( E_{0:T} \) by augmenting the endowments of the first generation \( (0,h)_h \in H \) by a vector of goods \( z \) at time \( T \).
Definition: Let $z \in \mathbb{R}^L$ be a vector of commodities for time $T+1$. Suppose that $-\sum_{h \in H} E_{T+1}^{T+1} z_h \leq \sum_{h \in H} E_{T+1}^{T+1} h \leq \sum_{h \in H} E_{T+1}^{T+1} z_h$. Let the augmented non-monetary economy $E_{0,T}(z,M)$ be identical to the non-monetary economy $E_{0,T}$, except that the endowment of each agent $(0,h)$ is augmented by $Mh \cdot z$ units of commodities at time $T+1$.

Theorem: (Geanakoplos–Brown, 1982). Fix an infinite integer $T$. The equilibria $q$ of the monetary economy $E_{0,\infty}^M$ are precisely obtained by taking standard parts of full market clearing equilibria $q^*$ of all the augmented non-monetary economies $E_{0,T}(z,M)$. The above theorem explains how it is possible to give agents $(0,h)$ extra purchasing power without disturbing market clearing in the economy $E_{0,\infty}$. The answer is that the purchasing power comes from owning extra commodities at date $T+1$, and equilibrium in $E_{0,\infty}$ does not require market clearing in date $T+1$ commodities.

The above theorem gives another view of why there are potentially $L$ dimensions of monetary equilibria: the augmenting endowment vector $z$ can be chosen from a set of dimension $L$. It also explains how money can have positive value: it corresponds to the holding of extra physical commodities. The theorem also explains how the ‘social contrivance of money’ can lead to Pareto-improving equilibria, even in OLG economies where there is already perfect financial intermediation. The holding of money can effectively bring more commodities into the aggregate private endowment. The manifestation of the ‘real money balances’ is the physical commodity bundle $z$ at date $T+1$. Money plays more than just an intermediation role.

Before concluding this section let us consider a simple generalization. Suppose that agents live for three periods. What plays the analogous role to $E_{0,T}$? The answer is that prices need to be specified through time $T+2$, but markets are only required to clear through time $T$. There are therefore $2L-1$ potential dimensions of indeterminacy, even in the one-sided economy. In general, we must specify the price vector up until some time $s$, and then require market clearing only in those commodities whose excess demands are fully determined by those prices.

This reasoning has an important generalization to production. Suppose that capital invested at time $t$ can combine with labour at time $t+1$ to produce output at time $t+1$, and suppose that all agents live two periods. Is there any difference between the case where labour is inelastically supplied, and the case where leisure enters the utility? In both cases the number of commodities is the same, but in the latter case the potential dimension of indeterminacy is one higher, since the supply of labour at any time might depend on further prices.

5 Land, the real rate of interest, and Pareto efficiency

Allais and Samuelson argued that the infinity of both time periods and agents radically changed the nature of equilibrium. Samuelson suggested that equilibrium might not be Pareto efficient, and that the real rate of interest might be negative, even if the economy did not shrink over time. In our one-good example from Section 1, the autarkic equilibrium has a negative real interest rate since each $q_t < 1$, and the real interest rate is $1/q_t - 1$.

They also thought that a second, new kind of equilibrium would emerge in which the real rate of interest is divorced from any of the considerations like impatience that Irving Fisher had stressed. They thought that in this new kind of equilibrium the real rate of interest would turn out to be equal to the rate of population growth, irrespective of the impatience of the consumers or the distribution of their endowments. Indeed, in the example from Section 1, the ‘golden rule’ equilibrium had real interest rate $1/q_t - 1 = 0$ in every period, irrespective of the utilities or the endowments, but equal to the population growth rate. Furthermore, as we saw in Section 3, Samuelson argued that it might not be necessary for an asset to be valued according to the present value of its dividends, contradicting yet another one of Fisher’s central concepts. Samuelson suggested that a piece of green paper might be worth a lot, even though it pays no dividends, because the holder might think he could sell it to somebody later, who would buy it on the expectation that he could sell it to somebody else later, ad infinitum. Later authors called this a rational bubble. It turns out that these views are incorrect if one includes in the model infinitely lived assets like land, that do pay dividends in every period.

Imagine an OLG economy as before with

$$u_t(x_t, x_{t+1}) = \frac{1}{2} \log x_t + \frac{1}{2} \log x_{t+1} (e_t^f, e_{t+1}^f) = (3, 1).$$
overlapping generations model of general equilibrium: The New Palgrave Dictionary of Economics

But let us also suppose there is one acre of land in the economy that produces a dividend $D_t=1$ apple every period for ever. Suppose the economy begins in period 1, with an old agent who owns the land and has an endowment of one apple, and a newly born agent as above. We suppose that buying the land at time $t$ gives ownership of all dividends from time $t+1$ up to and including the dividends in the period in which the asset is sold. The apple dividend from the land at time 1 is owned by the old agent at time 1 (who presumably acquired the land at time 0 and hence has the claim on the apple). At every period $t$ we need to find the contemporaneous price $q_t$ of the commodity and the price $\Pi_t$ of the land.

Every agent in the economy must decide how much to consume when young, and what assets to hold when young, and how much to consume when old. The decision in old age is trivial, since the agent cannot do better than selling every asset he has and using the proceeds to buy consumption goods.

Thus for every $t \geq 1$ we can describe the decision problem of generation $t$ by

$$\max_{y,z,\theta} u_t'(y, z) = \frac{1}{2} \log y + \frac{1}{2} \log z \quad \text{such that } q_t y + \Pi_t \theta = q_t' e_t' = q_{t+1} e_{t+1}' + \theta D_{t+1} + \Pi_{t+1} \theta = q_{t+1} + \theta + \Pi_{t+1} \theta.$$

For the original old generation, he optimizes simply by setting

$$x_1^0 = e_1^0 + D_1 + \Pi_1 = 1 + 1 = 2 + \Pi_1.$$  

Denote the optimal choice of agents $t \geq 1$ by $(x_t^t, x_{t+1}^t, \theta^t)$. Market clearing requires for each $t \geq 2$ that consumption of the old plus consumption of the young is equal to total output of goods, and also that demand equals the supply of land

$$x_{t-1}^t + x_t^t = e_{t-1}^t + e_t^t + D_t = 1 + 3 + 1 = 5 \theta^t = 1.$$

In period $t=1$ we must have

$$x_1^0 + x_1^1 = e_1^0 + e_1^1 + D_1 = 1 + 3 + 1 = 5, \quad \theta^1 = 1.$$

Sequential equilibrium is thus a vector $(x_1^1, (q_t, \Pi_t, (x_t^t, x_{t+1}^t, \theta^t))_{t=1}^\infty)$ satisfying the above conditions on agent maximization and market clearing.

Fisher's recipe for computing equilibrium with assets is to put the asset dividends into the endowments of their owners, and then find the usual general equilibrium with present value prices ignoring the assets. In this example that means giving agent 0 an endowment $e^0=(2,1,\ldots)$ of two apples in period 1 and one apple every period thereafter, and ignoring the land. Equilibrium with present value prices is then described exactly as in Section 1.

To solve for the present value prices $(p_1, p_2, \ldots)$ we can guess that since the economy is stationary, there will be stationary equilibrium $(p_1, p_2, \ldots) = (1, p, p^2, \ldots)$. For each $t \geq 2$, we must solve

$$\frac{1}{2} \left[ \frac{3 + p_1}{p} \right] + \frac{1}{2} [3 + p_1] = 1 + 3 + 1,$$
which gives a quadratic equation

\[ p^2 - 6p + 3 = 0 \]

which is solved by

\[ p = \frac{6 \pm (36 - 12) \cdot 5}{2} = 0.55, \quad r = 1 / p - 1 = 81.7\%. \]

The other root is greater than one, and could not be right, because it would give a real interest rate less than zero, which would make the present value of land infinite. Hence consumption when young and old is

\[ (y, z) = (1.775, 3.225). \]

Clearly these values clear the consumption market for all \( t \geq 2 \). We know by Walras’s Law that, if all markets but one clears, then the last will as well, so we don’t really have to check the period 1 market. But we will check it anyway. The present value of agent 0’s endowment is

\[ 2 + p1 + p^21 + ... = 2 + p / (1 - p) = 3.225 \]

and so indeed the period \( t=1 \) market clears.

