Secondly, since the purpose was now to maximize the disposable surplus, it would be in the proprietor's interest to change the forms of leasehold in order to encourage output and increase his returns. In this way, Smith traced the gradual change from the use of slave labour on the land, to the origin of the 'metayer’ system where the tenant had limited property rights, until the whole process finally resulted in the appearance of farmers properly so called ‘who cultivated the land with their own stock, paying a rent certain to the landlord’ (WN, III.ii.14). Smith added that the same process would, over time, tend to lead to an improvement in the conditions of leases, until the tenants could be ‘secured in their possession, for such a term of years as might give them time to recover with profit whatever they should lay out in the further improvement of land. The expensive vanity of the landlord made him willing to accept of this condition ….’ (WN, III.iv.13).

As a result of these two general trends, the great proprietors gradually lost their powers, both judicial and military, until a situation was reached where ‘they became as insignificant as any substantial burgher or tradesman in a city. A regular government was established in the country as well as in the city, nobody having sufficient power to disturb its operations in the one, any more than in the other’ (WN, III.iv.15).

Smith thus associated the decline in the feudal powers of the great proprietors with three general trends, all of which followed on the introduction of commerce and manufactures: the dissipation of their fortunes, the dismissal of their retainers, and the substitution of a cash relationship for the service relationships which had previously existed between the owner of land and those who cultivated it. He
noted elsewhere that ‘the gradual improvements of arts, manufactures, and commerce, the same causes which had destroyed the power of the great barons, destroyed in the same manner, through the greater part of Europe, the whole temporal power of the clergy’ (WN, V.i.g.25).

As a result, an economic system was generated where the disincentives to ‘industry’ had been removed from the agrarian sector, and where both sectors were, for the first time, fully interdependent at the domestic level.

Smith argued in effect that the quantitative development of manufactures based on the cities had eventually produced an important qualitative change in creating the institutions of the exchange economy, that is, of the fourth economic stage. It is in this situation that the drive to better our condition, allied to the insatiable wants of man (referred to in the Theory of Moral Sentiments), provided the maximum possible stimulus to economic growth, and ensured that the gains accruing to town and country were eventually both mutual and reciprocal. As Smith put it:

The great commerce of every civilized society, is that carried on between the inhabitants of the town and those of the country. It consists in the exchange of rude for manufactured produce, either immediately, or by the intervention of money, or of some sort of paper which represents money … The gains of both are mutual and reciprocal, and the division of labour is in this, as in all other cases, advantageous to all the different persons employed in the various occupations into which it is subdivided. (WN, III.i.1)

Such an economic and social structure effectively eliminated the direct dependence of the previous period, in that each productive service now commands a price. While the farmer, tradesman or merchant must depend upon his customers, yet ‘Though in some measure obliged to them all … he is not absolutely dependent upon any one of them’ (WN, III.iv.12). It will be noted that the whole process of historical change involved in the transition from the feudal to the commercial state depended on the activities of individuals who were unconscious of the ultimate end towards which such activities contributed. Or, as Smith put it in reviewing the actions of the proprietors and merchants during the latter stage of the historical process which we have outlined:

A revolution of the greatest importance to the public happiness, was in this manner brought about by two different orders of people, who had not the least intention to serve the public. To gratify the most childish vanity was the sole motive of the great proprietors. The merchants and artificers, much less ridiculous, acted merely from a view to their own interest, and in pursuit of their own pedlar principle of turning a penny wherever a penny was to be got. Neither of them had either knowledge or foresight of that great revolution which the folly of the one, and the industry of the other, was gradually bringing about. (WN, III.iv.17)

Finally it should be noted that while Smith regarded the processes of history as inherently complex, he did nonetheless associate these processes with certain economic, social and constitutional trends. The growth of ‘luxury and commerce’ is represented as the inevitable outcome of normal human drives, and associated with the appearance of new sources of wealth. These new forms of wealth allied to the high
The degree of personal liberty appropriate to the new patterns of dependence also brought with them a new social and political order – a form of ‘constitution’ which was often cited as an explanation for, and in defence of, the English Revolution Settlement. In this way Whig principles could be put on a sound historical basis; a point which is neatly illustrated by John Ramsay of Ochtertyre's comment on Lord Kames's abandonment of his early Jacobite leanings. Ramsay expressed no surprise that Kames should have finally concluded that the Revolution was ‘absolutely necessary’ after ‘studying history and conversing with first rate people’ – no doubt including Smith. Rather similar sentiments were expressed by John Millar when he remarked that ‘When we examine historically the extent of the tory, and of the whig principle, it seems evident, that from the progress of arts and commerce, the former has been continually diminishing, and the latter gaining ground in the same proportion’ (quoted in Skinner, 1996, p. 91). There is little doubt that Smith shared such opinions, or that he rejoiced in a situation where the personal liberty of the subject had been confirmed at the expense of the absolutist pretensions of kings and the power of the old feudal aristocracy.

The latter theme had been elaborated in Hume's essay ‘Of Refinement in the Arts’. Where ‘luxury nourishes commerce and industry’ Hume wrote, ‘the peasants, by a proper cultivation of the land, become rich and independent; while the tradesmen and merchants acquire a share of the property, and draw authority and consideration to that middling rank of men, who are the best and firmest basis of public liberty’ (1985, p. 277). Hume suggested that this development had brought about major constitutional changes, at least in England. The ‘lower house is the support of our popular government; and all the world acknowledges, that it owed its chief influence and consideration to the increase of commerce, which threw such a balance of property into the hands of the commons. How inconsistent then is it to blame so violently a refinement in the arts, and to represent it as the bane of liberty and public spirit!’ (1985, p. 278).

Hume's perception of the interconnection between economic growth and liberty moved Adam Smith to remark of ‘the most illustrious philosopher and historian of the present age’ (WN, V.i.g.3) that: ‘Mr Hume is the only writer who, so far as I know, has hitherto taken notice of it’ (WN, III.iv.4). This interesting but extraordinary statement was never corrected, perhaps as a tribute to Hume's originality.

The model

Smith's account of the origin of the exchange economy suggests that such an economic structure had to be regarded as a model with history. But he also recognized that this particular institutional structure must be associated with a particular set of ‘customs and manners’, to use Hume's phrase. The link here is with the analyses of the TMS and man's desire for approbation. It is a remarkable fact that the judgements offered with regard to the psychology of the ‘economic man’ are to be found in the TMS rather than in the WN.

For Smith, ‘Power and riches appear … then to be, what they are, enormous and operose machines contrived to produce a few trifling conveniences to the body, consisting of springs the most nice and delicate’ (TMS, IV.i.8). But Smith continued to emphasize that the pursuit of wealth is related not only to the desire to acquire the means of purchasing ‘utilities’ but also to the need for status.

From whence, then, arises that emulation which runs through all the different ranks of
men, and what are the advantages which we propose by that great purpose of human life which we call bettering our condition? To be observed, to be attended to, to be taken notice of … are all the advantages which we can propose to derive from it. (TMS, I.iii.2.1)

Smith also suggested that in the modern economy, men tend to admire not only those who have the capacity to enjoy the trappings of wealth, but also the qualities which contribute to that end. Smith recognized that the pursuit of wealth and ‘place’ was a basic human drive which would involve sacrifices which are likely to be supported by the approval of the spectator. The ‘habits of economy, industry, discretion, attention and application of thought, are generally supposed to be cultivated from self-interested motives, and at the same time are apprehended to be very praiseworthy qualities, which deserve the esteem and approbation of everybody’ (TMS, IV.2.8). Smith developed this theme in a passage which was added to the TMS in 1790:

In the steadiness of his industry and frugality, in his steadily sacrificing the ease and enjoyment of the present moment for the probable expectation of the still greater ease and enjoyment of a more distant but more lasting period of time the prudent man is always both supported and rewarded by the entire approbation of the impartial spectator. (TMS, VI.1.11)

The most polished accounts of the emergence of the exchange economy and of the psychology of the ‘economic man’ are to be found, respectively, in the third book of WN and in Part VI of TMS which was added in 1790. Yet both areas of analysis are old and their substance would have been communicated to Smith's students and understood by them to be what they might be seen to be: a preface to the treatment of political economy. It is a subtle argument taken as a whole. Nicholas Phillipson had argued that Smith's ethical theory ‘is redundant outside the context of a commercial society with a complex division of labour’ (1983, pp. 179, 182). John Pocock concluded that:

A crucial step in the emergence of Scottish social theory, is, of course, that elusive phenomenon, the advent of the four stages scheme of history. The progression from hunter to farmer, to merchant offered not only an account of increasing plenty, but a series of stages of increasing division of labour, bringing about in their turn an increasingly complex organisation of both society and personality. (1983, p. 242)

Early economic analysis

Hutcheson and the Lectures

The early analyses of questions relating to political economy are to be found primarily in two documents: the lectures delivered in 1762–63 and the text discovered by Cannan (1896, LJB). Cannan's discovery is the most significant in respect of both date and content. This version is the most complete and provides an invaluable record of Smith's teaching in this branch of his project in the last year of his
The Cannan version yielded two important results.

First, Cannan was able to confirm Smith's debts to Francis Hutcheson. Hutcheson's economic analysis was not presented by him as a separate discourse, but rather woven into the broader fabric of his lectures on jurisprudence. Perhaps it was for this reason that historians of economic thought had rather neglected him. But the situation was transformed as a result of Cannan's work as he first noted that the order of Smith's lectures on ‘expediency’ followed that suggested by Hutcheson, albeit, significantly, in the form of a single discourse. The importance of the connection was noted by Cannan (1896, xxv–xxvi; 1904, xxxvi–xli).

Renewed interest in Hutcheson's economic analysis revealed that it had its own history. It is evident that he admired the work of his immediate predecessor in the Chair of Moral Philosophy, Gerschom Carmichael (1672–1729), and especially his translation of, and commentary on, the works of Pufendorf. In Hutcheson's address to the ‘students of Universities’, the Introduction to Moral Philosophy (1742) is described thus:

The learned will at once discern how much of this compend is taken from the writings of others, from Cicero and Aristotle, and to name no other moderns, from Pufendorf's smaller work, De Officio Hominis et Civis Juxta Legem Naturalem which that worthy and ingenious man the late Professor Gerschom Carmichael of Glasgow, by far the best commentator on that book, has so supplied and corrected that the notes are of much more value than the text. (Taylor, 1965, p. 25)

It is to W.L. Taylor that we are indebted for the reminder that Carmichael and Pufendorf may have shaped Hutcheson's economic ideas, thus indirectly influencing Smith. Taylor concluded that:

The interesting point for the development of economic thought in all this is the very close parallelism between Pufendorf's De Officio and Hutcheson's Introduction to Moral Philosophy. Each man covered almost exactly the same field … The inescapable conclusion is that Francis Hutcheson to over almost in whole, from Carmichael, the economic ideas of Pufendorf. (1965, pp. 28–9)

Undoubtedly, both men followed a particular order of argument. Starting with the division of labour they sought to explain the manner in which disposable surpluses could be maximized, before going on to emphasize the importance of security of property and freedom of choice. This analysis led naturally to the problem of value and hence to the analysis of the role of money. What is distinctive about the analysis is the attention given to value in exchange where both writers emphasized the role of utility and disutility: perceived utility attaching to the commodities to be acquired, and perceived disutility embodied in the labour necessary to create the goods to be exchanged. The distinction between utility anticipated and realized is profoundly striking (Skinner, 1996, ch. 5). This tradition was continued by Smith both in LJ and WN, but with a change of emphasis towards the measurement of value – thus explaining Terence Hutchison's point that Smith retained some of his heritage (1988, p. 199; ch. 11). Cannan's account revealed that in his lectures, Smith was concerned with a system featuring the
activities of agriculture, manufacture and commerce (LJB, p. 210) where these activities are characterized by a division of labour (by sector and process) with the process of exchange facilitated by the use of money. The most polished area of analysis, as in the case of the WN, is that of price theory where Smith deployed his distinctions between ‘market’ and ‘natural’ price in a way which illuminated the processes by virtue of which ‘equilibrium’ positions tended to be attained. Examples such as these refer to particular (‘partial’) cases, but Smith may be said to have added further dimension to the argument by showing an understanding of the fact that the economic system can be seen under a more general aspect (Skinner, 1996, pp. 124–6).

This much is evident in his objection to particular regulations of ‘police’ (policy) on the ground that they distorted the use of resources by breaking what he called the ‘natural balance of industry’ while interfering with the ‘natural connexion of all trades in the stock’ (LJB, pp. 233–4). He concluded: ‘Upon the whole, therefore, it is by far the best police to leave things to their natural course’ (LJB, p. 235).

Smith's understanding of the interdependence of economic phenomena was quite as sophisticated as that of his master. Yet at the same time, it must be noted that his lecture notes do not confirm a clear distinction between factors of production (land, labour, capital) nor between those categories of return which correspond to them (rent, wages, profit). Nor is there any evidence of a macroeconomic model of the system as a whole: a model which Smith first met during his visit to Paris.

Paris, 1700. the Physiocrats

There was a great deal in Physiocratic writing that was to prove unattractive to some, most obviously, perhaps, the doctrine of legal despotism and a political philosophy which envisaged a constitutional monarch modelled upon the Emperor of China.

The attitudes of the disciplines to the teaching of the master, Quesnay, were also a source of aggravation, moving Hume to write to Morellet on the subject of his *Dictionnaire du Commerce*.

> I see that, in your prospectus, you care not to disoblige your economists … But I hope that in your work you will thunder them, and crush them, and pound them, and reduce them to dust and ashes! They are, indeed, the set of men the most chimerical and most arrogant that now exist. I wonder what could engaged our friend, M Turgot, to herd among them.

(Hume, Corr, ii.205)

Ironically, Turgot himself was as deeply opposed to authority and received doctrine as Hume had been. Hume's reaction also found an echo in France. Murray Rothbard has reminded us of an amusing passage in the works of Simon Nicolas Linguet (1736–1794), ridiculing the idea that the Physiocrats were not ‘a cult or sect’:

> Not a sect? You have a rallying cry, banners, a march, a trumpeter (Dupont), a uniform for your books, and a sign like freemasons. Not a sect? One cannot touch one of you but all rush to his aid. You laud and glorify each other, and attack and intimidate your opponents in unmeasured terms. (Rothbard, 1995, p. 377)
Smith himself objected to the fact that Quesnay's disciples followed 'implicitly, and without any sensible variation' the doctrine of the master such as there was 'upon this account little variety in the greater part of their works' (WN, IV.ix.38). But Smith did recognize that the system:

with all its imperfections, is, perhaps the nearest approximation to the truth that has yet been published upon the subject of political economy, and is upon that account well worth the consideration of every man who wishes to examine with attention the principles of that very important science. (IV.ix.38)

Quesnay's purpose was both practical and theoretical. As R.L. Meek has indicated, Quesnay announced his purpose in a letter to Mirabeau which accompanied the first edition of the *Tableau*.

I have tried to construct a fundamental *Tableau* of the economic order for the purpose of displaying expenditure and products in a way which is easy to grasp, and for the purpose of forming a clear opinion about the organisation which the government can bring about. (Meek, 1962, p. 108)

The statement is important in that it confirms the importance of government action in the context of a relatively underdeveloped economy which needed urgent support for the agrarian sector, a reform of the mercantile policies associated with Colbert, and in particular changes in the financial sector and in respect of fiscal policy. But Quesnay's statement also announced a clear understanding of the point that governments can act only on the basis of a knowledge of economic laws. Or, as Meek put it, with pardonable exaggeration:

With the physiocrats, for the first time in the history of economic thought, we find a firm appreciation of the fact that areas of decision open to policy makers in the economic sphere have certain limits, and that a theoretical model of the economy is necessary to define these limits. (1962, p. 370).

The model in question seeks to explore the interrelationships between output, the generation of income, expenditure and consumption – or in Quesnay's words, a 'general system of expenditure, work, gain and consumption' (Meek, 1962, p. 374) which would expose the point that 'the whole magic of a well ordered society is that each man works for others, while believing that he is working for himself’ (Meek, 1962, p. 70). Again, as Meek put it:

In this circle of economic activity, production and consumption appeared as mutually interdependent variables, whose action and interaction in any economic *period*, proceeding according to certain socially determined laws, laid, the basis for a reputation of the process in the next economic period. (Meek, 1962, p. 19)
The model has a deliberately *abstract* quality but also a number of deficiencies. There is no clear analysis of the division of labour, as Smith understood the term, and no analysis of the problem of price determination and the allocation of resources. There is no formal allowance made for profit *at this point* and nor is there a division between capitalists and wage labour – to name but a few issues of importance. But despite these criticisms, what Smith would have found in the ‘Oeconomical Table’ was a *model* of the economic process which represents the working of a macroeconomic process as one which involves a series of withdrawals of commodities (consumption and investment goods) from the market, which is matched in turn by a process of continuous replacement, by virtue of production *in the same time period*, all in the context of a capital-using system. Smith could hardly fail to be struck by this model, or by the transformation effected by Turgot, who, in effect, made good the bulk of the analytical deficiencies in Quesnay's account (Meek, 1973).

That Smith benefited from his examination of the French system taken as a whole was quickly noted by Cannan. In referring to the theories of distribution and to the macro-economic dimension, Cannan noted that:

> When we find that there is no trace of these theories in the *Lectures*, and that in the meantime Adam Smith had been to France … it is difficult to understand, why we should be asked, without any evidence, to refrain from believing that he came under physiocratic influence after and not before or during his Glasgow period. (1904, p. xxxi)

**Economic analysis**

A model of conceptualized reality

The concept of an economy involving a flow of goods and services, and the appreciation of the importance of inter-sectoral dependencies, were familiar in the 18th century. Such themes are dominant features of the work done, for example, by Sir James Steuart and David Hume. But what is distinctive about Smith's work, at least as compared to his *Scottish* contemporaries, is the emphasis given to the importance of *three distinct factors* of production (land, labour, capital) and to the three categories of return (rent, wages, profit) which correspond to them. What is distinctive to the modern eye is the way in which Smith deployed these concepts in providing an account of the flow of goods and services between the sectors involved and between the different socio-economic groups (proprietors of land, capitalists, and wage-labour). The approach is also of interest in that Smith, following the lead of the French *economists*, worked in terms of period analysis – the year was typically chosen, so that the working of the economy is examined within a significant time dimension as well as over a series of time periods. Both versions of the argument emphasize the importance of capital, fixed and circulating.

Smith can be seen to have addressed a series of problems which begin with an analysis of the division of labour, before proceeding to the discussion of value, price and allocation, and thence to the issue of distribution in any one time period and over time.

The analysis offered in the first book enabled Smith to proceed, in WN, Book II, to the discussion of both macro-statics and macro-dynamics, in the context of a model where all magnitudes are dated. What Smith had produced was a model of conceptualized reality which was essentially descriptive, and which was further illustrated by reference into an *analytical* system which, if on occasion subject to ambiguity,
was none the less so organized as to meet the requirements of the Newtonian ideal. The intellectual system was intended to be comprehensive.

Value

Although Smith's model, in its post-Physiocratic form, has several distinct elements, the feature on which he continued to place more emphasis was the division of labour. In terms of the content of the model outlined in previous chapters, a division of labour is of course implied in the existence of distinct sectors or types of productive activity. But Smith also emphasizes the fact that there was specialization by types of employment, and even within each employment. To illustrate the basic point, Smith chose the celebrated example of the pin; a very ‘trifling manufacture’ which none the less required some 18 processes for its completion.

In Smith's hands, the argument was important for two main reasons. First, he was at some pains to point out that the division of labour (by process) helped to explain the relatively high productivity of labour in modern times; a phenomenon which he ascribed to:

1. The increase in ‘dexterity’ which inevitably results from making a single, relatively simple operation ‘the sole employment of the labourer’.
2. The saving of time which would otherwise be lost in ‘passing from one species of work to another’.
3. The associated use of machines which ‘facilitate and abridge labour, and enable one man to do the work of many’ (WN, I.i.5).

He further observed that the existence of specialization (by employment) necessarily involves a high degree of interdependence, in that each separate manufacture tends to rely on the output of other industries for different goods and services. It thus follows that the individual customer who purchases a single commodity must at the same time acquire, in effect, the separate outputs of a ‘great variety of labour’. Smith added:

If we examine … all of these things, and consider what a variety of labour is employed about each of them, we shall be very sensible that without the assistance and co-operation of many thousands, the very meanest person in a civilised country could not be provided, even according to, what we very falsely imagine, the easy and simple manner in which he is commonly accommodated. (WN, I.ii.11)

However, the aspect of this discussion which is most immediately relevant is the light which it throws on the necessity of exchange. As Smith observed, once the division of labour is established, our own labour can supply us with only a very small part of our wants. He thus noted that even in the barter economy the individual can best satisfy the whole range of his needs by exchanging the surplus part of his own production, receiving in return the products of others. Where the division of labour is thoroughly established, it is to be expected that each individual is in a sense dependent on his fellows, and that ‘Every man thus lives by exchanging, or becomes in some measure a merchant’ (I.iv.1).
This observation brought Smith directly to the problem of value where he returned to an area which, interestingly, had become more a feature of Hutcheson's lectures than of his own. Here it is noteworthy that he employed the analytical (as distinct from the historical) device of the barter economy. However, despite the attempt to be ‘perspicuous’, these passages remain somewhat difficult largely because Smith uses a single term in handling two distinct but related problems.

The word VALUE, it is to be observed, has two different meanings, and sometimes expresses the utility of some particular object, and sometimes the power of purchasing other goods which the possession of that object conveys. (WN, I.iv.13).

The first problem concerns the forces which determine the rate at which one good, or units of one good, may be exchanged for another; the second is concerned basically with the means by which we can measure the value of the total stock of goods created by an individual, and which is used in exchange for others. We may take these issues in turn.

As regards the rate of exchange, Smith isolated two relevant factors: the usefulness of the good to be acquired, and the ‘cost’ incurred in creating the commodity to be given up. The first of the relevant relationships is obviously that which exists between ‘usefulness’ and value. The elements of Smith's argument become apparent in his handling of the famous paradox, namely that:

The things which have the greatest value in use have frequently little or no value in exchange; and, on the contrary, those which have the greatest value in exchange have frequently little or no value in use. Nothing is more useful than water: but it will scarce purchase anything. A diamond, on the contrary, has scarce any value in use; but a great quantity of other goods may frequently be had in exchange for it. (WN, I.iv.13)

The solution to this paradox can be stated in two stages, where the first involves an explanation as to why two such goods have some value, and the second an explanation as to why the two goods have different values.

Smith's handling of the first part of the problem is based on his recognition of the fact that both goods are considered to be ‘useful’ although noting that the ‘utilities’ of each are qualitatively different. In the former case (water) we place a value on the good because we can use it in a practical way, while in the latter (diamonds) we place a value on the good because it appeals to our ‘senses’, an appeal which, as Smith observed, constitutes a ground ‘of preference’, or ‘source of pleasure’. He concluded:

The demand for the precious stones arises altogether from their beauty. They are of no use, but ornaments. (WN, I.xi.c.32)

The utilities of the two goods thus emerge as being qualitatively different, although the significant point is seen to be that both have some value precisely because they represent sources of satisfaction to the individual.

Smith was then left with the second part of the initial problem, namely the explanation as to why the two goods have different values. Here again, the answer provided, while simple, is clear, embodying the
argument that merit (value) is a function of scarcity. As Smith put it: ‘the merit of an object which is in any degree useful or beautiful, is greatly enhanced by its scarcity’ (WN, I.xi.c.31). Even more specifically he remarked:

Cheapness is in fact the same thing with plenty. It is only on account of the plenty of water that it is so cheap as to be got for the lifting, and on account of the scarcity of diamonds (for their real use seems not yet to be discovered) that they are so dear. (LJB, pp. 105–6)

Smith introduced the second major element in the problem by observing that the rate at which the individual will exchange one good for another must be affected not only by the utility of the good to be acquired, but also by the ‘toil and trouble’ involved in creating the good exchanged. In this connection he recognized that in acquiring the means of exchange (goods in the barter case), the individual must undergo the ‘fatigues’ of labour and thus ‘lay down’ a ‘portion of his ease, his liberty, and his happiness’ (WN, I.v.7).

In dealing with the rate of exchange, Smith may be seen to have placed most emphasis on the supply side of the problem, and explicitly argued that in the case of the barter economy ‘the proportion between the quantities of labour necessary for acquiring different objects seems to be the only circumstance which can afford any rule for exchanging them for one another’ (WN, I.vi.1). Thus he suggested that if it takes twice the labour to kill a beaver as it does to kill a deer then ‘one beaver should naturally exchange for … two deer’; an argument which may owe something to Hutcheson's emphasis on labour embodied.

Smith left the analysis in this form although it will be apparent that the rate of exchange which he specified could only obtain where the perceived ratios of the utilities and disutilities are acceptable to the respective hunters. These are of course subjective judgements whose presence helps to confirm Cannan's opinion that the ‘germ’ of the WN is to be found in Hutcheson's treatment of value.

This is one way of looking at the problem of exchange value, which clearly shows a parallel with Hutcheson, but Smith seems to have treated it, not as an end in itself, but as a means of elucidating those factors which govern the value of the whole stock of goods which the individual creates, and which he proposes to use in exchange. It is of course the presence of this argument in the WN which helps to confirm Taylor's judgement to the effect that the treatment of value was dominated by a concern with the measurement of welfare. Looking at the problem in this way, Smith went on to argue that:

The value of any commodity … to the person who possesses it, and who means not to use or consume it himself, but to exchange it for other commodities, is equal to the quantity of labour which it enables him to purchase or command. Labour, therefore, is the real measure of the exchangeable value of all commodities. (WN, I.v.1)

Smith's meaning becomes clear when he remarks that the value of a stock of goods must always be in proportion to ‘the quantity … of other men's labour, or what is the same thing, of the produce of other men's labour, which it enables him to purchase or command. The exchangeable value of every thing must always be precisely equal to the extent of this power’ (WN, I.v.3). In other words, Smith is here arguing that the real value of the goods which the workman has to dispose of (in effect his income) must be measured by the quantity of goods (expressed in terms of labour units) which he can command, and
which he receives once the whole volume of (separate) exchanges has taken place. As Smith observed, a clear difference between the barter and modern economies is to be found in the fact that, while in the former, goods are exchanged for goods, in the latter, goods are exchanged for a sum of money, which may then be expended in purchasing other goods. Under such circumstances the individual, as Smith saw, very naturally estimates the value of his receipts (received in return for undergoing the ‘fatigues’ of labour) in terms of money, rather than in terms of the quantity of goods he can acquire by virtue of his expenditure. However, Smith was at some pains to insist that the real measure of welfare (that is, our ability to satisfy our wants) was to be found in ‘the money’s worth’ rather than the money, where the former is determined by the quantity of products (labour ‘commanded’) which either individuals or groups can purchase. On this basis, Smith went on to distinguish between the nominal and the real value of income, pointing out that if the three original sources of (monetary) revenue in modern times are wages, rent and profit, then the real value of each must ultimately be measured ‘by the quantity of labour which they can, each of them, purchase or command’ (WN, I.vi.9).

Price

Smith regarded rent, wages and profit as the types of return payable to the three ‘great constituent orders’ of society, and as the price paid for the use of the factors of production. The revenues which accrue to individuals and groups in society, and which permit them to purchase commodities, thus appear to be costs incurred by those who create commodities. These points were made quite explicitly by Smith when he remarked:

As the price or exchangeable value of every particular commodity, taken separately, resolves itself into some one or other or all of those three parts; so that of all the commodities which compose the whole annual produce of the labour of every country, taken complexly, must resolve itself into the same three parts, and be parcelled out among different inhabitants of the country, either as the wages of their labour, the profits of their stock, or the rent of their land. (WN, I.vi.17)

This argument obviously raises the problem of price and its determinants. To begin with, Smith assumed the existence of given ‘ordinary or average’ rates of wages, profit and rent; rates which may be said to prevail within any given society or neighbourhood, during any given time period. This assumption is of considerable importance, for two main reasons. First, it indicates that in dealing with the problem of price, Smith was working in terms of a given (stable) level of aggregate demand for them. Secondly, the assumption of given rates of return is important in that these rates determine the supply price of commodities. With these two points forming Smith's major premises, he proceeded to examine the determinants of price, and to produce a discussion which seems to involve two distinct, but related, problems. First, Smith set out to explain the forces which determine the prices of particular commodities. Secondly, he would appear to have used the above analysis as a means of explaining the phenomenon of general interdependence, and thus those forces which determine the manner in which a given stock of factors of production is allocated between different uses or employments.
In dealing with the first aspect of the problem, Smith implicitly examines the case of a single commodity manufactured by a number of sellers, opening the analysis by establishing a distinction between ‘natural’ and ‘market’ price. *Natural price* is now defined as that amount which is ‘neither more nor less than what is sufficient to pay the rent of the land, the wages of labour, and the profits of the stock … according to their natural rates’ (WN, I.vii.4). In other words, where natural price prevails, the seller is just able to cover his costs of production, including a margin for ‘ordinary or average’ profit. By contrast, *market price* is defined as that price which may prevail at any given point in time, being regulated ‘by the proportion between the quantity which is actually brought to market, and the demand of those who are willing to pay the natural price of the commodity’, the ‘effectual demanders’ (WN I. vii.8). These two ‘prices’ are inter-related, the essential point being that while in the short run the market and natural prices may diverge, in the long run they will tend to coincide. If for example, the quantity offered by the sellers was less than that which the consumers were willing to take at a particular (natural) price, the consequence would be a competition among *consumers* to procure some of a limited stock. The price would then rise above the natural price, and the rewards to factors (notably wages and profit in the short run) would diverge from the natural rates, leading to an influx of resources, and an expansion in the supply of the commodity, thus *tending* towards a return to a position of equilibrium. In making the latter point, Smith took note of the fact that in some cases demand could be postponed to another time period, while in others (for example, perishable necessaries) it could not. In the second case, where supply exceeds demand, market prices will sink and with them rates of factor payment until factors leave the employment and the supply of commodities is thus reduced. Here again the competition between *suppliers* to rid themselves of excess stock will be affected by the nature of the commodity (durable or perishable). It will be noted that Smith makes allowance for interrelated adjustments in commodity and factor prices, that he makes due allowance for competition *between and among* buyers and sellers, while noting the distinction between durable and perishable goods. Smith also observed that the result attained, namely that commodities in the long run are sold at their cost of production, can only hold good where there is perfect liberty (as distinct from perfect competition). The cost of production solution is, in short, only to be expected where free competition prevails.

The first stage of the discussion established that in the case of any one commodity, equilibrium will tend to be attained where the good is sold at its natural price, and where each of the relevant factors is paid for at its natural rate. Under these circumstances, equilibrium obtains precisely because there can be no tendency for resources to increase or decrease in this particular type of employment. Now it is evident that if this process, and this result, holds good for all commodities taken separately, it must also apply to all commodities ‘taken complexly’, at least where a competitive situation prevails. That is, where the conditions which form the assumptions of the competitive case are satisfied *over the whole economy*, a position of equilibrium will tend to be attained where each different type of good is sold at its natural price, and where each factor in each employment is paid at its natural rate. The economy can then be said to be in a position of ‘balance’, since where the above conditions are satisfied there can be no tendency to move resources within or between employments. Where the necessary conditions are not satisfied (for example, as a result of changes in tastes) they will naturally tend to be re-established as a result of simultaneous adjustments in the factor *and* commodity markets. It will be observed that departure from, and re-attainment of, a position of equilibrium depends upon the essentially self-interested actions and reactions of consumers and producers. Smith's treatment of price
and allocation thus provides one of the best examples of his emphasis on ‘interdependence’ and one of the most dramatic applications of his analogy of the Invisible Hand.

While Smith certainly conceived of ‘balance’ in terms of a situation where there was no tendency for resources to move between employments, he also recognized that a position of ‘balance’ need not involve an equality between monetary rates of return. The point follows directly from Smith's recognition of the fact that employments differ qualitatively and that such differences may serve to explain why, even in a position of ‘balance’, different money rates prevail. As Smith put it, ‘certain circumstances in the employments themselves … either really, or at least in the imaginations of men, make up for a small pecuniary gain in some, and counter-balance a great one in others’ (WN, I.x.a.2).

Thus, for example, he noted that money wage rates would tend to vary between different types of employment according to the difficulty of learning the trade, the constancy of employment, and the degree of trust involved. In the same way he observed that both wages and profit would vary with the agreeableness of the work, the cost of training, and the probability of success in particular fields. In short, he was suggesting that money rates of return would tend to equality within employments of similar types, so that over the whole economy the relevant ‘balance’ would be one involving net advantages.

Before passing to the next stage of the argument it may be useful to make two points both of which refer to the TMS while at the same time bearing upon the present discussions of the allocative mechanism. The treatment of the doctrine of net advantages is connected to the argument advanced in TMS to the effect that men are motivated by the desire to be approved of. In the present context the arguments suggest that where a profession is widely admired, public approbation may become part of the reward. On the other hand, Smith's analysis suggests that men may only be induced to enter and to remain in particular professions if public disapprobation is compensated by an appropriate monetary reward (the trades of the butcher and the inn-keeper are described as ‘odious’).

### Distribution

As we have seen, Smith's analysis of price and its determinants was built upon the assumption of given rates of factor payment of the kind that could prevail in a given time period – say one year. Briefly stated, the argument has three features: Smith attempts to explain why a particular form of return is paid to a particular factor of production (labour, capital and land); the nature of those forces which determine the rates of factor payment which prevail at a particular point in time, and finally, those forces which explain trends in factor payment over long periods of time.

**Wages:** Smith observed that payment for the factor labour is paid for by those classes which require the services involved. The process of wage determination in a *given time period* will then depend on the relative bargaining position of two groups (labour and entrepreneurs) in a situation where the legal advantages typically lay with the ‘masters’. Where labour is scarce to compared with the demand for it, wage rates will tend to be relatively high; relatively low in the opposite case. Smith was thus able to argue that wage rates would be relatively high or low depending on the size of the working population and on the size of the capital stock destined for the employment of the factor (the wages fund). Wage rates may also be relatively high or low depending on the current definition of the subsistence wage, where the latter is defined as a level sufficient to sustain a constant level of population (I.viii.15). The argument leads on to the issue of *long-term adjustment*; Smith's position being that where the wage rate
is below the subsistence level, population must contract, and where sustained above this level over a period of time, population must expand – the more typical case in the circumstances of, for example, Great Britain and the North American colonies.

In the context of the relatively short run it follows that wage rates may be equal to, above or below the subsistence rate and that the rates paid are related to the size of the working population and the size of the wages fund.

**Profit**: Smith did not consider that this form of return was payable for the work of ‘inspection and direction’ but rather as the reward accruing to those entrepreneurs who risked their capital in combining this factor with others, such as labour and land. The emphasis upon risk is to be noted.

At least as a broad generalization Smith felt able to argue that at *a given point* in time, the rate of profit prevailing would be determined by the capital stock available, taken in conjunction with the volume of business to be transacted by it. But Smith made an important qualification to this statement in arguing that even where the quantity of stock (capital) remains the same, the rate of profit will be related to the prevailing wage rate.