We can now translate this general equilibrium back into a sequential equilibrium. Taking \( q_t = 1 \) for every period and the real interest rate solving \( p = 1 / (1 + r) \), the present value of land is

\[ PV_{Land} = p1 + p^21 + ... = p / (1 - p) = \frac{1}{1 + r} 1 + \frac{1}{(1 + r)^2} 1 + ... = 1.225. \]

In every period the old will consume their endowment of 1 plus the dividend of 1 plus the value of the land they will sell, which gives exactly 3.225. The sequential equilibrium is

\[ (x_t^0, (q_t, \Pi_t, (x_t^1, x_{t+1}^1, \theta_t^1))_{t=1}^{\infty}) = (3.225, (1, 1.225, (1.775, 3.225, 1))_{t=1}^{\infty}). \]

Despite what Allais and Samuelson said, the rate of interest at the unique steady state is positive, higher than the growth rate of population. Moreover, as noted in Geanakoplos (2005), the real interest rate does respond to shocks in exactly the way Fisher argued. Consider the same model as before, but make all the consumers more impatient

\[ U(y, z) = \frac{2}{3} \log y + \frac{1}{2} \log z. \]
Then our master equation would become

\[ \frac{1}{3} \left( \frac{3 + p1}{p} \right) + \frac{2}{3} [3 + p1] = 1 + 3 + 1 \]

giving

\[ p = .419, \quad r = 139\%, \quad PVLand = .721. \]

As Fisher would have predicted, the real rate of interest does indeed increase, and the price of land decreases.

5.1 Pareto efficiency and bubbles

Observe that in our example the dividends of land represent 20 per cent of all endowments every period. Since the price of land must be finite, that means in any equilibrium the present value of all endowments must be finite. We know that implies equilibrium must be Pareto efficient.

Furthermore, if the value of aggregate endowments is finite, then money cannot have value and there can be no bubbles, because the old argument is correct that markets cannot clear if some agents are spending more than the value of their commodity endowments and nobody is spending less. Land makes the OLG economy look much more like an Arrow–Debreu economy.

5.2 Social security

The overlapping generations model is the workhorse model for examining social security. There is not space here to describe these studies. Observe simply that a pay-as-you-go system amounts to a simple transfer of endowments from each young person to each old person. We can immediately calculate the effects of such a transfer on our steady state interest rate and land value by recomputing the equilibrium for the OLG economy in which endowments are adjusted to (2,2) for every generation \( t \geq 1 \), and assuming the old generation 0 has an endowment of 2 apples at time 1 plus the land, which pays 1 apple every period. We get

\[ p = .38, \quad r = 161\%, \quad PVLand = .62. \]

This also confirms Fisher's contention that decreasing early endowments and increasing later endowments should raise the rate of interest and lower land values.

Notice that the pay-go system gives each agent the same number of apples when he is old that he gave up when he is young, which is a below market return on his original contribution. Social security lowers the utility of every agent except the first generation. Samuelson had argued that social security could make every agent better off. But his conclusion is false in the model with land. It is often said that if only every generation had more children, social security would give better returns, since the young would be able to share the burden of helping the old. The trouble with that reasoning is that it ignores the fact that higher population and output growth would mean higher real interest rates, which tend to make the social security rate of return as bad as before relative to market interest rates. There is no space to discuss this here.

6 Demography in OLG

In America since the early 20th century, the generations have alternated in size between big and small. Everybody knows about the
overlapping generations model of general equilibrium: The New Palgrave Dictionary of Economics

baby boom and echo baby boom, but the same pattern happened before. Recently many authors have suggested that the retiring of the baby boom generation will force stock prices to fall. This has been criticized on the grounds that demography is easy to predict. If agents knew that stock prices would fall when the baby boomers retired, they would fall now. These two opposing views can be analysed in the OLG model by allowing generation sizes to fluctuate.

Suppose the small generation is exactly as before, but now we alternate that small generation with a large generation that is identical in every respect, except that it is twice as big

\[ u^b(y, z) = \frac{1}{2} \log y + \frac{1}{2} \log (e^b_y, e^b_z) = (6, 2). \]

As before, suppose that land produces 1 unit of output each period. Begin at time 1 with a small generation of young, and suppose the old owns the land.

We investigate whether the price of land and the real interest rate alternate between periods.

Let \( r_b \) be the interest rate that prevails when the big generation \( b \) is young, and \( r_a \) prevail when the small generation \( a \) is young. Equilibrium can be reduced to two equations. The first describes market clearing for goods in odd periods when the small generation is young and the big generation is old, and the second equation describes market clearing in even periods, when the big generation is young and the small generation is old. As before, we let \( p_a = 1/(1+r_a) \) and \( p_b = 1/(1+r_b) \). Then

\[
\frac{1}{2} \left[ 6 + p_b b \right] + \frac{1}{2} \left[ 3 + p_a a \right] = 2 + 3 + \frac{1}{2} \left[ 3 + p_a a \right] + \frac{1}{2} \left[ 6 + p_b b \right] = 1 + 6 + 1.
\]

These can be simultaneously solved to get

\[
p_a = .418, \ r_a = 13.9\%, \ PV_{Land a} = 1.29
\]

\[
p_b = .912, \ r_b = 9.6\%, \ PV_{Land b} = 2.09.
\]

It is evident that the price of land is higher in the periods when \( b \) is young, since the interest rate is lower. Even though it is perfectly anticipated that when the big generation gets old, the price of land will fall, the price does not fall earlier because the interest rate is so low. (This point has been made by Geanakoplos, Magill and Quinzi, 2004.)

7 Impatience and uniform impatience

We have already suggested that it is useful in understanding the OLG model to consider variations, for example in which consumers live for ever. By doing so we shall also gain an important perspective on what view of consumers is needed to restore the usual properties of neoclassical equilibrium to an infinite horizon setting, a subject to which we return in Section 8.

Let us now allow for consumers \( t \in A \) who have endowments \( e^t \) that may be positive in all time periods, and also for arbitrary utilities \( u^t \) defined on uniformly bounded vectors \( x \in L = R^N \). For ease of notation we assume one good per period. A minimal assumption we need about utilities \( u^t \) is continuity on finite segments, that is, fixing \( x_s \) for all \( s > n \), \( u(x) \) should be continuous in \( x_1, \ldots, x_n \).
we also need uniform continuity on \( L \), in some topology, but we will not go into these details. We also assume \( \sum_{t \in A} \beta^t \) is uniformly bounded. In short, we suppose consumers may live for ever.

We shall find that in order to have Walrasian equilibria the consumers must be impatient. Suppose we try to form the truncated economy \( E_{0,T} \) as before, say for \( T \) finite. Since utility potentially depends on every commodity, we could not define excess demands in \( E_{0,T} \) unless we knew all the prices. To make it into a finite economy, let us call \( E'_{0,T} \) the version of \( E_{0,T} \) in which every agent is obliged to consume his initial endowment during periods \( t \leq 0 \) and \( t > T \). Clearly \( E'_{0,T} \) has an equilibrium. For this to give information about the original economy \( E_{0,\infty} \), we need that consumers do not care very much about what happens to them after \( T \), as \( T \) gets very far away. This requires a notion of impatience.

For any vector \( x \), let \( x \hat{n} \) be the vector which is zero for \( t > n \), and equal to \( x \) up until \( n \). Thus \( n \hat{x} \) is the initial \( n \)-segment of \( x \). To say that agent \( t \in A \) is impatient means that for any two uniformly bounded consumption streams \( x \) and \( y \), if \( u^t(x) > u^t(y) \), then for all big enough \( n \), \( u^t(n \hat{x}) > u^t(n \hat{y}) \). Let us suppose that all consumers are impatient. If these segments can be taken uniformly across agents, then we say the economy is uniformly impatient. Any finite economy with impatient consumers is uniformly impatient. Note that the OLG agents are all impatient, since none of them cares about consumption after he dies, but the economy is not uniformly impatient.

Even with an economy consisting of all impatient consumers, the truncation argument, applied at an infinite \( E'_{0,T} \), does not guarantee the existence of an equilibrium. For, once we take standard parts, ignoring the infinitely dated commodities, it may turn out that the income from the sale of an agent's endowed commodities at infinite \( t \), which he used to finance his purchase of commodities at finite \( t \), is lost to the agent. It must also be guaranteed that the equilibria of \( E'_{0,T} \) give infinitesimal total value to the infinitely dated commodities. Wilson (1981) has given an example of an economy, composed entirely of impatient agents, that does not have an equilibrium precisely for this reason.

On the other hand, if there are only finitely many agents, even if they are infinitely lived, then we have:

**Theorem:** (Bewley, 1972). Let the economy \( E \) be composed of finitely many, impatient consumers. Then there exists an equilibrium, and all equilibria are Pareto optimal.

The Pareto efficiency of equilibria in these Bewley economies can be derived from the standard proof of efficiency: since there is a finite number of agents, the value of the aggregate endowments is a finite sum of finite numbers, and therefore finite itself.

In the special case with separable, commonly discounted utilities of the form \( u^t(x) = \sum_{t=0}^{\infty} \delta^t v^t(x_t) \), with \( \delta < 1 \), we have:

**Theorem:** (Kehoe–Levine, 1985). In finite agent, separable commonly discounted utility economies, there is generically a finite number of equilibria.

This theorem has been extended by Shannon (1999) and Shannon and Zame (2002).

Returning to the case of an infinite number of consumers, Pareto efficiency of equilibria, if they exist, can be guaranteed as long as a finite number of the agents collectively hold a non-negligible fraction of total endowment. But that also would guarantee the existence of equilibrium, since in the economy \( E'_{0,T} \) we would then get the summability of the prices, meaning the endowments at infinity would have zero value, as Wilson (1981) pointed out.

It is extremely interesting to investigate the change in behaviour of an economy that evolves from individually impatient to uniformly impatient. Wilson (1981) considered an example with one infinitely lived agent, and infinitely many, overlapping, finite-lived agents, and showed that equilibria must exist, and all must be Pareto efficient. By the foregoing remarks, no matter what the proportion of sizes of the two kinds of consumers, equilibria must exist and be Pareto efficient. Muller and Woodford (1988) showed in a particular case that, when the single agent's proportion of the aggregate endowment is low enough, there is a continuum of equilibria, but if it is high enough there is no local indeterminacy.

### 8 Comparative statics for OLG economies

A celebrated theorem of Debreu assets that almost any Arrow–Debreu economy is regular, in the sense that it has a finite number of equilibria, each of which is locally unique. Small changes to the underlying structure of the economy (tastes, endowments, and so on) produce small, unique changes in each of the equilibria.

We have already seen that there are robust OLG economies with a continuum of equilibria. If attention is focused on one of them, how can one predict to which of the continuum of new equilibria the economy will move if there is a small change in the underlying structure of the economy, perhaps caused by deliberate government intervention? In what sense is any one of the new equilibria
near the original one? In short, is comparative statics possible? It is helpful at this point to recall that the OLG model is, in spirit, meant to represent a dynamic economy. Trade may occur as if all the markets cleared simultaneously at the beginning of time, but the economy is equally well described as if trade took place sequentially, under perfect foresight or rational expectations. Indeed, this is surely what Samuelson envisaged when he introduced money as an asset into his model. Accordingly, when a change occurs in the underlying structure of the economy, we can interpret it as if it came announced at the beginning of time, or as if it appeared at the date on which it actually affects the economy.

We distinguish two kinds of changes to the underlying structure of an economy $\tilde{E}$ starting from an equilibrium $\tilde{q}$. Perfectly anticipated changes, after which we would look for a new equilibrium that cleared all the markets from the beginning of time, represent one polar case, directly analogous to the comparative statics experiments of the Arrow–Debreu economy. At the other extreme we consider perfectly unanticipated changes, say at date $t=1$. Beginning at the original economy and equilibrium $\tilde{q} = (\ldots, \tilde{q}_{-1}, \tilde{q}_0, \tilde{q}_1, \ldots)$, we would look, after the change from $\tilde{E} = E_{-\infty, \infty}$ to $E_{-\infty, \infty}$, at time $t=1$ (say to the endowment or preferences of the generation born at time 1), for a price sequence $q = (\ldots, q_{-1}, q_0, q_1, \ldots)$ in which $q_t = \tilde{q}_t$ for $t \leq 0$, and $Z^{t-1}_t(q_{t-1}) + Z^t_t(q_t) = 0$ for $t \geq 2$. But at date $t=1$ we would require $q_1$ to satisfy $Z^0_1(q_1, \tilde{q}_0) + Z^1_1(q_1) = 0$, where $Z^0_1(q_1, \tilde{q}_0)$ represents the excess demand of the old at time 1, given that when they were young they purchased commodities on the strength of the conviction that they could surely anticipate prices $\tilde{q}_0$, but not to discover prices $q_{1a}$ instead.

To study these two kinds of comparative statics, we must describe what we mean by saying that two price sequences are nearby. Our definition is based on the view that a change at time $t=1$ ought to have a progressively smaller impact the further away in time from $t=1$ we move. We say that $q$ is near $\tilde{q}$ if the difference $|q_t - \tilde{q}_t|$ declines geometrically to zero, both as $t \to \infty$ and as $t \to -\infty$.

We have already noted in Section 1 that the multiplicity of OLG equilibria is due to the fact that at any time $t$ the aggregate behaviour of the young generation is influenced by their expectations of future prices, which (under the rational expectations hypothesis) depends on the next generation's expectations, and so on. Accordingly we restrict our attention to generations whose aggregate behaviour $Z^t$ satisfies the expectations sensitivity hypothesis:

$$\text{rank} \frac{\partial Z^t_t(p_t, p_{t+1})}{\partial p_{t+1}} = \text{rank} \frac{\partial Z^t_{t+1}(p_t, p_{t+1})}{\partial p_t} = L.$$

For economies composed of such generations we can apply the implicit function theorem, exactly as in Section 1, around any equilibrium $q$ to deduce the existence of the forward and backward functions $F_t$ and $B_t$. We write their derivatives at $\tilde{q}$ as $D_t$ and $D^{-1}_t$, respectively.

For finite Arrow–Debreu economies, Debreu gave a definition of regular equilibrium based on the derivative of excess demand at the equilibrium. He showed that comparative statics is sensible at a regular equilibrium, and then he showed that a ‘generic’ economy has regular equilibria. We follow the same program.

We say that the equilibrium $\tilde{q}$ for the expectations sensitive OLG economy $\tilde{E}$ is Lyapunov regular if the long-run geometric mean of the products $D^*_t D_t D_{t-1} D_{t-1} \cdots D^*_1 D_1$ and $D^{-1}_t D^{-1}_{t-1} \cdots D^{-1}_1$ converge and if to these products we can associate 2L–1 eigenvalues, called Lyapunov exponents. The equilibrium is also non-degenerate if in addition none of these Lyapunov exponents is equal to 1.

**Theorem:** (Geanakoplos–Brown, 1985). Let $\tilde{E} = E_{-\infty, \infty}$ be an expectations-sensitive economy with a regular non-degenerate equilibrium $\tilde{q}$. Then for all sufficiently small perfectly anticipated perturbations $E$ of $\tilde{E}$ (including $\tilde{E}$ itself) $E$ has a unique equilibrium $q$ near $\tilde{q}$.