In the long run, however, Smith suggested that the rate of profit would tend to fall, thus establishing a proposition which was to have enduring vitality. Over time, Smith contended that the rate of profit would tend to decline, partly in consequence of an increase in the capital stock, and partly as a result of the increasing difficulty of finding ‘a profitable method of employing any new capital’. He continued:

> When the stocks of many rich merchants are turned into the same trade, their mutual competition naturally tends to lower its profit, and when there is a like increase of stock in all the different trades carried on in the same society, the same competition must produce the same effect in them all. (I.xi.2)

It then follows that the ‘diminution of profit is the natural effect of prosperity’ (I.x.10).

**Rent**: is formally defined as the ‘price paid for the use of land’ (I.xi.a.1). Looked at this way, Smith made a point which is reminiscent of the French economists, in arguing that rent constitutes a surplus in the sense that it accrues to the owner of land independently of any effort made by him (I.xi.8) and that rent payments are generally the highest that can ‘be got in the actual circumstances of the land’ (I.xi.a.1). The reference to actual circumstances is important since Smith recognized that rent would vary both with the fertility and the situation of the land.

The analysis serves to suggest that at *any point in time*, or during any annual period, rent payments will be related to the stock of land actually in use where the latter is in turn related to the level of population. The argument also indicates that rent payments will be related not only to the fertility of the land and its situation, but also to the prevailing rates of profit and wages – another reminder of the interdependence of the different rates of return (I.xi.a.8).

In the long run, Smith suggested that rent payments in the aggregate would tend to increase owing to the increased use of the available stock of land (I.xi.2). He added that the real value of the landlord's receipts would also increase over time since all ‘those improvements in the productive powers of labour, which tend directly to reduce the real price of manufactures, tend indirectly to raise the real rent of land’ (I.xi.4).

The argument just reviewed thus has a short- and long-run dimension. Smith was concerned with long-run trends in rates of return which, as in the short-run case, are interrelated. Thus Smith suggests that profits will decline as the size of the capital stock increases, that high rates of accumulation of capital
will generate high market wage rates, leading to an increase in the level of population and in land use. But so far no explanation has been offered as to the source of the crucial increase in capital; a gap which was to be filled in the analyses of Book II.

Macroeconomics

Smith's analysis of the ‘circular flow’ may be seen as a direct development of certain results already stated in connection with the theory of price. To begin with, it will be recalled that costs of production are incurred by those who create commodities, thus providing individuals with the means of exchange. It therefore follows that if the price of each good in a position of equilibrium comprehends payments made for rent, wages and profit, according to their natural rates, then ‘it must be so with regard to all the commodities which compose the whole annual produce of the land and labour of every country, taken complexly’ (WN, II.i.ii.2). On this basis, Smith concluded that ‘The whole price or exchangeable value of that annual produce, must resolve itself into the same three parts, and be parcelled out among the different inhabitants’ (WN, II.i.ii.2). If we ignore the problem of distribution (that is of a given level of income between rent, wages and profit), the result which Smith was endeavouring to establish may be stated to involve a relationship between aggregate output and aggregate income. In his own words, ‘The gross revenue of all the inhabitants of a great country, comprehends the whole annual produce of their land and labour’ (WN, II.i.ii.5).

It will be evident that a particular level of income, created by a particular level of aggregate output, represents that power to purchase goods which is available to all the members of ‘a great society’. Smith then went on to observe that this level of purchasing power would be divided into two funds, consumption and saving. In fact, Smith offered no formal explanation of the forces which would determine the actual distribution of aggregate income or purchasing power between these two uses, at any particular point in time. He did, however, suggest that proprietors and labourers would tend to devote a high proportion of their income to consumption, the latter by virtue of the size of their receipts in relation to their basic needs, and the former by virtue of the habits of ‘expence’ associated with that class. The problem of balancing future against present enjoyments thus appeared to be mainly relevant for the entrepreneurial groups; groups whose functions and objectives dispose them to frugality, at least while actively engaged in the pursuit of fortune.

But Smith did clarify the problems here considered from the standpoint of expenditure. For example, he noted that the proportion of annual income for consumption, taking all groups ‘complexly’, would be used to purchase commodities which were either perishable or durable in character. He also noted that this type of expenditure could involve the purchase of services; services of kind which do not directly contribute to the annual output of commodities in physical terms and which thus cannot be said to contribute to the level of income associated with it. Smith formally described such labour as ‘unproductive’, but did not deny that such services were useful. With regard to savings Smith identified two sources and two uses. For example, he identified the agrarian, trading, and manufacturing interests as groups wherein ‘the owners themselves employ their own capitals’ (WN, II.iv.5), as distinct from the monied interest who may lend either for the purpose of consumption or of production.

Smith went on to argue that the undertaker or entrepreneur, engaged in agriculture, manufacture or trade could employ their own or borrowed resources for productive purposes, and divided their capitals into two categories both of which are reminiscent of Physiocratic teaching. Fixed capital was defined as that...
portion of savings used to purchase ‘useful machines’ or to improve, for example, the productive powers of land, the characteristic feature being that goods are created, and profits ultimately acquired, by using and retaining possession of the investment goods involved. Circulating capital was defined as that portion of savings used to purchase investment goods other than ‘fixed implements’, such as labour power or raw materials, the characteristic feature being that goods are produced through temporarily ‘parting with’ the funds so used. Smith made three points in the context of this discussion:

1. ‘Every fixed capital is both originally derived from, and requires to be continually supported by, a circulating capital’ (WN, II.i.24);
2. ‘No fixed capital can yield any revenue but by means of a circulating capital (WN, II.i.25),
while in addition
3. ‘different occupations require very different proportions between the fixed and circulating capitals employed in them’ (WN, II.i.6).

Macroeconomics (II)

While these points are important of themselves, they were to gain further significance when Smith moved to the next stage of his argument: the development of his version of the ‘circular flow’ where, again following the Physiocratic lead, he examined the functioning of the system in a given time period (such as a year). Taking the economic system as a whole, Smith suggested that the total stock of society could be divided into three categories:

There is, first, that part of the total stock which is reserved for immediate consumption, and which is held by all consumers (capitalists, labour and proprietors) reflecting purchases made in previous time periods. The characteristic feature of this part of the total stock is that it affords no revenue to its possessors since it consists in ‘the stock of foods, clothes, household furniture, etc. which have been purchased by their proper consumers, but which are not yet entirely consumed’ (WN, II.i.12).

Secondly, there is that part of the total stock which may be described as ‘fixed capital’ and which will be distributed between the various groups in society. This part of the stock, Smith suggested, is composed of the ‘useful machines’ purchased in preceding periods but currently held by the undertakers engaged in manufacture; the quantity of useful buildings and of ‘improved land’ in the possession of the ‘capitalist’ farmers and the proprietors, together with the ‘acquired and useful abilities’ of all the inhabitants (WN, II.i.13–17); that is, human capital.

Thirdly, there is that part of the total stock which may be described as ‘circulating capital’ and which again has several components, these being:

1. The quantity of money necessary to carry on the process of circulation. In this connection Smith observed that ‘The sole use of money is to circulate consumable goods. By means of it, provisions, materials, and finished work, are bought and sold, and distributed to their proper consumers. The quantity of money, therefore, which can be annually employed in any country must be determined by the value of the consumable goods annually circulated within it’ (WN, II. iii.23).
2. The stock of provisions and other agricultural products which are available for sale during the current period, but which are still in the hands of either the farmers or merchants.
3. The stock of raw materials and work in progress, which is held by merchants, undertakers, or those capitalists engaged in the agricultural sector (including mining, and so on).

4. The stock of manufactured goods (consumption and investment goods) created during the previous period, but which remain in the hands of undertakers and merchants at the beginning of the period examined (WN, II.i.19–22).

The logic of the process can be best represented by artificially separating the activities involved much in the manner of the Physiocratic model with which Smith was familiar. Let us suppose that at the beginning of the time period in question, the major capitalist groups possess the total net receipts earned from the sale of products in the previous period, and that the undertakers engaged in agriculture open by transmitting the total rent due to the proprietors of land, for the current use of that factor. The income thus provided will enable the proprietors to make the necessary purchases of consumption (and investment) goods in the current period, thus contributing to reduce the stocks of such goods with which the undertakers and merchants began the period. Secondly, let us assume that the undertakers engaged in both sectors, together with the merchant groups, transmit to wage labour the content of the wages fund, thus providing this socio-economic class with an income which can be used in the current period. It is worth noting in this connection that the capitalist groups transmit a fund to wage labour which formed a part of their savings, providing by this means an income which is available for current consumption. Thirdly, the undertakers engaged in agriculture and manufactures will make purchases of consumption and investment goods from each other, through the medium of retail and wholesale merchants, thus generating a series of expenditures linking the two major sectors. Finally, the process of circulation may be seen to be completed by the purchases made by individual undertakers within their own sectors. Once again these purchases will include consumption and investment goods, thus contributing still further to reduce the stocks of commodities which were available for sale when the period under examination began, and which formed part of the circulating capital of the society in question.

Given these points, we can represent the working of the system in terms of a series of flows whereby money income, accruing in the form of rent, wages and profit, is exchanged for commodities in such a way as to involve a series of withdrawals from the ‘circulating’ capital of society. As Smith pointed out, the consumption goods withdrawn from the existing stock may be entirely used up within the current period, used to increase the stock ‘reserved for immediate consumption’, or to replace the more durable goods, for example, furniture or clothes, which had reached the end of their lives in the course of the same period. Similarly, the undertakers, as a result of their purchases, may add to their stocks of raw materials and/or their fixed capital, or replace the machines which had finally worn out in the current period, together with the materials used up as a result of current productive activity. Looked at in this way, the ‘circular flow’ could be seen to involve purchases which take goods from the circulating capital of society, which is in turn matched by a continuous process of replacement by virtue of current production of materials and finished goods – where both types of production require the use of the fixed and circulating capitals of individual entrepreneurs. It is an essential part of Smith's argument that all available resources will normally be used:

In all countries where there is tolerable security, every man of common understanding will endeavour to employ whatever stock he can command in procuring either present enjoyment or future profit. If it is employed in procuring present enjoyment, it is a stock
Smith elaborated on this argument in drawing attention to the point that the differing ways in which the entrepreneurial classes employ their capitals were interdependent. The point is reminiscent of Turgot:

A capital may be employed in four different ways: either, first, in procuring the rude produce annually required for the use and consumption of the society; or, secondly, in manufacturing and preparing that rude produce for immediate use and consumption; or, thirdly, in transporting either the rude produce from the places where they abound to those where they are wanted; or, lastly, in dividing particular portions of either into such small parcels as suit the occasional demands of those who want them. (WN, II.v.1).

Macroeconomics (III). the sources of growth

In choosing to examine the working of the economy during a given time period such as a year, Smith gave his model a broadly short-run character although it is obviously one which included a time dimension. At the same time Smith did not seek to formulate equilibrium conditions (as Quesnay had done) for the model, at least in the sense that he did not try to develop an argument which used specified assumptions of a quantitative kind as a means of showing the conditions which must be satisfied before the following time period could open under conditions identical to those prevailing in the period actually examined.

Nor in dealing with the ‘flow’ did Smith suggest that the level of output attained during any given period would be exactly sufficient to replace the goods used up during its course. On the contrary, he argued that output levels attained in any year would be likely to exceed previous levels: an important reminder that Smith's predominant concern was with economic growth. In this connection, Smith noted that the ‘annual produce of the land and labour of any nation can be increased in its value by no other means, but by increasing either the number of its productive labourers, or the productive power of those labourers who had before been employed’ (WN, II.iii.32). Smith also observed that both the above sources of increased output required an ‘additional capital’ devoted either to increasing the size of the wages fund or to the purchase of ‘machines and instruments which facilitate and abridge labour’; an additional capital which can only be acquired through net savings.

By what a frugal man annually saves, he not only affords maintenance to an additional number of productive hands, for that or the ensuing year, but like the founder of a public workhouse, he establishes as it were a perpetual fund for the maintenance of an equal number in all times to come. (WN, II.iii.19)
It will be observed that net savings attained during the course of a single annual period will lead to higher output and income, where the latter becomes available during the course of the period examined. The argument can be extended from this point, in that higher levels of output and income attained in any one year make it possible to reach still higher levels of savings and investment in subsequent years, thus generating further increases in output and income. Once started, the process of capital accumulation and thus economic growth may be seen as self-generating, indicating that Smith's flow is to be regarded as spiral rather than as a circle of given dimensions. This indeed is the burden of Smith's argument in Book II; a fact which helps to explain some of its recurrent themes.

First, Smith frequently argued that net savings will always be possible during each annual period:

Whatever a person saves from his revenue he adds to his capital, and either employs it himself in maintaining an additional number of productive hands, or enables some other person to do so, by lending it to him for an interest, that is, for a share of the profits. As the capital of an individual can be increased only by what he saves from his annual revenue or his annual gains, so the capital of a society, which is the same with that of all the individuals who compose it, can be increased only in the same manner. (WN, II.ii.15)

Secondly, Smith emphasized that:

Parsimony, by increasing the fund which is destined for the maintenance of productive hands, tends to increase the number of those whose labour added to the value of the subject upon which it is bestowed. It tends therefore to increase the exchangeable value of the land and labour of the country. It puts into motion an additional quantity of industry, which given an added value to the annual produce. (WN, II, iii.18)

Smith's basic theme is that economic growth depends upon the accumulation of capital, and he went on from this point to draw attention to those factors which affect its rate. In this connection he noted a number of issues:

1. The incidence of commercial failure since ‘every injudicious project in agriculture, mines, fisheries, trade or manufactures, tends to diminish the funds destined for the maintenance of productive labour’ (II.iii.26).
2. The cost of factors needed to maintain productive assets in a state of normal efficiency (II.ii.7).
3. The area of investment to which a specific injection of capital was applied – it being Smith's contention, for example, that agriculture would support a great quantity of productive labour even than manufactures (see. for example, WN, II.v).
4. The extent to which resources are devoted to the purchase of productive as distinct from unproductive labour. Productive labour for Smith involves the creation of commodities or ‘fixed subjects or vendible commodities’ which may be either investment or consumption goods and which contribute directly to the generation of income. Other forms of labour are described as unproductive although Smith did not deny that such services are useful. For example, he pointed out that the services of artists have a value to those who wish to pay for them. In the same way
the services provided by governments are essential to the well-being of society. Yet all such services are by definition unproductive:

The sovereign … with all the officers both of justice and war who serve under him, the whole army and navy, are unproductive labourers. They are the servants of the public, and are maintained by a part of the annual produce of the industry of other people. (II.iii.2)

It therefore follows that the rate of growth will be affected especially by the size of the government sector. Smith concluded:

According … a smaller or great proportion …is in any one year employed in maintaining unproductive hands, the more in the one case and the less in the other will remain for productive, and next years produce will be greater or smaller accordingly. (II.iii.3)

Policy

Smith's analytical apparatus, allied to his judgement with respect to the probable trends of the economy, led him to advance the claims of economic liberty; claims which had already featured in LJ and which date back to his days in Edinburgh (Stewart, IV.25). The argument is repeated in WN, where Smith called upon the sovereign to discharge himself from a duty:

in the attempting to perform which he must always be exposed to innumerable delusions, and for the proper performance of which no human wisdom or knowledge could ever be sufficient; the duty of superintending the industry of private people, and of directing it towards the employments most suitable to the interests of the society. (WN, IV.ix.51)

The statement is familiar, yet conceals a point of great significance; namely, that while the institutions of the exchange economy are consistent with the emergence of personal freedom (for example, under the law), they are not of themselves sufficient to establish what Smith described as the ‘system of natural liberty’ (WN, IV.ix.51). In fact, one of the most important functions of government is that of identifying and removing impediments to the effective working of the economy. Smith drew attention, for example, to the adverse effects of the statute of apprenticeship, and of corporate privileges. Regulations of this kind were criticized on the ground that they were both impolitic and unjust: unjust in that controls over qualification for entry to a trade were a violation ‘of this most sacred property which every man has in his own labour’ (WN, I.x.c.12) and impolitic in that such regulations are not of themselves sufficient to guarantee competence. But Smith particularly emphasized that the regulations in question would adversely affect the working of the market mechanism. The ‘statute of apprenticeship obstructs the free circulation of labour from one employment to another, even in the same place. The exclusive privileges of corporations obstruct it from one place to another, even in the same employment’ (WN, I.x.c.42). He also commented on the problems presented by the Poor Laws and the Laws of Settlement (WN, IV. ii.42), which further restricted the free movement of labour from one geographical location to another. Smith objected to positions of privilege, such as monopoly power, which he regarded as creations of the
civil law. The institution was again represented as impolitic and unjust: unjust in that a monopoly position is one of privilege and advantage, and therefore ‘contrary to that justice and equality of treatment which the sovereign owes to all the different orders of his subjects’, impolitic in that the prices at which goods so controlled are sold are ‘upon even occasion the highest that can be got’ (WN, I. vii.27). He added that monopoly is ‘a great enemy to good management’ (WN, I.xi.b.5) and that the institution had the additional defect of restricting the flow of capital to the trades affected as a result of the legal barriers to entry which were involved.

It is useful to distinguish Smith's objection to monopoly from his criticism of one expression of it; namely, the mercantile system of regulation which he described as the ‘modern system’ of policy, best understood ‘in our own country and in our own times’ (WN, IV.2). Smith asserted that mercantile policy aimed to secure a positive balance of trade through the control of exports and imports, a policy whose ‘logic’ was best expressed in terms of the Regulating Acts of Trade and Navigation, which currently determined the pattern of trade between Great Britain and her colonies and which were designed to create in effect a self-sufficient Atlantic Economic Community.

Smith objected to current policies of the type described on the ground that they artificially restricted the market and thus damaged opportunities for economic growth. It was Smith's contention that such policies were liable to that general objection which may be made to all the different expedients of the mercantile system, ‘the objection of forcing some part of the industry of the country into a channel less advantageous than that in which it would run of its own accord’ (WN, IV.v.a.24). In WN Smith placed more emphasis on interference with the allocative mechanism than he had done in LJ, where greater attention had been given to the inconsistency which was involved in seeking a positive balance of trade, an argument which relied heavily on Hume's analysis of the specie flow.

While it is difficult to judge the extent to which the claim for economic liberty explains the contemporary reception of WN, it may have been a major factor, at least in Britain (Schumpeter, 1954, p. 185). There can be no doubt that later generations found Smith's argument (and rhetoric) attractive. The celebrations to mark the 50th anniversary of the book showed a wide and continuing acceptance of the doctrines of free trade. In 1876, at a dinner held by the Political Economy Club to mark the centenary of WN, one speaker identified free trade as the most important consequence of the work done by ‘this simple Glasgow professor’, and predicted that

> there will be what may be called a large negative development of Political Economy tending to produce an important beneficial effect; and that is, such a development of Political Economy as will reduce the functions of government within a smaller and smaller compass. (Black, 1976, p. 51)

This view still commands wide contemporary support. There can be no argument with Jacob Viner's contention that ‘Smith in general believed that there was, to say the least, a strong presumption against government activity’ (Viner, 1928, p. 14). But as Viner also reminded his auditors during the course of the Chicago conference which celebrated the 150th anniversary of the publication of WN, ‘Adam Smith was not a doctrinaire advocate of laissez-faire. He saw a wide and elastic range of activity for government’ (1928, pp. 153–4). A number of examples, all identified by Viner in a classic article, may briefly be reviewed here.
First, Smith was prepared to justify specific policies to meet particular needs as these arose; the principle of intervention ad hoc. He defended the use of stamps on plate and linen as the most effectual guarantee of quality (WN, I.x.c.13), the compulsory regulation of mortgages (WN, V.i.i.h.17), the legal enforcement of contracts (WN, I.ix.16) and government control of the coinage. In addition, he supported the granting of temporary monopolies to mercantile groups, to the inventors of new machines and, not surprisingly, to the authors of new books (WN, V.i.e.30). He further advised governments that where they were faced with taxes imposed by their competitors, retaliation could be in order, especially if such action had the effect of ensuring the ‘repeal of the high duties or prohibitions complained of. The recovery of a great foreign market will generally more than compensate the transitory inconveniency of paying dearer during a short time for some sorts of goods’ (WN, IV.ii.39).

Secondly, Smith advocated the use of taxation, not as a means of raising revenue but as a source of social reform, and as a means of compensating for what would now be described as a defective telescopic faculty. In the name of the public interest, Smith supported taxes on the retail sale of liquor in order to discourage the multiplication of alehouses (WN, V.ii.g.4) and differential rates on ale and spirits in order to reduce the sale of the latter (WN, V.ii.k.50). He advocated taxes on those proprietors of land who demanded rents in kind, and on those leases which prescribed a certain form of cultivation. In the same way, Smith argued that the practice of selling a future, for the sake of present, revenue should be discouraged on the ground that it reduced the working capital of the tenant and at the same time transferred a capital sum to those who would use it for the purposes of consumption (WN, V.ii.c. 12) rather than investment which would directly support productive labour.

Smith was well aware, to take a third example, that the modern version of the ‘circular flow’ depended on paper money and on credit; in effect, a system of ‘dual circulation’ involving a complex of transactions linking producers and merchants, and dealers and consumers (WN, II.ii.88). It is in this context that he advocated control over the rate of interest, to be set in such a way as to ensure that ‘sober people are universally preferred, as borrowers, to prodigals and projectors’ (WN, II.iv.15). He was also willing to regulate the small note issue in the interests of a stable banking system. To those who objected to such a proposal Smith replied that the interests of the community required it, and concluded that ‘the obligation of building party walls, in order to prevent the communication of fire, is a violation of natural liberty, exactly of the same kind [as] the regulations of the banking trade which are here proposed’ (WN, II.ii.94). Although Smith's monetary analysis is not regarded as amongst the strongest of his contributions, it should be remembered that as a witness of the collapse of the Ayr Bank, he was acutely aware of the problems generated by a sophisticated credit structure, and that it was in this context that he articulated a very general principle; namely, that ‘those exertions of the natural liberty of a few individuals, which might endanger the security of the whole society, are, and ought to be, restrained by the laws of all governments; of the most free, as well as of the most despotical’ (WN, II.ii.94).

Fourthly, emphasis should be given to Smith's contention that a major responsibility of government must be the provision of certain public works and institutions for facilitating the commerce of the society which were ‘of such a nature, that the profit could never repay the expense to any individual or small number of individuals, and which it, therefore, cannot be expected that any individual or small number of individuals should erect or maintain’ (WN, V.i.c.1). The examples of public works which he provided include roads, bridges, canals and harbours – all thoroughly in keeping with the conditions of the time and with Smith's emphasis on the importance of transport as a contribution to the effective operation of the market and to the process of economic growth. But although the list is short by modern standards,
the discussion is of interest for two main reasons. First, Smith contended that public works or services should only be provided where market forces have failed to do so; secondly, he insisted that attention should be given to the requirements of efficiency and equity.

As Nathan Rosenberg (1960) has pointed out in an important article, Smith did not argue that governments should *directly* provide relevant services; rather, they should establish institutional arrangements so structured as to engage the motives and interests of those concerned. Smith tirelessly emphasized the point that in every trade and profession ‘the exertion of the greater part of those who exercise it, is always in proportion to the necessity they are under of making that exertion’ (WN, V.i. f.4); teachers, judges, professors, civil servants and administrators alike.

With regard to equity, Smith argued that public works, such as highways, bridges and canals should be paid for by those who use them and in proportion to the wear and tear occasioned – an expression of the general principle that the beneficiary should pay. He also defended direct payment on the ground of efficiency since only by this means would it be possible to ensure that necessary services would be provided where there was an identifiable need (WN, V.i.d.6).

Yet Smith recognized that it would not always be possible to fund or to maintain public services without recourse to general taxation. In this case he argued that ‘local or provincial expenses of which the benefit is local or provincial’ ought to be no burden on general taxation since ‘It is unjust that the whole society should contribute towards an expense of which the benefit is confined to a part of society’ (WN, V.i.i.3). However, he did agree that a general contribution would be appropriate in cases where public works benefit the whole society and cannot be maintained by the contribution ‘of such particular members of the society as are most immediately benefited by them’ (WN, V.i.i.6).

But here again, the main features of the system of liberty are relevant in that they affect the way in which taxation should be imposed. Smith pointed out on welfare grounds that taxes should be levied in accordance with the canons of equality, certainty, convenience and economy (WN, V.ii.b), and insisted that they should not be raised in ways which infringed the liberty of the subject – for example, through the odious visits and examinations of the tax-gatherer. Similarly, he argued that taxes ought not to interfere with the allocative mechanism (as, for example, taxes on necessities or particular employments) or constitute important disincentives to the individual effort on which the effective operation of the whole system depended (for example, taxes on profits or on the produce of land).

**Ethics and history**

The policy views which have just been considered are closely related to Smith's economic analysis. Others are only to be fully appreciated when seen against the background of his work on ethics and jurisprudence.

It will be recalled that for Smith moral judgement depends on a capacity for acts of imaginative sympathy, and that such acts can only take place within the context of some social group (TMS, III.i.3). However, Smith also observed that the mechanism of the impartial spectator might well break down in the context of the modern economy, due in part to the size of the manufacturing units and of the cities which housed them.

Smith observed that in the actual circumstances of modern society, the poor man could find himself in a situation where the ‘mirror’ of society (TMS, III.i.3) was ineffective. The ‘man of rank and fortune is by
his station the distinguished member of a great society, who attend to every part of his conduct, and who thereby oblige him to attend to every part of it himself'. But the ‘man of low condition’, while ‘his conduct may be attended to’ so long as he is a member of a country village, ‘as soon as he comes into a great city, he is sunk, in obscurity and darkness. His conduct is observed and attended to by nobody, and he is therefore very likely to neglect it himself, and to abandon himself to every sort of low profligacy and vice’ (WN, V.i.g.12).

In the modern context, Smith suggests that the individual thus placed would naturally seek some kind of compensation, often finding it not merely in religion but in religious sects; that is, small social groups within which he can acquire ‘a degree of consideration which he never had before’ (WN, V.i.g.12). Smith noted that the morals of such sects were often disagreeably ‘rigorous and unsocial’, recommending two policies to offset this.

The first of these is learning, on the ground that science is ‘the great antidote to the poison of enthusiasm and superstition’. Smith suggested that government should institute ‘some sort of probation, even in the higher and more difficult sciences, to be undergone by every person before he was permitted to exercise any liberal profession, or before he could be received as a candidate for any honourable office of trust or profit’ (WN, V.i.g.14). The second remedy was through the encouragement given to those who might expose or dissipate the folly of sectarian bitterness by encouraging an interest in painting, music, dancing, drama – and satire (WN, V.i.g.15).

If the problems of solitude and isolation consequent on the growth of cities explain Smith’s first group of points, a related trend in the shape of the division of labour helps to account for the second. In the earlier part of the argument, Smith had emphasized the gain to society at large which arose from improved productivity. But he noted later that this important source of economic benefit could also involve social costs:

In the process of the division of labour, the employment of the far greater part of those who live by labour, that is, of the great body of the people, comes to be confined to a few very simple operations; frequently to one or two. But the understandings of the greater part of men are necessarily formed by their ordinary employments. The man whose life is spent in performing a few simple operations, of which the effects too are, perhaps, always the same, or very nearly the same, has no occasion to exert his understanding, or to exercise his invention in finding out expedients for removing difficulties which never occur. (WN, V.i.f.50)

Smith went on to point out that despite a dramatic increase in the level of real income, the modern worker could be relatively worse off than the poor savage, since in such primitive societies the varied occupations of all men – economic, political and military – preserve their minds from that ‘drowsy stupidity, which, in a civilized society, seems to benumb the understanding of almost all the inferior ranks of people’ (WN, V.i.f.51). It is the fact the ‘labouring poor, that is the great body of the people’ will fall into the state outlined that makes it necessary for government to intervene.

Smith’s justification for intervention is, as before, market failure, in that the labouring poor, unlike those of rank and fortune, lack the leisure, means or (by virtue of their occupation) the inclination to provide education for their children (WN, V.i.f.53). In view of the nature of the problem, Smith’s programme seems rather limited, based as it is on the premise that ‘the common people cannot, in any civilized
society, be so well instructed as people of some rank and fortune' (WN, V.i.f.54). However, he did argue that they could all be taught ‘the most essential parts of education … to read, write, and account’ together with the ‘elementary parts of geometry and mechanics’ (WN, V.i.f.54, 55). Smith added:

The publick can impose upon almost the whole body of the people the necessity of acquiring those most essential parts of education, by obliging every man to undergo an examination or probation in them before he can obtain the freedom in any corporation, or be allowed to set up any trade either in a village or town corporate. (WN, V.i.f.57; italics supplied)

Distinct from the above, although connected with it, is Smith's concern with the decline of martial spirit, which is the consequence of the nature of the fourth, or commercial, stage. He concluded that:

Even though the martial spirit of the people were of no use towards the defence of society, yet to prevent that sort of mental mutilation, deformity and wretchedness, which cowardice necessarily involves in it, from spreading themselves through the great body of the people would still deserve the most serious attention of government. (WN, V.i.f.60)

Smith went on to liken the control of cowardice to the prevention of ‘a leprosy or any other loathsome and offensive disease’ – thus moving Jacob Viner to add public health to Smith's already lengthy list of governmental functions (Viner, 1928, p. 150). Such concerns have enabled Winch (1978) to find in Smith evidence of the language of an older, classical, concern with the problem of citizenship. Others (for example, see contributions in Hont and Ignatieff, 1983) have located Smith more firmly in the tradition of civic humanism.

The historical dimension of Smith's work also affects the treatment of policy, noting as he did that in every society subject to a process of transition, ‘Laws frequently continue in force long after the circumstances, which first gave occasion to them, and which could also render them reasonable, are no more’ (WN, III.i.4). In such cases Smith suggested that arrangements which were once appropriate but are now no longer so should be removed, citing as examples the laws of succession and entail; laws which had been appropriate in the feudal period but which now had the effect of liming the sale and improvement of land. The continuous scrutiny of the relevance of particular laws is an important function of the ‘legislator’ (Haakonssen, 1981).

In a similar way, the treatment of justice and defence, both central services to be organized by the government, are clearly related to the discussion of the stages of history, an important part of the argument in the latter case being that a gradual change in the economic and social structure had necessitated the formal provision of an army (WN, V.i.a.b).

But perhaps the most striking and interesting features emerge when it is recalled that for Smith the fourth economic stage could be seen to be associated with a particular form of social and political structure which determines the outline of government and the context within which it must function. It may be recalled in this connection that Smith associated the fourth economic stage with the elimination of the relation of direct dependence which had be a characteristic of the feudal agrarian period.

Politically, the significant and associated development appeared to been the diffusion of power
consequent on the emergence of new forms of wealth which, at least in the peculiar circumstances of England, had been reflected in the increased significance of the House of Commons. Smith recognized that in this context government was a complex instrument, that the pursuit of office was itself a ‘dazzling object of ambition’ – a competitive game with as its object the attainment of ‘the great prizes which sometimes come from the wheel of the great state lottery of British politics’ (WN, IV. vii.c.75).

Yet for Smith the most important point was that the same economic forces which had served to elevate the House of Commons to a superior degree of influence had also served to make it an important focal point for sectional interests – a development which could seriously affect the legislation which was passed and thus affect that extensive view of the common good which ought ideally to direct the activities of Parliament.

It is recognized in the Wealth of Nations that the landed, moneyed, manufacturing and mercantile groups all constitute special interests which could impinge on the working of government. Smith referred frequently to their ‘clamourous importunity’, and went so far as to suggest that the power possessed by employers generally could seriously disadvantage other classes in the society’ (WN, I.x.c.61; cf. I. viii.12,13).

Smith insisted that any legislative proposals emanating from this class:

"ought always to be listened to with great precaution, and ought never to be adopted till after having been long and carefully examined, not only with the most scrupulous, but with the most suspicious attention. It comes from an order of men, whose interest is never exactly the same with that of the public, who have generally an interest to deceive and even to oppress the public, and who accordingly have, upon many occasions, both deceived and oppressed it. (WN, I.xi.p.10)"

He was also aware of the dangers of manipulation arising from deployment of the civil list (LJA, iv.175–6).

It is equally interesting to note how often Smith referred to the constraints presented by the ‘confirmed habits and prejudices’ of the people, and to the necessity of adjusting legislation to what ‘the interests, prejudices, and temper of the times would admit of’ (WN, IV.v.b.40, 53, and V.i.g; cf. TNS, VI.ii.2.16). Such passages add further meaning to the discussion of education. An educated people, Smith argued, would be more likely to see through the interested complaints of faction and sedition. He added a warning and a promise in remarking that:

"In free countries, where the safety of government depends very much on the favourable judgment which the people may form of its conduct, it must surely be of the highest importance that they should not be disposed to judge rashly or capriciously concerning it. (WN, V.i.f.61)"

Aftermath

J.S. Mill, the archetypal classical economist, of a later period, is known to have remarked that ‘The Wealth of Nations is in many parts obsolete and in all, imperfect’. Writing in 1926, Edwin Cannan
observed:

Very little of Adam Smith's scheme of economics has been left standing by subsequent enquirers. No one now holds his theory of value, his account of capital is seen to be hopeless confused, and his theory of distribution is explained as an ill-assorted union between his own theory of prices and the Physiocrat fanciful Economic Table. (1926, p. 123)

In view of authoritative judgements such as these, it is perhaps appropriate to ask what elements in his story should command the attention of the modern historian or economist. A number of points might be suggested.

First, there is the issue of scope. As we have seen, Smith's approach to the study of political economy was through the examination of history and ethics. The historical analysis is important in that he set out to explain the origins of the commercial stage. The ethical analysis is important to the economist because it is here that Smith identifies the human values which are appropriate to the modern situation. It is here that we confront the emphasis on the desire for status (which is essentially Veblenesque) and the qualities of mind which are necessary to attain this end: industry, frugality, prudence.

But the TMS also reminds us that the pursuit of economic ends takes place with a social context, and the men maximize their chances of success by respecting the rights of others. In Smith's sense of the term, 'prudence' is essentially rational self-love. In a favourite passage from the TMS (II.i.2.1) Smith noted, with regard to the competitive individual, that:

In the race for wealth, and honours, and preferments, he may run as hard as he can, and strain every nerve and muscle, in order to outstrip all his competitors. But if he should justle, or throw down any of them, the indulgence of the spectators is entirely at an end. It is violation of fair play, which they cannot admit of.

Smith's emphasis upon the fact that self-interested actions take place within a social setting and that men are motivated (generally) by a desire to be approved of by their fellows, raises some interesting questions of continuing relevance. For example, in an argument which bears upon the analysis of the TMS, Smith noted in effect that the rational individual may be constrained in respect of economic activity or choices by the reaction of the spectator of his conduct – a much more complex case than that which more modern approaches may suggest. Smith made much of the point in his discussion of Mandeville's 'licentious system' which supported the view that private vices were public benefits, in suggesting that the gratification of desire should be consistent with observance of the rules of property – as defined by the spectator, that is, by an external agency. In an interesting variant on this theme, Etzioni has noted that we need to recognize 'at least two irreducible sources of valuation or utility: pleasure and morality' (1988, 21–4; cf. Oakley, 1994).

Secondly, there is a series of issues which arise from Smith's interest in political economy as a system. The idea of a single all-embracing conceptual system, whose parts should be mutually consistent, is not easily attainable in an age where the division of labour has increased the quantity of science through specialization. Smith was aware of the division of labour in different areas of sciences, and of the fact
that specialization often led to systems of thought which were inconsistent with each other (Astronomy, IV, 35, 52, 67). But the division of labour within a branch of science, for example, economics, has led to a situation where sub-branches of a single subject may be inconsistent with one another.