Thus the comparative statics of perfectly anticipated changes in the structure of $\tilde{E}$ around a regular, non-degenerate equilibrium, is directly analogous to the Arrow–Debreu model. The explanation for the theorem is that a perfectly anticipated change at time 0 gives rise to price changes that have a forward stable manifold (on which prices converge exponentially back to where they started) and a backward stable manifold, and that there is only one price at time 0 that is on both the forward and the backward stable manifolds. Note, incidentally, that one implication of the above theorem is that neutral policy changes, like jawboning or changing animal spirits, that is, those for which $\tilde{q}$ itself remains an equilibrium, cannot have any effect if they are perfectly anticipated and move the economy to nearby equilibria.
Theorem: (Geanakoplos–Brown, 1985). Let $\tilde{E}$ be an expectations-sensitive economy with a regular equilibrium $\tilde{Q}$. Then, for all sufficiently small perfectly unanticipated perturbations $E$ of $\tilde{E}$ (including $\tilde{E}$ itself), the set of unanticipated equilibria $q$ of $E$ near $\tilde{Q}$ is either empty, or a manifold of dimension $r$, $0 \leq r \leq L$ ($L=1$ if there is no money in the economy), where $r$ is independent of the perturbation.

The above theorem allows for the possibility that an unanticipated change may force the economy onto a path that diverges from the original equilibrium; the disturbance could be propagated and magnified through time. And if there are nearby equilibria, then there may be many of them. (Indeed, that is basically what was shown in Section 4.) In particular, an unanticipated neutral policy change could be compatible with a continuum of different equilibrium continuations. The content of the theorem is that, if there is a multiplicity of equilibrium continuations, it is parameterizable. In other words, the same $r$ variables can be held fixed, and for any sufficiently small perturbation, there is exactly one nearby equilibrium which also leaves these $r$ variables fixed. We shall discuss the significance of this in the next section.

This last theorem was proved first, in the special case of steady-state economies, by Kehoe–Levine, in the same excellent paper to which we have referred already several times. The theorem quoted here, together with the previous theorem on the comparative statics of perfectly anticipated policy changes, refers to economies in which the generations may be heterogeneous across time. Let us suppose that $A$ is a compact collection of generational characteristics, all of which obey the expectations-sensitive hypothesis. Let us suppose that each generation’s characteristics are drawn at random from $A$, according to some Borel probability measure. If the choices are made independently across time, then the product measure describes the selection of economies. Almost any such collection will have a complex demographic structure, changing over time. The equilibrium set is then endogenously determined, and will be correspondingly complicated. It can be shown, however, that

**Theorem:** (Geanakoplos–Brown, 1985). If the economy $E$ is randomly selected, as described above, then with probability 1, $E$ has at least one Lyapunov regular equilibrium.

Note that the regularity theory for infinite economies stops short of Arrow–Debreu regularity. In the finite economies, with probability one all the equilibria are regular.

### 9 Keynesian Macroeconomics

Keynesian macroeconomics is based in part on the fundamental idea that changes in expectations, or animal spirits, can affect equilibrium economic activity, including the level of output and employment. It asserts, moreover, that publicly announced government policy also has predictable and significant consequences for economic activity, and that therefore the government should intervene actively in the marketplace if investor optimism is not sufficient to maintain full employment.

The Keynesian view of the indeterminacy of equilibrium and the efficacy of public policy has met a long and steady resistance, culminating, in the sharpest attack of all, from the so-called new classicals, who have argued that the time-honoured microeconomic methodological premises of agent optimization and market clearing, considered together with rational expectations, are logically inconsistent with animal spirits and the non-neutrality of public monetary and bond-financed fiscal policy.

The foundation of the new classical paradigm is the Walrasian equilibrium model of Arrow–Debreu, in which it is typically possible to prove that all equilibria are Pareto optimal and that the equilibrium set is finite; at least locally, the hypothesis of market clearing fixes the expectations of rational investors. In that model, however, economic activity has a definite beginning and end. Our point of view is that for some purposes economic activity is better described as a process without end. In a world without a definite end, there is the possibility that what happens today is underdetermined, because it depends on what people expect to happen tomorrow, which in turn depends on what people tomorrow expect to happen the day after tomorrow, and so on.

Consider the simple one-good per period overlapping generations economy with money $E^M_0$, which we discussed in Section 3. Generation 0 is endowed with money when old, and equilibrium can be described with the contemporaneous commodity prices $\bar{p} = (\bar{P}_1, \bar{P}_2, \ldots)$ where we take the price of money to be fixed at 1. (In this case, as we saw in Section 3, contemporaneous prices are also present value prices.) It is helpful to reinterpret the model as a simple production economy. Imagine that the endowment $\theta_t$ in the first period of life is actually labour, which can be transformed into output, $y_t$, according to the production function, $y_t = \epsilon_t$. We would then think of any purchases of goods by the old generation as demand for real output to be produced by the young. The young in turn now derive utility from leisure in their youth and consumption in their old age. Equilibrium in which consumption of the old is higher can be interpreted as an equilibrium with less leisure and higher output.

The indeterminacy of rational expectations equilibrium has the direct interpretation that optimistic expectations by themselves can cause the economy’s output to expand or contract. In short the economy has an inherent volatility. The Keynesian story of animal spirits causing economic growth or decline can be told without invoking irrationality or non-market clearing.

In fact, the indeterminacy of equilibrium expectations is especially striking when seen as a response to public (but unanticipated)
policy changes. Suppose the economy is in a long-term rational expectations equilibrium $\bar{p}$, when at time 1 the government undertakes some expenditures, financed, say, by printing money. How should rational agents respond? The environment has been changed, and there is no reason for them to anticipate that $(\bar{p}_2, \bar{p}_3, \ldots)$ will still occur in the future. Indeed, in models with more than one commodity (such as we will shortly consider) there may be no equilibrium $(p_1, p_2, p_3, \ldots)$ in the new environment with $p_2 = \bar{p}_2$, $p_3 = \bar{p}_3$, and so on. There is an ambiguity in what can be rationally anticipated.

We argue that it is possible to explain the differences between Keynesian and monetarist policy predictions by the assumptions each makes about expectational responses to policy, and not by the one's supposed adherence to optimization, market clearing, and rational expectations, and the other's supposed denial of all three.

Consider now the government policy of printing a small amount of money, $\Delta M$, to be spent on its own consumption of real output – or equivalently to be given to generation $t=0$ (when old) to spend on its consumption. Imagine first that agents are convinced that this policy is not inflationary, that is, that $\bar{p}_1$ will remain the equilibrium price level during the initial period of the new equilibrium. This will give generation $t=0$ consumption level $(M + \Delta M) / \bar{p}_1$. As long as $\Delta M$ is sufficiently small and the initial equilibrium was one of the Pareto-suboptimal equilibria described in Section 1, there is indeed a new equilibrium price path $p$ beginning with $p_1 = \bar{p}_1$. Output at time 1 rises by $\Delta M / \bar{p}_1$, and in fact this policy is Pareto improving. On the other hand, imagine instead that agents are convinced that the path of real interest rates $p/p_{t+1}$ will remain unchanged. In this economy, price expectations are a function of $p_1$. Recalling the initial period market-clearing equation, it is clear that $p_1$ and all future prices rise proportionally to the growth in the money stock. The result is that output is unchanged and the old at $t=1$ must pay for the government's consumption. If the government's consumption gives no agent utility, the policy is Pareto worsening.

This model is only a crude approximation of the differences between Keynesian and monetarist assumptions about expectations and policy. It is quite possible to argue, for example, that holding $p_2/p_1 = \bar{p}_2/\bar{p}_1$ (the future inflation rate) fixed is the natural Keynesian assumption to make. This ambiguity is unavoidable when there is only one asset into which the young can place their savings. We are thereby prevented from distinguishing between the inflation rate and the interest rate. Our model must be enriched before we can perform satisfactory policy analysis. Nevertheless, the model conveys the general principle that expected price paths are not locally unique. There is consequently no natural assumption to make about how expectations are affected by policy. A sensible analysis is therefore impossible without externally given hypotheses about expectations. These can be Keynesian, monetarist, or perhaps some combination of the two.

Geanakoplos and Polemarchakis (1985) build just such a richer model of macroeconomic equilibrium by adding commodities, including a capital good, and a neoclassical production function. With elastically supplied labour, there are two dimensions of indeterminacy. It is therefore possible to fix both the nominal wage, and the firm's expectations ('animal spirits'), and still solve for equilibrium as a function of policy perturbations to the economy. These institutional rigidities are more convincing Keynesian, and they lead to Keynesian policy predictions. Moreover, taking advantage of the simplicity of the two-period lived agents, the analysis can be conducted entirely through the standard Keynesian (Hicksian) IS–LM diagram.

Keynesians themselves often postulate that the labour market does not clear. For Keynesians, lack of labour market clearing has at least a threefold significance, which it is perhaps important to sort out. First, since labour is usually taken to be inelastically supplied, it makes it possible to conceive of (Keynesian) equilibria with different levels of output and employment. Second, it makes the system of demand and supply underdetermined, so that endogenous variables like animal spirits (that is, expectations) which are normally fixed by the equilibrium conditions can be volatile. Third, it creates unemployment that is involuntary. By replacing lack of labour market clearing at time 1 with elastic labour supply and lack of market clearing ‘at infinity’ one can drop what seems to many an ad hoc postulate, yet retain at least the first two desiderata of Keynesian analysis.

### 10 Neoclassical equilibrium vs. classical equilibrium

The Arrow–Debreu model of general equilibrium, based on agent optimization, rational expectations, and market clearing, is universally regarded as the central paradigm of the neoclassical approach to economic theory. In the Arrow–Debreu model, consumers and producers, acting on the basis of individual self-interest, combine, through the aggregate market forces of demand and supply, to determine (at least locally) the equilibrium distribution of income, relative prices, and the rate of growth of capital stocks (when there are durable goods). The resulting allocations are always Pareto optimal.

Classical economists at one time or another have rejected all of the methodological principles of the Arrow–Debreu model. They replace individual interest with class interest, ignore (marginal) utility, especially for waiting, doubt the existence of marginal product, and question whether the labour market clears. But by far the most important difference between the two schools of thought is the classical emphasis on the long-run reproduction of the means of production, in a never-ending cycle. Thus the celebrated classical economist Sraffa writes in Appendix D to his book:

It is of course in Quesnay's *Tableau Economique* that is found the original picture of the system of production and consumption as a circular process, and it stands in striking contrast to the view presented by modern theory, of a one-way avenue that leads from 'Factors of Production' to 'Consumption Goods.'

The title of his book, *Production of Commodities by Means of Commodities*, itself suggests a world that has no definite beginning, and what is circular can have no end.

In the Arrow–Debreu model time has a definite end. As we have seen, that has strong implications. With universal agreement about when the world will end, there can be no reproduction of the capital stock. In equilibrium it will be run down to zero. Money, for example, can never have positive value. Rational expectations will fix, at each moment, and for each kind of investment, the expected rate of profit.

In the classical system, by contrast, the market does not determine the distribution of income. Sraffa (1960, p. 33) writes:

> The rate of profits, as a ratio, has a significance which is independent of any prices, and can well be ‘given’ before the prices are fixed. It is accordingly susceptible of being determined from outside the system of production, in particular by the money rates of interest. In the following sections the rate of profits will therefore be treated as the independent variable.

Other classical writers concentrate instead on the real wage as determined outside the market forces of supply and demand, for example by the level of subsistence or the struggle between capital and labour. Indeterminacy of equilibrium seems at least as central to classical economists as it is to Keynesians.

Like Keynesians, classics often achieve indeterminacy in their formal models by allowing certain markets not to clear in the Walrasian sense. (Again like Keynesians, the labour market is usually among them.) Thus we have called the equilibrium in Section 4 in which some of the markets were allowed not to clear a 'classical equilibrium'.

What the OLG model shows is that, by incorporating the classical view of the world without definite beginning or end, it is possible to maintain all the neoclassical methodological premises and yet still leave room for the indeterminacy which is the hallmark of both classical and Keynesian economics. In particular this can be achieved while maintaining labour market clearing. The explanation for this surprising conclusion is that the OLG model is isomorphic to a finite-like model in which indeed not all the markets need to clear. But far from being the labour markets, under pressure to move towards equilibrium from the unemployed clamouring for jobs, these markets are off ‘at infinity’, under no pressure towards equilibrating.

We have speculated that, once one has agreed to the postulate that the resources of the economy are potentially as great at any future date as they are today, then uniform impatience of consumers is the decisive factor, according to Walrasian principles, which may influence whether the market forces of supply and demand determine a locally unique, Pareto-optimal equilibrium, or leave room for extra-market forces to choose among the continuum of inefficient equilibria. In these terms, the Arrow–Debreu model supposes a short-run impatient economy, and OLG a long-run patient economy.

11 Sunspots

So far we have not allowed uncertainty into the OLG model. As a result we found no difference in interpreting trade sequentially, with each agent facing two budget constraints, or ‘as if’ the markets all cleared simultaneously at the beginning of time, with each agent facing one budget constraint. Once uncertainty is introduced these inpts become radically different. In either case, however, there is a vast increase in the number of commodities, and hence in the potential for indeterminacy.

If we do not permit agents to make trades conditional on moves of nature that occur before they are born, then agents will have different access to asset markets. Even in finite horizon economies, differing access to asset markets has been shown by Cass and Shell (1983) to lead to ‘sunspot effects’.

A ‘sunspot’ is a visible move of nature which has no real effect on consumers, on account of preferences, or endowments, or through production. In the Arrow–Debreu model it also could have no effect on equilibrium trade; this is no longer true when access to asset markets differs.

The sunspot effect is intensified when combined with the indeterminacy that can already arise in an OLG economy. Consider the simple one good, steady state OLG economy of Section 2. Suppose that there is an equilibrium two cycle in present value prices $p = (\ldots, p_{-1}, p_0, p_1, \ldots)$ with $p_{2\tau} = p^S$ and $p_{2\tau+1} = p^R$, for all $\tau \in T$. Now suppose that the sun is known to shine on even periods, and hide behind rain on odd periods. The above equilibrium is perfectly correlated with the sun, even though no agent’s preferences or
endowments are. As usual, the same prices for \( t \geq 0 \) support an equilibrium, given the right amount of money, in \( E_{0, \infty}^{M, S} \). More generally, suppose that the probability of rain or shine, given the previous period's weather, is given by the Markov matrix

\[
\pi = (\pi_{SS}, \pi_{SR}, \pi_{RS}, \pi_{RR}).
\]

A steady state equilibrium for \( E_{0, \infty}^{M, S} \), given \( \pi \), is an assignment of a money price for the commodity, depending only on that period's weather, such that, if all agents maximize their expected utility with respect to \( \pi \), then in each period the commodity market and money market clears. Azariadis (1981) essentially showed that, if there is a two-cycle of the certainty economy, then there is a continuum of steady state sunspot equilibria.

The sunspot equilibria, unlike the cyclical equilibria of Section 2, are Pareto suboptimal whenever the matrix \( \pi \) is non-degenerate.

The combination of the dynamic effects of the infinite horizon OLG model with the burgeoning theory of incomplete markets under real uncertainty, is already on the agenda for the next generation's research.

Article

Samuel Loyd (the single 'l' seems to have been a device adopted by his father to shake off Welsh relatives), Lord Overstone, was born on 25 September 1796, the son of Lewis Loyd, a Unitarian minister turned banker, and Sarah Loyd (née Jones), the daughter of a Manchester banker. Lewis Loyd's drive and ability transformed an obscure provincial bank into a major concern. An MP from 1819 to 1826, Overstone only began to devote himself seriously to banking after the death of his mother in 1821. Though perhaps lacking his father's flair, he was a shrewd and successful banker, influential with his contemporaries. He retired from business only in 1850, on his elevation to the peerage by Lord John Russell.