To take a third point, it may be noted that one of the most significant features of Smith's vision of the economic process lies in the fact that it has a significant time dimension. For example, in dealing with the problem of value in exchange, Smith made due allowance for the fact that the process involves judgements with regard to the utility of the commodities to be acquired, and the disutility involved in creating the goods to be exchanged. In the manner of his predecessors (Hutcheson, Carmichael and Pufendorf), Smith was aware of the distinction between utility (and disutility) anticipated and realized, and, therefore, of the process of adjustment which would inevitable take place through time.

Smith's theory of price, which allows for a wide range of changes in taste, is also distinctive in that it allows for competition among and between buyers and sellers, while presenting the allocative mechanism as one which involves simultaneous and interrelated adjustments in both factor and commodity markets.

As befits a writer who was concerned to address the problems of change, and adjustments to change, Smith's position was also distinctive in that he was not directly concerned with the phenomenon of equilibrium. For Smith, the ‘nature’ (supply) price was, as it were:

The central price, to which the prices of all commodities are continually gravitating … whatever may be the obstacles which hinder them from settling in this centre of response and continuance, they are constantly tending towards it. (WN, I.viii.15)

But perhaps the most intriguing feature of the macro model is to be found in the way in which it was linked to the analytics of Book I and in the way in which it was specified. As noted earlier, Smith argued that incomes were generated as a result of productive activity, thus making it possible for commodities to be withdrawn from the ‘circulating’ capital of society. As he pointed out, the consumption goods withdrawn from the existing stock may be used up in the present period, or added to the stock reserved for immediate consumption; or used to replace more durable goods which had reached the end of their lives in the current period. In a similar manner, entrepreneurs and merchants may also add to their stocks of materials, or to their holding of fixed capital, while replacing the plant which had reached the end of its operational life. It is equally obvious that entrepreneurs and merchants may add to, or reduce their inventories in ways which will reflect the changed patterns of demand for consumption and investment goods, and their past and current levels of production. Variation in the level of inventories has profound implications for the conventional theory of the allocative mechanism.

Smith's emphasis upon the point that different ‘goods’ have different life-cycles also means that the pattern of purchase and replacement may vary continuously as the economy moves through different time periods, and in ways which reflect the various age profiles of particular products as well as the pattern of demand for them. If Smith's model of the circular flow is to be seen as a spiral, rather than a circle, it soon becomes evident that this spiral is likely to expand (and possibly contract) through time at variable rates. This point does not seem to have attracted much attention.

It is perhaps this total vision of the complex working of the economy that led Mark Blaug to comment on Smith's distinctive and sophisticated grasp of the economic process and to distinguish this from his contribution to particular areas of economic analysis.
Blaug noted that:

In appraising Adam Smith, or any other economist, we ought always to remember that brilliancy in handling purely economic concepts is a very different thing from a firm grasp of the essential logic of economic relationships. Superior technique does not imply superior insight and vice-versa. Judged by standards of analytical competence, Smith is not the greatest of eighteenth century economists. But for an acute insight into the nature of the economic process, it would be difficult to find Smith's equal. (1985, p. 57)

Joseph Schumpeter, not always a warm critic of ‘A. Smith’, yet regarded WN as ‘the peak success of (the) period:

Though the *Wealth of Nations* contained no really novel ideas, and though it cannot rank with Newton's *Principia* or Darwin's *Origin* as an intellectual achievement, it is a great performance all the same and fully deserved its success. (1954, p. 185)

Writing from a different, but related, point of view, A.L. Macfie noted that ‘the Scottish method was more concerned with giving a broad, well balanced picture seen from different points of view than with logical rigour’ (1967, 22–3).

It has been argued above that Smith's approach to the study of political economy has some distinctive features which deserve the attention of the modern student of the discipline, but which do not seem to loom large in modern teaching. But nor can it be said that the classical system which was to follow Smith did any better.

Richard Teichgraeber's research (1987) revealed that there ‘is no evidence to show that many people exploited his arguments with great care before the first two decades of the nineteenth century’. He concluded:

It would seem at the time of his death that Smith was widely known and admired as the author of the *Wealth of Nations*. Yet it should be noted that only a handful of his contemporaries had come to see his book as uniquely influential. (1987, p. 363)

But, as we have seen, there were commentators who understood Smith's analytical purpose, notably Thomas Pownall and Smith's biographer, Dugald Stewart. The latter indeed became an important channel of communication between Smith and a later generation of students – many of whom were to contribute to debates published by the *Edinburgh Review* in the early part of the new century (Winch, 1994, p. 91). Amongst the contributors we can number J.R. McCulloch (1789–1864), editor of the *Scotsman*, discipline of Ricardo and a writer who contributed nearly 80 articles to the *Review* between 1818 and 1837.

However, Black made a different point in his ‘Historical Perspective’ in observing that for Smith's early successors the *Wealth* was ‘not so much a classical monument to be inspected, but as a structure to be examined and improved where necessary (1976, p. 44). It was thought that there were ambiguities in respect of Smith's treatment of value, interest, rent, population theory and the theory of economic
growth. These ambiguities were reduced by the work of T.R. Malthus (1766–1834) whose *Essay on the Principle of Population* was first published in 1798; by the French economist, J.B. Say (1826–1896), *Traite d'economie politique* (1803) and especially by David Ricardo (1772–1823), *Principles* (1817). In this context we can name a number of writers who developed the short-run and dynamic themes associated with Say and Ricardo, such as James Mill (1773–1836), *Elements of Political Economy* (1821) and, of course, his son John Stuart Mill (1806–1873) whose *Principles* brought to close this early version of the classical system.

Among Say's contributions we must number a version of the classical short-run macroeconomic system which accepted the view that the supply of commodities generates income and purchasing power, and also the Smithian assumption that the only use of money was to circulate commodities while also accepting Smith's assumption that an act of savings would normally be matched by a decision to invest. In the relatively short run, the tendency of the economy was to full employment; a situation sustained by self-regulating mechanisms such as Smith's theory of price and allocation; a theory which was not seriously questioned. In Ricardo's case the emphasis was upon a generalized statement of Smith's labour embodied theory of value, a revised theory of rent, and a theory of growth which under the assumptions of constant technique and a closed economy, suggested that the normal progression of an economy was from an advancing state to a stationary state where no further growth was possible. Both models are formal, operating under specified assumptions. They are also essentially mathematical in character even if they clearly do owe much to Smith.

But there are important differences, arising not least from the fact that Smith's own approach was not narrowly 'mathematical' (Macfie, 1967, pp. 22–3), as compared, for example, with Ricardo (Baumol, 1962).

There was another difficulty arising from the fact that there was a tendency to assume that the basis of the subject of political economy dated from 1776, the year in which the *Wealth of Nations* first appeared. Donald Winch quotes an important passage from J.-B. Say, Smith's committed, but by no means uncritical, disciple. Say wrote that:

> Whenever the inquiry into the *Wealth of Nations* is perused with the attention it so well merits, it will be perceived that until the epoch of its publication, the science of political economy did not exist. (Quoted in Winch, 1994, p. 103)

Terence Hutchison has argued that the ‘losses and exclusions which ensued after 1776, with the subsequent transformation of the subject and the rise to dominance of the English classical orthodoxy were immense’ (1988, p. 370). One such loss was the Physiocratic concept of the circular flow, to which Smith owed so much. Other losses occurred as a result of ignoring the contributions of Smith's close friend, David Hume, and the work of the latter's friend, Sir James Steuart (1713–1780), *Principles* (1767). The use of the historical method as applied to economic analysis and policy was one such loss and so too was the concern with structural unemployment, and the model of ‘primitive’ (pre-capitalist) accumulation. In addition the classical orthodoxy showed little interest in the problems presented by differential rates of growth in the context of international trade – hardly surprising in view of the fact that Smith largely ignored the problems identified by his two Scottish predecessors.

Ironically, Smith's own work did not always benefit from the work of those who 'inspected' the edifice.
Here attention may be drawn to Smith's version of the 'circular flow' with its complex focus on period analysis and on the fact that all commodities have different life-cycles. Nor was much attention given to the Smithian use of time.

Ironically, the new orthodoxy also made it possible to think of political economy as a discipline which was quite separate from ethics and jurisprudence, thus obscuring Smith's true purpose. In referring to the way in which Smith organized his system of social science (ethics, jurisprudence, economics) Hutchison observed in a telling passage, that Smith was led as it by an Invisible Hand to promote an end which was no part of his original intention, that of ‘establishing political economy as a separate, autonomous disciple’ (1988, p. 355). A.L. Macfie made a related point in observing that ‘it is a paradox of history that the analytics of Book I, in which Smith took his own line, should have eclipsed the philosophical and historical methods in which he so revelled, and which showed his Scots character’ (1967, p. 21).

Bruce David Smith was born on 21 September 1954 in St. Paul, Minnesota, and died in Rochester, Minnesota, on 9 July 2002. Smith graduated with a BA in economics from the University of Minnesota in 1977 and obtained his Ph.D. in economics from the Massachusetts Institute of Technology in 1981. Smith's career began as an assistant professor at Boston College (1981–2). From there he moved to the research department at the Federal Reserve Bank of Minneapolis (1982–6), which was where his lifelong research interests in monetary history, monetary theory and financial intermediation blossomed among colleagues like Thomas Sargent, Neil Wallace, Ed Prescott, John Boyd and Warren Weber. After visits to Carnegie-Mellon and the University of California at Santa Barbara, he moved to the University of Western Ontario as an associate professor from 1987 to 1990. Smith moved to Cornell University in 1990 and finally to the University of Texas at Austin in 1996, where he was the Fred Hofheinz Regent's Professor of Economics.

Smith's scholarly research consists of nearly one hundred published papers (a complete list of Smith's papers can be found in the Federal Reserve Bank of Minneapolis Quarterly Review, 2002). His research includes widely cited papers about monetary history, the causes and consequences of banking panics, the impact of financial market development on per-capita income and growth, the impact of inflation on financial market development, the macroeconomic effects of various types of credit market imperfections, and the optimal conduct of monetary and exchange rate policy.

The importance of financial intermediation for economic growth and stability underlies nearly all of Smith's research. In ‘Taking intermediation seriously’ (2003), his last single-authored paper, Smith argues that the information and spatial frictions which underlie a welfare-improving role for intermediation have important implications for the conduct of monetary policy. In particular, Smith lays out various theoretical models that show not only how excessive monetary expansion can lead to
decreases in growth, but also how restrictive monetary policy (for instance, the Friedman rule) can be suboptimal.

One of Smith’s most widely cited articles, ‘Financial Intermediation and Endogenous Growth’ (1991), co-authored with Valerie Bencivenga, provides a theoretical foundation for a large body of empirical research that finds a correlation between measures of financial market development and real output growth. Bencivenga and Smith provide a model with production externalities where liquidity provided by banks allows private agents to reduce the fraction of their savings held in the form of unproductive liquid assets and to increase their holdings of productive capital assets inducing growth.

Smith viewed economic history as a laboratory for understanding money and the theory of financial intermediation that he argued remains relevant for present-day policy. In ‘Some colonial evidence on two theories of money: Maryland and the Carolinas’, he argues that data from North and South Carolina is inconsistent with the quantity theory of money. For example, while the per capita stock of paper money more than tripled from 1755 to 1760, the price level increased by only seven per cent. On the other hand, data from Maryland, which had a unique method of backing the value of its currency with deliveries of sterling from the Bank of England, appears to be consistent with what Smith calls the Sargent–Wallace approach, where the value of money is determined in the same way that other privately issued assets are priced as the expected present discounted value of future cash flows (in this case, claims to sterling deliveries).

Abstract

Vernon Lomax Smith shared the 2002 Nobel Prize in Economics for his contributions to the development of experimental economics. Among his insights is the idea that ‘institutions matter’: trading institutions affect the efficiency of a market, and the optimal institution depends on the market context. He has made important contributions to market and institutional design, public goods, bargaining, experimental methodology and the philosophy of science.

Article

Vernon Lomax Smith is an American economist who shared the 2002 Nobel Prize in Economics (with the psychologist Daniel Kahneman) for his pioneering work on the methodology of laboratory experiments in economics. He is a remarkable scholar and a true pioneer in the quest to understand market institutions (such as auction mechanisms) and nonmarket institutions (such as bargaining rules), as well as the structure and motivation of individual behaviour. His methodological contributions helped overturn the traditional notion of economics as an inherently non-experimental science.

Smith was born on 1 January 1927 in Wichita, Kansas. He studied electrical engineering at the California Institute of Technology, receiving a bachelor's degree in 1949, then earned an MA in economics from the University of Kansas in 1952, and a Ph.D. from Harvard University in 1955. Smith's first teaching position was at the Krannert School of Management at Purdue University (1955–67), where he began his work in experimental economics. After appointments at Stanford, the University of Massachusetts, the Center for Advanced Study in the Behavioral Sciences and Caltech, in 1975 he
accepted a position at the University of Arizona, where he was to spend the next 26 years and build a body of research that would result in a Nobel Prize. Since 2001, Smith has been Professor of Economics and Law at George Mason University, where he is a research scholar in the Interdisciplinary Center for Economic Science, and a Fellow of the Mercatus Center.

Author or co-author of over 200 articles and books on capital theory, finance, natural resource economics and experimental economics, Smith has served on editorial boards of journals including (among many others) the American Economic Review. He has been influential in professional organizations, serving as president of the Public Choice Society, the Economic Science Association, and the Western Economic Association. His honours are many: he is a Fellow of the Econometric Society, the American Association for the Advancement of Science, and the American Academy of Arts and Sciences, and a Distinguished Fellow of the American Economic Association. He was elected a member of the National Academy of Sciences in 1995. Smith's collected papers were published by Cambridge University Press in 1991, with a second volume in 2000.

The press release issued by the Royal Swedish Academy of Sciences on the occasion of the 2002 Nobel Prize summarizes the contributions that earned Smith the award:

Vernon Smith has laid the foundation for the field of experimental economics. He has developed an array of experimental methods, setting standards for what constitutes a reliable laboratory experiment in economics. In his own experimental work, he has demonstrated the importance of alternative market institutions, e.g., how the revenue expected by a seller depends on the choice of auction method. Smith has also spearheaded ‘wind-tunnel tests’, where trials of new, alternative market designs – e.g., when deregulating electricity markets – are carried out in the lab before being implemented in practice. His work has been instrumental in establishing experiments as an essential tool in empirical economic analysis. (Press Release: The Bank of Sweden Prize in Economic Sciences in Memory of Alfred Nobel, 9 October 2002)

Smith's early contributions focused on markets and how different ways of organizing exchange might lead to different outcomes. The next phase built upon the principles learned in the laboratory to design new institutions, as deregulation and privatization created unprecedented opportunities for the emergence of new markets around the world. Later work turned to the behaviour of agents in bilateral bargaining situations, involving pairs or small groups of participants, and exploring the nature and role of personal social exchange in decision-making in these settings. Recent research has explored the relationship between brain functions and decision-making (2001), the emergence of exchange systems in the absence of extant institutions that are typically imposed exogenously in experimental economies (2006a; 2006b), and the philosophy of science as it relates to the experimental method in economics. In every phase of his broad research agenda, he has produced important insights and critical methodological innovations.

Markets work, but not for the reasons we think

Vernon Smith tells the story of his early experiments (see Smith, 1991, pp. 154–8). As a graduate student at Harvard, he participated in the classroom experiment of Edward Chamberlin. As a teaching
exercise, Chamberlin gave students seller costs or buyer values, then instructed them to circulate in the room, and negotiate prices with their counterparts. He then collected the prices, and displayed them, purportedly to illustrate that markets do not work as the perfectly competitive model suggests.

When Smith started teaching at Purdue, he adapted Chamberlin's experiment to his own classes, making a few modifications so that the market more closely resembled a stock market. He distributed costs and values to the participants, as Chamberlin had done, but had traders call out bids and offers. A pit boss recorded the bids and offers on the blackboard, and a trade occurred when a buyer accepted a seller's offer, or a seller accepted a buyer's bid. He also repeated the market, to allow students to learn the mechanics of the trading situation. He says, ‘These two changes seemed to be the appropriate modifications to do a more credible job of rejecting competitive price theory’ (1991, p. 155). To his surprise, the market converged in a couple of rounds to the predicted competitive equilibrium price and quantity. Thinking this might just be a fluke, he repeated it in another class, with the same result. Finally, imagining that the result might depend on the symmetric producer and consumer surpluses in his particular set-up, he ran another market with highly asymmetric surpluses, and once again ‘the darned thing converged to competitive equilibrium’. In all cases, after a few rounds, all trades were taking place within a few cents of the same price. One can almost imagine him saying, ‘Well look at that. Markets work!’ These early ‘double oral auction’ (DOA, also referred to as an oral double auction) market experiments were published as Smith (1962), which also reports tests of the effects of shifts in supply and demand.

This exercise is such a strong illustration of the power of competitive markets that many economists use a classroom version of it to introduce their students to the supply and demand model. Participating in this experiment brings the model to life, and experiencing convergence to competitive equilibrium is an unforgettable lesson for students. By conducting his early experiments in the classroom, Smith inadvertently taught us how to teach economics.

These studies were followed by comparisons of different trading institutions. For example, compared with the posted offer institution found in most retail markets, where sellers post prices and buyers choose whether to buy, the DOA converges more quickly, and responds faster to changes in demand or supply. Smith termed it a ‘disciplining’ institution: the DOA is disciplining in the sense that buyers and sellers quickly discover whether they have left money on the table, and can modify their decisions immediately. In a posted offer market, this is less clear, as buyers who do not win the auction do not find out about other's values.

Another important contribution of Smith's early work is to discover the interactions between market structure and trading institutions in determining the outcome in the market. His work showed that market power is much harder to exercise in the DOA than in a posted offer market, where the monopolist can more easily sustain monopoly prices (Smith, 1981). This result stands outside standard economic theory, as research in industrial organization says little or nothing about the trading institution. A major contribution of experimental economics, and Smith's work in particular, is the insight that ‘institutions matter’. This insight belongs in every Principles of Economics course, though it has not yet made its way into standard texts.

This new-found understanding of how markets and institutions work could then be harnessed to design new markets and institutions, using the laboratory as a ‘wind tunnel’. The development of computer-assisted ‘smart markets’ expanded market design to a whole range of complex policy applications. Smith's work contributed to the design of many such markets, including airport landing slots, natural
gas, wholesale electricity, as well as the design of the Arizona Stock Exchange, and the highly profitable auction by the US Federal Communications Commission of the portions of the microwave spectrum used for cellular phones, among other applications.

While Smith is known for his work showing how markets work, he also has explored situations when they might not work so well. This work showed that implementing the common knowledge assumption of perfectly competitive markets and game theory can be difficult, and this failure can lead to unexpected outcomes. For example, Smith and his colleagues have contributed to the growing field of behavioural finance by replicating the propensity of asset markets to bubble and crash. When valuations are based on subjects’ beliefs about others’ knowledge, beliefs and strategies, prices can deviate substantially from the underlying fundamentals of the asset (1988). In addition, he shows that more information is not necessarily better. When subjects are given information about others’ payoffs, fulfilling one of the theoretical assumptions of competitive markets, this can delay or distort convergence to equilibrium (Smith, 1976).

**Dominated strategies are for playing**

What happens where there is no competitive market to discipline trading behaviour? While people often act in accordance with the rational actor model in competitive situations, the negotiated outcomes of bargaining games allow scope for other motives to emerge. In the 1980s, laboratory tests of game-theoretic models began to produce results that revealed a penchant for fairness on the part of the participants. In a series of papers, Smith and his colleagues explored the importance of social distance between subjects. The greater the social distance, the more likely subjects were to behave selfishly in a dictator game (where one player decides the allocation of an endowment between himself and a counterpart) (1994; 1996a).

Subjects also take advantage of strategies that, according to theory, they should never play. Smith and his colleagues were the first to show that subjects will take advantage of an opportunity to punish a counterpart for unfair behaviour, even when that choice is costly for them (1996b). In this study and others, dominated strategies are chosen by subjects, when they are useful to punish bad behaviour by reducing a counterpart's payoff.

**People are more rational than the agents in our models**

Smith's Nobel lecture (Smith, 2003) surveys the territory that has been colonized by laboratory experimental economics. He organizes the research by distinguishing two types of rationality: constructivist, by which he means the sort of rationality built into the standard social science model of 'economic man'; and ecological, by which he refers to the use of reason to understand the emergent order and embodied intelligence of cultural rules, norms, and the institutions that result from regular human interactions, but that are not deliberately designed. Experimental economics taught Smith that our understanding of economic phenomena requires both constructivist and ecological rationality. From the discussion it is clear that his own research began with the constructivist model, but from his experience in the laboratory, he grew to appreciate that the richness of human behaviour required an augmented view. Smith's view of rationality grew out of a profound curiosity about and respect for human behaviour, and was shaped by his experience in the laboratory and his careful observation of

SNP: nonparametric time series analysis

A. Ronald Gallant
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

SNP is a method of nonparametric multivariate time series analysis. It employs an expansion in Hermite functions to approximate the conditional density of a multivariate process. An appealing feature of the expansion is that it is a nonlinear nonparametric model that directly nests the Gaussian VAR model, the semiparametric ARCH model, the Gaussian GARCH model, and the semiparametric GARCH model. The unrestricted SNP expansion is more general than any of these models. The SNP model is fitted using conventional maximum likelihood together with a model selection strategy that determines the appropriate order of expansion.

Article

SNP is a method of multivariate nonparametric time series analysis. SNP is an abbreviation of ‘semi-nonparametric’ which was introduced by Gallant and Nychka (1987) to suggest the notion of a statistical inference methodology that lies halfway between parametric and nonparametric inference. The method employs an expansion in Hermite functions to approximate the conditional density of a multivariate process. The leading term of this expansion can be chosen through selection of model parameters to be a Gaussian vector autoregression (VAR) model, a semi-parametric VAR model, a Gaussian ARCH model (Engle, 1982), a semiparametric ARCH model, a Gaussian GARCH model (Bollerslev, 1986), or a semiparametric GARCH model, either univariate or multivariate in each case. The unrestricted SNP expansion is more general than that of any of these models. The SNP model is fitted using maximum likelihood together with a model selection strategy that determines the appropriate order of expansion. Because the SNP model possesses a score, it is an ideal candidate for the auxiliary model in connection with efficient method of moment estimation (Gallant and Tauchen, 1996). Due to its leading term, the SNP approach does not suffer from the curse of dimensionality to the same extent as kernels and splines. In regions where data are sparse, the leading term helps to fill in smoothly between data points. Where data are plentiful, the higher-order terms accommodate deviations from the leading term. The method was first proposed by Gallant and Tauchen (1989) in connection with an asset pricing application. A C++ implementation of SNP is at http://econ.duke.edu/webfiles/arg/snp/, together with a User's Guide, which is an excellent tutorial introduction to the method. Important adjuncts to SNP estimation are a rejection method for simulating from the SNP density developed in Gallant and Tauchen (1992), which can be used, for example, to set bootstrapped confidence intervals as in Gallant, Rossi and Tauchen (1992); nonlinear error shock analysis as described in Gallant, Rossi and Tauchen (1993), which develops the nonlinear analog of conventional error shock analysis for linear VAR models; and re-projection, which is a form of nonlinear Kalman filtering that can be used to forecast the unobservables of nonlinear latent variables models (Gallant and Tauchen, 1998).

As stated above, the SNP method is based on the notion that a Hermite expansion can be used as a general purpose approximation to a density function. Letting $\mathbf{z}$ denote an $M$-
vector, we can write the Hermite density as \( h(z) = \left[ p(z) \right]^2 \varphi(z) \) where \( p(z) \) denotes a multivariate polynomial of degree \( K_z \) and \( \varphi(z) \) denotes the density function of the (multivariate) Gaussian distribution with mean zero and variance the identity matrix. Denote the coefficients of \( p(z) \) by \( a \), which is a vector whose length depends on \( K_z \) and \( M \).

When we wish to call attention to the coefficients, we write \( p(z;a) \).

The constant of proportionality is \( 1 / \int \left[ p(s) \right]^2 \varphi(s) \, ds \) which makes \( h(z) \) integrate to one. As seen from the expression that results, namely

\[
h(z) = \frac{\left[ p(z) \right]^2 \varphi(z)}{\int \left[ p(s) \right]^2 \varphi(s) \, ds},
\]

we are effectively expanding the square root of the density in Hermite functions of the form \( p(z) \sqrt{\varphi(z)} \). Because the square root of a density is always square integrable and because the Hermite functions of the form \( p(z) \sqrt{\varphi(z)} \) are dense for the collection of square integrable functions (Fenton and Gallant, 1996), every density has such an expansion.

Because \( \left[ p(z) \right]^2 / \int \left[ p(s) \right]^2 \varphi(s) \, ds \) is a homogeneous function of the coefficients of the polynomial \( p(z) \), the coefficients can only be determined to within a scalar multiple. To achieve a unique representation, the constant term of the polynomial part is put to 1. Customarily the Hermite density is written with its terms orthogonalized and the C++ code is written in the orthogonalized form for numerical efficiency. But reflecting that here would lead to cluttered notation and add nothing to the ideas.

A change of variables using the location-scale transformation \( \mathcal{V} = R \mathcal{Z} + \mu \), where \( R \) is an upper triangular matrix and \( \mu \) is an \( M \)-vector, gives

\[
f(\mathcal{V}|\Theta) \propto \left[ p(R^{-1}(\mathcal{V} - \mu)) \right]^2 \left\{ \frac{\varphi[R^{-1}(\mathcal{V} - \mu)]}{|\det(R)|} \right\}
\]

The constant of proportionality is the same as above, \( 1 / \int \left[ p(s) \right]^2 \varphi(s) \, ds \). Because \( \left\{ \frac{\varphi[R^{-1}(\mathcal{V} - \mu)]}{|\det(R)|} \right\} \) is the density function of the \( M \)-dimensional, multivariate, Gaussian distribution with mean \( \mu \) and variance-covariance matrix \( \Sigma = RR^t \), and because the leading term of the polynomial part is 1, the leading term of the entire expansion is proportional to the multivariate, Gaussian density function. Denote the Gaussian density of dimension \( M \) with mean vector \( \mu \) and variance matrix \( \Sigma \) by \( \eta_M(\mathcal{V}|\mu, \Sigma) \) and write

\[
f(\mathcal{V}|\Theta) \propto \left[ p(z) \right]^2 \eta_M(\mathcal{V}|\mu, \Sigma)
\]

where \( z = R^{-1}(\mathcal{V} - \mu) \) for the density above.

When \( K_z \) is put to zero, one gets \( f(\mathcal{V}|\Theta) = \eta_M(\mathcal{V}|\mu, \Sigma) \) exactly. When \( K_z \) is positive, one gets a Gaussian density whose shape is modified due to multiplication by a polynomial in \( z = R^{-1}(\mathcal{V} - \mu) \). The shape modifications thus achieved are rich enough to accurately approximate densities from a large class that includes densities with fat, \( t \)-like tails, densities with tails that are thinner than Gaussian, and skewed densities (Gallant and Nychka, 1987).

The parameters \( \Theta \) of \( f(\mathcal{V}|\Theta) \) are made up of the coefficients \( a \) of the polynomial \( p(z) \) plus \( \mu \) and \( R \) and are estimated by maximum likelihood which is accomplished by minimizing \( s_M(\Theta) = (-1/n) \sum_{t=1}^n \log \left[ f(\mathcal{V}_t|\Theta) \right] \). As mentioned above, if the number of parameters \( p_\Theta \) grows with the sample size \( n \), the true density and various features of it such as derivatives and moments are estimated consistently (Gallant and Nychka, 1987).

This basic approach can be adapted to the estimation of the conditional density of a multiple time series \( \{ y_t \} \) that has a Markovian structure. Here, the term ‘Markovian structure’ is
taken to mean that the conditional density of the \( M \)-vector \( y_t \) given the entire past \( y_{t-1}, y_{t-2}, \ldots \) depends only on \( L \) lags from the past. For convenience, we will presume that the data are from a process with a Markovian structure, but one should be aware that, if \( L \) is sufficiently large, then non-Markovian data can be well approximated by an SNP density (Gallant and Long, 1997). Collect these lags together as \( x_{t-1} = (y_{t-1}, y_{t-2}, \ldots, y_{t-L}) \), where \( L \) exceeds all lags in the following discussion.

To approximate the conditional density of \( \{y_t\} \) using the ideas above, begin with a sequence of innovations \( \{z_t\} \). First consider the case of homogeneous innovations; that is, the distribution of \( z_t \) does not depend on \( x_{t-1} \). Then, as above, the density of \( z_t \) can be approximated by

\[
\phi(z) \approx [p(z)]^{2} \varphi(z)
\]

where \( z = R^{-1}(y - \mu \chi) \). The constant of proportionality is as above, \( 1 / \int [p(s)]^{2} \varphi(s) ds \). The leading term of the expansion is \( \eta_M(y \mu \chi, \Sigma) \) which is a Gaussian vector autoregression or Gaussian VAR. When \( K_z \) is put to zero, one gets \( \eta_M(y \mu \chi, \Sigma) \) exactly. When \( K_z \) is positive, one gets a semiparametric VAR density.

To approximate conditionally heterogeneous processes, proceed as above but let each coefficient of the polynomial \( p(z) \) be a polynomial of degree \( K_z \) in \( x \). A polynomial in \( z \) of degree \( K_z \), whose coefficients are polynomials of degree \( K_z \) in \( x \) is, of course, a polynomial in \( z, x \) of degree \( K_z + K_x \). Denote this polynomial by \( p(z, x) \). Denote the mapping from \( x \) to the coefficients \( a \) of \( p(z) \) such that \( p(z, x) = p(z, \chi) \) by \( a_x \) and the number of lags on which it depends by \( L_p \). The form of the density with this modification is

\[
f(y, \theta) \approx [p(z, x)]^{2} \eta_M(y \mu \chi, \Sigma)
\]

where \( z = R^{-1}(y - \mu \chi) \). The constant of proportionality is \( 1 / \int [p(s, x)]^{2} \varphi(s) ds \). When \( K_z \) is zero, the density reverts to the density above. When \( K_z \) is positive, the shape of the density will depend upon \( x \). Thus, all moments can depend upon \( x \) and the density can, in principle, approximate any form of conditional heterogeneity (Gallant and Tauchen, 1989).

In practice the second moment can exhibit marked dependence upon \( x \). In an attempt to track the second moment, \( K_z \) can get quite large. To keep \( K_z \) small when data are marked conditionally heteroskedastic, the leading term \( \eta_M(y \mu \chi, \Sigma) \) of the expansion can be put to a Gaussian GARCH rather than a Gaussian VAR. SNP uses a modified BEKK expression as described in Engle and Kroner (1995); the modifications are to add leverage and level effects.

\[
\Sigma x_{t-1} = R_0 + \sum_{i=1}^{L_0} Q_i x_{t-1} - \mu \Gamma_0 - \sum_{i=1}^{L} P_i (y_{t-i} - \mu x_{t-i}) (y_{t-i} - \mu x_{t-i})' + \sum_{i=1}^{L} \max[0, V_i (y_{t-i} - \mu x_{t-i})] \max[0, V_i (y_{t-i} - \mu x_{t-i})]' + \sum_{i=1}^{L} W_i (y_{t-i} - \mu x_{t-i})' W_i.
\]
Above, \( R_0 \) is an upper triangular matrix. The matrices \( P_i, Q_i, V_i, \) and \( W_i \) can be scalar, diagonal, or full \( M \times M \) matrices. The notation \( x_{t-1}^{(1)} \) indicates that only the first column of \( x_{t-1} \) enters the computation. The \( \max(0, x) \) function is applied elementwise. Because \( \Sigma x_{t-1} \) must be differentiable with respect to the parameters of \( \mu_{t-2} \), the \( \max(0,x) \) function is approximated by a twice continuously differentiable cubic spline. Defining \( R x_{t-1} \) by the factorization \( \Sigma x_{t-1} = R x_{t-1} R' x_{t-1}^{-1} \) and writing \( x \) for \( x_{t-1} \), the SNP density becomes

\[
  f(\mu, \theta) \approx \left[ \rho(z, x) \right]^{\Sigma x_{t-1}} = R x_{t-1} R' x_{t-1}^{-1} \]

where \( z = R x_{t-1}^{-1} (y - \mu x) \). The constant of proportionality is \( 1 / \int [\rho(z, x)]^{\Sigma x_{t-1}} \varphi(z) \, dz \). The leading term \( g_M(\mu x, \Sigma x) \) is Gaussian ARCH if \( L_g = 0 \) and \( L_r > 0 \) and Gaussian GARCH if both \( L_g > 0 \) and \( L_r > 0 \) (leaving aside the implications of \( L_v \) and \( L_w \)).

social capital

Partha Dasgupta
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Social capital is an aggregate of interpersonal networks. Belonging to a network helps a person to coordinate his strategies with others. Where the state or the market is dysfunctional, communities enable people to survive, even if they do not enable them to live well. But communities often involve hierarchical social structures; and the theory of repeated games cautions us that communitarian relationships can involve allocations where some of the parties are worse off than they would have been if they had not been locked into the relationships. Even if no overt coercion is visible, such relationships could be exploitative.

Article

Definitions?

The idea of social capital sits awkwardly in contemporary economic thinking. Although it has a powerful, intuitive appeal, the object has proven hard to track as an economic good. One can argue (Arrow, 2000) that it is misleading to use the term ‘capital’ to refer to whatever it is that ‘social capital’ happens to be, because capital is usually identified with tangible, durable and alienable objects (for example, buildings and machines), whose accumulation can be estimated and whose worth can be assessed. There is much to agree with this. But in regard to both heterogeneity and intangibility, social capital would seem to resemble knowledge and skills. So one can also argue that, since economists have
not shied away from regarding knowledge and skills as forms of capital, we should not shy away in this case either.

In an early definition, social capital was identified with those ‘features of social organization, such as trust, norms, and networks that can improve the efficiency of society by facilitating coordinated actions’ (Putnam, Leonardi and Nanetti, 1993, p. 167). The characterization suffers from a weakness: it encourages us to amalgamate strikingly different objects, namely (and in that order), beliefs, behavioural rules, and such forms of capital assets as interpersonal links (or ‘networks’), without establishing reasons why such an inclusive definition would prove useful in gaining an understanding of our social world. Subsequently, Putnam (2000, p. 19) suggested a redefinition: ‘social capital refers to connections among individuals – social networks and the norms of reciprocity and trustworthiness that arise from them.’ Since then authors have defined social capital even more inclusively, where attitudes towards others make their appearance as well: ‘Social capital generally refers to trust, concern for one’s associates, a willingness to live by the norms of one’s community and to punish those who do not’ (Bowles and Gintis, 2002, p. F419).

These definitions tell us that ‘social capital’ is an ingredient in the workings of civil society (Putnam, 1993; 2000). In a parallel development, the theory and empirics of common-property resources in poor countries (for example, coastal fisheries, village tanks, local forests, pasture lands, and threshing grounds) have revealed the character of those local institutions that enable mutually beneficial courses of action to be undertaken within communities (Dasgupta and Heal, 1979; Jodha, 1986; Ostrom, 1990; Dasgupta and Mäler, 1991; Bromley, 1992; Baland and Platteau, 1996). Development economists have also studied rotating savings and credit associations, irrigation management systems, and credit and insurance arrangements in poor countries (Ostrom, 1990; Udry, 1990; Besley, Coate and Loury, 1992; Grootaert and van Bastelaer, 2002). These studies suggest that social capital is a measure of the worth of communitarian institutions.

Where the state is weak or indifferent or rapacious, where markets do not work well or are even non-existent, communities enable people to survive, even if they do not enable them to live well. That may be why scholars writing on social capital have frequently imbued the notion with a warm glow. But there is a dark side to communities, often involving hierarchical social structures (for example, the Hindu caste system), rent-seeking groups, the Mafia, and street gangs. Omniously, the theory of repeated games (Fudenberg and Maskin, 1986) cautions us that communitarian relationships can involve allocations where some of the parties are worse off than they would have been if they had not been locked into those relationships; even though no overt coercion is visible, such relationships can be exploitative (see Dasgupta, 2000; 2005).

**Why do people keep promises?**

In order not to prejudge the character of communities, it is best not to worry about defining social capital, but to ask instead a fundamental question facing any group of people who have agreed on a joint course of action: under what contexts can the members trust one another to try to carry out their terms of the agreement?

Four points come to mind:

(i) **Mutual affection.** Consider the situation where the people involved care about one another. The
household is the most obvious example of an institution based on affection. To break a promise we have made to someone we care about is to feel bad. So we try not to do so.

(ii) **Pro-social disposition.** Another situation is where people are trustworthy, or where they reciprocate if others have behaved well towards them. Evolutionary psychologists have suggested that we are adapted to have a general disposition to reciprocate. Development psychologists have found that pro-social disposition can be formed by communal living, role modelling, education, and receiving rewards and punishments (be it here or in the afterlife).

We do not have to choose between the two viewpoints; they are not mutually exclusive. Our capacity to have such feelings as shame, guilt, fear, affection, anger, elation, reciprocity, benevolence, jealousy, and our sense of fairness and justice have emerged under selection pressure. Culture helps to shape preferences, expectations, and our notion of what constitutes fairness. Such notions in turn influence behaviour, which is known to differ among societies. But cultural coordinates enable us to identify the situations in which shame, guilt, fear, affection, anger, elation, reciprocity, benevolence, and jealousy arise; they do not displace the centrality of those feelings in the human make-up. By internalizing norms of behaviour, people enable the springs of their actions to include them. In short, they have a disposition to obey the norm, be it personal or social. When they do violate a norm, neither guilt nor shame would typically be absent, but frequently they will have rationalized the act. Making a promise is a commitment for such people; and it is essential for them that others recognize it to be so.

People are trustworthy to varying degrees. So, although pro-social disposition is not foreign to human nature, no society could rely on it exclusively; for how is one to tell to what extent someone is trustworthy?

Societies everywhere have therefore tried to establish institutions where people have the incentive to do business with one another. The incentives differ in their details, but they have one thing in common: *those who break agreements without acceptable cause are punished*. Broadly speaking, there are two ways in which the right incentives are created.

(iii) **External enforcement.** It could be that the agreement is translated into an explicit contract and enforced by an established structure of power and authority; that is, an *external enforcer*.

By an external enforcer we imagine here, for simplicity, the state. (There can, of course, be other external enforcement agencies; for example, tribal chieftains, warlords and so forth.) Consider that the rules governing transactions in the formal marketplace involve legal contracts backed by an external enforcer, namely, the state. So it is because you and the supermarket owner are confident that the state has the ability and willingness to enforce contracts that you and the owner of the supermarket are willing to transact when you go there to purchase goods.

What is the basis of that confidence? Simply to invoke an external enforcer for solving the credibility problem will not do; for why should the parties trust the state to carry out its tasks in an honest manner? A possible answer is that the government worries about its reputation. So, for example, a free and inquisitive press in a democracy, aided by a demanding civil society, helps to sober the government into believing that incompetence or malfeasance would mean an end to its rule, come the next election. Knowing that the government worries, the parties trust it to enforce agreements.

The above argument involves a system of interlocking beliefs about one another's abilities and intentions, one that supports an equilibrium in which the agreement is kept. Unfortunately, non-cooperation can also be held together by its own bootstraps. At a non-cooperative equilibrium the parties do not trust one another to keep their promises, because the external enforcer cannot be trusted to
enforce agreements. To ask whether cooperation or non-cooperation would prevail is to ask which system of beliefs has been adopted by the parties about one another's intentions. Social systems have multiple equilibria.

(iv) Mutual enforcement in long-term relationships. Suppose the group of parties in question expect to face similar transaction opportunities in each period over an indefinite future. Imagine, too, that the parties cannot depend on the law of contracts because the nearest courts are far from their residence. There may even be no lawyers in sight. In rural parts of sub-Saharan Africa, for example, much economic life is shaped outside a formal legal system. But even though no external enforcer may be available, people there do transact. Credit involves saying, ‘I lend to you now with your promise that you will repay me’; and so on. But why should the parties be sanguine that the agreements will not turn sour on account of malfeasance?

They would be sanguine if agreements were mutually enforced. The basic idea is this: a credible threat by members of a community that stiff sanctions would be imposed on anyone who broke an agreement could deter everyone from breaking it. The problem then is to make the threat credible. As the theory of repeated games has shown, the solution to the credibility problem in this case is achieved by recourse to social norms of behaviour.

By a social norm we mean a rule of behaviour (or strategy) that is followed by members of a community. For a rule of behaviour to be a social norm, it must be in the interest of everyone to act in accordance with the rule if all others were to act in accordance with it. Social norms are equilibrium rules of behaviour. The theory of repeated games has shown that, if people discount the future benefits from cooperation at a low enough rate, there are social norms that support cooperation.

As with the case of external enforcement, even when cooperation is a possible equilibrium under mutual enforcement, non-cooperation is an equilibrium too. If each party were to believe that all others would break the agreement from the start, each party would break the agreement at that stage. Failure to cooperate could be due simply to a collection of unfortunate, self-confirming beliefs.

Social capital as interpersonal networks

In common parlance, we reserve the term ‘society’ to denote a collective that has managed to equilibrate at a mutually beneficial outcome. Underlying each of the four contexts I have alluded to in which people trust one another to cooperate is a system of mutual beliefs. Because such a system of beliefs is likely to arise only if the parties know one another (at least indirectly), I believe it is best to regard social capital as interpersonal networks. The advantage of such a lean notion is that it does not prejudge the asset's quality. Just as a building can remain unused and a wetland can be misused, so a network can remain inactive or be put to use in socially destructive ways. There is nothing good or bad about interpersonal networks: other things being equal, it is the use to which a network is put by members that determines its quality.

Interpersonal networks are systems of communication channels linking people to one another. Networks include as tightly woven a unit as a nuclear family or a kinship group, and one as extensive as a voluntary organization, such as Amnesty International. We are born into certain networks and enter new ones. Personal relationships, whether or not they are long term, are emergent features within networks, and involve systems of mutual beliefs. For example, Seabright (1997) has suggested that civic engagements and communal activities heighten the disposition to cooperate (context (ii) above). The
The idea is that trust begets trust and that this gives rise to a positive feedback between civic and communal activities and a disposition to be so engaged. That positive feedback is, however, tempered by the cost of additional engagements (time), which, typically, rises with increasing engagements.

Networks and human capital

How did people who now interact with one another get to connect in the first place? In village economies in poor countries the answer is simple: mostly they have known one another from birth. People engaged in long-term relationships based on social norms (contexts (ii) and (iv) above) – or communities, for short – have to know one another, at least indirectly through people they know personally. Communities are personal and exclusive. Members have names, personalities and attributes. An outsider's word is not as good as an insider's. Markets, in contrast, are impersonal and inclusive.

In his pioneering work, Coleman (1988) saw social capital as an input in the production of human capital. In modern, mobile societies, people have to invest resources trying to meet people. Some of the investment is pleasurable, some not. Even so, just as academics are paid for what they mostly like doing anyway (as a return on investment in their education), networking would be expected to pay dividends even when maintaining networks is a pleasurable activity.

Burt (1992) has found among business firms in the United States, controlling for age, education and experience, that employees enjoying strategic positions in networks are more highly compensated than those who are not. His findings confirm that some of the returns from investment in network creation are captured by the investor. However, because of network externalities, not all the returns can be captured by the investor: when A and B establish a channel linking them, the investment improves both A's and B's earnings, but it also improves the earnings of C, who was already connected to B. The findings of Burt and his colleagues imply that membership in networks is a component of someone's 'human capital'. If firms pay employees on the basis of what they contribute to profitability, they would look not only at the conventional human capital employees bring with them (for example, health, education, experience, personality), but also the personal contacts they possess. It would be informative to untangle networks from the rest of human capital. This could reveal the extent to which returns from network investment are captured by the investor. But measurement problems abound. They may be insurmountable because of the pervasive externalities to which they give rise.

Micro-behaviour and macro-performance

How do network activities translate into the macro-performance of economies? The discussion in the previous section implied that to the extent that the worth of contacts is reflected in wages and salaries, social capital is a component of human capital. It should be noted though that in poor countries, where labour markets can malfunction badly, or can even be non-existent, attributing returns to the various factors of production is especially problematic. But even if we were to leave that problem aside, we know that networks give rise to externalities. This makes the translation from micro-behaviour to macro-performance an especially difficult subject.

To illustrate, consider a simple formulation of economy-wide production possibilities. Let individuals be indexed by \( j \) (\( j = 1, 2, \ldots \)). Let \( K \) denote the economy's stock of physical capital and \( L_j \) the labour-hours...
put in by person $j$. I do not specify the prevailing system of property rights to physical capital, nor do I describe labour relations, because to do so would be to beg the questions being discussed here. But it is as well to keep in mind that in a well-developed market economy $K$ would be dispersed private property, in others $K$ would be in great measure publicly owned, in yet others much would be communally owned, and so forth. It is also worth remembering that in market economies labour is wage based, that in subsistence economies ‘family labour’ best approximates the character of labour relations, and that labour cooperatives are not unknown in certain parts of the world; and so on.

Let $h_j$ be the human capital of person $j$ (years of schooling, health). His or her effective labour input is then $h_j L_j$. $h_j$ is what one may call ‘traditional human capital’ (we leave aside the networks to which $j$ belongs). Human capital is embodied in workers. Given the economy's knowledge base and institutions (the latter I take here to be the engagements brought about by the interpersonal networks), human capital in conjunction with physical capital produces an all-purpose output, $Y$, which we may call gross national product (GNP). Each of the aggregate indices requires for its construction prices for the multitude of components that make up the aggregate. In industrial market economies, the required prices are typically market prices. When externalities are pervasive, the construction of such indices poses special problems. Let us therefore assume away problems of aggregation by imagining the economy to possess a single good, $Y$. Problems nevertheless remain in measuring the pathways that link micro-behaviour to macro-performance. Let us study them.

Total factor productivity

Write $H = \sum_j (h_j L_j)$. $H$ is aggregate human capital. Now suppose that output possibilities are given by the relationship

$$Y = AF(K, H), \quad (A > 0),$$

(1)

where $F$ is the economy's aggregate production function. $F$ is non-negative and is assumed to be an increasing function of both $K$ and $H$.

In eq. (1) $A$ is total factor productivity. It is a combined index of institutional capabilities (including the prevailing system of property rights) and publicly shared knowledge. A macroeconomy characterized by the production function $F$ would produce more, other things being equal, if $A$ were larger (that is, if publicly shared knowledge was greater or institutional capabilities higher). Of course, the economy would also produce more, other things being equal, if $K$ or $h_j$ or $L_j$ were larger. In short, technological possibilities for transforming the services of physical and human capital into output, when embedded in the prevailing institutional structure of the economy, account for eq. (1).

Consider now a scenario where civic cooperation increases in the community: the economy moves from a bad equilibrium system of mutual beliefs to a good one. The increase would make possible a more efficient allocation of resources in production. A question arises: would the increase in cooperation
appear as a heightened value of $A$, or would it appear as an increase in $H$, or as increases in both? The answer lies in the extent to which network externalities are like public goods. If the externalities are confined to small groups (that is, small groups are capable of undertaking cooperative actions on their own – with little effect on others – and take such actions in the good equilibrium), the improvements in question would be reflected mainly through the $h_j$'s of those in the groups engaged in increased cooperation. On the other hand, if the externalities are economy-wide (as in the case of an increase in quasi-voluntary compliance in the economy as a whole owing to an altered set of beliefs, even about members of society one does not personally know), the improvements would be reflected mainly through $A$. Either way, the directional changes in macro-performance (though not the magnitude of the changes) would be the same. Other things being equal, an increase in $A$ or in some of the $h_j$'s (brought about by whichever of the mechanisms we have considered) would mean an increase in GNP, an increase in wages, salaries and profits, and possibly an increase in investment in both physical and human capital. The latter would result in faster rate of growth in output and consumption, and, if a constant proportion of income were spent on health, a more rapid improvement in health as well.

Interpreting cross-section findings

It will be useful to connect the macroeconomic account to the findings from less aggregated data. In his analysis of statistics from the 20 administrative regions of Italy, Putnam (1993) found civic tradition to be a strong predictor of contemporary economic indicators. He showed that indices of civic engagement in the early years of the 20th century were highly correlated with employment, income and infant survival in the early 1970s. Putnam also found that regional differences in civic engagement can be traced back several centuries and that, controlling for civic traditions, indices of industrialization and public health have no impact on current civic engagement. As he put it, the causal link appears to be from civics to economics, not the other way round. How do his findings square with the formulation in eq. (1)?

The same sort of question can be asked of even less aggregated data. Narayan and Pritchett (1999) have analysed statistics on household expenditure and social engagements in a sample of some 50 villages in Tanzania, to discover that households in villages where there is greater participation in village-level social organizations on average enjoy greater income per head. The authors have also provided statistical reasons for concluding that greater communitarian engagements result in higher household expenditure rather than the other way round. To analyse these findings in terms of our macroeconomic formulation, consider two autarkic communities, labelled by $i (=1, 2)$. I simplify by assuming that members of a community are identical. Denote the human capital per person in community $i$ by $h_i$. By $h_i$ I now mean not only the traditional forms of human capital (health and education), but also network capital. Let $L_i$ denote the number of hours worked by someone in $i$, by $N_i$ the size of $i$'s population, and by $K_i$ the total stock of physical assets in $i$. Aggregate output, $Y_i$, is

$$Y_i = A_i F(K_i, N_i h_i L_i).$$

(2)
Improvements in civic cooperation are reflected in increases in $A$, or $h$, or both. It follows that if civic cooperation were greater among people in community 1 than in community 2, we would have $A_1 > A_2$, or $h_1 > h_2$, or both. Imagine now that the two communities have the same population size, possess identical amounts of physical capital, and work the same number of hours. GNP in community 1 would be greater than GNP in community 2 (that is, $Y_1 > Y_2$). More generally, an observer would discover that, controlling for differences in $K$ and $L$, there is a positive association between a community's cooperative culture (be it total factor productivity, $A_i$, or human capital, $h_i$) and its mean household income ($Y_i/N$). This is one way to interpret the finding reported in Narayan and Pritchett (1999).

Consider now a different thought-experiment. Imagine that in year 1900 the two communities had been identical in all respects but for their cooperative culture, of which community 1 had more (that is, in 1900, $A_1 > A_2$, or $h_1 > h_2$, or both). Imagine next that, since 1900, both $A_i$ and $h_i$ have remained constant. Suppose next that people in both places have followed a simple saving rule: a constant fraction $s_K (>0)$ of aggregate output has been invested each year in accumulating physical capital. (For the moment I imagine that net investment in human capital in both communities is nil.) In order to make the comparison between the communities simple, imagine finally that the communities have remained identical in their demographic features. It is then obvious that in year 1970 community 1 would be richer than community 2 in terms of output, wages and salaries, profits, consumption and wealth. This is one way to interpret Putnam's (1993) findings.

Notice that we have not had to invoke possible increases in total factor productivity ($A_i$) or human capital ($h_i$) to explain why a cooperative culture is beneficial. Total factor productivity and human capital have done all the work in our analysis of the empirical finding: we have not had to invoke secular improvements in them to explain why a more cooperative society would be expected to perform better economically.

As the communities in our thought experiment are both autarkic, there is no flow of physical capital from one to the other. This is an economic distortion for the combined communities: the rates of return on investment in physical capital in the two places remain unequal. The source of the distortion is the enclave nature of the two communities, occasioned in our example by an absence of markets linking them. There would be gains to be enjoyed if physical capital could flow from community 2 to community 1.

Autarky is an extreme assumption, but it is not a misleading assumption. What the model points to is that, to the extent that social capital is exclusive, it inhibits the flow of resources, in this case a movement of physical capital from one place to the other. Put another way, if markets fail to function well, capital does not move from community 2 to community 1 to the extent it ideally should. When social networks within each community block the growth of markets, their presence inhibits economic progress.

**Dark matters**

Two potential weaknesses of resource allocation mechanisms built on social capital are easy enough to
Exclusivity. Networks are exclusive, not inclusive. This means that ‘anonymity’, the hallmark of competitive markets, is absent from the operations of networks. When market enthusiasts proclaim that one person's money is as good as any other person's in the market place, it is anonymity they invoke. In allocation mechanisms governed by networks, however, ‘names’ matter. Transactions are personalized. This implies inefficiencies: resources are unable to move to their most productive uses.

Inequalities. The benefits of cooperation are frequently captured by the more powerful within the network. McKean (1992), among others, has discovered that the local elite (usually wealthier households) capture a disproportionate share of the benefits of common-property resources, such as coastal fisheries and forest products. Her finding is consistent with the possibility that all who cooperate benefit.

Exploitation within networks

The reason why social capital continues to radiate a warm glow in the literature is that the subject has been motivated by examples of the Prisoner's Dilemma. However, one-period games involving the use of common property resources don't give rise to the Prisoner's Dilemma (Dasgupta, 2005). Consider an indefinitely repeated game among N players, in which (a) the stage game possesses a unique Nash equilibrium and (b) the ‘min-max’ payoffs of the players are lower than their respective payoffs in the Nash equilibrium. As is well known (Fudenberg and Maskin, 1986), if the players discount their future payoffs at a low enough rate, there are social norms that can sustain an outcome where the time-average of the per-period payoff to a player is less than the payoff at the unique Nash equilibrium. That player would be worse off in a long-term relationship with the others than if the players were not in a long-term relationship. The social norm sustaining that outcome would be exploitative of the player.

Inequality is not the same as exploitation, which is why to demonstrate exploitation in an empirically satisfactory way will prove to be very hard: any such demonstration would involve comparison of an observable state of affairs with a counterfactual. However, some stark examples are suggestive. In Indian villages, access to local common-property resources is often restricted to the privileged (for example, caste Hindus), who are also among the more prosperous landowners. The outcasts (euphemistically called members of ‘schedule castes’) are among the poorest of the poor. Stark inequities exist, too, in patron–client relationships in agrarian societies, which make it very likely that the ‘client’ is worse off in consequence of that relationship than without it. Ogilvie (2003) has unearthed striking differences between the life chances of women in 17th-century Germany (embedded in dense networks) and the life chances of women in 17th-century England (not so embedded in dense networks): English women were better off.

Morals

Social capital is an aggregate of interpersonal networks. From the economic point of view, belonging to a network helps a person to coordinate his strategies with others. We should not prejudge the character of the strategies on which members of a network coordinate. As with any other form of capital asset, social capital can be put to good use or bad.

Abstract

Since the late 1970s there has been a dramatic shift of focus in social choice theory, with structured sets of alternatives and restricted domains of the sort encountered in economic problems coming to the fore. This article provides an overview of some of the recent contributions to four topics in normative social choice theory in which economic modelling has played a prominent role: Arrovian social choice theory on economic domains, variable-population social choice, strategy-proof social choice, and axiomatic models of resource allocation.

Article

With the exception of the research on single-peaked preferences and their multidimensional generalizations, for the most part the early literature on social choice theory dealt with abstract sets of alternatives and domains of preferences and feasible sets that exhibited little structure. Since the late 1970s there has been a dramatic shift of focus, with structured sets of alternatives and restricted domains coming to the fore. In particular, a great deal of attention has been directed towards the kinds of concrete problems that arise in economics, with alternatives being allocations of goods and preferences and feasible sets satisfying the sorts of restrictions encountered in economic models. In this article, we
provide an overview of some of the recent contributions to four topics in normative social choice theory in which economic modelling has played a prominent role: Arrovian social choice theory on economic domains, variable-population social choice, strategy-proof social choice, and axiomatic models of resource allocation. Structured environments have also been considered in positive social choice theory, notably in the political economy literature. See Austen-Smith and Banks (2005) for an introduction to this literature. Other areas of social choice theory have also been active in recent years: see Arrow, Sen and Suzumura (2002; 2008) for recent surveys of these topics.

**Arrovian social choice on economic domains**

Arrow's theorem (see Arrow, 1963) is concerned with the aggregation of profiles of individual preference orderings into a social ordering of a set of alternatives $X$. Let $\mathcal{R}$ denote the set of all orderings of $X$. In Arrow's theorem, there is a finite set of individuals $N=\{1, \ldots , n\}$ with $n \geq 2$, each of whom has a weak preference ordering $R_i$ on $X$. An (Arrovian) social welfare function $f$ assigns a social ordering $\mathcal{R} = f(\mathcal{R}_i)$ of $X$ to each profile $\mathcal{R}=(R_1, \ldots , R_n)$ of individual preference orderings in some domain $\mathcal{D}$ of profiles. Arrow's theorem demonstrates that it is impossible for a social welfare function to satisfy independence of irrelevant alternatives, henceforth IIA (the social ranking of a pair of alternatives depends only on the individual rankings of these alternatives), weak Pareto (if everyone strictly prefers one alternative to a second, then so does society), and nondictatorship (nobody's strict preferences are always respected) if the domain is unrestricted ($\mathcal{D} = \mathcal{R}^n$) and $|X| \geq 3$.

Arrow's theorem is not directly applicable to economic problems. In economic problems, both the social alternatives and the individual preferences exhibit considerable structure and, therefore, a social welfare function only needs to be defined on a restricted domain of preference profiles. For a comprehensive survey of the literature on Arrovian social choice on economic domains, see Le Breton and Weymark (2008).

When $X$ is a subset of the real line $\mathbb{R}$, a preference $R_i$ is *single-peaked* if there is a unique best alternative $\pi (R_i)$ in $X$, the *peak*, and alternatives on the same side of the peak are worse the further away from the peak they are. Let $\mathcal{S}$ denote the set of all single-peaked preferences on $X$. If the alternatives in $X$ are different levels of a single public good, it is natural to expect individual preferences to be single-peaked. Black (1948) has shown that ranking pairs of alternatives by majority rule produces a social ordering if the individuals have single-peaked preferences when $n$ is odd. More generally, it follows from results in Moulin (1980) that on $\mathcal{S}^n$, any *generalized median social welfare* function satisfies all the Arrow axioms except his domain assumption with nondictatorship strengthened to anonymity (permuting preferences leaves the social ordering invariant). These functions are defined by first *fixing* $n-1$ single-peaked preferences (which can be interpreted as being the preferences of phantom voters) and then, for any profile of single-peaked preferences in $\mathcal{S}^n$ of the $n$ real individuals, applying majority rule to the resulting profile of $2n-1$ preferences, both real and phantom. Note that the total number of preferences in one of these profiles is odd, so Black's theorem applies. Each specification of the preferences of the phantom voters defines a distinct generalized median social welfare function. Ehlers and Storcken (2002) have characterized all the social welfare functions on this domain that satisfy IIA and weak Pareto.
A domain $\mathcal{D}$ of preference profiles is Arrow inconsistent if no social welfare function satisfying Arrow's three non-domain axioms exists on $\mathcal{D}$. In a seminal article, Kalai, Muller and Satterthwaite (1979) identified a sufficient condition for $\mathcal{D}$ to be Arrow inconsistent when $\mathcal{D}$ is the Cartesian product of individual preference domains $\mathcal{D}_i$. A set of alternatives is free if preference profiles are unrestricted on this set. A domain is saturating if (i) there are at least two free pairs, (ii) any two free pairs of alternatives can be connected to each other by means of a series of overlapping free triples, and (iii) any other pair of alternatives is trivial in the sense that there is only one way in which any individual ranks these alternatives. When each of the individual preference domains $\mathcal{D}_i$ is the same, saturating preference domains are Arrow inconsistent. Because a free pair is part of a free triple when the domain is saturating, Arrow's theorem implies that there is a dictator on this pair when IIA and weak Pareto are satisfied. The same person must be a dictator on all free pairs because adjacent free triples in the connection procedure have two alternatives in common. On trivial pairs, by weak Pareto, everyone is a dictator. This method of showing that a domain is Arrow inconsistent is known as the local approach.

Kalai, Muller and Satterthwaite (1979) have also shown that, when $\mathcal{X} = \mathbb{R}^m_+$, interpreted as the set of all allocations of $m$ divisible public goods, the domain of all profiles of classical public goods preferences (that is, continuous, strictly monotonic, and convex preferences) is saturating and, hence, is Arrow inconsistent when $m \geq 2$. Other examples of saturating domains include the set of all expected utility preferences on the set of lotteries on three or more certain outcomes (Le Breton, 1986) and the set of Euclidean spatial preferences on $\mathbb{R}^m_+$ or $\mathbb{R}^m$, that is, preferences for which there is a global best alternative and alternatives are ranked by the negative of their distance from this alternative (Le Breton and Weymark, 2002). The Arrow inconsistency of the spatial preference domain was originally shown by Border (1984) using a different proof strategy.

When alternatives are allocations of private goods and individuals only care about their own consumption, Bordes and Le Breton (1989) have identified a strengthening of the concept of a saturating domain that implies that the domain is Arrow inconsistent. If $\mathcal{X}$ consists of all the allocations of two or more divisible private goods in which everyone is guaranteed to receive a positive amount of some good, then the domain satisfies this condition if individuals can have any classical private goods preference, that is, a preference that is continuous, strictly monotonic, and convex over own consumption (see also Maskin, 1976; Border, 1983).

The examples considered so far all have the feature that the set of alternatives has a Cartesian structure. If $\mathcal{X}$ incorporates feasibility constraints, this is not the case. Using a modification of the local approach, Bordes, Campbell and Le Breton (1995) have shown that the domain of classical private goods preferences is Arrow inconsistent if the set of alternatives is the set of feasible allocations with positive consumptions of all goods for an exchange economy with two or more divisible private goods. Bordes and Le Breton (1990) have also adapted the local approach to analyse Arrow consistency in assignment, matching and pairing problems. In an assignment problem, one of $n$ indivisible objects is assigned to each of the $n$ individuals. In a matching problem, there are two groups of $n$ individuals with each person from one group matched to one person from the other group. In a pairing problem, an even number $n$ of individuals is grouped in pairs. If the preference domains in these problems are such that individuals only care about which individual or good they are matched, paired or assigned to, but are otherwise unrestricted, then the domain is Arrow inconsistent when $n \geq 4$.

The preceding discussion suggests that economic domain restrictions do not provide a satisfactory way of circumventing Arrow's social welfare function impossibility theorem when the set of alternatives is not one-dimensional. This conclusion is reinforced by the results in Redekop (1995) that show that, in order for a subset of a domain of Arrow-inconsistent economic preferences to be Arrow consistent, the sub-domain must be topologically small. Roughly speaking, this requirement severely limits the amount of preference diversity that can be present in the domain.

Arrow's theorem can also be formulated in terms of a social choice correspondence. For each preference profile $\mathbf{R}$ in its preference domain $\mathcal{P}$, a social choice correspondence $C$ specifies the socially optimal alternatives $C(\mathbf{A}, \mathbf{R})$ in each agenda $\mathbf{A}$ (feasible subset of $X$) in its agenda domain $\mathcal{A}$. In its choice-theoretic formulation, the Arrow axioms are Arrow's choice axiom (for a fixed preference profile, if agenda $A$ is a subset of agenda $B$, then the set of alternatives chosen in $A$ consists of the restriction to $A$ of the set of alternatives chosen from $B$ when this restriction is nonempty), independence of infeasible alternatives (the alternatives chosen from an agenda only depend on the preferences for alternatives in this agenda), Pareto optimality (only Pareto optimal alternatives are chosen), and nondictatorship (the chosen alternatives are not always a subset of one individual's best feasible alternatives). Arrow's theorem shows that these conditions are inconsistent if the preference domain is unrestricted and the agenda domain consists of all the finite subsets of $X$. When the agenda domain is closed under finite unions (as is the case in the choice-theoretic version of Arrow's theorem), Arrow's choice axiom is necessary and sufficient for the chosen alternatives in each admissible agenda to be generated by maximizing a profile-dependent social ordering of $X$ (see Hansson, 1968).

In some economic applications, the ability to restrict the agenda domain, not just the preference domain, has weakened the constraints on the admissible social choice correspondences sufficiently for the Arrovian axioms to be consistent. This observation was first made by Bailey (1979), who noted that the set of feasible allocations in an exchange economy does not contain a finite number of alternatives, and so does not satisfy Arrow's agenda domain assumption. While the example Bailey used to show the consistency of the Arrow axioms is problematic, as Donaldson and Weymark (1988) have shown, if each agenda in the agenda domain is the set of feasible allocations for an exchange economy with divisible private goods (different aggregate endowments yield different agendas) and if each profile in the preference domain is a profile of classical private goods preferences for which no individual is indifferent between a consumption bundle with strictly positive components and one that has zero consumption of some good, then the Arrow axioms are consistent. For example, the equal division Walrasian social choice correspondence satisfies these axioms. For each exchange economy, this correspondence selects the set of Walrasian (competitive) equilibrium allocations using an equal division of the aggregate endowment as each individual's endowment vector.

When production is possible, an agenda is the set of feasible allocations given the aggregate resource endowment and the production technologies. Possible restrictions on agendas include compactness, comprehensiveness (that is, they satisfy free disposal), and convexity. When there are only public goods, Le Breton and Weymark (2002) have shown that the Arrow axioms are consistent if the preference domain includes only Euclidean spatial preferences on $\mathbb{R}^m_+$ with $m \geq 2$ and the agenda domain includes only compact sets with nonempty interiors. With these domain assumptions, a social choice correspondence satisfying the Arrow axioms can be constructed by fixing a utility representation for each preference and then using an individualistic Bergson–Samuelson social welfare function to choose
the best alternatives from each agenda for each preference profile.

In both of these examples, one of the choice-theoretic versions of the Arrow axioms is vacuous. In the exchange economy example, it is Arrow's choice axiom, whereas in the spatial example, it is independence of infeasible alternatives. For a public goods economy with at least two divisible goods, none of the Arrow axioms is vacuous if the agenda domain includes only compact comprehensive sets with nonempty interiors and the preference domain includes only classical public goods preferences. By means of an example, Donaldson and Weymark (1988) have shown that the Arrow axioms are consistent with these domain assumptions. However, their example exhibits dictatorial features and it is not known if the axioms are still consistent if nondictatorship is replaced with anonymity (permuting preferences for a given agenda does not change the set of chosen alternatives). Donaldson and Weymark have also established a private goods version of this possibility theorem.

Arrovian impossibility results have also been obtained with the social choice correspondence framework using a strengthened form of independence of infeasible alternatives, due to Donaldson and Weymark (1988), called independence of Pareto-irrelevant alternatives. This condition requires the chosen alternatives from each agenda to depend only on the preferences over the Pareto optimal alternatives.

For example, for public goods economies, Duggan (1996) has shown that this strengthened independence condition and the other Arrow axioms are inconsistent if \( X = \mathbb{R}^m \) with \( m \geq 3 \), the agenda domain consists of all the compact, comprehensive and convex subsets of \( X \), and the preference domain is the set of all profiles of classical public goods preferences for which individual preferences are strictly convex in own consumption.

In contrast with the local approach used to analyse social welfare functions, no unifying methodology has been developed to investigate the consistency of Arrow's choice-theoretic axioms, with the consequence that little is yet known about where the boundary between possibility and impossibility for social choice correspondences lies.

**Variable-population social choice**

The Arrovian framework is based on ordinal preferences that are interpersonally noncomparable and, hence, any social decision rule that makes use of interpersonal utility comparisons, such as classical utilitarianism, is ruled out from the outset. Sen (1974) has argued that this informational poverty plays a fundamental role in precipitating Arrovian impossibilities, and has proposed a generalization of the concept of an Arrovian social welfare function called a social welfare functional to allow for interpersonal utility comparisons. Each individual \( i \) is assumed to have a utility function \( U_i \) on the set of alternatives \( X_i \) in which he is alive and a social welfare functional maps each admissible profile of individual utility functions into a social ordering of the set of all alternatives \( X \). In fixed-population social choice, \( X_i = X \) for all \( i \). There is an extensive literature that has investigated the implications for the functional form of these functionals of combining different assumptions concerning the measurability and interpersonal comparability of utility with various normative criteria, including analogues of the Arrovian axioms, when there is a fixed population: see Bossert and Weymark (2004) for a survey. In this section, we provide an introduction to the main issues that arise in selecting appropriate social objective functions when the population size is not fixed. A detailed treatment of this topic and further references

Social choice (new developments): The New Palgrave Dictionary of Economics may be found in Blackorby, Bossert and Donaldson (2005).

Since the 1980s, population ethics has established itself as an important branch of moral philosophy. Parfit (1984) has been particularly influential in bringing this issue to the attention of philosophers and, more generally, to scholars in various disciplines interested in applied ethics. An up-to-date account of variable-population issues in moral philosophy is given by Broome (2004). Although there are many economic applications of variable-population social choice, such as the design of aid packages (that may have population consequences) for developing countries, the choice of budgets devoted to prenatal care, and policies affecting the intergenerational allocation of resources, the economics literature, with few exceptions, did not initially pay much attention to this topic. Much of the recent interest in these issues can be traced to the influential article by Blackorby and Donaldson (1984), who extended the welfarist model of social choice to allow for a variable population.

In this setting, each alternative \(x \in X\) is a complete description of the relevant state of affairs including the size and composition of the population. Furthermore, alternatives are interpreted as full histories of the world, from the remote past to the distant future. Thus, the set of those alive in \(x\) contains everyone who has ever lived in this alternative and not merely those who are alive in a given period. This assumption is important to avoid counter-intuitive conclusions regarding the termination of lives. As a consequence, ending someone's life does not change population size; it affects the lifetime and, possibly, the lifetime utility of the person in question.