In 1837 he entered, with considerable effectiveness, the arena of monetary controversy with his Reflections suggested by a perusal of Mr. J. Horsley Palmer's pamphlet on the Causes and Consequences of the pressure on the Money Market. This was not his first statement on the matter; he had been a witness before the 1832 committee on the renewal of the Bank Charter. But it was the start of his pre-eminence as a monetary writer, a pre-eminence which was to prove decisive in the debates leading up to the renewal of the Bank Charter in 1844 and which shaped the institutional framework of British monetary policy from that time until the First World War. Overstone's monetary thought starts from a position that the economy contains an endogenous trade cycle – he was indeed one of the first people to identify the stages of the cycle. Monetary policy could then be procyclical, responding to the needs of customers (the Banking principle) or it could act counter-cyclically so as to stabilize the level of prices and activity (the Currency principle). The theoretical position underlying the latter was as follows. In the upswing of the cycle money income rose, exports were less competitive, and a balance of payments deficit developed. Counter-cyclical contraction of the currency, in line with the loss of specie through the balance of payments deficit, would then moderate the upswing and prevent it getting out of
hand. Conversely, in the lower half of the cycle, with a balance of payments surplus, the money supply would be increased. (O'Brien, 1971; O'Brien, 1975; Wood, 1939)

The origins of this position were threefold: Hume's theory of the balance of payments, positing a direct link between the money supply, the price level, exports, and imports: the Ricardian theory of the equilibrium distribution of the precious metals (that when countries were in relative money income equilibria, there would be no net flows of precious metal) deriving from Hume; and the Ricardian definition of ‘excess’. The last is particularly crucial. If specie was flowing out then, by definition, there was excess currency. This idea leads in turn to the principle, formulated in 1826 by several writers, of ‘metallic fluctuation’: a paper currency should fluctuate in amount exactly as an identically circumstanced metallic one would do.

On this basis Overstone emerged as a critic of the ‘Palmer Rule’ under which the Bank allowed drains of specie to fall on deposits equally with notes: unless deposits were as important as notes in correcting the price level in relation to the balance of payments, the drain might exhaust the specie without correcting the balance of payments. Overstone's emphasis was on control of currency as the high-powered money base, with deposits as part of an inverted credit pyramid lacking any independent effect of their own, and dependent upon the currency base if banks behaved properly with respect to reserve ratios.

Thus, fundamental to monetary control was separation of departments in the Bank: the Banking department followed Banking principles, but the Issue department must follow Currency principles and thus stabilize economic activity, following automatic rather than discretionary procedures.

The role of the rate of interest in all this was twofold: short-run balance of payments correction, although this could only be a palliative if relative money incomes were out of line, and the production of an effect on confidence which in turn affected liquidity preference through increasing precautionary reserve holdings when the rate was raised, thus reducing the effectiveness of a given money supply. This variation in liquidity preference with confidence was an important part of the analysis, and was built into the 1844 Act with weekly publication of the Bank reserves, which were supposed to cause prudent adjustment of other reserves. This in turn would avoid the Bank of England's having to act as lender of last resort, a role which Overstone opposed as incompatible both with inducing the rest of the system to respond counter-cyclically and with the necessary limitation of the high-powered base.

Overstone was a many-sided man. But it is as a monetary theorist that he is chiefly remembered.

Owen, Robert (1771–1858)

N.W. Thompson

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

autarky; class conflict; labour time; Owen, R.; pecuniary and non-pecuniary penalties; poverty alleviation; socialism

Article

Born in Newtown, Montgomeryshire (Powys), in 1771, Robert Owen was in many ways both the child and the victim of his age, making his fortune as a cotton manufacturer involved in the industrial transformation of Britain and dissipating it in his efforts to eliminate its evils. With the purchase of the New Lanark cotton mills in 1797 Owen did, for a time, successfully combine the roles of factory owner and social reformer, showing how a humanized working environment might effect a reformation in human character. For the modern social scientist, one interesting innovation Owen implemented was the silent monitor, a four-sided block that was hung next to each worker's machine; a supervisor would turn the block to a colour that reflected the worker's effort during the day; colours were recorded in a 'book of character'. (See Podmore, 1906, based on Owen's autobiography.) The silent monitor was meant to substitute for corporal punishment as a discipline device; it resonates with recent thinking on social sanctions; see pecuniary versus non-pecuniary penalties.

Owen's success in the New Lanark venture encouraged him to devote his life to the regeneration of mankind and it also provided him with the funds necessary to attempt this. However, further practical experiments proved disastrous. The cooperative communities he established, such as those at New Harmony Indiana in 1824 and Queenwood in Hampshire in 1839, soon collapsed, while his efforts in 1832 to socialize money through a National Equitable Labour Exchange proved equally disastrous. However, such failures never inspired self-doubt and Owen remained to the end of his long life a living embodiment of hope's capacity to triumph over experience.

As a cotton manufacturer Owen grasped the potential for material abundance which industrialization was creating in early 19th-century Britain; yet as an acute observer of economic life he was equally aware of the existence of widespread material impoverishment. His chief concern in his economic writings was, therefore, to investigate this paradox of poverty in the midst of abundance and show how it...
might be resolved.

For Owen the realization of economic prosperity for all was obstructed by the tendency, in a competitive market economy, for rapid mechanization to create ‘a most unfavourable disproportion between the demand for and supply of labour’. This resulted in its progressive devaluation which in turn caused a diminution in consumption and a general economic crisis as manufacturers responded to a deficiency of effective demand by reducing output and laying off labour. As Owen phrased it, ‘It is want of a profitable market that alone checks the successful and otherwise beneficial industry of the labouring classes’.

To remove this constraint upon production and to realize the potentialities of industrial development, Owen believed that ‘Human labour [should] acquire its natural and intrinsic value, which would increase as science advanced’, and to secure this Owen argued in such works as his Report to the County of Lanark (1821) that goods should be valued according to the labour time that they embodied and exchanged against labour notes rather than conventional money. Such a socialization of exchange, Owen believed, would give labour its whole product and further ensure that aggregate supply and aggregate demand expanded *pari passu*.

It was these ideas which bore practical fruit in the National Equitable Labour Exchange, where attempts were made to value goods and reward labour in terms of time. As might be expected this institution suffered a speedy demise. However, it was never seen by Owen as more than a stepping stone to his ideal of a ‘new moral world’ of neo-autarkic cooperative communities, where each would contribute to the common stock according to ability and consume according to need. Insulated thus against the exploitation and vagaries of a competitive market economy, material well-being could be assured and the character of man created anew.

Owen's economic writing was only one facet of a more general attempt to construct a science of society – a science which would have both an explanatory and prescriptive power and which could be used to determine the means necessary to transform man from an egotistical, competitive atom into a truly social being. It was this broader intellectual enterprise which enthused and interested British socialist thinkers in the first half of the 19th century, as can be seen, for example, in their redefinition of ‘political’ as ‘social’ or ‘moral’ economy.

Engels in *The Condition of the Working Class in England* (1844) remarked that, ‘English socialism arose with Owen, a manufacturer, and proceeds therefore with great consideration towards the bourgeoisie’, and, undoubtedly, Owen's tendency to stress the socially harmonious future and the ultimate reconcilability of class antagonism, rather than the social hostilities of the present, left its quietistic mark upon Owenite socialism. Yet for socialist writers such as Thompson, Gray and Bray, Owen's real legacy was methodological rather than ideological. What they imbibed from Owen was a particular, social scientific way of approaching the condition of labour rather than any unwillingness to unearth the roots of social antagonism.

Palander, Tord Folkeson (1902–1972)

T. Puu

Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

bonds; choice under uncertainty; duopoly; factor substitution; land use; location theory; monopolistic competition; Palander, T. F.; rent; spatial monopoly; Stockholm School

Article

Palander became an engineer at the Royal College of Technology in Stockholm, before studying economics at Stockholm University. He published his dissertation *Beiträge zur Standortstheorie* (Contributions to Location Theory) in 1935. He was appointed Professor of Economics at the Business School of Gothenburg in 1941 and at Uppsala University in 1947. The dissertation is a standard reference in location theory; it was never published in English, though a Japanese edition was published in 1984.