For each \(x \in X\), \(u_i = U_i(x)\) is the lifetime well-being (utility) of any individual \(i\) alive in \(x\) and \(U(x)\) is the vector of utilities of these individuals. The standard convention is to assign a lifetime utility level of zero to a neutral life. A life, taken as a whole, is a neutral life from the viewpoint of the individual leading it if it is as good as a life without any experiences (a state of permanent unconsciousness). Note that it is not necessary to invoke states of non-existence of an individual in order to define the notion of neutrality. In particular, it is not claimed that an individual can gain or lose by being brought into existence. Therefore, an existing person's life is worth living if the individual's lifetime utility is positive. Welfarism is the principle that the only features of an alternative that are socially relevant are the utilities of the individuals alive in this alternative. Welfarism implies that the social ordering of \(X\) for any profile of individual utility functions in the domain of the social welfare functional can be determined by a single social welfare ordering of all possible vectors of individual utilities \(\mathcal{U} = \bigcup_{n \in \mathbb{N}} \mathbb{R}^n\), where \(\mathbb{N}\) is the set of positive integers; that is, if a social welfare functional is welfarist, there exists an ordering \(R\) on \(\mathcal{U}\) such that alternative \(x \in X\) is at least as good as alternative \(y \in X\) for the profile of utility functions \(U\) if and only if \(U(x)RU(y)\). The set of individuals alive in \(x\) and \(y\) need not be the same. Thus, given welfarism, the problem of variable-population social evaluation can be reduced to the problem of establishing a social welfare ordering \(R\) on the set \(\mathcal{U}\) of all utility vectors (of varying dimension). If there are \(n \in \mathbb{N}\) individuals alive in an alternative, without loss of generality they can be labelled \(1, \ldots, n\) provided that the standard anonymity property is satisfied. A representation of the restriction of \(R\) to fixed-population comparisons is an individualistic Bergson-Samuelson social welfare function.

The most commonly discussed examples of variable-population social welfare orderings are extensions of utilitarianism. According to average utilitarianism (AU) (resp. classical utilitarianism (CU)), average (resp. total) utilities are used as the criterion to compare any two utility vectors. Formally, for all \(n, m \in \mathbb{N}\), all \(u \in \mathbb{R}^n\), and all \(v \in \mathbb{R}^m\), \(uRUv\) if and only if \(\frac{1}{n}\sum_{i=1}^{n} u_i \geq \frac{1}{m}\sum_{i=1}^{m} v_i\) (resp. \(uRCUv\) if and
only if $\sum_{i=1}^{n} u_i \geq \sum_{i=1}^{m} v_i$). Clearly, fixed-population comparisons are the same according to $R_{AU}$ and $R_{CU}$, but this is not necessarily the case if $n$ and $m$ differ.

Average utilitarianism is rejected by most contributors to this area. Its fundamental problem is that the value of adding a person, *ceteris paribus*, depends on the utilities of those alive. This has rather unfortunate consequences. Suppose, for example, that everyone is extremely well-off in an alternative and we consider the addition of an individual who, if brought into existence, would have a lifetime utility just slightly below the average of the existing population and no one else's utility is affected.

According to AU, this person should not be brought into existence. The following example is even more disturbing. Consider a society in which everyone is extremely miserable by all standards (and well below neutrality). AU recommends the *ceteris paribus* addition of anyone with a lifetime utility slightly above the average, even if this utility level is well below neutrality.

Classical utilitarianism suffers from what Parfit (1984) calls the *repugnant conclusion*. A variable-population social welfare ordering $R$ implies the repugnant conclusion if, for any population size $n$, for any positive level of utility $\xi$ (no matter how high), and for any level of utility $\varepsilon \in (0, \xi)$ (no matter how close to zero), there exists a population size $m > n$ such that a population with $n$ people in which everyone has a lifetime utility of $\xi$ is considered inferior to a population of $m$ individuals each of whom has a lifetime utility of $\varepsilon$; that is, for any situation in which everyone alive has an arbitrarily high level of well-being, there is always a situation of mass poverty (with everyone arbitrarily close to neutrality) that is considered superior.

In order to avoid the repugnant conclusion and, at the same time, the counter-intuitive implications of average utilitarianism, Blackorby and Donaldson (1984) have proposed *critical-level utilitarianism* (CLU) with a positive critical level as an alternative criterion. CLU employs a parameter $\alpha \in \mathbb{R}$ (the critical level) and is defined by letting, for all $n, m \in \mathbb{N}$, all $u \in \mathbb{R}^n$, and all $v \in \mathbb{R}^m$, $uR_{CLU}v$ if and only if $\sum_{i=1}^{n} [u_i - \alpha] \geq \sum_{i=1}^{m} [v_i - \alpha]$. The special case corresponding to $\alpha = 0$ is CU. The parameter $\alpha$ has an intuitive interpretation: it is the level of utility that, if experienced by an additional person, makes the alternative resulting from the *ceteris paribus* addition of such a person to any given society as good as the original. Because the critical level is constant, the problems of AU alluded to above are avoided. If, moreover, $\alpha$ is positive, the repugnant conclusion is avoided because there is a positive difference between the critical level and the level of utility representing neutrality.

In addition to providing a thorough analysis of critical-level utilitarianism and its main alternatives, Blackorby, Bossert and Donaldson (2005) have discussed several extensions of the basic model. For example, the critical-level utilitarian orderings can be generalized by considering transformed utilities rather than the utilities themselves. If the transformation is chosen to be strictly concave, the corresponding social ordering represents inequality aversion in utilities. Furthermore, they have considered orderings that use non-welfare information such as birth dates and lifetimes in addition to lifetime utilities, as well as variants that incorporate uncertainty. Moreover, they have analysed variable-population choice problems and applications.

### Strategy-proof social choice

A *social choice* function $g$ chooses one alternative from the set of alternatives $X$ for each preference
profile in the domain $\mathcal{D}$. If it is only known that the true profile is in $\mathcal{D}$, in order to implement the desired choice $g(R)$ when the profile is $R$, individuals must have an incentive to truthfully report their preferences. *Strategy-proofness* is the requirement that nobody can obtain a preferred outcome by reporting a false preference regardless of what the preferences of the other individuals are. Strategy-proofness places severe constraints on the kinds of social choice functions that can be considered and, on some domains, conflicts with other social desiderata (for introductions to recent developments in strategy-proof social choice theory, see Sprumont, 1995; Barberà, 2001).

The classic result on strategy-proofness is the Gibbard (1973)–Satterthwaite (1975) theorem, which shows that no social choice function $g$ can satisfy both nondictatorship and Pareto optimality when $\mathcal{D} = \mathbf{R}^n$ if $|X| \geq 3$. The same conclusion follows if Pareto optimality is replaced with *unanimity*, the requirement that an alternative is chosen if everybody agrees that it is uniquely best. Either of these conditions implies that the range $rg(g)$ of $g$ is all of $X$ when the domain is unrestricted. A variant of the Gibbard–Satterthwaite theorem states that on an unrestricted domain, if $|rg(g)| \geq 3$, then strategy-proofness implies that someone must be a dictator on $rg(g)$ (that is, $g$ always chooses one of this person's best alternatives on $rg(g)$).

More positive results are obtained if it is known that preferences are single-peaked. Moulin (1980) has shown that if $X \subseteq \mathbf{R}$, $\mathcal{D} = \mathbf{S}^n$, and the social choice function $g$ only depends on the peaks of the individual preferences, then $g$ satisfies strategy-proofness if and only if it is a minmax social choice function and it satisfies strategy-proofness, Pareto optimality and anonymity if and only if it is a generalized median social choice function. A *minmax* social choice function $g$ is defined by specifying an alternative $x_S$ in the closure of $X$ for each coalition of individuals with $x_T \leq x_S$ if $S \subseteq T$ and setting

$$g(R) = \min \left\{ \max \left\{ \pi(R_i), x_S \right\} \right\}, \quad \forall R \in \mathbf{S}^n.$$

For each $R \in \mathbf{S}^n$, a *generalized median social choice* function chooses the median of the actual individual preference peaks and the fixed peaks of $n-1$ phantom voters. These functions are minmax rules in which the alternatives $x_S$ are the same for coalitions of the same size. Barberà, Gul and Stacchetti (1993) have provided an alternative characterization of minmax rules in terms of winning coalitions that has proved to be quite useful. If, as is the case with minmax rules, the chosen alternative for each profile depends only on each person's most-preferred alternative(s) on the range, the social choice function satisfies the *tops-only* property. On the domain $\mathbf{S}^n$, Barberà and Jackson (1994) have shown that the tops-only property assumed by Moulin (1980) is implied by strategy-proofness if either $rg(g)$ is an interval or $g$ satisfies Pareto optimality.

The original strategies used to prove the Gibbard–Satterthwaite theorem cannot be adopted to analyse strategy-proofness when preferences are continuous. The problem is that these proofs alter profiles by moving two alternatives to the top two positions in a person's preference, but this is not possible with continuous preferences if $X$ is a connected set, as there can be no second-ranked alternative. This difficulty was overcome by Barberà and Peleg (1990) who established a version of the Gibbard–
Satterthwaite theorem for continuous preferences on a metric space of alternatives using the option set methodology introduced by Laffond (1980), Satterthwaite and Sonnenschein (1981), and Barberà (1983). An option set identifies the set of outcomes that are feasible given the preferences of a subgroup of individuals for some admissible reported preferences of the rest of the population. For example, when there is a dictator $d$, the option set generated by $R_d$ consists of the best alternatives on the range for this preference and the option set generated by any other person's preference is the whole range. The option set methodology proceeds by identifying the structure imposed on option sets by the properties that one wants the social choice function to satisfy.

In order for a social choice function to be strategy-proof, it must ignore most of the information about individual preferences. On many domains in which all admissible preferences have unique best alternatives on the range, strategy-proofness implies the tops-only property provided that the range of the social choice function satisfies some regularity condition. Weymark (2004) has proposed a proof strategy for establishing the tops-only property that avoids the model specificity of earlier proofs.

A social choice function defined on a domain of profiles of separable preferences on a product set of alternatives is decomposable if the value chosen for a component depends only on the individual marginal preferences for that component. The first decomposability results were established by Border and Jordan (1983) who, for example, showed that, for the domain of all profiles of separable quadratic preferences on a multidimensional Euclidean space, a social choice function satisfies strategy-proofness and unanimity if and only if it decomposes into strategy-proof, unanimous social choice functions on each component. Furthermore, these one-dimensional mechanisms can be any member of Moulin's class of minmax social choice functions. Since the development of the option set methodology, decomposability results for strategy-proof social choice functions have been established for a number of other domains of separable preferences. For example, Barberà, Gul and Stacchetti (1993) have shown that, if $X$ is a discrete product set in a Euclidean space and individuals can have any separable preference that satisfies a multidimensional analogue of single-peakedness, then the conclusions of Border and Jordan’s theorem hold if the range of the social choice function is all of $X$. Whether strategy-proofness and auxiliary conditions such as unanimity imply decomposability depends on how much preference variability is present in the domain. Establishing a decomposability theorem typically involves first showing that the tops-only property is satisfied, as in Barberà, Gul and Stacchetti (1993). Much of the literature on this issue has been synthesized and extended by Le Breton and Sen (1995; 1999).

If $X$ is a product set, but only a subset $Z$ of $X$ is feasible, decomposability results are still possible, but not every combination of the corresponding one-dimensional social choice functions is admissible. For example, using the model in Barberà, Gul and Stacchetti (1993) with the best alternative for each preference required to be in $Z$, Barberà, Massó and Neme (1997) have shown that any social choice function $g$ that is strategy-proof and whose range is $Z$ is decomposable into one-dimensional minmax rules on each component, but, in order for a combination of such minmax rules to always produce a feasible outcome, $g$ must satisfy a rather complicated condition called the intersection property.

In the preceding discussion, everyone has the same set of admissible preferences, and so it is possible that they might agree on what is best. When there are private goods and individuals care only about their own consumption, one generally expects there to be distributional conflicts. We illustrate the implications of strategy-proofness with private goods in two problems: the allotment problem and the exchange of divisible goods.
In an **allotment problem**, there is a fixed amount $\Omega$ of a divisible good to allocate. If individuals care only about own consumption, each person's preference is defined on $X=[0, \Omega]$. If these preferences are single-peaked, a prominent solution to this problem is the **uniform rule** (see Benassy, 1982) which, for each admissible profile $R \in S^n$, chooses the unique allocation $x=(x_1, \ldots, x_n) \in X^n$ ($x_i$ is person $i$'s allocation) for which (i) if $\Omega \leq \sum_{i=1}^n \pi(R_i)$, there exists $\lambda \in \mathbb{R}^+$ such that, for all $i \in N$, $x_i = \min\{\pi(R_i), \lambda\}$ and (ii) if $\Omega \geq \sum_{i=1}^n \pi(R_i)$, there exists $\lambda \in \mathbb{R}^+$ such that, for all $i \in N$, $x_i = \max\{\pi(R_i), \lambda\}$.

Sprumont (1991) has shown that, if the domain is the set of all profiles of continuous single-peaked preferences on $X$, then a social choice function satisfies strategy-proofness, Pareto optimality and private-goods anonymity (permuting preferences results in the same permutation of the individual allocations) if and only if it is the uniform rule. Sprumont's article also includes the first explicit theorem about the tops-only property in the strategy-proofness literature.

When $X$ is the set of allocations of an exchange economy with two or more divisible private goods, the general conclusion is that strategy-proofness and Pareto optimality conflict with other desirable properties for a social choice function on a sufficiently rich domain of classical private goods preference profiles. If the aggregate endowment is privately owned and participation in the collective choice procedure is voluntary, the social choice function must satisfy individually rationality; that is, each person is guaranteed a consumption bundle weakly preferred to his endowment. Hurwicz (1972) has shown that strategy-proofness, Pareto optimality and individual rationality are inconsistent for two-person, two-good exchange economies on such a preference domain. This impossibility theorem has only recently been extended to the general $n$-person, $m$-good case by Serizawa (2002).

With monotonic preferences, a dictator in an exchange economy always receives the whole endowment. For the domain of classical private goods preference profiles, Zhou (1991) has shown that strategy-proofness, Pareto optimality and nondictatorship are inconsistent when there are at least two goods, but only two individuals. When there are at least three individuals, Satterthwaite and Sonnenschein (1981) have shown by example how to construct Pareto optimal, strategy-proof, nondictatorial social choice functions for this domain. In their example, someone is *bossy* (that is, there is an individual who can change the consumption bundle of someone else by reporting a different preference without affecting his or her own consumption bundle) and, for each profile, one of two individuals receives all of the endowment. It is generally agreed that bossy mechanisms are unsatisfactory. Serizawa and Weymark (2003) have shown that any social choice function that satisfies strategy-proofness and Pareto optimality cannot guarantee everyone a consumption bundle bounded away from the origin on a rich domain of classical private goods preferences.

Given that any strategy-proof and Pareto optimal social choice function $g$ must fail even minimal distributional desiderata on such domains, Barberà and Jackson (1995) have explored the implications of abandoning Pareto optimality. For private ownership exchange economies with classical private goods preferences, they have shown that if $g$ is strategy-proof, nonbossy, and satisfies some other auxiliary conditions, then trade must be restricted to occur in a limited set of fixed proportions with possibly upper limits on the amounts that can be exchanged. In the case of two goods and two individuals, if $g$ satisfies strategy-proofness and individual rationality, there are only two such proportions, and the choice procedure resembles the fixed-price trading rules studied by Benassy (1982) with different buying and selling prices for each good.
Axiomatic models of resource allocation

The literature on axiomatic models of resource allocation has a close affinity to the literature on Arrovian social choice on economic domains. As is the case with Arrovian social choice when there are multiple agendas, the research on axiomatic models of resource allocation investigates the implications of normative criteria (axioms) when both individual preferences and the set of feasible agendas satisfy the kinds of restrictions found in economic models. What distinguishes this literature is the set of axioms considered, many of which rely on the special structure provided by economic models for their definition. In this section, we present a very selective introduction to the models and axioms considered in this literature and describe a few of the theorems that have been obtained. For a comprehensive survey of this literature, see Thomson (2008).

In an allocation problem, there is an aggregate social endowment \( \Omega \in \mathbb{R}^m_+ \) of \( m \) private goods that are to be allocated among \( n \geq 2 \) individuals based on their preferences. In the canonical allocation problem, \( m \geq 2 \) and all goods are divisible. An economy is then described by a pair \( E=(\mathcal{R}, \Omega) \), where \( \mathcal{R} \) is a profile of classical private goods preferences. Let \( \mathcal{E} \) denote the set of all such economies. Given the endowment \( \Omega \), the corresponding agenda \( A(\Omega) \) is the set of feasible allocations \( x=(x_1, \ldots, x_n) \) that exhaust \( \Omega \), where \( x_i \in \mathbb{R}^m_+ \) is person \( i \)'s consumption bundle.

A solution is a mapping that selects a subset of the feasible allocations for each economy in \( \mathcal{E} \). Note that a solution \( \varphi \) can be identified with a social choice correspondence \( C \) by setting \( C(A(\Omega), \mathcal{R})=\varphi(E) \) for all \( E \in \mathcal{E} \). A solution satisfies efficiency if it always chooses Pareto optimal allocations and it satisfies no envy if, at any selected allocation, nobody strictly prefers anyone else's allocated consumption bundle. No envy, which was independently introduced by Tinbergen (1953), Foley (1967), and Kolm (1972), is the fundamental fairness condition considered in this literature. An example of a solution satisfying both efficiency and no envy for this class of economies is the equal division Walrasian solution \( \varphi^W \), which is defined from the equal division Walrasian social choice correspondence in the manner described above. The literature on fair allocation has expanded the scope of the canonical model in several respects. For example, economies with varying populations or with production have been considered. In addition, variations of this model have been explored, for example, by allowing for indivisibilities or, when there is only one good, preference restrictions such as single-peakedness.

An alternative set-up with public goods has also been examined. The existence of solutions satisfying efficiency and no envy in public goods environments is a more complex matter than in the private goods case, largely because arguments involving pure exchange cannot be invoked when there are public goods. Furthermore, the technology that permits us to transform private goods into public goods is also important. With some additional assumptions, however, efficiency and no envy can be satisfied (see Diamantaras, 1991, for example).

Prominent among the new axioms that have been introduced and used in characterizations of existing and new solutions is consistency, which is discussed in detail in Thomson (1990). In order to define consistency, the notion of a solution must be extended to include economies with different numbers of individuals. Let \( x \) be an allocation that is selected by such a solution for an \( (n+1) \)-person economy. Now suppose that person \( k \) leaves the economy with the consumption \( x_k \). Define a reduced \( n \)-person economy...
social choice (new developments): The New Palgrave Dictionary of Economics

by removing $k$ and subtracting $x_k$ from the total endowment. Consistency demands that the allocation $(x_1, \ldots, x_{k-1}, x_{k+1}, \ldots, x_{n+1})$ is selected in the reduced economy.

Other important properties include monotonicity conditions with respect to the quantities of the resources available, with respect to the technology, or with respect to the population. A solution $\phi$ satisfies resource monotonicity if, whenever the social endowment expands, no one becomes worse off in any chosen allocation. In private goods models with production, an axiom similar in spirit to resource monotonicity is technology monotonicity. It requires that if the only difference between two economies is that the technology of one dominates that of the other, then everyone should be at least as well-off in any allocation chosen for the former economy as in any allocation chosen for the latter. Population monotonicity is a solidarity axiom. As is the case for consistency, it applies in models with variable population. Suppose that the population is expanded, but the total endowment is unchanged. Population monotonicity demands that the burden imposed on the existing population by the presence of the additional individuals is shared by all its members; no one who is present before the population expansion is better off as a consequence of the population augmentation.

If there is only one divisible good, each economy $E=(R, \Omega)$ defines an allotment problem, as in the preceding section. When all preference profiles are single-peaked, the uniform solution simply applies the uniform rule for the allotment problem to each economy in the domain. In addition to the characterization of this solution presented in the preceding section, there have been axiomatizations of the uniform solution using no envy, consistency, and variants of either resource monotonicity or population monotonicity, among other axioms (see Thomson, 2008).

If some of the goods to be allocated are indivisible, much of the theory developed in the context of perfectly divisible goods still applies. Due to the specific nature of the problem of allocating indivisible objects, some interesting additional results can be obtained. As an illustration, consider an assignment problem in which $n$ indivisible objects are to be allocated to $n$ individuals and there is also a perfectly divisible good (‘money’) that can be consumed in any amount, positive or negative: see Thomson (2008) for references to contributions that permit the number of goods and individuals to differ. A commodity bundle for person $i$ is now a pair $(t_i, j) \in \mathbb{R} \times \mathbb{N}$, where $t_i$ (resp. $j$) is the amount of money (resp. object) allocated to $i$. It is assumed that $i$'s preference $R_i$ on $\mathbb{R} \times \mathbb{N}$ is strictly monotonic in money and that money can be used to compensate for the receipt of a less desirable good in the sense that, for all $t_i \in \mathbb{R}$ and all $j, k \in \mathbb{N}$, there exists $s_i \in \mathbb{R}$ such that $i$ is indifferent between $(s_i, k)$ and $(t_i, j)$. An economy now consists of a preference profile $R$ with the properties introduced above, an aggregate endowment of money $T \in \mathbb{R}$, and the $n$ indivisible objects. Because the set of objects is fixed, an economy can be characterized by a pair $E=(R, T)$. A feasible allocation for $E$ is a pair $(t, \rho)$, where $t \in \mathbb{R}^n$ is a vector of balanced monetary allocations (that is, $\sum_{i=1}^n t_i = T$) and $\rho : \mathbb{N} \rightarrow \mathbb{N}$ is a permutation with $\rho$ (i) specifying the object allocated to person $i$.

Solutions and the efficiency and no-envy axioms are defined in the usual manner. If the monetary allocations are restricted to be non-negative, it is clear that solutions satisfying no envy may not exist. For example, if $T=0$ and everyone regards the same object as being uniquely best regardless of the amount of money received, whoever is allocated this object is envied by everyone else because no monetary compensations are possible. Sufficient conditions for the existence of solutions satisfying no envy with non-negative monetary allocations are discussed in Thomson (2008). As is to be expected,
these conditions ensure that there is a sufficient amount of money available to carry out the requisite compensation payments.

In the case of perfectly divisible goods, we have noted that the equal division Walrasian solution $\varphi_W$ satisfies efficiency and no envy. Interestingly, in the indivisible good model considered here, the allocations generated by an adaptation of this Walrasian solution to the present framework are the only allocations satisfying no envy (see Svensson, 1983). Moreover, efficiency follows as a consequence of no envy. In this model, for an economy $E$, if everyone is provided with the same endowment $t_0 \in \mathbb{R}^+$ of money, a Walrasian equilibrium is a feasible allocation $(t, \rho)$ and a price $p_k \in \mathbb{R}^+$ for each good $k \in N$ such that the bundle $(t_i, \rho(i))$ is weakly preferred by individual $i$ among all bundles that have values no more than $t_0$. The solution $\varphi_W$ is then defined by letting $\varphi_W(E)$ be the set of Walrasian equilibrium allocations that can be obtained in this way.

A number of fairness principles besides no envy have been considered in the literature (see Fleurbaey and Maniquet, 2008; Thomson, 2008). Particularly notable among them is egalitarian equivalence, which is due to Pazner and Schmeidler (1978). In the canonical allocation problem, egalitarian equivalence requires that, for each economy $E = (R, \Omega)$, each selected allocation $x$ has the property that there exists a consumption bundle $z_0 \in \mathbb{R}^m$ that everyone is indifferent to. Pazner and Schmeidler (1978) have shown that on the domain of economies $E$ for this problem, solutions exist that satisfy both egalitarian equivalence and Pareto optimality. However, egalitarian equivalence need not satisfy independence of infeasible alternatives, as the egalitarian allocation $(z_0, \ldots, z_0)$ associated with $x$ need not be feasible.

There is now an extensive literature that employs the framework and many of the axioms described in this section to re-examine the foundations of egalitarian theories. If individuals are held responsible in part for the outcomes they receive, conditional versions of egalitarianism demand that individual differences caused by factors beyond the individuals’ control should be compensated for, whereas inequities that can be attributed to choices for which an individual is responsible do not attract that kind of equalization. Variants of this theory have been advocated by, for example, Roemer (1993): see Fleurbaey and Maniquet (2008) for a detailed survey of this literature.

**Concluding remarks**

As noted above, the response of Sen (1974) to Arrovian social welfare function impossibilities was to abandon the ordinal non-comparability of individual utilities built into the Arrow framework. However, he maintained the spirit of IIA by assuming that the social ranking of any two alternatives should depend only on the individual utilities obtained with them. This independence assumption is the cornerstone of the welfarist approach employed in the literatures on social choice with interpersonal utility comparisons and on variable-population social choice.

A different resolution of the Arrovian dilemma has been described and defended in Fleurbaey (2007). Rather than abandoning ordinal non-comparability, Arrow’s IIA assumption is relaxed so as (i) to allow the social ranking of a pair of alternatives to depend on how these alternatives are ranked relative to some other alternatives and (ii) to incorporate some principle of fairness. This proposal has been
explored in a series of articles by Fleurbaey and various co-authors. For example, Fleurbaey, Suzumura and Tadenuma (2005) have shown that, when the alternatives are the set of all allocations of \( m \geq 2 \) divisible private goods and the domain of the social welfare function is the set of profiles of classical private goods preferences, then weak Pareto and a private goods version of anonymity are compatible with an independence condition that incorporates fairness considerations of the sort embodied in egalitarian equivalence. Independence conditions such as this or ones based on envy-freeness employ non-local information about preferences, including information about alternatives that may not be feasible if resource constraints are taken into account. This line of research provides a bridge between the literatures on Arrovian social choice on economic domains and axiomatic models of resource allocation discussed above by employing some form of independence condition (as in the former) while at the same time requiring social decisions to be fair (as in many of the latter contributions).

Abstract

This article is a critical survey of the literature of social choice theory, first formalized by Kenneth Arrow in 1951. Social choice theory deals with the aggregation of some measure of individual welfare into a collective measure. It takes different forms according both to what is being aggregated (interests, judgements, and so on) and to the purpose of the aggregation. The methodology of social choice has greatly clarified a range of hitherto obscure problems.

Article

Social choice theory, pioneered in its modern form by Arrow (1951), is concerned with the relation between individuals and the society. In particular, it deals with the aggregation of individual interests, or judgements, or well-beings, into some aggregate notion of social welfare, social judgement or social choice. It should be obvious that the aggregation exercise can take very different forms depending on exactly what is being aggregated (e.g., the personal interests of different people, or their moral or political judgements) and what is to be derived on that basis (e.g., a measure of social welfare, or public decisions regarding what is to be done or what outcomes are to be accepted). The formal similarities between these exercises in the analytical format of aggregation should not make us overlook the diversities in the nature of the exercises performed (see Sen, 1977a, 1986). In fact, the axioms chosen for
different exercises are often quite divergent, and the general conception of aggregation in social choice theory permits such variation.

1 Welfare economics and social choice

Although the origins of social choice theory – in one form or another – can be traced back at least two hundred years (Borda, 1781; Condorcet, 1785; Bentham, 1789), the formal theory of social choice was initiated by Kenneth Arrow (1951) less than four decades ago. Arrow drew on some existing notions of welfare economics. One concept of a social welfare function had been introduced by Bergson (1938). This was defined in a very general form indeed: as a real-value function \( W(.) \), determining social welfare, ‘the value of which is understood to depend on all the variables that might be considered as affecting welfare’ (p. 417). Such a social welfare function – swf for short – might be thought to be a real-valued function defined on \( X \), the set of alternative social states. It is a bit more permissive to see a Bergson social welfare function as an ordering \( R \) of \( X \) (more permissive because not all orderings can be numerically represented).

Various uses to which a swf can be put in welfare economics were investigated, particularly by Samuelson (1947). His exercises made use of several criteria that a swf may be required to satisfy, including the Pareto criterion, demanding that unanimous individual preference over any pair of states should yield the corresponding social preference over that pair.

None of the conditions that Samuelson imposed on a swf for his exercises required any general specification of how the social ordering might change if different sets (strictly, \( n \)-tuples) of individual orderings were considered. If any \( n \)-tuple of individual preference orderings is called a ‘profile’, then Samuelson’s exercises – and those considered by Bergson – were all ‘single-profile’ problems, without additional requirements of inter-profile consistency.

Arrow (1951) defined a social welfare function – henceforth \( SWF \) (to be distinguished from a Bergson–Samuelson swf) – as a functional relation specifying one social ordering \( R \) for any given \( n \)-tuple of individual orderings \( (R_i) \), with one ordering \( R_i \) for each person \( i \): \( R = f(R_i) \).

Note that if a Bergson–Samuelson swf is defined as a social ordering \( R \) (rather than as a real-valued function \( W(.) \)), then an Arrow SWF is a function the value of which would be a Bergson–Samuelson swf. Arrow’s exercise, in this sense, is concerned with the way of arriving at a Bergson–Samuelson swf. Arrow proceeded to impose a few conditions that any reasonable SWF could be expected to satisfy. His ‘impossibility theorem’ (more formally called ‘the General Possibility Theorem’) shows that no SWF can satisfy all these conditions together. One of the conditions deals specifically with the multiple-profile characteristics of a \( SWF \), viz., the independence of irrelevant alternatives (condition I). This requires that the chosen alternatives from any subset of social states must remain unaltered as long as the individual preferences over this subset remain unaltered, even though the individual preferences may have been revised over other subsets. Another condition is a weak version of the Pareto principle (condition P) which requires that unanimous strict preference over a pair must be reflected in the same strict preference for the society. Another requirement is that of unrestricted domain (condition U), which demands that the domain of the \( SWF \) must include all logically possible \( n \)-tuples of individual orderings, that is, the \( SWF \) should be able to specify a social ordering \( R \) no matter what the individual orderings happen to be. Finally, there is a condition of non-dictatorship (condition D), which demands that there is
no individual such that if he or she prefers any \( x \) to any \( y \), then \( x \) is socially preferred to \( y \), no matter what the other individuals prefer.

One version of the ‘impossibility theorem’ of Arrow establishes that, if the set of individuals is finite and the number of distinct social states is at least three, then there is no social welfare function (SWF) satisfying conditions U, I, P, and D.

This result has been the starting point of much of modern social choice theory. Even though the focus has somewhat shifted in recent years from impossibility results to other issues, there is no question at all that Arrow's formulation of the social choice problem in presenting his ‘impossibility theorem’ laid the foundations of social choice theory as it has evolved.

Two interpretational issues may be sorted out first before formal social choice theory is considered for a general examination. The first issue concerns the interpretation of ‘social preference’. As has already been remarked, the nature of the social choice exercise can vary in many different ways, and one source of variation is the nature of the end-point that is sought (in particular the interpretation of \( R \)). Consider the relation of strict social preference \( xPy \). It can be given different interpretations depending on the nature of the exercise. For example, \( xPy \) can stand for the judgement that society is better off in state \( x \) than in state \( y \). Such a judgement can be the view of a particular individual (in his or her capacity as an aggregating judge), or the mechanical outcome of some institutional process of aggregating judgements (e.g., the result of a voting procedure). Or, alternatively, \( xPy \) can stand for the statement that, in the choice exactly over the pair \( (x, y) \), \( x \) alone must be chosen. A further alternative is to interpret \( xPy \) as the requirement that \( y \) must not be chosen from any set which contains \( x \) (whether or not it contains any other alternative). These and other interpretations give different views of ‘social preference’, and careful attention has to be paid to the nature of the exercise depending on the interpretation given. Although Arrow's ‘impossibility theorem’ and similar results apply to all the interpretations (and here there is a genuine economy in the general axiomatic method), extensive variations in the relevance of the results to different types of problems must be recognized.

Second, a different source of variation relates to the interpretation of the individual preference orderings.

The individual ordering can stand for the ranking of personal well-being, and if so, the exercise is one of well-being aggregation. An example may be found in arriving at overall judgements of the well-being of the community based on rankings of individual well-beings. To take a very different type of example, in making a committee decision, the different judgements of the members of the committee may be aggregated together in an overall judgement or an overall decision, and that exercise is one of judgement aggregation.

This is not to deny that the judgements of members of the committee may, in fact, be influenced by their individual interests, but the nature of the exercise is primarily that of aggregating the possibly divergent judgements of the members of a committee to arrive at an over-all committee view.

In some other exercises, for example, in electing a candidate or a member of Parliament or a Mayor, the individual votes may well reflect a clear-cut mixture of individual interests and political beliefs, so that the exercise may have features of interest aggregation as well as judgement aggregation. Once again, it is worth emphasizing that while the formal results such as Arrow’s ‘impossibility theorem’ apply to each of the interpretations, the exact substantive content of the result would depend on the particular interpretation chosen.

The specific context of Arrow's exercise was that of supplementing the work of Bergson and Samuelson in deriving social welfare functions for welfare-economic studies. If the individual orderings are interpreted as utility rankings of individuals, and social preferences interpreted as a judgement of social
welfare, the Arrow theorem asserted that there is no way of combining individual utility orderings into an overall social welfare judgement satisfying the four specified conditions. The result can be easily translated into a choice-theoretic framework by adopting a choice-based notion of ‘social preference’, e.g., the ‘base’ relation or the ‘revealed preference’ relation of social choice. On this interpretation, it would appear that there is no way of arriving at a social choice procedure specifying what is to be chosen (over pairs, or over larger subsets), satisfying the appropriately interpreted (i.e., in terms of choice) conditions specified by Arrow (see Blair, Bordes, Kelly and Suzumura, 1976; and Sen, 1977a, 1982).

This is, of course, a negative result. A great deal of social choice theory, at least in the early stage, consisted of trying to deal with this result, suggesting different interpretations, different extensions, different ways of ‘resolution’, and other responses to the ‘impossibility’ identified by Arrow. The main lines of response to Arrow's result will be examined presently. It is, however, worth emphasizing that the ‘impossibility theorem’ must not be seen as primarily a ‘negative’ achievement. The axiomatic method, as used here, can take a set of axioms which look reasonable enough and then derive some joint implications of these axioms. If the implications are unacceptable, the axioms can be re-examined. Interpreted thus, the axiomatic method is a procedure for assessing a set of principles reflected in the axiom structure, and it persistently invites attention to the content and acceptability of the axioms chosen.

Arrow's impossibility result brought out the unviability of the welfare-economic structure that had emerged in the discussion preceding the birth of modern social choice theory. After the rejection of ‘interpersonal comparisons’ of well-being (on this see Robbins, 1932, 1938), it was increasingly accepted that social choices or social judgements would have to be based on individual utility orderings without interpersonal comparisons. The four axioms chosen by Arrow make a good deal of sense in that context, and had indeed been used – formally or informally – in the pre-existing literature. What Arrow's theorem demonstrates is the unviability of that structure. The primary impact of Arrow's initial result was to demand that the entire question of the basis of social welfare judgement be re-examined. While this is, in one sense, a negative result, in another sense it opened up various ways of reformulating the social choice problem as a result of the demonstrated unviability of the pre-existing approach. The later literature in social choice theory bears testimony to the fact that many of these ways have been found to be both feasible and useful. Several of these approaches will be examined later on in this note, but the positive contribution of the negative impossibility result presented by Arrow has to be kept in view to see these advances in their appropriate perspective.

2 Variations and extensions of Arrow's impossibility result

The literature of social choice theory contains a large number of theorems that take the form of presenting variations of the type of impossibility identified by Arrow. In fact, Arrow himself has presented several distinct versions. The one presented in 1951 contained a formulative error, which was identified and corrected by Blau (1957). A later version, which was the one cited in the last section, is presented in Arrow (1963). Various other variations can be found in the literature, modifying one condition or another, and presenting impossibility results based on conditions that are more demanding in some respects and less demanding in others (see particularly Blau, 1957; Murakami, 1968; Pattanaik,
social choice: The New Palgrave Dictionary of Economics

1971; Fishburn, 1973, 1974; Hansson, 1976; Brams, 1976; Plott, 1976; Kelly, 1978; Monjardet, 1979; Roberts, 1980b; Chichilnisky, 1982; McManus, 1982; Suzumura, 1983; Hurley, 1985; Nitzan and Paroush, 1985, among many others). Each of Arrow's conditions has been modified in one way or another in these different variants.

One particular variation, which is both illuminating and simple, relates to results presented by Wilson (1972) and Binmore (1976). This shows that given unrestricted domain and independence, all permissible social welfare functions will either have social rankings ‘imposed’ irrespective of individual preferences, or have a dictator, or have a ‘reverse dictator’ (a person such that whenever he prefers \( x \) to \( y \), society prefers \( y \) to \( x \)). Arrow's impossibility theorem can be seen as a corollary of this when the Pareto principle is also demanded, since Pareto will eliminate both ‘imposition’ and ‘reverse dictatorship’, leaving dictatorship as the only remaining possibility.

One line of variation that has been very extensively investigated is that of weakening the demand of ‘collective rationality’, i.e., relaxing the requirement that social choice must be based on a social ordering (complete, reflexive and transitive). The ‘range’ of the social welfare function is supposed to include only social orderings, and the proposed relaxation weakens that demand. It can be shown that if the transitivity of only strict social preference is demanded (without also demanding the transitivity of social indifference), then all of Arrow's conditions can be simultaneously satisfied and there is no impossibility (see Sen, 1969, 1970; see also Schick, 1969).

This condition of transitivity of strict preference, formally called ‘quasi-transitivity’, when imposed on social preferences, for a social welfare function satisfying unrestricted domain, independence and the Pareto principle, has the effect of confining social choice procedures to ‘oligarchies’ (this result was first presented in an unpublished paper by Gibbard, and reported in Sen, 1970). An oligarchic group consists of a set of individuals such that if any one of them prefers any \( x \) to any \( y \), then \( x \) must be taken to be socially preferred to or indifferent to \( y \), and if all the individuals in that group unanimously prefer \( x \) to \( y \), then \( x \) must be taken to be socially strictly preferred to \( y \). One extreme case of oligarchy is that of a one-person oligarchy, which corresponds to Arrow's dictatorship. The other extreme makes the oligarchy group include every individual in the community. In this latter case, the fact that all of them taken together happen to be decisive is not remarkable (it follows in fact immediately from the Pareto principle). But it also gives every member of the community ‘veto’ power in the sense that whenever anyone prefers any \( x \) to any \( y \), this precludes the possibility of \( y \) being socially strictly preferred to \( x \), and this has the effect of producing lots of social indifferences all around (see Sen, 1969).

This ‘veto’ result can be obtained even without demanding quasi-transitivity of social preference, by supplementing the weaker demand of ‘acyclicity’ (i.e. the absence of strict preference cycles) with some other conditions, as has been investigated by Mas-Colell and Sonnenschein, 1972; Schwartz, 1972, 1986; Guha, 1972; Brown, 1974, 1975; Blau, 1976; Blau and Deb, 1977; Monjardet, 1979, and others. Partial ‘veto’ results have been established with still weaker conditions (see Blair and Pollak, 1982; Kelsey, 1984).

On a somewhat different line of investigation, it has been possible to somewhat weaken the condition of full transitivity of social preference and still retain exactly the impossibility identified by Arrow, i.e., dictatorship following from conditions U, I and P. This is easily done by replacing the requirement of ordering by that of having ‘semi-orders’, but it can be relaxed further (see Blair and Pollak, 1979; Blau,
These investigations of relaxation of collective rationality have not been confined only to the weakening of transitivity of social preference. It is possible to drop the requirement of completeness of social preference, permitting the possibility that many pairs of states \( x \) and \( y \) may be not socially rankable vis-à-vis each other, and still the impossibility result may survive if the Arrow conditions are correspondingly redefined to cover this case with sufficient richness of social ranking, in line with Arrow's original motivation (see Barthelemy, 1983; Weymark, 1983).

Yet another line of investigation consists of relaxing the requirement that social choice must be ‘binary’ in nature, in the sense of the choice function being representable by a binary relation (whether or not that binary relation \( R \) is called social preference). Some positive possibility results were obtained by Schwartz (1970, 1972), Fishburn (1973), Plott (1973), Bordes (1976), and Campbell (1976), by demanding consistency conditions on choice functions that are weaker than the requirement of binary choice.

One way of doing this is to convert preference cycles into indifference classes. For example, take the case of the so-called ‘paradox of voting’ in which person 1 prefers \( x \) to \( y \), and \( y \) to \( z \), person 2 prefers \( y \) to \( z \), and \( z \) to \( x \), and person 3 prefers \( z \) to \( x \), and \( x \) to \( y \). In this case the majority rule yields \( x \) being socially preferred to \( y \), \( y \) being socially preferred to \( z \), and \( z \) being socially preferred to \( x \), producing a strict preference cycle, with no alternative that is not beaten by another alternative. If, in this case, all the three alternatives are declared socially indifferent, by converting the cycle into an indifference class, then much of Arrow's requirements can be retained. However, one type of consistency will certainly be violated by this formulation of social choice, to wit, relating social choice over the pair \( (x, y) \) to that over the triple \( (x, y, z) \). Due to the majority preference for \( x \) over \( y \), and the demand of the ‘independence’ condition (I) that individual preferences only over \( (x, y) \) be considered when choosing over this pair only, \( x \) must be chosen and \( y \) rejected in the choice over the pair \( (x, y) \). But in the choice over the triple \( (x, y, z) \), even state \( y \) can be selected as a member of the indifference class, when the majority cycle is converted into indifference. The choosability of \( y \) from the larger set \( (x, y, z) \), and its non-choosability from the smaller set \( (x, y) \) contained in the larger set, does violate a standard condition of consistency of choice, variously called Property \( \alpha \) or the ‘Chernoff condition’, or standard ‘contraction consistency’. In the absence of this consistency, the choice function cannot possibly be represented in a binary form, i.e., through a binary relation \( R \) such that the choices correspond to the \( R \)-maximal elements (with \( R \) being derived from the internal properties of choice, e.g., \( xRy \) when \( x \) is chosen in the presence of \( y \)). But this condition (Property \( \alpha \)) is, in fact, much weaker than the requirement that the choice function be binary.

Since binariness may not in itself be a compelling requirement, the plausibility of this line of resolution of Arrow's impossibility depends on the value of the consistency conditions that these ‘solutions’ may actually satisfy. By imposing some relatively appealing consistency conditions, it can be shown that the dictatorship result of Arrow, and the other related results regarding oligarchy, veto power, etc., derived in the binary framework can reappear easily enough in non-binary choice as well (see Blair, Bordes, Kelly and Suzumura, 1976; Sen, 1977a). It can also be pointed out that even when the social choice procedures do not satisfy binariness in the sense of being representable by a binary relation, there would, of course, be binary relations that are generated by the choice function. For example, the ‘revealed preference’ relation (\( xRy \) if \( x \) is chosen in the presence of \( y \)) will be defined by any choice
social choice: The New Palgrave Dictionary of Economics

function, since the choice of any alternative (say, $x$) from any set containing another alternative (say, $y$), will yield the deduction $x \mathcal{R} y$. The issue of binariness arises when it is further demanded that is what is chosen from each subset consists exactly of the $\mathcal{R}$-maximal elements of that set, according to that binary relation $\mathcal{R}$. It can be shown that binariness in this form demands much the same thing whether we concentrate on the ‘revealed preference’ relation, or the ‘base relation’ (the latter being defined as: $x \mathcal{R} y$ if and only if $x$ is chosen specifically from the pair $x, y$). Binariness according to the ‘revealed preference’ relation is equivalent to that according to the ‘base’ relation (see Herzberger, 1973).

Although the demands of binariness provide one way of re-establishing Arrow's 'impossibility' results, a different way is not to demand binariness at all, but to translate all of Arrow's demands to one specific binary relation generated by social choice, e.g., the ‘revealed preference’, or the ‘base’ relation. The Arrow theorem will hold exactly in the same way for each such interpretation of $\mathcal{R}$, provided the Arrow conditions are correspondingly reinterpreted. In this sense binariness is not a central issue in the inescapability of the ‘impossibility’ result of Arrow (on this see Sen, 1977a, 1982; on related matters, see Grether and Plott, 1982; Suzumura, 1983; and Matsumoto, 1985).

One general conclusion that seems to emerge from these investigations of relaxation of ‘collective rationality’ properties is the durability and robustness of Arrow’s ‘impossibility’ result. The tension between different types of principles seems to survive various ways of relaxing these principles, and the particular ‘impossibility theorem’ of Arrow is a centre piece of a much broader picture. Demands on consistency of social choice can be dramatically changed without the ‘impossibility’ features disappearing.

3 Domain restrictions

When presenting his impossibility result, Arrow had suggested the possibility that a resolution might be found in terms of restricting the domain of the social welfare function (no longer requiring that it works no matter what the individual preferences happen to be). It is, of course, clear that there are many preference combinations for which such procedures as the method of majority decision will yield perfectly consistent social choice. Arrow (1951) himself had explored a particular type of restriction of individual preferences called ‘single-peaked preferences’ (earlier discussed by Black, 1948). This corresponds to the case in which the alternatives can be so arranged on a line that everyone’s intensity of preference has one peak only, i.e., the preference drops monotonically as we move from left to right, or rises monotonically, or it rises to a peak and then falls. Arrow showed that if individual preferences are single-peaked and the number of voters is odd, then majority decision will yield transitive social preference.

The positive possibility result for single-peaked preferences can be generalized in many different ways. It can be shown that individual preferences being single-peaked in every triple of alternatives is equivalent to the condition that in every triple there is one state such that no one regards it to be ‘worst’. It can be shown that a similar agreement on some alternative being regarded as not ‘best’ would do, and so would an agreement on some alternative being not ‘medium’. Altogether, this sufficiency condition is called ‘value restriction’, and the particular type of agreement (whether ‘not best’, or ‘not worst’, or ‘not medium’) may vary from triple to triple (see Sen, 1966). Also the requirement of oddness of the number of voters can be eliminated if the demand is not for full transitivity of social preference, but only the
absence of preference cycles and the existence of a majority winner (Sen, 1969). In this general line of investigation, necessary and sufficient conditions for transitivity as well as acyclicity of majority decisions (i.e., for the existence of a majority winner) have been identified by Inada (1969, 1970) and Sen and Pattanaik (1969). The former requirement is called ‘extremal restriction’. The relationships among these and other related conditions are discussed in Inada (1969), Sen (1970), Pattanaik (1971), Fishburn (1973), Salles (1976), Slutsky (1977), Kelly (1978), Monjardet (1979), Blair and Muller (1983), Larsson (1983), Suzumura (1983), Dummett (1984), Arrow and Raynaud (1986), Jain (1986) among many others.

On a different line of analysis, domain conditions can be specified not only in terms of general qualitative correspondence of individual preferences, but also in terms of number-specific requirements on the distribution of voters over the different preferences (see particularly Plott, 1967; Tullock, 1967, 1969; Saposnik, 1975; Slutsky, 1977; Gaertner and Heinecke, 1978; Grandmont, 1978; Dummett, 1984). These domain conditions all deal specifically with the method of majority decision, but the problem can be investigated more generally. Domain conditions for other voting rules have been investigated (see, for example, Pattanaik, 1971). More recently, the necessary and sufficient domain conditions for the existence of any social welfare function satisfying all of Arrow's other conditions (whether or not based on counting majority) have been investigated (see Kalai and Muller, 1977, and Maskin, 1976; see also Dasgupta, Hammond and Maskin, 1979; Kalai and Ritz, 1980, and Chichilnisky and Heal, 1983). These domain restrictions are indeed very demanding, and counterexamples can be found without any loss of plausibility in terms of real-life situations (see particularly Kramer, 1973). But if these restrictions are not fulfilled, then there is no general ‘solution’ to be found in opting for the majority rule, or some other rule like that. Indeed, it can be shown for the majority rule that the cycles that may be generated may well be extremely extensive, yielding ‘total cycles’ involving all social states (see Schofield, 1978; McElvee, 1979). This line of investigation too, like the one on collective rationality (discussed in the last section), yields rather discouraging results. No general solution of impossibility theorems of the type presented by Arrow can be easily found by opting for a rule like the majority decision, hoping that the domain conditions will be somehow satisfied.

In many economic decisions, it is quite straightforward to see that these conditions will indeed be all violated. However, when the number of alternatives happen to be small, and when there is complex balancing of conflicting considerations, as in many political contexts (elections, committee decisions over rival proposals, etc.), there might possibly be some room for optimism. If cycles or other types of intransitivities turn out to be rather rare in these cases, then the approach of domain restriction may well offer some help. In contrast, in welfare-economic problems, that hope is very limited. Indeed, if we take such a simple social-welfare problem as the division of a given cake between three or more individuals, with each person voting according to his or her own share of the cake, it can be easily shown that there will indeed be majority cycles. But it is worth noting in this context that the method of majority decision is not particularly appropriate for such economic problems anyway. Any distribution of the given cake can be improved by choosing one of the persons (even the poorest one) and dividing a part of his or her share for the benefit of all others, thereby producing an ‘improvement’ according to the majority rule. Indeed, we can go on ‘improving’ the distribution in this way, following the majority ranking procedure, making the worst-off individual more and more worse off all the time. As a criterion for welfare-economic judgement, majority rule is, in fact, a non-starter. The recognition of this fact
makes it less tragic that majority cycles will tend to arise easily enough in many economic problems involving distributional variations. The majority rule would not have offered any ‘real solution’ to the task of making social welfare judgements in this type of economic problems even if it had been fully consistent. It is more in the context of political decisions involving a few diverse alternatives (rather than welfare-economic judgements in general) that majority rule and related decision procedures have some prima facie plausibility. It is, thus, of some interest that it is in the context of these problems that the domain conditions investigated by the social choice literature are of direct relevance and offer some hope.

4 Manipulability and implementation

A different type of problem for voting procedures arises from the possibility of ‘manipulation’ of the decision mechanism by the voters voting ‘dishonestly’. A voting procedure is ‘manipulable’ when it is in the interest of some voter for some set of individual preferences to vote differently from his or her sincere preference.

The ubiquity of the possibility of manipulation had been conjectured for a long time, but it was established only recently in a remarkable theorem first presented by Gibbard (1973), and then by Satterthwaite (1975). A similar result, and a pointer to positive possibility if the conditions are relaxed, was presented by Pattanaik (1973.) The Gibbard–Satterthwaite manipulation theorem establishes that every non-dictatorial voting scheme with at least three distinct outcomes must be manipulable.

Gibbard established this theorem as a corollary of another one dealing with ‘game forms’ in general, of which voting schemes happen to be special cases. A game form does not restrict the strategies to be chosen by the individuals to the orderings of social states (i.e., to ‘ballots’), and each person's strategy set can be any set of signals. Gibbard established that no non-dictatorial game form with at least three possible outcomes can be ‘straightforward’ (a concept first used by Farquharson, 1956), in the sense that each person would have a dominant strategy (i.e., a best strategy with respect to his ordering of the outcomes, irrespective of what the strategies of others might be). Thus for every non-dictatorial game form of this type, there is at least one person who does not have a dominant strategy for some preference ordering of outcomes. From this the manipulability theorem follows immediately. If a voting scheme were non-manipulable, then everyone would have had a dominant strategy, viz., recording his or her true preference irrespective of what others do. Since the existence of dominant strategies is disestablished, so is the existence of honest dominant strategies.

Various variations of this discouraging result and some avenues of escape have been investigated in the literature, which is quite vast (but excellent discussions can be found in Barbera, 1977; Pattanaik, 1978; Laffont, 1979; Peleg, 1984; Brams and Fishburn, 1983; Moulin, 1983; and Jain, 1986).

The focus on ‘honest’ revelation of preferences has gradually given way to discussions of equilibrium and of implementation (for an early pointer in this direction, see Dummett and Farquharson, 1961). If the object of the exercise is effectiveness in the sense of getting an appropriate outcome (rather than seeking honesty as such), then the thing to investigate is indeed the existence of an effective mechanism rather than a ‘strategy-proof’ one. If, for example, a non-strategy-proof mechanism yields an equilibrium of dishonest behaviour that produces the same outcome as honest revelation of preferences would, then that mechanism could well be regarded as successful in terms of effectiveness.
The shift in attention towards equilibrium and implementation has opened up new lines of investigation, which are being explored (see particularly Dutta and Pattanaik, 1978; Dasgupta, Hammond and Maskin, 1979; Sengupta and Dutta, 1979; Peleg, 1984; Moulin, 1983). The implementation literature also links up with more standard problems of public economics, in which it has received attention in a somewhat different but related form (see, particularly, Groves and Ledyard, 1977; Green and Laffont, 1979; Laffont, 1979).

5 Information: utility, compensations and fairness

The alleged impossibility of interpersonal comparisons of utility was entirely accepted in the early works on social choice theory. Arrow's (1951) format gave no room to interpersonally comparable utility information, and indeed took utility information in the form of non-comparable ordinal utility rankings. This was entirely in line with the dominant position of welfare economics at that time. Even though there were formats for interpersonal comparisons of utility suggested in some contributions to welfare economics (see particularly Vickrey, 1945, and Harsanyi, 1955), these suggestions were not followed up in the formal social-choice-theoretic literature until much later.

There had been earlier attempts to by-pass the need for utility comparisons by using the notion of compensation tests (e.g., whether the gainers could compensate the losers), and this had led to the identification of problems of internal consistency as well as of cogency (see Kaldor, 1939; Hicks, 1939; Scitovsky, 1941; Little, 1950; Samuelson, 1950; Baumol, 1952; Gorman, 1953; Graaff, 1957). The problem of cogency is perhaps deeper, in some ways, than that of consistency. To make sure that gainers have gained so much that they can compensate the loser does, of course, have some immediate plausibility as a requirement. However, the relevance of the compensation tests suffers from the following limitation. If compensations are not paid, then it is not clear in what way the situation can be taken to be an improvement (since those who have lost may well be a great deal poorer, needier or more deserving – whatever our criteria for such judgments might be – than the gainers). And if compensations are in fact paid, then after the compensation what we observe is a Pareto improvement, so that no compensation tests are in fact needed. Thus, the compensation approach suffers from having to face a choice between being unconvincing or being irrelevant.

Another approach that by-passes the need for interpersonal comparisons proper is that of ‘fairness’, presented first by Foley (1967). Here a person's advantage is judged by comparing his bundle of goods with those enjoyed by others, and a situation is called ‘equitable’ if no individual prefers the bundle of goods enjoyed by another person to his own. If an allocation is both Pareto optimal and equitable then it is called ‘fair’. (There is some non-uniformity of language in the literature, and sometimes the term ‘fair’ has been defined simply as ‘equitable’, e.g., in Feldman and Kirman, 1974 and Pazner and Schmeidler, 1974.) This approach has been pursued by a number of authors (such as Kolm, 1969; Schmeidler and Vind, 1972; Varian, 1974, 1975; Goldman and Sussangkarn, 1978; Archibald and Donaldson, 1979; Crawford, 1979; Crawford and Heller, 1979; Svensson, 1980; Champsaur and Laroque, 1982; Suzumura, 1983, and others). There are interesting problems of the existence of fair allocations and of the consistency of fairness with other principles.

It should be noted that the comparisons involved in the calculus of ‘fairness’ are not interpersonnal ones,
social choice: The New Palgrave Dictionary of Economics

but in fact comparisons of different positions that the same individual might occupy (e.g., having commodity bundles), as it is evaluated by the given person. The criterion of ‘non-envy’ does clearly have some appeal, even though it can be argued, that our deprivations may be related not only to other people's commodity bundles but also to non-commodity features of their advantage. For example, a person with a disability may well prefer to be in somebody else's position without that disability, but that is not the same thing as envying that other person's commodity bundle. As such, it could be argued, that the informational base of the fairness calculus is fundamentally limited.

Another difference between the ‘fairness’ approach and the standard social-choice-theoretic procedures relates to the more limited aim of the former. As Varian (1974) puts it, the fairness criterion in fact limits itself to answering the question as to whether there is a ‘good’ allocation (pp. 64–5). It is certainly true that social choice theory has been abundantly more ambitious, perhaps unrealistically so. On the other hand, it can be argued, that even the features of ‘goodness’ identified by the approach of fairness (e.g., equitability with efficiency) may often fail to be satisfied by any feasible allocation at all, so that the question of ranking the ‘non-good’ allocations is not really avoidable. In addition, it can be argued that insofar as the foundation of the ‘fairness’ approach is based only on comparing the commodity bundles of different persons without going further into the relative advantages enjoyed by the persons (taking everything into account), the criterion of ‘goodness’ used in the ‘fairness’ literature is itself rather a limited one. It is perhaps for these reasons that the use of interpersonal comparisons of well-being in social choice theory (in the literature on social welfare functionals, to be discussed presently) has tended to aim at going a great deal further than the ‘fairness’ literature was programmed to achieve.

6 Social welfare functionals and interpersonal comparisons

The empirical problem of obtaining information on interpersonal comparisons of utility has to be distinguished from the formal problem of accommodating such information within the structure of social choice theory. The format of social welfare functions used by Arrow, and the related formats of collected choice rules (involving such various forms as social decision functions, social choice functions, etc.), make no provision for any utility information finer than that of non-comparable individual orderings. One way of extending that framework is to permit the use of more utility information, through what have been called ‘social welfare functionals’ (SWFL): $R = F\{\{U_i\}\}$. For each set (strictly, $n$-tuple) of utility functions $U_i, \ldots, U_n$ (one function per person), the social welfare functional $F$ determines exactly one social ordering $R$. However, since utility functions can be nominally varied through alternative presentations without involving any ‘real’ change (e.g., doubling all the utility numbers), any social welfare functional has to be combined with some ‘invariance’ requirement. If two utility $n$-tuples $(U_i)$ and $(U_i^*)$ are judged to be informationally equivalent, differing from each other only in representation, then $F\{U_i\} = F\{U_i^*\}$. The assumed structure of measurability and interpersonal comparability of utilities can be incorporated through specifying these invariance requirements (see Sen, 1970, 1977b; d'Aspremont and Gevers, 1977; Roberts, 1980a; Blackorby, Donaldson and Weymark, 1984).

Arrow's social welfare function is a special case of a social welfare functional with the invariance requirement corresponding to ordinal non-comparability (i.e., if one $n$-tuple of utility functions is
replaced by another obtained from the first by taking positive, monotonic transformations of each utility function – not necessarily the same for all – then the social ordering $R$ determined by the first $n$-tuple will also be yielded by the second). It is obvious that Arrow’s ‘impossibility theorem’ can be translated in the format of social welfare functionals with ordinal non-comparability. More interestingly, this result can be generalized to the case of cardinal non-comparability also. When individual utilities can be cardinally measured but not in any way interpersonally compared, the same impossibility result continues to hold (see Sen, 1970). On the other hand, introducing interpersonal comparability without cardinality (i.e., using ordinal comparability only) does resolve the Arrow dilemma, and various possible SWFLs exist fulfilling all of Arrow's conditions in this case. An example is provided by Rawls's maximin rule (or the lexicographic version of it), defining these exercises in terms of utility comparison, rather than that of indices of ‘primary goods’, as in Rawls's own framework.

Richer utility information can be systematically used to admit various social choice procedures not admissible in Arrow's framework. The use of various axioms to characterize particular rules utilizing richer utility information can be found in an influential and important contribution by Suppes (1966). In the recent years the more formal frameworks of social choice theory (in particular, that of SWFLs) have been extensively used to derive axiomatically a number of standard aggregation procedures, such as the Rawlsian lexicographic maximin, utilitarianism, and some others (see particularly Hammond, 1976, 1977, 1979; Strasnick, 1976; d'Aspremont and Gevers, 1977; Arrow, 1977; Sen, 1977b; Deschamps and Gevers, 1978, 1979; Maskin, 1978; Gevers, 1979; Roberts, 1980a; Blackorby, Donaldson and Weymark, 1984; d'Aspremont, 1985). While these results are formal and do not address the question of the empirical content of interpersonal comparisons of utility (though this too is discussed by Hammond, 1977), the axiom structures have been related to various empirical insights thrown up by the substantive literature on interpersonal comparisons.

One format that has also been investigated relates to the intermediate possibility of making partial interpersonal comparisons of utilities. Various formal structures of partial comparability and partial cardinality have, in fact, been investigated in the social-choice-theoretic literature (see Sen, 1970; Blackorby, 1975; Fine, 1975; Basu, 1979; Bezembinder and van Acker, 1979). This is a less ambitious approach, admitting that not all types of interpersonal comparisons may be possible, and such comparability may be at best partial, with many undecided cases. Nevertheless some definite results can be obtained even on the basis of the incomplete structures.

Various other informational frameworks involving richer utility data can be and have been investigated, and some of them lend themselves to fruitful social-choice-theoretic use. One of the structures that need further investigation is the problem of combining $n$-tuples of ‘extended orderings’ reflecting each person's interpersonal comparisons. These are ordinal structures, but instead of there being one interpersonal comparison covering all the individuals in the different possible positions, this starts with the set of interpersonal comparisons made by different individuals (one ‘extended ordering’ per person), and addresses the problem of aggregation in that framework. Some interesting results in this area have been obtained (see Hammond, 1976; Kelly, 1978; Suzumura, 1983; Gaertner, 1983). The task, however, is rather a difficult one, since the information to marshall is extremely extensive, and progress in this area has tended to be rather slow. On the other hand, since social choice theory has to be concerned with the problem of combining different persons’ possibly divergent views, that ‘extended’ problem certainly has a good deal of relevance and potential importance.
7 Liberty and rights

The informational limitations of the early social-choice-theoretic structures have led to responses in the later literature not only in the form of enriching the utility information (by the use of such structures as social welfare functionals, SWFL), but also that of making more systematic use of non-utility information. One of the areas that has been investigated in this context is that of rights in general and of liberty in particular. Liberty can be an important consideration in matters of social choice, but it cannot be adequately captured in terms of utility information, however rich it might be. If it is asserted that a person should be free to do what he or she likes in certain purely personal matters, that assertion is based on the non-utility characteristics of the ‘personal nature’ of these choices, and not primarily on utility considerations. As John Stuart Mill (1859) had argued, even if others might be offended by someone's personal behaviour in such matters as religious practice, it would not be appropriate to count the disutility of the offended in the same way as the utility of the person whose freedom of religious practice is under consideration. Various notions of ‘protected spheres’, ‘personal domains’, etc., have been formalized in the social-choice-theoretic literature in specifying domains of personal liberty.

It is not really surprising that conditions of liberty or rights which make essential use of non-utility information may clash with exclusively utility-based principles, such as the Pareto principle. Non-utility considerations cannot be immovable objects if utility considerations, even in a rather limited context (as in the Pareto principle), are made into an irresistible force. One role of this type of impossibility result lies in pointing to the possibility that utility data may not be informationally adequate for social judgement or social choice, even when the utility information comes in the most articulate and complete form. Other lessons have also been suggested, and each interpretation has also been substantively disputed.

While impossibility results like this have received good deal of attention, relatively little effort has so far been spent on investigating the positive implications of various theories of rights, liberties and freedom,
The need for caution in formulating the demands of liberty because of problems of internal consistency has in fact been investigated. But the more general question of developing a fruitful and positive theory of rights and liberty within the general structure of social choice theory has not yet been much investigated.

8 Independence and neutrality

The independence of irrelevant alternatives, used by Arrow, plays a major part in the social choice formats in the Arrovian tradition. It is also crucial for Arrow's impossibility theorem. The nature, implications and acceptability of the independence condition have been subjected to a good deal of critical examination in the literature (see particularly Gärdenfors, 1973; Hansson, 1973; Ray, 1973; Fine and Fine, 1974; Fishburn, 1974; Mayston, 1974; Young, 1974a, 1974b; Binmore, 1976; Kelly, 1978; Pattanaik, 1978; Moulin, 1983; Suzumura, 1983; Peleg, 1984; Hurley, 1985; Schwartz, 1986).

One of the objections that was originally raised about the relevance of Arrow's impossibility theorem related to the acceptability of the independence condition. Some authors (in particular Little, 1950 and Samuelson, 1967) argued that seeking inter-profile consistency in any form (including Arrow's 'independence' condition) is largely gratuitous. It was also argued that traditional welfare economics had never sought such a condition, and because of the crucial use of condition I, 'Arrow's work has no relevance to the traditional theory of welfare economics, which culminates in the Bergson–Samuelson formulations' (Little, 1950, pp. 423–5). 'For Bergson,' argued Samuelson (1967), 'one and only one of the … possible patterns of individuals’ orderings is needed’ (pp. 48–9), and the question of inter-profile consistency does not arise.

In response to this line of objection, several ‘single-profile impossibility theorems’ in the spirit of Arrow's original theorem have been derived and discussed (see particularly Parks, 1976; Kemp and Ng, 1976; Pollak, 1979; Roberts, 1980b; Rubinstein, 1981; Hurley, 1985). These results depend on dropping inter-profile consistency in favour of rather strong intra-profile requirements, typically including some condition of single-profile neutrality, requiring that whatever combination of individual orderings be decisive for establishing \( xRy \) should be sufficient for establishing \( aRb \) if each individual ranking over \((x, y)\) is the same as that over \((a, b)\) in that given profile. The nature of the alternatives – whether \( x \) and \( y \), or \( a \) and \( b \) – is, thus, not to make any difference, in relating individual preferences over particular pairs to social preference over those pairs, for any given profile of individual preferences.

These results are interesting, but it must be noted that the requirements on which they are based (e.g., of single-profile neutrality) are rather strong. Also the dictatorial result that follows from the other conditions is that of single-profile dictatorship, which might not be thought to be as objectionable as the existence of one inter-profile dictator who wins for every possible preference profile (as in Arrow's theorem).

No matter what one thinks of these single-profile impossibility results, it can certainly be argued that the original objection raised by Little and Samuelson about the relevance of inter-profile conditions for social choice theory is hard to sustain. Given the motivation underlying demands for consistency in the relation between individual preferences and social choice, it is not at all clear why such consistency requirements should be thought to be applicable only for a given profile and not between different profiles of individual preferences (no matter how close these profiles are in relevant respects).
It could, of course, be argued that utility orderings (or preferences) are not an adequate informational base anyway for social choice, and if that position were taken, then the very idea of a social welfare function would have to be rejected in favour of some richer informational formulation, such as a social welfare functional SWFL. If, on the other hand, the motivation underlying the use of a social welfare function is accepted, and it is agreed that for a given preference n-tuple (i.e., a given profile), there is only one social ordering, then it is not clear why it would be thought to be perfectly okay that social preferences might change over a given pair when there is a change of individual preferences over some pair of alternatives quite unconnected with this particular one. The need for some interprofile consistency is hard to deny altogether. It could, of course, be argued that Arrow's particular inter-profile condition is not the appropriate one to use for inter-profile consistency, but that would not be an objection to inter-profile conditions as such, only to the particular formulation of Arrow's condition I. It should also be noted that there are other inter-profile conditions that can be used in order to generate impossibility results like Arrow's, without any use of condition I (see in particular Chichilnisky, 1982).

If Arrow's condition I is dropped, a number of alternative possibilities do, in fact, open up for social choice procedures. For one thing, ‘positional’ information can be used to rank alternative social states and to arrive at social choice. In fact, in an early contribution to social choice theory, Borda (1781) had used a decision procedure that violates condition I in arriving at overall rankings based on rank-order weights. This method – often called the Borda rule – is a special case of a general class of ‘positional’ rules. The general properties of ‘positional’ rules have been fruitfully investigated by Gärdnerfors (1973) and Fine and Fine (1974), among others. The Borda ruling in particular has also received attention, and various particular rules have been investigated, critically examined and axiomatized (see Young, 1974a; Fishburn and Gehrlein, 1976; Hansson and Sahlquist, 1976; Gardner, 1977; Farkas and Nitzan, 1979; and Nitzan and Rubinstein, 1981, among others).

Positional rules take note of the fact that an alternative x preferred to another alternative y may be proximate to each other in a person's preference ordering without any other alternative in between, or may be separated by the existence of one or more other alternatives intermediate between the two. The rationale of positional rules relates to attaching importance to the placing of intermediate alternatives in individual preferences, which can be taken as suggesting that the gap between the two must be, other things given, larger. This argument is not entirely convincing. Many intermediate alternatives can be placed in a small interval, while large intervals may happen to be empty because of the contingent fact that there happens to be no other alternative that fits in just there. On the other hand, if information is thought to be extremely hard to get in social choice (a view that was certainly taken by Borda, 1781), then it is not entirely unreasonable to attach some significance to the fact that the placing of intermediate alternatives might be indicative of something. With some implicit assumption of uniformity of distribution of alternatives over the preference line (or some other suitable belief), the positional rules may have some clear rationale, and the Borda rule in particular might be particulary handy and useful. It is possible to use positional information also in the context of richer informational base, e.g., when interpersonal comparisons of utilities are permissible. Indeed ‘interpersonal positional rules’ may have some distinct advantage both (1) over rules that make non-positional use of interpersonal comparably individual orderings, and (2) over non-comparable positional rules. Such interpersonal positional rules may also be demonstrably more reasonable, in some contexts, than voting procedures like the majority rule which use neither interpersonal comparisons nor positional information (on this see Sen, 1977b;
9 Concluding remarks

In understanding the literature of social choice theory it is important to bear in mind that while there are considerable analytical similarities between different problems tackled in this vast literature, the interpretations of the results and of their implications must take note of the particular nature of each of the substantively different problems. The axiomatic method, which has been so extensively used in the literature, offers enormous scope for efficient economy, but that economy will be self-defeating if the substantive differences are not carefully taken into account in interpreting exactly the content of the theorems derived. For example, the classic ‘impossibility’ result of Arrow may impose informational constraints that are much more reasonable in aggregating political preferences of different individuals over a small set of alternative proposals (or candidates) than in arriving at aggregative judgements of social justice taking note of conflicting individual interests over possible distributions of commodity vectors.

There is sometimes a temptation to see social choice theory as providing a particular ‘method’ of dealing with problems of aggregation. There is some truth in this diagnosis, in the sense that the discipline of axiomatic procedures has some exacting demands. On the other hand, the axioms can vary a great deal, and the interpretation of the axioms also will vary with the nature of the problems considered. The monolithic view of something called ‘the social-choice-theoretic approach’, which is often referred to both by those who wish to use it and those who wish to criticize it, may be deeply misleading. For some arguments on different sides on this question, see Elster and Hylland (1986).

There are, in fact, two different ways of seeing social choice theory. First, it is a field, and in this field there is scope for having different approaches. There are many problems of interpersonal aggregation, and in the broader sense, social choice theory is a field in which such aggregation – of different types – is studied. Second, social choice theory also provides a method of analysis, in which the insistence on the explicitness of axioms and on the clarity of assumptions imposes exacting formulational demands. Indeed, some of the more notable achievements of social choice theory have come from this insistence on explicitness and clarity (e.g., Arrow's own demonstration of the impossibility of combining a set of assumptions that were being implicitly invoked in the literature of the welfare economics of that period, including eschewing interpersonal comparisons of utility). While the second interpretation is a narrower one than the first, it is nevertheless broad enough to permit different types of axioms to be used, and different political, economic and social beliefs to be incorporated in the axiom structure. Neither interpretation would give any cogency to the search for ‘the social-choice-theoretic approach’.