Chapters III–X of the *Beiträge* contain a very detailed discussion of spatial economics from the classics to recent developments up to the date of Palander's own contribution. The Ricardian and von Thünen land rent theories, the Launhardt–Weber theories of location and market area formation are penetrated, and the spatial facets of Hotelling's and Chamberlin–Robinson's then fresh monopolistic competition theories are for the first time given due regard. Palander aims at an integration of classical location and land use theories with modern developments in general economics. Bringing in profit maximization under price-dependent demand and the possibility of spatial monopoly is one step in this direction. Another is the stress on the importance of factor substitution. Palander is extremely critical of Andreas Predöhl's attempts in this direction. His own planned contribution was withdrawn from the manuscript just before its publication, and the problem first got a satisfactory solution with the contribution by Leon Moses in 1958.

Palander's most original contributions are contained in Chapters XII–XIV. The central theme is to extend the classical models, where transportation is assumed to be along straight lines, to more realistic situations where transport rates are distance dependent, or traffic crosses different media, like land and sea. In the last context, the neat refraction law of traffic was discovered. These contributions set the stage for Martin Beckmann's (1952) continuous model of transportation.
One of the most attractive features of Palander's work is the artwork, which must be considered unsurpassed until the advent of computer graphics. Palander brings graphical analysis combined with simple algebra and analysis to perfection.

Palander remained in the USA as a Rockefeller Fellow during 1936, studying Chamberlin's monopolistic competition theory. His own contributions are a brief abstract in English of a presentation at the Cowles Commission conference at Colorado College 1936 (‘Instability in Competition between Two Sellers’) and an article in Swedish, ‘Konkurrens och marknadsjämvikt vid duopol och oligopol’ (‘Competition and Market Equilibrium in Duopoly and Oligopoly’), published in Ekonomisk Tidskrift (later Scandinavian Journal of Economics) in 1939. Palander's particular interest was the stability of adjustment processes in classical Cournot and similar types of duopoly.

Palander belonged to the informal group of economists called the ‘Stockholm School’ and wrote an extensive critical review of their methods, ‘Stockholmskolan begrepp och metoder’ (1941). Palander's remarks concern in particular the lack of rigorous dynamic analysis.

Palander took a great interest in Keynesian macroeconomics. He edited a translation of the General Theory into Swedish in 1945 (sysselsättningsproblemet), with commentary, and wrote an extensive mathematical and graphical analysis of the work in 1942. This article, in comparison to the similar works by Hicks and Klein, contains a thorough analysis of all the different variants with the relations expressed in monetary, real and wage units.

Palander's later work was mainly pedagogical, and his last research interest concerned monetary theory in connection with choice under uncertainty. He wrote a monograph (in Swedish) on the effects of index bonds upon an inflationary economy in 1957. Among his consultancies the most important was to the Swedish Railway Board on fare tariff policy.

Palgrave, Robert Harry Inglis (1827– 1919)

Murray Milgate
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
Palgrave, R. H. I.; central banking; Palgrave's Dictionary of Political Economy

Article

Palgrave was born in London, the third of four male children of Francis Palgrave and Elizabeth Turner. He was named after Robert Harry Inglis – an Old Tory, Member of Parliament, and a friend of Palgrave's father. Quite incidentally, this R.H. Inglis edited some works by the economist Henry Thornton. Palgrave was denied the formal education provided for his two elder brothers, instead entering the banking business of Gurney & Co. (in which his maternal grandfather had been a partner) in Great Yarmouth at the age of 16. Palgrave himself subsequently became a partner in the bank, and married in 1859 a daughter of Mr George Brightwen, who was related to the Gurney family.

Family

Palgrave's father was born Francis Cohen in 1788, the son of Meyer Cohen, member of the London Stock Exchange during most of the years that the Ricardo's were members. Francis Cohen altered his name to Palgrave in 1823 upon marriage to Elizabeth Turner – Palgrave being Elizabeth Turner's mother's maiden name. She, in turn, was the daughter of Dawson Turner, a partner in the English country bank Gurney & Co. in Great Yarmouth. Sometime during the second decade of the 19th century, Francis Cohen renounced the Jewish faith and embraced the Christian religion in the form of the teachings of the Church of England. He was a medievalist of some repute, publishing The Rise and Progress of the English Commonwealth in 1832, and The History of the Anglo-Saxons in 1837. He was Deputy Keeper of H.M. Public Records, was knighted in 1832, and his literary friends included Macaulay and Henry Hallan (who Palgrave was to quote to moving effect in his editorial preface to the final volume of his Dictionary).

His first son, Francis Turner Palgrave (1824–1897), is still widely known today for his famous Golden Treasury of English Lyrics and Verse, the first edition of which appeared in 1861. He was educated at
Palgrave, Robert Harry Inglis (1827–1919) : The New Palgrave Dictionary of Economics

Charterhouse and Balliol College, Oxford, going up in 1843, and in 1846 acted as assistant private secretary to Gladstone. Between 1850 and 1855 he directed a government teacher training college near Twickenham. Thereafter he was engaged in the Department of Education in London until his retirement in 1884. In 1885 he was elected into the Professorship of Poetry at Oxford (with the support of Alfred Tennyson, whom he had met in his days near Twickenham).

The second son has William Gifford Palgrave (1826–1888), the least ‘typical’ of the family. After Charterhouse and Trinity College, Oxford, he moved to India, becoming a lieutenant in the 8th Bombay Regiment. He soon converted to Roman Catholicism, entered a Jesuit mission in Madras, and was ordained a priest of the Order. He remained as a missionary in India until 1853 when he was recalled to Rome. Later in that same year he went as a missionary to Syria. The Dictionary of National Biography reports that ‘he could and did pass without difficulty for a native of the East’, adding that ‘the often repeated story that he had officiated as Imaum in mosques is without foundation’. When hostilities between the Druse and the Maronite Christians broke out, the Maronites invited him to become their leader – an invitation which it seems he declined. A massacre of Christians in Damascus in June 1881 precipitated his return to Europe. There he reported to Napoleon III on the Syrian situation. This contact led him into an expedition in 1862–3 across the Middle East. This was financed by the French government, to whom he was to ‘report on the state of the Arab attitude’ towards France. Subsequent to this venture he returned to England.

At ‘home’ again, he published his Narrative of a Year’s Journey Through Central and Eastern Asia in 1865. This was the most widely read narrative on that region until the accounts of T.E. Lawrence appeared on the scene. He broke with the Jesuits, and became a diplomat in the service of the British government. He was dispatched to Abyssinia, and then went as consul to St. Thomas in the West Indies in 1873. There followed postings in Manila (1876), Bangkok (1879), and Uruguay (1884). He died in Montevideo on 30 September 1888.

The youngest son, Reginald Francis Douce Palgrave (1829–1904), was Clerk of the House of Commons. He was the only sibling to survive to see the publication of the Dictionary and Palgrave consistently requested Macmillan to forward to him complimentary copies of the work as it appeared.

Works

It is said that ‘as quite a young boy’ Palgrave received from his father a copy of the Wealth of Nations, which he treasured throughout his life. That book seems to exert a power so mysterious that few who take it up and study it seriously have been able to avoid the fate of a career in economics. However, his activities at Gurney & Co. in Great Yarmouth, while immersing him in the daily business of economics, delayed the entry of his name into its literature until 1870, when he received the Statistical Society's Taylor Prize for an essay on local taxation in Britain and Ireland.

The work by which Palgrave's name will be perpetuated is, of course, his Dictionary of Political Economy, one of the finest achievements of Victorian scholarship. Shortly after the publication of its last appendix he was knighted (1909).

Here, we shall consider only his other writings, all of which dealt with some aspect of banking practice or theory. His publications of 1873, 1874 (a and b) and 1877 typify a kind of statistical analysis of central banking, and their results are largely collated and summed up in Bank Rate and the Money Market of 1903. Of this book, Schumpeter commented:
On matters of policy, he opposed bimetallism, opposed the monetary policy of the government in India, pushed for stability in Bank Rate, and was a supporter of the kind of regulations embodied in Peel's Act of 1844. However, in a review of Bagehot's *Lombard Street* (1874b) he formulated clearly the idea that the central bank was effectively an arm of government and thus a vehicle through which governments could effectuate monetary policy. The idea of the Bank of England as an autonomous agency governed only by the legislative provisions of its act of establishment was thereby altered. The new conception which was to take root was of a central bank more familiar nowadays than it was at that time.