One reason why social choice theory has received as much attention as it has in the last few decades relates to the importance of the field with which that theory has been concerned (and which characterizes that theory in the broader sense). Another reason has been the fruitfulness of making implicit ideas explicit, and of following their implications consistently and clearly. As a methodological discipline, social choice theory has contributed a great deal to clarifying problems that had been obscure earlier. While insistence on clarity at all costs has also some limitations (sometimes the narrowness of the axiom structure used in social choice theory has indeed been seen as a limitation), social choice theory has undoubtedly been a creative tradition among other methodological traditions that can be used to analyse economic, social and political problems involving group aggregation. The vast literature
surveyed in this article can be ultimately judged by what has been achieved in terms of clarifying the obscure and illuminating the unclear. Perhaps the successes have been rather mixed, but that fact is not surprising.

social contract

Abstract

Social contract theory is a theory about how the moral assessment of actions, practices, institutions, laws, constitutions, or related items is based – directly or indirectly – on the consent – actual or hypothetical – of the members of society. Hobbes, Locke, Rousseau, and Kant represent the main historical figures. Rawls, Gauthier, and Scanlon are the main contemporary figures.

Article

Social contract theory, as I shall understand it here, is a theory about how the moral assessment of actions, practices, institutions, laws, constitutions, or related items is based – directly or indirectly – on the consent – actual or hypothetical – of the members of society. Although social contract theories could be formulated to require merely that a majority of the members society consent to the relevant item, such formulations are not particularly plausible and generally have not been advocated. The standard requirement is that all members consent to the item, and I shall assume this in what follows. Social contract theory is also sometimes understood to be (a) an empirical theory about how government actually arose, or (b) a metaethical theory about the general nature of morality and moral reasons. Here, however, we shall focus on contractarianism as a substantive theory of justice. The origins of social contract theory can be traced back to the discussion of justice (in the voice of Glaucon) by Plato (c. 430–347 bce) in The Republic (1961), but systematic development of the theory really started in the 17th century, with the beginnings of the modern state and the challenging of the
alleged divine right of kings and aristocrats to rule. The first comprehensive statement of social contract theory came from Thomas Hobbes (1588–1679) in his *Leviathan* (1651), in which he offered a social contract justification for almost unlimited powers of the state. Other important historical figures associated with social contract theory include John Locke (1632–1704) (1690), Jean-Jacques Rousseau (1712–78) (1762), and Immanuel Kant (1724–1804) (1785). Since the publication of John Rawls's *A Theory of Justice* (1971), there has been a significant renewal of interest – among economists, political scientists, and philosophers – in social contract ethical and political theory.

Social contract theory can be used to address several quite different topics. It might be formulated (a) as a full theory of *individual morality* (ethics), (b) as a theory of *what duties we morally owe each other* (which does not include any impersonal duties), (c) as a *theory of political authority* in the sense of the conditions under which we have a duty to obey the dictates of others, (d) as a theory of *legitimacy* in the sense of the conditions under which others are not permitted to forcibly interfere with our actions (even if wrong), or (e) as a theory of the moral permissibility or *justice of political institutions*. For simplicity, I shall focus on social contract theory as a theory of the justice of political institutions – although most remarks apply to most other versions.

There are two broad kinds of social contract theory: *actual* contract (rights-based) theory and *hypothetical* contract theory (contractarianism or contractualism). I consider each in turn.

**Actual social contract theory**

Actual social contract theory holds that a set of political institutions (for example) is just if and only if it has been directly consented to by those governed or conforms to the requirements of a constitution to which all have consented. The best-known actual social contract theory is that of Locke (1690) – although it has also been interpreted as a hypothetical contract theory (see below).

In order for consent to have moral force, the agent must be rationally competent and the consent must be free (not coerced) and suitably informed (for example, not based on fraud). Establishing exactly what is required for consent to be valid is a very important topic. For excellent discussion, see Simmons (1993). Actual consent can be explicit (as in ‘I hereby consent’) or implicit (as when one allows a friend to enter one's house without explicitly granting permission). Identifying the exact conditions under which an action other than explicit consent is nonetheless a case of (implicit) consent is an important topic insightfully analysed by Simmons (1993). Given that explicit consent is extremely rare, most actual social contract theories (plausibly) allow both kind of consent to have moral force.

Actual social contract theories presuppose that individuals have certain (choice-protecting) natural rights of self-governance (a kind of natural freedom). Any restriction of this natural freedom is deemed unjust unless the individual has consented to it. Given the insecurity of life, health, and possessions in the absence of government, it typically makes sense for people to give up some of their natural freedom and submit to the authority of government – on the condition that the political authority thus established does a reasonably good job protecting people's pre-political rights. When they do so, actual social contract theory holds that the resulting political institutions are just.

Actual social contract theory faces three important challenges. One is whether individuals have the natural rights that the theory postulates. A second is that, for almost all existing societies, there never was a relevant universal agreement on political institutions – which entails, given the theory, that no set
Hypothetical social contract theory

Given the problem of securing universal actual consent to political institutions (or any set of rules), most contemporary social contract theories appeal to hypothetical consent. They hold that political institutions (for example) are just if and only if (a) they would be universally agreed to under specified conditions, or (b) they conform to a political constitution that would be agreed to under specified conditions. For brevity, call these theories contractarian.

Contractarian theories differ in their specification of the circumstances under which the relevant hypothetical agreement takes place. These conditions include the motivations and beliefs of the parties to the agreement as well as the non-agreement point (the outcome if no agreement is made). Hobbesian approaches provide realistic, morally neutral, specifications of the circumstances, and attempt thereby to reduce morality to individual or collective rationality. They specify that individuals are mainly interested in promoting their own wellbeing and assume that agents have reasonably full knowledge of their situation. The non-agreement point (state of nature) is a state of war of all against all in which there is neither government nor morally constrained behaviour. Hobbes (1651), Buchanan (1975), and Gauthier (1986) are all in this tradition. (See also Hampton, 1986; Kavka, 1986; and Binmore, 1994; 1998.) A main objection to the Hobbesian approach is that it yields an impoverished conception of morality: individuals are protected by morality only to the extent that cooperation with them is useful to others. Because babies, young children and severely disabled people offer others no benefits from cooperation, knowledgeable predominantly self-interested agents would not enter into agreements with them. Such vulnerable individuals might be protected by the terms of the hypothetical agreement, but that would be only to the extent that others happen to care about them (for example, parents for their children). Absent any such contingent concern, such individuals are deemed merely resources to be exploited.

Lockean forms of contractarianism are similar to Hobbesian ones except that the non-agreement point (state of nature) is not pre-moral. (As indicated above, Locke, 1690, has been read both as an actual social contract theory and as a hypothetical social contract theory.) Although there is no government, individuals have certain natural rights, and generally respect the rights of others. Although the non-agreement point is not the dire Hobbesian state of war of all against all, the absence of a generally accepted adjudication and enforcement agency often leads to feuds when someone believes that her rights have been violated without adequate rectification. In addition, the absence of government makes it difficult to provide various public goods (such as roads and national defence). The result is that it would be rational for all to agree to give up some of their natural rights and to establish a state.

Kantian forms of contractarianism (sometimes called ‘contractualism’) view the social contract device as representing reasonable reciprocity between moral equals who are self-legislating free and equal members of the kingdom of ends. Harsanyi (1953; 1955) and Rawls (1971), for example, allow that individuals are primarily concerned with promoting their own good, but they impose a veil of ignorance that blocks parties from having any knowledge of their capacities, positions, or desires. One objection to
this approach is that it eliminates all individual differences and thus reduces the agreement to the choice of one individual behind the veil of ignorance. Scanlon (1998), by contrast, allows individuals full knowledge of their situations, but stipulates that the parties are motivated by a desire to reach a fair and reasonable agreement (as opposed to simply promoting their own good). (Habermas, 1993, is similar in spirit.) So understood, contractarianism takes ability to justify our conduct to each other as central to morality. Of course, the notion of a fair and reasonable agreement is a moral notion and does an enormous amount of work here.

I shall not here attempt to adjudicate between Hobbesian, Lockean and Kantian contractarianism. Instead, I shall focus on general challenges to contractarianism. Contractarianism is sometimes charged with ignoring the interests of beings – such as animals, infants and fetuses – that are not able to communicate linguistically, make commitments, and so on. Although some Hobbesian contractarian theories do ignore these interests, this is not an essential part of contractarianism. Some theories (such as Scanlon's) take these interests into account by allowing that trustees representing the interests of such beings are parties to the agreement.

A more fundamental criticism of contractarianism, often raised by Marxists, feminists and communitarians, is that it is individualistic. Contractarianism is indeed normatively individualistic, which is to say that it claims that the ultimate right-making features are features of individual people (viz. their consent), not irreducible features of collectivities. It does not, however, assume ontogenetic (or developmental) individualism, the view that denies that individual people are shaped and formed by the social context in which they find themselves. Nor does it assume ontological individualism, the view that individual persons are ontologically prior to society. Nor is contractarianism committed to the view that people are (inevitably or contingently) egoistic or materialistic in their desires (for example, caring only about the bundle of material goods that they control). Many contractarian theorists have made such assumptions, but such assumptions are not essential to contractarianism.

The main challenge to contractarianism questions the claim that hypothetical consent has any normative force. We generally deem it wrong for someone to take one's car without one's permission, even if one would have consented had one been asked. Moreover, in those cases where hypothetical consent seems to have some moral force, it may be because it is an indicator of what is in that person's interests. For example, my hypothetical consent for you to move my car away from the fire is an indication that it is in my interest that you do so. It may be that the appeal to my interests is what is doing the moral work here and that hypothetical consent does no real work.

Consent under the right conditions is clearly normatively significant. Whether actual or hypothetical consent can do all the work required of it for contractarian theories is a matter of ongoing debate.

Abstract

Social democracy refers to a political theory, a social movement or a society that aims to achieve the egalitarian objectives of socialism while remaining committed to the values and institutions of liberal democracy. This article examines the historical development of all three forms of social democracy. It shows that social democracy was one of the most creative and durable influences on the politics and economics of the advanced industrialized nations during the 20th century and that, in spite of some setbacks, it retains a distinctive political agenda for the future.

Article

Social democracy refers to a political theory, a social movement or a society that aims to achieve the egalitarian objectives of socialism while remaining committed to the values and institutions of liberal democracy. Born in an era of sharp ideological polarities and intense social conflicts, social democracy has often been seen as a pragmatic compromise between capitalism and socialism. As Leszek Ko•akowski has put it: ‘The trouble with the social-democratic idea is that it does not stock or sell any of the exciting ideological commodities which totalitarian movements – communist, fascist, or leftist – offer dream-
hungry youth.’ Instead of an ‘ultimate solution for all human misfortune’ or a ‘prescription for the total salvation of mankind’, said Kœakowski, social democracy offers merely ‘an obstinate will to erode by inches the conditions which produce avoidable suffering, oppression, hunger, wars, racial and national hatred, insatiable greed and vindictive envy’ (Kœakowski, 1982, p. 11). For much of the 20th century, the comparative modesty of this ambition led many to underestimate social democracy. Both the Marxist Left and the free market Right disparaged the purportedly unimaginative parties and trade unions that were the principal carriers of social democratic ideas, and scorned the vacillating compromises they saw as inherent in a social democratic analysis of politics. But if we review the historical development of social democracy, it becomes clear that such interpretations misjudge its character and significance. In fact, social democracy deserves to be recognized as one of the 20th century’s most creative and durable influences on the politics and economics of the advanced industrialized nations.

**Formation**

What would later be called ‘social democracy’ first emerged in the late 19th century in the labour movements of north-west Europe. Early non-European outposts were also established in Australia and New Zealand around the same time. In nations such as Britain, France, Germany and Sweden, advocates of the interests of the working class inhabited polities that were characterized by rapid industrialization and the slow, inconsistent emergence of liberal constitutionalism and democratic citizenship. These circumstances created a complex structure of constraints and opportunities for labour movements that differed from those in southern or eastern Europe. In this relatively liberal environment, the politicized elements of the working class could build powerful political parties and trade unions to represent and protect their interests, and ultimately, or so they hoped, use democratic means to abolish the profound poverty and social oppression that working-class leaders saw as the ineluctable consequences of industrialization. The leaders and theorists of these movements, figures such as Keir Hardie, Jean Jaurès, Eduard Bernstein and Hjalmar Branting, were influenced by a variety of ideological traditions, most obviously Marxism, but also progressive liberalism, republicanism and ‘utopian’ socialism (for one account of such non-Marxist influences see Stedman Jones, 2004). They drew upon all of these intellectual currents as they began to sketch the outlines of a social democratic political theory. While important first approximations of this ‘revisionist’ socialism were articulated in the late 19th century by the Fabian Society and the Independent Labour Party in Britain, and by the republican socialists led by Jaurès in France (see Tanner, 1997; Berman, 2006, pp. 28–35), the frankest and most influential theoretical case for social democracy in this period was made by Bernstein, who explicitly confronted the forces of Marxist orthodoxy led by Karl Kautsky within the German Sozialdemokratische Partei Deutschlands (SPD). Bernstein’s ideas, most fully expressed in his 1899 book *The Preconditions of Socialism*, laid the foundations for subsequent social democratic thinking by directly contesting two doctrines central to the self-understanding of Marxism during this period: historical materialism and the class struggle. Bernstein argued that capitalism was not doomed to collapse of its own accord, as a result of inevitable internal crises and the immiseration of the mass of the population. On the contrary, he thought that capitalism had in fact shown itself to be a flexible and adaptable economic system, capable of sustaining itself for the foreseeable future. While there was therefore no inevitability to the collapse of capitalism, continued Bernstein, it was certainly possible for significant modifications to be made to its
social democracy: The New Palgrave Dictionary of Economics

structure through political action. In a democratic society, progressive social reforms could significantly improve the position of the working class. In this sense, Bernstein provocatively added, ‘what is usually termed “the final goal of socialism” … is nothing to me, the movement is everything’ (Bernstein, 1898, pp. 168–9). Bernstein was equally sceptical of the doctrine of class struggle. In contrast to the widespread Marxist assumption that socialism required the working class to monopolize political power, he stressed that cross-class alliances would be necessary for socialists to enter government, and that socialism was in any case best seen as addressed to the people as a whole rather than as an ideology tethered to only one social group. In these senses, Bernstein presented social democracy as the ‘legitimate heir’ of liberalism, with its aim being ‘the development and protection of the free personality’ (Bernstein, 1899, p. 147).

Bernstein’s revisionism was extremely controversial, but his strategic vision appeared increasingly relevant to party leaders after the First World War, as socialist parties began to mobilize greater political support and found themselves on the cusp of power in many nations. The Russian revolution had now established a clear distinction between two different forms of socialist struggle, the reformist and the revolutionary. In response, the socialist parties of north-west Europe (and of Australia and New Zealand) were increasingly drawn towards reformism in practice, if not always in theory. Before the Second World War, however, the experience of such parties in government was for the most part short-lived and ineffective. In Britain, France and Germany, notionally socialist parties endured traumatic periods in government. Faced by economic crisis and ultimately depression, these parties had few intellectual resources to draw upon as they found themselves fighting capitalist crisis armed only with socialist rhetoric. At the 1931 congress of the SPD, the trade union leader Fritz Tarnow aptly summarized the dilemma: ‘Are we standing at the sickbed of capitalism not only as doctors who want to heal the patient, but also as prospective heirs who can’t wait for the end and would gladly help the process along with a little poison?’ (quoted in Berman, 2006, p. 110).

However, one party did manage to advance beyond this dilemma, and in effect forged the path that would later be followed by other socialist parties after 1945: the Swedish Socialdemokratiska Arbetarepartiet (SAP). In office more or less continuously from 1932, the SAP's achievement under their leader Per Albin Hansson was twofold. First, in political terms, the Swedish social democrats created a durable and popular political identity that encompassed the industrial working class but reached beyond this social constituency. In particular, the Swedish social democrats forged a cross-class alliance with the agrarian party, creating a coalition of workers and farmers that guaranteed the SAP's hold on office. Second, the social democratic-led governments of this period introduced a range of policies that would later be seen as virtually definitive of social democratic policymaking, although they were not generally regarded as such at this time. Two broad policy agendas were pursued in Sweden: first, the use of counter-cyclical measures to engineer an upturn in the economy. Influenced by the early (pre-\textit{General Theory}) writings of Keynes and the so-called ‘Stockholm School’ of Swedish economists, the social democratic finance minister Ernst Wigforss undertook active state intervention such as public works to fight depression, in effect developing a form of ‘proto-Keynesianism’. Similar remedies had been proposed within the Labour Party in Britain and the German SPD, but only in Sweden were senior social democratic politicians sufficiently open to these ideas and in a position to implement them. Although the Swedish economy's subsequent recovery was impressive, the role of the government's expansionary polices in this recovery is debatable; their importance as a political symbol is less so. In any case, as Erik Lundberg has argued, perhaps the real merit of the SAP-led government's economic programme
social democracy: The New Palgrave Dictionary of Economics

‘consisted fundamentally in the avoidance of backward or unintelligent policy measures’, something that certainly cannot be said of every government of this period (Lundberg, 1985, p. 9). Second, and complementary to this ‘proto-Keynesianism’, the Swedish social democrats introduced a range of social welfare measures, including unemployment insurance, a housing programme, and enhanced state pensions (for further discussion of this government, see Sassoon, 1996, pp. 42–6; Tilton, 1990, pp. 39–69; Berman, 2006, pp. 152–76).

By the outbreak of the Second World War, the parameters of social democratic ideology had been established. First, social democrats were committed to parliamentary democracy rather than violent insurrection or direct democracy. This not only meant that social democrats saw peaceful, constitutional methods as the best means of reforming capitalism, but also that they saw a system of parliamentary representation as the most plausible form of democratic government and the mass party as the best vehicle for aggregating and advancing their political objectives. These democratic commitments meant that in the early 20th century social democrats often led the struggle to expand the franchise to all men and women. Second, social democrats tailored their electoral appeals to the ‘people’ as a whole and not simply to one social class. From its inception, social democracy has been understood by its advocates as aiming at the construction of cross-class coalitions. A form of ‘social patriotism’ has dominated social democratic political discourse, which presented economic redistribution as synonymous with the national interest. As Per Albin Hansson famously argued in 1928, the Swedish social democrats sought to establish Sweden as a ‘people's home’ (folkhemmet) where ‘no one looks down upon anyone else … and the stronger do not suppress and plunder the weaker’ (quoted in Tilton, 1990, p. 127). Third, social democrats believed that it was above all through legislation and government policy that this vision of an egalitarian society would be realized (for further discussion of these three points, see Esping-Andersen, 1985, pp. 4–11; Przeworski, 1985). Animating all three of these basic social democratic assumptions was a distinctive political theory that sought to combine a strong commitment to individual freedom and democracy with the recognition that freedom and democratic participation can only be accessed by all citizens in circumstances of relative material equality (see Jackson, 2007). Nonetheless, there remained significant disagreement before the Second World War about precisely which policies could best advance these political ideals. Many on the Left ultimately believed that some form of collective ownership of capital was the most coherent route to greater equality. The policy instruments characteristically associated with social democracy, and pioneered in Sweden, had yet to be firmly established in the minds and hearts of social democrats themselves.

Golden age

The period from 1945 to the early 1970s is often referred to as the ‘golden age’ of social democracy. One difficulty with this characterization is that social democratic parties were not always in government when many of the reforms identified as ‘social democratic’ were actually implemented. Although the electoral prospects of social democratic parties were considerably brighter than before the war, this was not a period in which social democratic parties established electoral hegemony (except in Scandinavia). A second difficulty with describing this period as a golden age for social democracy is that it could be countered that these years were above all a period of extraordinary success and dynamism for capitalism. The golden age, it might be argued, was in fact a long post-war capitalist boom, which
brought sustained economic growth and rising living standards for all. Social democracy could therefore be said to be basically irrelevant to this more fundamental economic trend. Both of these caveats need to be taken seriously, but in my view they do not decisively undermine the case for identifying this era as a broadly social democratic one.

Three crucial post-war developments in the political economy of the advanced industrialized nations have rightly been seen as illustrating the powerful influence of social democracy in this period: the establishment of ‘social citizenship’ in Western Europe; the emergence of full employment as a legitimate, and in some cases pre-eminent, objective of government policy; and the increased role given to trade unions in economic policymaking. Post-war social conditions bred much greater popular support for these initiatives than had existed pre-war: the radicalizing impact of a ‘people's war’ against fascism, coupled with deep-seated hostility towards the maladies of unregulated capitalism manifested in the 1930s, meant that both the public and political elites were receptive to new policy frameworks of a broadly social democratic kind. The most influential authors of such frameworks, William Beveridge and John Maynard Keynes, identified themselves as progressive liberals (although it should be noted that in the 1940s, Beveridge was much more sympathetic to socialism than is often recognized: see Harris, 1997, pp. 428–43, 480). However, while the ideas of Beveridge and Keynes significantly modified earlier social democratic thinking, there was no doubt that their proposals meshed with basic social democratic aspirations, enhanced the economic credibility of social democracy as a model for public policy, and offered a practical way forward for parties of the Left previously committed to an imprecise socialist rhetoric. Conservative parties did their best to keep pace with the perceptible march leftwards of public opinion and expert advice, but as they did so they inevitably abandoned their own ideological terrain. The ideological common sense of the age was now based around progressive taxation, public spending and state intervention in the economy.

Social democrats had long emphasized the need to reshape the pattern of resource distribution thrown up by the market so that all citizens could exercise the rights associated with democratic citizenship and be ‘decommodified’, that is have access to an income based on their needs, rather than on their success or otherwise in the labour market (Esping-Andersen, 1990, pp. 21–3). The most advanced welfare states of the immediate post-war period – in Britain and Sweden – were created by social democratic governments. The 1945–51 British Labour government led by Clement Attlee enacted William Beveridge's vision of the welfare state: unemployment insurance, pensions and family allowances all largely followed Beveridge's lead, while Aneurin Bevan's universal and tax-funded National Health Service built on and in some respects deepened Beveridge's ideas. By 1950, the British sociologist T.H. Marshall could write that in Britain social rights had been added to the civil and political rights of each citizen. ‘Social citizenship’ was now a reality (Marshall, 1950). The post-war SAP governments in Sweden were slower off the mark than the Labour Party in undertaking welfare measures, but by the 1950s the celebrated universalism of the Swedish welfare state had begun to emerge. Most importantly, an expanded pension scheme introduced in 1959, the ATP, gave the middle class a stake in the welfare state. As in the 1930s, the SAP were shrewd at building cross-class alliances, this time breaking with the farmers to create a wage-earners’ coalition between blue- and white-collar employees, organized around universal, but also earnings-related, pension rights (Esping-Andersen, 1985, pp. 108–10; Eley, 2002, pp. 318–9).

Of course, the welfare state was not exclusively a social democratic initiative: other ideological traditions and political actors played a role in its creation, notably the Christian Democratic parties of
social democracy: The New Palgrave Dictionary of Economics

Austria, Germany and Italy. But social democracy possesses a distinctive vision of welfare, which has dominated the post-war political trajectory of certain nations (notably in Scandinavia) and which has also been influential in other national welfare systems (for example, Britain). The social democratic welfare state is universal in scope and egalitarian in its impact, rather than targeted as a residual measure at those on low incomes. And, even where these social democratic features are absent from a nation's social policy, it has often been the electoral threat from the Left that has prompted the Right to undertake its own social reforms.

The second policy development of this period that can fairly be classified as social democratic is the emergence of full (male) employment as a central political goal. The ‘right to work’, an old leftist slogan, was obviously connected to the ‘social rights’ discussed above. The post-war vision of social citizenship was premised on the assumption that every able-bodied male citizen would be in paid work, both as a matter of social justice, and for the more pragmatic reason that income tax and social insurance payments were needed to fund the new welfare state. The advantages of full employment from a social democratic perspective were clear. As the economist Thomas Balogh wrote, full employment ‘removes the need for servility, and thus alters the way of life, the relationship between the classes. It changes the balance of forces in the economy’ (quoted in Scharpf, 1991, p. 16). In comparison to the labour movement's impotence under the mass unemployment of the 1930s, the more or less full employment of the golden age strengthened the hand of labour in conflicts with capital, significantly increasing the bargaining power of wage-earners.

Prior to the golden age, social democrats had usually maintained that only a substantial socialization of the economy would enable governments to secure full employment. The post-war influence of Keynes was decisive in shifting social democratic thinking on this question, and in enabling social democrats to formulate a radical but economically credible policy agenda. Keynes was thought to have demonstrated that state regulation and intervention could in fact stabilize capitalism, since full employment and steady economic growth could be maintained by an expansionary fiscal policy aimed at sustaining economic demand in periods of economic downturn. This conviction was apparently vindicated by the economic boom of the post-war years, although it is doubtful whether some of the policies conventionally labelled as ‘Keynesian’ played a significant role in sustaining this period of economic stability. Discretionary government intervention and deficit spending did not play a large role in the political economy of the social democratic golden age. Indeed, leading social democratic nations such as Norway and Sweden had the largest budget surpluses in the Organisation for Economic Co-operation and Development (OECD) in the 1960s. More significant was the growth of public spending: the rise of the welfare state was itself a measure that helped to boost aggregate demand and stabilize the business cycle (Glyn, 1995, p. 42).

Cordial relations with the trade union movement were critical to the success of Keynesian policymaking, since under conditions of full employment some form of wage restraint was necessary to avoid inflationary pay settlements. Trade unions now emerged as central players in post-war politics and corporatist wage-bargaining was a key feature of the new economic order. Once again, Sweden was in the vanguard of this development. Two trade union economists, Gösta Rehn and Rudolf Meidner, developed the so-called ‘Rehn–Meidner model’, which incorporated an active labour market policy and solidaristic wage bargaining into a comprehensive economic strategy designed to maintain growth and employment, lower inflation and narrow income inequality. The Rehn–Meidner model was adopted by the SAP in the late 1950s and was an important influence on the policy of successive social democratic
social democracy: The New Palgrave Dictionary of Economics

governments in Sweden. Under these governments, the principle of ‘equal pay for equal work’ was implemented, so that, once the fair rate for a certain job had been agreed by employers and the unions, less efficient firms could no longer enjoy the subsidy of paying their employees lower wages than those undertaking the same job elsewhere in the economy. Poorly performing firms now had an incentive to improve their efficiency or they would go out of business; the active labour market policy was designed to find work for those who found themselves unemployed as a result. Social democratic objectives were therefore harnessed to an attempt to improve economic efficiency and engineer a more dynamic economy (see Turvey, 1952; Tilton, 1990, pp. 189–214; Sassoon, 1996, pp. 203–6). Although no other social democratic party developed an economic strategy of comparable sophistication to the Rehn–Meidner model, the greater involvement of trade unions in economic policy-formation, and the widespread negotiation of agreements over pay and conditions between employers and trade unions, can be seen as a further example of the influence of social democracy after the Second World War.

It is unlikely that, shorn of these three distinctively social democratic elements, post-war capitalism could have secured the same progressive economic outcomes visible in the golden age: steady economic growth, low unemployment, low inflation, rising wages and narrowing income inequality. This radical shift in the character of capitalism inevitably prompted lively debate among social democrats about their political objectives. While many social democrats had earlier assumed that their ultimate objective (however distant) was the creation of a new order called ‘socialism’ (and thus the abolition of capitalism), it now seemed that many of their aspirations could in fact be realized in the context of a reformed capitalism. Reflecting on this point, and on the electoral failures of some social democratic parties in the 1950s and early 1960s, reformist leaders began to articulate a new social democratic revisionism, initiating fresh theoretical controversy with the Left of their parties. The SPD ostentatiously settled its account with Marxism in 1959, with its adoption of the Bad Godesberg Programme. This new statement of SPD priorities dispensed with the socialist end goal that had previously been a constitutive feature of party rhetoric and accepted that what had previously been seen as short-term goals were now exhaustive of social democratic objectives: full employment, a just distribution of wealth, and consistent economic growth. Likewise, in the British Labour Party, revisionists such as the party leader Hugh Gaitskell and his ally Anthony Crosland set out the case for a democratic socialism that discriminated more carefully between ends and means. They defined socialist ends as certain durable ethical principles, in particular the pursuit of greater economic equality, rather than as the attainment of a particular model of economic organization. Equality, argued the British revisionists, could in fact be realized through a variety of means, including some socialization of industry or collective capital ownership, but also through a strong welfare state, the regulation of the labour market, Keynesian economic management, and the progressive taxation of income and wealth. A compelling intellectual case for this was set out in Crosland's 1956 book *The Future of Socialism*, which has remained an essential reference point for debates about social democratic strategy in Britain ever since.

By the late 1960s, revisionist social democracy had therefore acquired a sharper theoretical definition and had some significant policy achievements to its credit. A revival in the electoral popularity of both Willy Brandt's SPD and Harold Wilson's Labour Party saw both parties in government as the 1960s drew to a close. But by then the golden age was also nearing its end.

Crisis and adaptation
While social democracy was certainly an indispensable ingredient of the social capitalism that permeated western Europe after the Second World War, it would be foolish to neglect the importance of capitalism itself to this distinctive phase of economic history. Strong economic growth and rising productivity had provided the necessary economic conditions for expansive social reforms; by the mid-1970s, these conditions were no longer in place. Instead, social democrats were placed under severe pressure by a threefold crisis.

First, a global economic slowdown was triggered by various factors, including a general decline in the growth of labour productivity and increases in the price of raw materials after the OPEC oil price rises of 1973 and 1979. Growing industrial conflict between unions and employers added to the gloomy economic outlook. The result was a period of rising unemployment and inflation, and low levels of economic growth, across all industrialized nations.

Second, the 1970s saw the beginning of a marked change in the class structure of industrialized economies and a feminization of their workforces. The core constituency of social democratic parties – workers in manufacturing industries – declined as a proportion of the labour force, while there was a substantial increase in the proportion of employees working in service industries. At the same time, there was a steady rise in female employment rates, particularly in the service sector. The male breadwinner model that had been taken for granted in earlier social democratic thinking was now outdated, while the shift to service-sector employment, or so it was claimed, fractured class solidarity and thus the electoral base of social democracy. The growth of service sector employment also created problems for social democratic economic policy: increased employment in private sector services was associated with greater wage inequality, which raised the prospect of a trade-off between the two social democratic goals of full employment and greater income equality. By the 1990s, one social democratic route to resolving this trade-off, namely, increasing employment in public sector services (the policy pursued in Sweden in the 1970s and 1980s) was said to be ruled out by the budgetary constraints imposed on governments by increasingly tax-resistant electorates and financial markets nervous of budget deficits (Iversen and Wren, 1998).

Third, in response to the previous two developments, the intellectual basis of social democracy was subjected to a concerted and ingenious attack. A ‘New Right’ emerged, which was quick to attribute the blame for the economic downturn of the 1970s to ham-fisted Keynesian intervention in the market, over-powerful trade unions enforcing inflationary pay settlements and wasteful public expenditure on welfare programmes, since the latter undermined individual responsibility and required efficiency-inhibiting levels of direct taxation. Although primarily influential in English-speaking countries, the ‘neoliberal’ prescriptions of austere counter-inflationary measures, welfare state retrenchment, privatization and deregulation set the tone for the discussion of economic policy throughout the industrialized nations in the 1980s and 1990s. The policymaking autonomy of national governments was in any case reduced in this period by the (neoliberal-inspired) relaxation of capital controls across the OECD in the 1980s and the associated growth in capital mobility across national boundaries.

These developments led many to claim that the prospects for social democracy within one country were bleak, a point apparently underlined by the electoral dominance of conservative parties in some nations during the 1980s and 1990s, in particular Britain and Germany. There is no doubt that social democrats were defeated on a number of important issues in this period and were forced to adapt their programmatic objectives to take account of the changed economic and political context. But did this necessarily signal the end of the basic social democratic aspirations discussed earlier? There are three...
reasons for thinking this latter conclusion is too strong. First, although clearly a period of social
democratic retreat, social democratic parties remained electorally viable. Second, some established
social democratic institutions remained resilient in the face of neoliberal attack. Third, a new
revisionism had developed by the end of the 20th century, which sketched out a plausible, if modest,
agenda for the pursuit of greater economic equality and full employment in the revivified global
capitalism of the new millennium. This survey of social democracy will conclude by elaborating on
these three points.

First, then, although frequently remembered as a period of electoral failure for the Left, in fact the
1970s, 1980s and 1990s also saw some significant social democratic victories. France was led by its first
socialist head of state, François Mitterrand, from 1981 to 1995; in newly democratized Spain the
socialist party under Felipe González remained in power for over a decade after 1982; in Australia Bob
Hawke and then Paul Keating presided over the longest ever period of Labor government, from 1983 to
1996. The SAP largely maintained its grip on power in Sweden (albeit with periods out of office
between 1976–82 and 1991–4), while the Austrian social democrats were in office throughout the 1970s
and 1980s, either as a single-party government or in coalition. By the 1990s, after long periods in
opposition, the British Labour Party under Tony Blair and the SPD under Gerhard Schröder had returned
to power. This evidence undermines the crude sociological determinism that associates the electoral
fortunes of social democratic parties with the proportion of manual workers in the labour force. In fact
there has never been an obvious correlation between social democratic party support and the size of the
working class. Social democratic parties have had low levels of support when there has been a high
proportion of manual workers in the labour force, for example the SPD in the 1950s and 1960s, and have
had high levels of support when that proportion has been in decline, for example the SAP after the 1970s
(Kitschelt, 1994, p. 41). Of course, electoral success is by itself an insufficient measure of social
democratic resilience. All the governments of the Left just mentioned have faced criticism for conceding
too much ground to the Right, and some have been accused of implementing the dictates of neoliberal
capitalist restructuring at the expense of pursuing a distinctively social democratic course. How valid are
these claims?

Here we reach the second point mentioned earlier: although a perceptible swing to the Right occurred in
public policy in this period, sometimes under nominally social democratic governments, this backlash
was never far-reaching enough to undo the most deeply entrenched of the social democratic institutions
established after 1945. Although the welfare state and progressive taxation of income were placed under
considerable pressure, they remained at the heart of the public understanding of social justice in most
industrialized nations with significant labour movements. Even in Britain, where the Thatcher
government carried out the most thorough attack on the achievements of the golden age, Bevan's
National Health Service remained intact, and quite substantial redistribution continued to take place
through the tax and benefit system. As the 21st century began, 12.3 per cent of the UK population were
living in poverty, but the tax and benefit system still reduced by 6 per cent the number of British
citizens left in poverty by the market (Glyn, 2006, p. 171). Between 1980 and 2001 social spending
actually increased as a share of GDP across the OECD. Although the rate of increase was slower than in
previous decades, in this period social spending in northern European countries, those most influenced
by social democracy, increased more than in ‘liberal’ economies (Glyn, 2006, pp. 165–6). While the
scale of the free-market triumph should therefore be kept in proportion, equally the problems that
confronted social democracy as traditionally understood should not be underestimated. In particular,
after the 1970s the attainment of full employment became a much more elusive and apparently intractable political goal. Some social democratic governments, for example in Austria and Sweden, had initially had some success in responding to the downturn in the 1970s with a classical Keynesian reflation, but in general this period saw an increase in unemployment rates, and greater scepticism among both policymaking elites and public opinion about the capacity of governments to maintain full employment, or at least about whether it was possible to do so while simultaneously narrowing inequality.