In 1877, Palgrave became financial editor at the *Economist*, and on Bagehot's death took over its editorship. He remained there until 1883. He also edited the *Banking Almanac* until his death, and was briefly editor of the *Banker's Magazine* to which he contributed regularly after 1880.

Palgrave was also closely involved in the public affairs of the nation. In 1875 he gave evidence before the House of Commons Select Committee on Banks of Issue (George Goschen being the Committee's economic expert) on behalf of the Country Bankers’ Association, and in 1885 he was a member of the Royal Commission on Depression of Trade and Industry. In the memorandum of evidence submitted to that Commission, Alfred Marshall remarked that he would not cover matters already dealt with in Mr Palgrave's memorandum since he was in broad agreement with that document. It is said that as a boy Palgrave dreamed of becoming a Fellow of the Royal Society – a dream which became reality in 1882, thanks in part to the support he received from Jevons. The latter's correspondence with Palgrave from that period (held in the archives of King's College, Cambridge) speaks both to the modesty of Palgrave and the genuine friendship of which Jevons was capable. There is a postcard from Jevons, dated on the day the names of elected Fellows were published in the *Times*, containing no other communication than the name of its addressee: 'R.H. Inglis Palgrave, F.R.S.'

Palgrave's Dictionary of Political Economy

Murray Milgate
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords

Inglis Palgrave's Dictionary of Political Economy appeared in volume form sequentially in 1894, 1896 and 1899. However, 1894 was not the year in which the Dictionary began publication. Under an earlier publishing plan, subsequently abandoned, a first part of the Dictionary (covering the entries Abatement to Bede) appeared in 1891, followed by two more in the next year (extending the project well into the letter C). Furthermore, 1899 does not accurately represent the completion date of the work. It was not until 1908, when the appendix to the third volume was published, that its publication could be said to have been complete. It took 17 years to effect the publication of the Dictionary – better than 20 years of work if one takes into account the fact that the contractual agreement between Palgrave and Macmillan is dated 1888.

Though the original contract called for a work in two volumes, it seems that this plan was subsequently revised to entail publication in parts, each of 120–130 pages in length, and to appear at quarterly intervals. It was envisaged that the entire work would run to between 12 and 14 parts.

The rationale behind the adoption of this plan seems to have derived from a number of considerations. In the first place, the French Dictionnaire d’économie politique and the German Handwörterbuch der Staatswissenschaften had already been appearing in parts, and Palgrave specifically cited these instances in support to the plan. Closer to home, the Dictionary of National Biography was also appearing in parts at the time, and successfully at that. Commercial considerations exerted due influence. Palgrave argued that ‘each part of the Dictionary, as it comes out, may be expected to be noticed …, each volume would only receive a similar notice’, so that ‘parts will be more frequently [brought] before public notice’. He was also concerned that any delay in commencing publication might allow competitors to beat him to the market.

The fact of sequential publication, whether in parts or in volumes, went hand in hand with sequential
writing and sequential planning. In 1892, after this process had actually begun, Palgrave argued that it brought two substantial externalities – he might receive ‘a good many valuable suggestions and hints’, and he could easily refer contributors to the later parts back to earlier published parts in order to avoid overlap. But there were diseconomies as well. With the prospect of publication extending over four or five years, even if it was kept to a strict schedule, there was a real danger of contributor exhaustion. Perhaps more importantly, there was no way of making adjustments for recent advances, or correcting oversights, or taking advantage of the valuable advice an editor receives, if the relevant material had already gone to press.

The original Dictionary does seem to have suffered some of these disadvantages. Soon after 1899 it was in need of revisions substantial enough to require the printing of separate appendices (published separately at first, and bound in with subsequent reprints). Some of the reasons for this will be touched upon later. What is more, just how exhausted its contributors became during the process can be witnessed in the record of one of the most loyal among their number – F.Y. Edgeworth. In the first volume there were 77 entries from his pen. In the second, the tally had fallen to 38. In the third volume it was down to 17 (in the Higgs edition there are 10 more, mostly addenda to existing entries). Not only did Edgeworth's entries shrink in total number, they shrank in average length as well.

While little concrete detail is readily to hand concerning the editorial practices that Palgrave adopted, there is sufficient evidence available from which to make some fairly confident conjectures. To begin with, it is clear that the list of entries was planned well ahead, despite the more immediate horizons imposed by the choice of sequential publication. In November 1889, for example, before anything had been published, Palgrave reported to Macmillan that he had planned the list of entries down to the letter K. In a letter of 16 March 1892, he reported that he had ‘forwarded a considerable number of articles … in the S’ to the printer. Yet it is equally clear that there was no attempt to generate a list of entries that was in any significant sense ‘complete’ prior to the commissioning of contributors.

Just how Palgrave arrived at the actual entries to be included is not so easily established. It seems to have been a combination of his own ideas, and those of specialist contributors in particular fields. The list of entries classified by contributor to the original Dictionary (compiled by K. Newman and appearing as an appendix of the present work) reveals a pattern whereby certain contributors wrote nearly every entry in a given field. It seems likely that Palgrave simply gave them a free hand to generate the key entries in that field. This probably explains some of the singularities of the pattern of contributions in the original work. How else, for example, might one explain the fact that Mr F.E. Allum of the Royal Mint at Perth, Western Australia, contributed over 100 entries on various media of exchange – from the English Angel to the Japanese Yen. Or that A. Courtois fils contributed a similar number of biographical entries on (mainly) French writers – from the marquis d’Audiffret to Louis François Michel Raymond Wolowski. How free were the contributors’ hands in determining the length of entries is indicated, perhaps, by the fact that M. Courtois fils produced two-and-a-half columns on the obscure Wolowski, and just two on Quesnay.

If the practice of deferring to ‘specialists’ seems to have introduced certain idiosyncrasies, in other cases it bore fruit, that of Edgeworth being exemplary. It is hardly necessary to add that even with his specialists, Palgrave experienced the usual problems of tardiness in the delivery of sacredly promised entries, and of restraining contributors to limits, even if flexible, as to length. On the whole, however, he seems to have handled these with admirable tolerance and forbearance – though at one point he did suggest that Macmillan might consider sending a man round to Robert Giffen’s residence to await on the
delivery of his promised essay on Bagehot (which, as it transpired, he did not obtain) – and with not a little creativity in the re-titling of entries so that they would appear further down the alphabet.

The reaction to the Dictionary can be considered from two rather different perspectives, that of the economics profession itself and that of the market. As to the latter, there were two phases, the first covering the three parts which appeared before the first ‘recognized’ volume in 1894, the second covering the subsequent period.

The first phase was a clear commercial failure. The first part had gone to the printers in June of 1891 and was published that year. Within a few months Palgrave was already alert to its lack of success in the market. In a letter to Macmillan dated 14 March 1892 he expresses himself ‘extremely disappointed to find that the sale of the Dictionary has been so small’. At about the same time, the publishers began to suggest abandoning the existing publishing plan, in favour of a format more like that which actually appeared. Initially, Palgrave held out against these suggestions. But the similarly disappointing sales of the second and third parts, which appeared in 1892, seems to have reconciled Palgrave to a change of plan. In November of that year little sign remains of the vigorous defence he had made of the earlier plan just a year before. Instead he writes: ‘I do not wish myself to suggest a change from parts of volumes, but … as you appear to have this in your mind, I have now planned out the work as far as the next volume would extend, should you desire it be dealt with as a whole’.

The professional reaction to the Dictionary was generally favourable, as might have been expected given the fact that almost all economists of any repute had already endorsed the enterprise by agreeing to contribute. Of course, any encyclopedia is vulnerable to criticism. Why one particular title for an entry, rather than some other? Why include some unimportant subject or author, and neglect other more worthy ones? There was also some critical comment on the work's sequential appearance. Ever a supporter, Edgeworth effectively put paid to this avenue of attack: ‘not even Homer brings forward all his Greeks at once, but makes one the hero of the third, another of the fifth book’ (1892, p. 525).