Third, this more pessimistic political climate prompted a fresh attempt to revise party programmes in order to adapt social democratic politics to this new ‘post-industrial’ era. The resulting ‘post-industrial social democracy’ can be distilled into three elements (see Vandenbroucke, 2001; White, 1999). First, the acceptance of certain constraints on the policymaking autonomy of national governments and of some strict assumptions about how governments can maintain economic growth and stability. In particular, social democratic politicians ruled out the use of large budget deficits and significant tax increases to fund social democratic goals. Although this was sometimes presented as the result of immutable economic changes (for example ‘globalization’), it is perhaps more accurate to see this commitment as a political one. After the tumultuous events of the 1970s, social democratic parties were obliged to impress on both financial markets and the electorate their competence as economic managers and to signal that there would be no return to the high inflation and sluggish economic growth that marked the end of the golden age. While this commitment undoubtedly set strict limits on the activities of social democratic governments, it nonetheless still left some latitude for egalitarian policy interventions (remember, for example, that budget deficits were never a core feature of social democratic policymaking in the golden age). The second element of this new revisionism therefore stressed the importance of supply-side measures to improve both economic efficiency and social justice. Social democrats became increasingly interested in supplementing ex post redistribution through the welfare system with an attempt to equalize the ex ante distribution of financial assets and human capital. In particular, investment in education and training, and active labour market programmes, were seen as key instruments that would both boost employment rates and improve productivity. Similarly, social democratic policymakers expressed some interest in ensuring a more equitable distribution of financial assets through universal ‘stakeholder’ grants (Paxton, White and Maxwell, 2006). Third, the reduction of poverty and inequality through the welfare state and labour market regulation remained a social democratic priority, but with a distinctive focus on two issues: first, ensuring that the welfare state contributes to the reduction of unemployment by improving the incentives for low-paid workers to enter, and remain in, the labour market; and second, ensuring that the welfare state adequately supports family life and female participation in the workforce. The increased use of in-work benefits such as earned income tax credits was proposed to address the first of these issues, while the expansion of welfare systems to include universal nursery provision (an objective already accomplished in Scandinavia) was proposed to assist with the second. Although these aspirations were more modest than the equivalent programmes of social democratic parties in the ‘golden age’, they were nonetheless recognizably social democratic, and in crucial respects departed from neoliberalism. In particular, the revisionist emphasis on increasing employment through supply-side measures and generous in-work benefits offered an answer to the claim that in the ‘post-industrial’ economy there must be an inevitable trade-off between employment and equality. However, there was undoubtedly a tension at the heart of this revisionism: these new methods of reducing inequality and unemployment still required significant social spending,
but the acceptance of tax resistance and budgetary restraint limited the resources available to social democratic governments. Critics were correct to point out that a social democracy cannot be obtained on the cheap.

At the beginning of the 21st century those countries most deeply influenced by social democracy, in essence the Scandinavians, still differed significantly from those in which social democracy had penetrated less thoroughly. In Sweden, 6.4 per cent of the population lived in poverty; in Britain, the equivalent figure was 12.3 per cent, and in the United States 17 per cent (Glyn, 2006, p. 171). As Koakowski has suggested, social democracy ‘has invented no miraculous devices to bring about the perfect unity of men or universal brotherhood’ (Koakowski, 1982, p. 11). But when we review the history of social democracy during the 20th century it is clear that it has some non-negligible achievements to its credit. In particular, social democrats have greatly improved the position of the disadvantaged in the industrialized nations, and have ensured that the interests of the poor were represented in political systems formerly monopolized by the rich.

Economists use a social discount rate to evaluate future costs and benefits. To arrive at a suitable magnitude, market interest rates are adjusted for taxes, transactions costs, and risk. Over time the discount rate debate has become more complex. It is agreed that no single discount rate will apply to all choices, and that the proper discount rate will be context-dependent.

Article

Discount rates are required to evaluate the future costs and benefits of economic policies. It is widely recognized, for instance, that a dollar today is worth more than a dollar five years from now. But how much more?

All cost–benefit analyses with a temporal element must choose a rate or rates of discount. Discount rates are especially important for evaluating global warming, the loss of biodiversity, hazardous waste disposal, and related environmental issues. Infrastructure investments, such as roads, bridges, and tunnels, often last for generations. In these cases many costs and benefits come in the relatively distant future.

Consider Table 1, which compares present and future benefits using various positive rates of discount:

- Estimated number of future benefits equal to one present benefit based on different discount rates

**Years in the future** 1% 3% 5% 10%
Just as economists use discount rates, so do they require a rate of compounding when measuring compensation for past injustices. For instance, if we are to make restitution for some previous loss, we must decide how to convert past dollar amounts into a present sum.

Economists (for example, Lind et al., 1982) typically suggest that a discount rate for dollars should have two components: the productivity of capital, and the social rate of time preference. The productivity of capital refers to our ability to turn present resources into a larger future value. If, for instance, we have a dollar today we can invest it and reap greater value in the future, at least on average. This is one reason why current resources are worth more than future resources. The social rate of time preference refers to our impatience. Even if we cannot invest capital productively, many of us would rather consume today than one year from now. This provides another reason why current resources might be of greater value than future resources.

Observed market rates of interest will not reflect these values with complete accuracy. First, governments typically tax the return to capital. The social return on capital is therefore greater than the private return. Second, private capital markets face some degree of transactions costs, credit rationing, and bureaucratic regulation. Once again, the social return to capital is likely higher than the private return. Third, government taxation and borrowing (to fund projects) will involve deadweight loss and crowding out. All of these variables should be reflected in any proper measure of the cost of capital, and for these reasons we should not simply take market interest rates as given.

A related debate concerns whether governments should take risk into account when using a social discount rate. Kenneth Arrow (1971) argued that the government should use a riskless rate. A riskless rate, of course, will be much lower. Short-term US Treasury securities often yield no more than a 1 per cent real rate of return; the average rate of return on private capital in the United States can run as high as 10 or 15 per cent.

According to Arrow's reasoning, government faces little or no financial risk from bad policies, given that it can spread costs across a very large number of taxpayers. Nonetheless, this argument has been criticized from at least two directions. First, private corporations can spread their risks across a large number of diversified shareholders. Second, Arrow's argument focuses too much on the purely financial side of risk. Financial losses on a project are, taken alone, mere transfers. The relevant risks include possible variation in the value of the project for its intended beneficiaries. When one measures these risks, the absolute size of the government, or the number of taxpayers, is of little concern.

Changing discount factors over time may lower the effective social discount rate (Weitzman, 2001). In this case the lowest discount rate will have a highest contribution to an expected value calculation made from the vantage point of today. Richard Posner (2004, pp. 153–4) summarizes the argument:

Suppose there's an equal chance that the applicable interest rate throughout this and future centuries will be either 1 percent or 5 percent. The present value of $1 in 100 years is 36.9 cents if the interest rate used to compute the present value is 1 percent but only .76 cents
Social discount rate: The New Palgrave Dictionary of Economics

(a shade over three-quarters of a cent) if it is 5 percent. Now consider the 101st year and remember the assumption that the two alternative discount rates are equally probable. If the interest rate used to discount the future to the present value is 1 percent, then the present value of $1 at the end of that year will have shrunk from 36.9 cents to 36.6 cents. If instead the interest rate used is 5 percent, the present value of .76 cents will have shrunk to about .75 cents. This means that the average present value of $1 at the end of the 101st year will be 18.68 cents, implying an average discount rate of less than 2 percent, rather than 3 percent. The reason is that the more rapid decline in value under the higher discount rate (5 percent) reduces its influence on present value.

In other words, when there is uncertainty about future discount rates, the lower rates have a greater relative weight the further we look into the future.

In recent times ‘gamma discounting’ has become a popular approach. Weitzman (2001, p. 260) notes, ‘even if every individual believes in a constant discount rate, the wide spread of opinion on what it should be makes the effective social discount rate decline significantly over time.’ This is for the same reason as discussed above. More generally, many individuals will argue that the present is more important than 30 years from now, but that after some point further differences in time should cease to matter. Perhaps what happens 300 years from now is not much less important than what happens 200 years from now. This view has found significant support in polls of both ordinary and distinguished economists (Weitzman, 2001).

Most of the debate has focused on discounting dollars; but the discounting of utility is a separate issue. Most likely, the discount rate on utility should be lower than the discount rate on dollars. Utility is not ‘productive’ over time as is invested capital; we are therefore left with only the rate of time preference as a discount factor. And for inter-generational policies, the rate of social time preference is arguably zero. Before individuals are born, they do not experience a disutility of waiting (Cowen and Parfit, 1992).

Another question is how much discounting should apply to very large changes in individual welfare. Recall that cost–benefit analysis is best suited to analysing small changes at the margin, where market prices (adjusted for risk, taxes, and transactions costs) measure values. So it is reasonable to argue that a dollar today is worth more than a dollar 20 years from now. But what if we are discounting lives across hundreds of years? Is a single life today really worth more than the entire survival of the human race 500 years from now? It is quite easy to generate such a conclusion, for reasonable parameter values, through the uncritical application of discounting. In these cases it appears that a more explicit ethical judgement should override the cost–benefit approach.

In sum, the debate over discount rates has seen continual progress. Most economists now agree that there is no single correct rate of social discount for all problems. Instead, the proper discount rate depends on the problem under consideration, the time horizon, the assumptions about risk, and the magnitude of the associated costs and benefits. A social discount rate is a very useful tool, and it can nicely complement our broader normative judgements. But it does not remove the need to keep the relevant ethical issues in mind.

Abstract

Social insurance expenditures are the largest and fastest-growing component of government expenditures in the developed world. The design of social insurance programmes reflects the trade-off between insurance and incentives. This article reviews the impact of social insurance programmes on both insurance against adverse events and incentives for adverse behaviour. It concludes with lessons for optimal social insurance programme design.

Article

Social insurance expenditures are the largest and fastest-growing component of government expenditures in the developed world. In the United States, for example, only about four per cent of federal government spending in 1953 was devoted to social insurance; by 2003, this had grown eleven-fold to 44 per cent of federal spending (Gruber, 2005). There has been a corresponding growth in research into the behavioural impacts of a wide variety of social insurance programmes. This article reviews that research and its implications for policy, and loosely follows the structure of Gruber (2005), Chapter 12.

At its core, the design of social insurance reflects a trade-off between insurance and incentives. As laid out nicely by Baily (1978), the optimal level of social insurance benefits sets equal the consumption
smoothing gains from a social insurance programme to the moral hazard costs of that programme. Programmes that serve largely to displace existing efficient forms of consumption smoothing are less valuable than programmes that greatly increase the ability to smooth consumption around adverse events. Programmes that induce large distortions by insuring adverse behaviour are less valuable than programmes that target those who are truly adversely impacted and not changing their behaviour to qualify. The research on social insurance within economics has largely focused on the latter of these issues, the moral hazard induced by social insurance programmes. More recently there has been more attention paid to the former issue, with an eye towards optimal programme design.

Institutional features of social insurance programmes

Social insurance programmes are distinguished from other types of government spending by four characteristics. Workers participate by ‘buying’ insurance through payroll taxes or mandatory contributions by themselves or their employer. These contributions make them eligible to receive benefits if some measurable event occurs, such as disability or on-the-job injury. These benefits are conditioned only on making contributions and on the occurrence of the adverse event. And they are typically not means-tested: benefits do not depend on the level of one's current income or assets.

The most common social insurance programme the world over is public pensions through programmes such as Social Security in the United States; in the United States, this is the single largest government expenditure (see Gruber and Wise, 1999, for an overview of social security programmes in developed nations). The other major source of social insurance around the world is social health insurance, such as through programmes like Medicare in the United States, which provides universal health insurance coverage to the elderly, or National Health Insurance in Canada, which provides universal health insurance coverage to the entire population; see Cutler (2002) for an overview of health insurance programmes in developed nations.

Why have social insurance?

In the canonical expected utility model, with insurance available at actuarially fair prices, optimizing consumers will choose to fully insure themselves against idiosyncratic risk. Yet, in markets without social insurance, we often observe much less than full insurance. This motivates the desire for government interventions through programmes such as social insurance.

The major theoretical justification for social insurance is adverse selection in private insurance markets. As noted in the classic analysis of Akerlof (1970), asymmetric information between buyers and sellers can lead to market failure, whereby trades that would be beneficial to both insured and insurer are not made. Private insurers may be wary that the individuals demanding insurance from them represent the highest risks in the population, leading the insurer to be unwilling to offer insurance at a price that corresponds to the risk of the average person. As shown in the equally classic Rothschild and Stiglitz (1976) model, this can lead to a breakdown of the insurance market, or at best to a situation where high-risk individuals buy full insurance at high prices, while low-risk individuals are only partially insured at low prices. While there is controversy over the extent of adverse selection in some insurance markets, this is clearly an enormous problem in markets such as those for annuities or health insurance. (The
issue of adverse selection in health insurance markets is discussed in Cutler and Zeckhauser, 2000, who summarize in particular the very compelling Cutler and Reber, 1998, article on this issue. Finkelstein and Poterba, 2004, present evidence for adverse selection in annuities markets.)

While market failure is the most appealing justification to economists for social insurance, other rationales may be much more important to policymakers. One such rationale is administrative efficiency. While the government may be less efficient at producing goods than the private sector, it is clearly more efficient at providing insurance; for example, while health insurance administrative costs are 12 per cent of premiums in the private US health insurance market, they are 1.3 per cent of premiums under Canadian National Health Insurance (Gruber, 2005). Even more important in practice is paternalism. Politicians fear that individuals simply will not insure themselves appropriately against sizable risks, so that social insurance is required to ensure proper protection.

The benefits of social insurance

The arguments presented above suggest a number of reasons why private insurance markets may not make it possible for a risk-averse individual to satisfy his desire for consumption smoothing. Yet they do not suggest that consumption smoothing is completely unavailable, because individuals may have private means to smooth consumption: their own savings, labour supply of family members, borrowing from friends, and so on. The justification for social insurance depends on the extent to which social insurance is more efficient than a consumers’ own private consumption smoothing mechanisms. If social insurance is simply displacing, or ‘crowding out’, equally efficient self-insurance, then there is no gain to the government intervention (but there may be costs, discussed below). The extent to which individuals can self-insure against adverse events will obviously vary with the predictability of the risk (for example, disability may be much less predictable than retirement), the size of the risk (for example, the total income loss from disability or retirement may be much larger than that from unemployment), and the availability of other forms of consumption smoothing (for example, own savings or spousal labour supply).

Tests for the extent of self-insurance against risk have typically proceeded by examining whether individuals can smooth their consumption across adverse events without social insurance, or, relatedly, the extent to which social insurance programmes simply crowd out other forms of self-insurance rather than smoothing consumption. For example, Gruber (1997) and Browning and Crossley (2001) find there is relatively modest consumption smoothing benefits to unemployment insurance during jobless spells. On the other hand, available evidence suggests that retirement income support only partially crowds out private retirement savings, so that there is a real impact on consumption in retirement from programmes such as Social Security. (The evidence on Social Security and savings is described in Gruber, 2005, ch. 13. International evidence on Social Security and consumption is presented in Gruber and Wise, 2008.) There is also evidence of a crowd-out effect of public health insurance in the United States, both from the general provision of this insurance and the asset limitations that accompany qualification for these programmes (Gruber and Yelowitz, 1999). In developing countries, a very large literature finds that families are typically quite good at insuring themselves against modest risks, but not against large risks like disability (Case, 1995; Gertler and Gruber, 2002).

The limitations of these consumption-based tests, however, are highlighted by Chetty and Looney
As they point out, individuals may be using very inefficient means of smoothing consumption, so that even if social insurance doesn't increase consumption smoothing it raises social efficiency. A further difficulty arises because even inefficient consumption smoothing mechanisms (such as savings for idiosyncratic and large risks, which are better insured by pooling across individuals) may have social benefits (if there is too little savings for other reasons such as capital taxation). Clearly, more work is needed to fully evaluate the benefits side of the social insurance equation.

The costs of social insurance

The costs side of social insurance is moral hazard, the adverse behaviour that is encouraged by insuring against an adverse event. As with adverse selection, moral hazard arises due to asymmetric information in insurance markets. By trying to insure against an adverse event (true injury), the insurer may encourage individuals to pretend that an adverse event has happened to them when it actually hasn't. For example, a common type of social insurance in developed nations is insurance against on-the-job injuries (the workers’ compensation programme in the United States), which provides partial income replacement for those injured at work. Since work-based injury is often difficult to verify, however (for example for back strains or mental stress), workers may claim to be injured on the job simply to take a partially paid vacation. The rise in leisure induced by the combination of financial incentives and imperfect observability is an example of moral hazard.

Moral hazard can arise along many dimensions. In examining the effects of social insurance, three types of moral hazard play a particularly important role. The first is reduced precaution against entering the adverse state; for example, because individuals have medical insurance that covers illness, they may reduce preventive activities to protect their health. The second is increased expenditures when in the adverse state; for example, because individuals have medical insurance, they may use more medical care than they otherwise would, or because individuals have workers’ compensation they don't work hard to rehabilitate their injury. Finally, there may be supplier responses to insurance against the adverse state; for example, physicians may provide too much care to those with health insurance or firms may not be careful enough in protecting workers with injury insurance.

An enormous literature has arisen in public finance to assess the importance of moral hazard in social insurance programmes. The pioneer of this literature was Martin Feldstein, whose work in the early 1970s emphasized the labour market distortions caused by Social Security, unemployment insurance, and other programmes. A large literature has followed up on these issues, as review comprehensively by Krueger and Meyer (2002). In this section, I briefly review the key conclusions from this literature.

Much of the work in this area has been focused on the effects of retirement income security programmes on retirement behaviour: by insuring the elderly against income loss from retirement, these programmes may induce retirement. The literature within countries typically concludes that these programmes are an important, but not the dominant, reason for earlier retirement. Cross-country comparisons such as Gruber and Wise (1999), however, suggest that in the long run these programmes may play the dominant role in determining retirement behaviour.

A second area of much focus has been the impact of unemployment insurance: higher unemployment insurance benefits have been shown to significantly increase unemployment durations (for example, Meyer, 1989), while there is no evidence that the longer durations are resulting in more effective job
search. A more limited set of studies has uncovered even larger evidence of responsiveness of injury and illness durations to the financial incentives embedded in workers’ compensation and related programmes (for example, Krueger, 1991; Pettersson-Lidbom and Thoursie, 2006). The evidence for programmes that compensate for permanent disability suggests more modest effects on disability rates (for example, Gruber, 2000), which is consistent with the better ability to monitor long-run disability than short-run inability to work.

Unemployment and, to some extent, work-related injury reflect not only the decisions of employees but those of employers also. In most countries, the taxes that finance these insurance programmes are not experience-rated; that is, employers pay tax rates that do not depend on the utilization of the system by their workers. In the United States, there is experience rating, but it is only partial. A small but important literature suggests that this imperfect experience rating is a large source of adverse selection, as workers and firms combine to increase government-subsidized leisure through, for example, temporary layoffs (Topel, 1983; Anderson and Meyer, 2000).

There is also a large literature on moral hazard in medical expenditure programmes. There is clear evidence from the seminal Rand Health Insurance Experiment in the United States that the insured use care excessively, as those randomized into less generous insurance plans used less health care with no adverse impact on health (Newhouse and the Insurance Experiment Group, 1993). At the same time, a number of studies find that having no health insurance is associated with adverse health outcomes (for example, Lurie et al., 1984; Currie and Gruber, 1996a; 1996b). These findings suggest a ‘medical effectiveness’ curve which relates spending to health improvements: the curve is steep for initial health care use, but flattens out for the excessive care used by those with all health expenditures covered.

As with other social insurance programmes, there are also important supply-side moral hazard issues in health care. A number of studies document the importance of reimbursement structures for the treatment of patients by health providers, finding in particular that prospective reimbursement systems that ensure that providers bear part of the risk for excessive treatment lead to less utilization without adverse health impacts (Newhouse, 1996).

**Optimal social insurance**

These sets of findings have important implications for the optimal design of social insurance programmes. First, social insurance should be only partial. For example, replacement rates under labour market-based programmes (the extent to which social insurance benefits replace earnings before the adverse event) should be less than full, much less so in several cases. The fact that consumption smoothing is not full, while moral hazard is important, suggests in the framework of Baily (1978) less than full replacement. There is too little work on most of these programmes to state the optimal replacement rates with confidence, but there are clear directions for reform. The enormous moral hazard associated with Workers’ Compensation in the United States or with social security in many European nations, for example, suggests that there may be welfare gains from reducing benefit levels.

Another important example is health care, where the optimal insurance policy is one in which individuals bear a large share of medical costs within some affordable range, and are only fully insured when costs become unaffordable. This structure is optimal because coverage for all medical expenditures (what is often called ‘first dollar coverage’, since all dollars of medical spending, starting
with the first dollar, are covered) has little consumption smoothing benefit, but a large moral hazard cost. The consumption smoothing benefit from first dollar coverage is small because there is little utility gain to risk-averse individuals from insuring a small risk. At the same time, this first dollar coverage has substantial moral hazard cost because it encourages individuals to overuse the medical system, demanding care for which the social costs exceed the social benefits. An example of an optimal insurance plan would be Feldstein's (1973) ‘major risk insurance’ plan, in which individuals would face a high co-payment (such as 50 per cent) on all services until they spent a sizable share of their income (such as ten per cent) on medical care, beyond which there would be no more co-payments.

The second lesson is that there should be more supply-side risk bearing in insured markets. For example, more tightly experience rating employers for the costs of unemployed or injured workers could significantly reduce overuse of these social insurance systems. And more risk bearing by providers in the medical system has been shown to reduce utilization without adversely impacting health.

Finally, these findings also open the question of moving from the traditional ‘defined benefit’ approach to social insurance to a ‘defined contribution’ approach where individuals are mandated to provide for their own protection against adverse events. This model has been seen most forcefully in the debate over US Social Security privatization, whereby the traditional programme under which today's workers save collectively for today's retirees would be replaced by one where individuals saved for their own retirement. Partial privatization is in use in a number of countries, but is a source of contentious debate in the United States (see Gruber, 2005, ch. 13, for a brief review of the arguments on both sides of this debate).

This debate has not generally proceeded, however, to other social insurance programmes. For example, Feldstein and Altman (1998) have suggested a programme under which individuals save in their own unemployment insurance accounts for jobless spells. Using such mandatory savings accounts to finance short-run risks can potentially provide the consumption smoothing benefits of unemployment insurance while reducing the moral hazard costs of the programme. This is an approach worth consideration in other social insurance contexts, where the essential question becomes the value of the redistribution that is lost by such ‘self-insurance’ approaches.

social insurance

Abstract

Individuals face uncertainty about their labour income, due to chronic and temporary medical conditions or to unemployment spells. The individual burden of these risks can be eased by social insurance. Income taxation and government transfer programmes, such as disability and unemployment insurance, are the most common forms of social insurance. The challenge in the design of social insurance programmes is the impossibility of fully distinguishing between low income by choice and low income by necessity. This article reviews leading theories of optimal social insurance under private information and points to possible directions of future research.

Individuals face uncertainty about their labour income. Chronic medical conditions can arise that reduce or remove their ability to work. Alternatively, unemployment spells can occur, temporarily reducing their earnings. The individual burden of these risks can be eased by private insurance and by social insurance schemes. A social insurance scheme is a government transfer programme whereby individuals who claim a condition or state that reduces their labour income, such as disability or unemployment, obtain a transfer from the government for the duration of this state. Social insurance can also be carried
The design of optimal social insurance is a classic problem in economics. This problem is interesting because neither private insurance or public arrangements can fully distinguish between low income by choice and low income by necessity. For example, the diagnosis of medical factors is often subjective, and symptoms for certain conditions, such as back pain or recurrent migraines, are hard to verify. If full insurance for chronic medical conditions were available, individuals could exploit this by reporting fake symptoms to claim insurance benefits and stop working. Similarly, an unemployed worker's ability to find new employment depends on the effort she exerts in the job search. If full unemployment insurance is available, an unemployed worker would have no incentive to search for a new job if her search effort cannot be monitored. Private information on earning ability implies that full insurance might defeat itself by removing the incentive to work. Hence, the essential trade-off in the design of optimal social insurance schemes is the one between risk sharing and incentives.

The trade-off between insurance and incentives

Consider the following simple social insurance problem (the set-up for this example is adapted from Diamond and Mirrlees, 1978). Individuals live for two periods. In the first period of their lives, they are endowed with one unit of consumption and they consume. In the second period, they consume and they may work if they are able to. The probability of being able to work is $\pi$, a number between zero and 1. Work is publicly observable and the probability distribution of ability is known, but ability is private information. Preferences over consumption in each period are represented by $u(c)$, where $c \geq 0$ is consumption and the function $u$ is strictly increasing and strictly concave. The utility cost of working if able is $\gamma$, a number strictly greater than zero. An individual produces one unit of output if she works, zero otherwise.

The government wishes to induce able agents to work in period two and to maximize their lifetime expected utility, given by:

$$u(c_1) + n u(c_2^W) + (1 - n) u(c_2^N) - n \gamma,$$

where $c_1$ is consumption in period one and $c_2^W$ and $c_2^N$ are consumption conditional on work and no work in period two.

There is no private insurance, but the government is able to pool risk by distributing consumption, conditional on work in period two, so that the expected value of lifetime consumption equals the expected value of lifetime work for any individual. Individuals cannot save but the government has access to a storage technology with return $R > 0$. Hence, an individual's lifetime consumption profile must satisfy the constraint:

$$Rc_1 + n c_2^W + (1 - n) c_2^N \leq R + n.$$
Since the government cannot observe ability, the consumption profile must also satisfy an incentive compatibility constraint:

\[ u(c_2^W) - \gamma \geq u(c_2^n), \]  

(2)

to ensure that able individuals will work. The optimal social insurance scheme satisfies the following two inequalities when the incentive compatibility constraint (2) is binding:

\[ \frac{u'(c_2^W)}{u'(c_2^n)} < 1, \]  

(3)

\[ \frac{u'(c_1)}{Eu'(c_2)} < R, \]  

(4)

where \( Eu'(c_2) \) is the expected marginal utility of consumption in period two. It immediately follows from (3) that full insurance is not possible and \( c_2^W > c_2^n \). Hence, private information implies that the first-best optimum is not attainable. Equation (4) is derived from the government's Euler equation and uncovers another dimension of the incentive problem. It implies that the consumption path associated with the optimal insurance scheme displays a wedge between the marginal intertemporal rate of substitution and the intertemporal rate of transformation, \( R \). This intertemporal wedge indicates that the marginal cost of transferring consumption to period two is greater than the value of forgone consumption at time one. The additional cost stems from the need to maintain
incentive compatibility. This requires consumption to be conditional on work and therefore stochastic in
the second period. Since utility from consumption is strictly concave, a given increase in expected utility
requires more resources when consumption is stochastic rather than deterministic.
The intertemporal wedge implies that individuals would prefer to reduce their consumption in the first
period. Thus, in general, the optimal intertemporal consumption profile cannot be obtained without
preventing access to the capital market or imposing a tax on savings. For example, Golosov and
Tsyvinski (2006) study optimal disability insurance in competitive equilibrium and show that the
intertemporal wedge requires disability benefits to be asset-tested.
Private information on individuals’ ability to work gives rise to adverse selection in the social insurance
problem. The resulting partial insurance and the presence of an intertemporal wedge (4) hold generally
with adverse selection (Golosov, Kocherlakota and Tsyvinski, 2003) and also characterize social
insurance under moral hazard (Rogerson, 1985), as in the unemployment example described in the
introduction. Moreover, (4) exemplifies a general feature of social insurance with private information,
that is, that the government would want to control trade in related commodities (Atkinson and Stiglitz,
1976; Varian, 1980).

**Long-run inequality**

Social insurance models with infinite horizons generate normative implications for long-run
consumption inequality. The key step in deriving these implications is to formulate the social insurance
problem recursively. The pioneering work of Green (1987) provides an early example of a recursive
solution to a dynamic social insurance problem with infinite horizon and constant discounting. The main
insight is to restate the optimal social insurance scheme as a contract between the government (the
principal) and individuals (the agents). Such a contract retains memory of the history of outcomes and
assigns current transfers and promises of future transfers based on that history and the current outcome.
Despite their large dimensionality, such histories can be summarized by agents’ promised value. (These
results can be found in Spear and Srivastava, 1987; Thomas and Worrall, 1990; Abreu, Pierce and
Stacchetti, 1990; Phelan and Townsend, 1991.) This one-dimensional object, which corresponds to an
agent's expected lifetime utility at a point in time, encodes an agent's history and permits a recursive
formulation of the problem. Incentive compatibility implies that current transfers and promises of future
transfers will depend on promised utility and on the current outcome. The government's promises of
future transfers can be represented as continuation values that determine agents’ promised utility in the
subsequent period.
For example, in an infinite horizon version of the earlier disability insurance example, the individual
history for some period \( t > 1 \) is the sequence of work outcomes from period 1 to period \( t - 1 \). This can
be summarized by an individual's expected lifetime utility at the beginning of time \( t \), her promised value.
The optimal consumption allocation at time \( t \) and the continuation value will depend on the promised
value and on the current work outcome. The continuation value corresponds to an individual's expected
lifetime utility in the subsequent period. Hence, individuals’ future consumption depends on current
work and on the past history of work.
The history dependence of the consumption path resulting from an optimal insurance scheme implies
that the trade-off between insurance and incentives shapes the evolution of the consumption distribution.
Specifically, incentive compatibility implies that not only current transfers but also continuation values will be conditional on current outcomes. An immediate consequence is that the degree of consumption inequality tends to continually increase. An additional implication can be derived from the intertemporal wedge, which implies that individuals will face a downward-sloping path of promised lifetime utility under the optimal social insurance scheme.

Taken together, these results give rise to an extreme conclusion. Consumption inequality should grow without bound, with all individuals in the population converging to their minimum promised lifetime utility, except for a vanishing fraction converging to their bliss point. This *immizeration* property is robust. It obtains in partial (Green, 1987; Thomas and Worrall, 1990) and general (Atkeson and Lucas, 1992) equilibrium, under weak assumptions on preferences (Phelan, 1998), and holds in adverse selection and, in somewhat weaker form (Pavoni, 2004), in moral hazard environments.

The radical implications for consumption inequality generated by optimal social insurance models have prompted research on alternative normative criteria for the government's problem, based on an intergenerational interpretation of the infinite horizon framework. In standard models of social insurance, future generations are considered only indirectly, via the altruism of the earlier ones. Phelan (2006) proposes a government objective with equal weight on all future generations and shows that this implies a finite amount of inequality in the limit. Farhi and Werning (2005) explore a class of social insurance allocations that take into account individuals currently alive, as well as future generations, by assigning the latter a vanishingly small weight in the government's objective. They find that long-run inequality remains bounded and all individuals avoid misery.

The recursive principal–agent approach to social insurance problems underlies most macroeconomic applications. Two recently prominent areas of interest are optimal income taxation with unobserved skills and optimal unemployment insurance with hidden effort.

**Optimal income taxation**

Income taxes are an important instrument for social insurance. Hence, the basic trade-off between insurance and incentives also underlies the design of optimal tax systems. This intuition drives Mirrlees's (1971) seminal study of optimal income taxes. The main assumption is that labour income is observable but it depends on individual effort and skills, which are private information. Taxes are restricted to depend on labour income only, but, conditional on this, the government is relatively unconstrained. Lump-sum taxes and arbitrarily progressive or regressive tax schemes can all be part of the armoury. Mirrlees studies a static economy and finds that optimal marginal income taxes are low and sharply declining in income. Diamond (1998) and Saez (2001) find that marginal income taxes are high and sharply increasing in income at low income levels. Diamond and Saez's results can be interpreted as a prescription for a rapid phase-out of social benefits for low-income individuals, which is consistent with the US system. The properties of the optimal marginal income tax are very sensitive on the assumed properties of the skill distribution, which explains the difference in findings. Albanesi and Sleet (2006) and Kocherlakota (2005) apply Mirrlees's approach to dynamic economies and derive implications for optimal capital and labour income taxes. The optimal taxes depend on the agents’ history. This is achieved by conditioning the tax payments on the entire history of labour income, or, equivalently, on outstanding wealth when skill shocks are i.i.d. The properties of optimal
capital income taxes stem from the intertemporal wedge associated with the optimal consumption path. As noted earlier, this wedge implies that individuals would like to save more for two reasons: their lifetime consumption path is downward-sloping and they face consumption risk, given that the optimal scheme provides only partial insurance. Capital income must then be taxed to prevent this excessive saving. The optimal marginal asset tax, however, has a very specific form: it is decreasing in labour income. Hence, it is stochastic and negatively correlated with consumption. Excessive saving is discouraged by making after-tax returns on assets correlate positively with labour income, and thus reducing the hedging value of holding assets. Albanesi and Sleet (2006) also study the properties of marginal labour income taxes and find that they should be high at low income and decreasing in wealth. Kocherlakota (2006) provides an extensive review of these findings. Albanesi (2006) studies optimal capital income taxes in economies with moral hazard and idiosyncratic capital returns. She shows that the intertemporal wedge can be negative in this class of economies. In this case, the optimal marginal capital income taxes are increasing in income.

**Unemployment insurance**

Hopenhayn and Nicolini (1997) consider the design of optimal unemployment insurance under moral hazard. The probability of finding a new job depends on the unemployed worker's search effort, which is private information. (Shimer and Werning, 2005, analyse optimal unemployment insurance in a search model with adverse selection.) The unemployed worker is risk averse and cannot borrow or save. Upon finding a new job, the worker will be employed for ever at a fixed wage. The optimal unemployment insurance scheme is self-financing and comprises two elements: a sequence of unemployment benefits and a lump-sum tax levied when the worker finds new employment. The presence of moral hazard implies that the replacement ratio – that is, the fraction of previous salary transferred to the worker in the form of unemployment benefits – must be strictly smaller than one when the worker is searching for a new job. Hence, the optimal scheme provides only partial insurance against unemployment. The main results are that unemployment benefits should be decreasing over the course of the unemployment spell and the employment tax is increasing with the length of the unemployment spell, under mild conditions on preferences. The decreasing benefits result – first derived in the seminal paper of Shavell and Weiss (1979) – is a manifestation of the intertemporal wedge in this setting. The intertemporal wedge implies that promised utility should be decreasing as long as the worker is unemployed, which requires unemployment benefits to decrease over time. The employment tax result stems from consumption smoothing, since continuation utility rises discretely when a worker becomes employed. By taxing a newly employed worker, the government optimally smooths this jump in consumption. A worker's promised utility declines further for longer unemployment spells, hence, the employment tax is increasing with the length of unemployment.

Pavoni (2004) enriches Hopenhayn and Nicolini's model by introducing a realistic feature: a worker's human capital depreciates over the unemployment spell. The optimal unemployment insurance programme displays two novel features. First, if human capital depreciates rapidly enough during unemployment, benefits are bounded below by a minimal assistance level. Second, the optimal employment tax should decrease with the length of the unemployment spell. These new findings are a consequence of the fact that a worker's wage upon employment depends positively on her human capital.
As human capital depreciates over the length of the unemployment spell, expected utility upon employment declines. This reduces and eventually eliminates the government's need to decrease benefits over time to induce a decline in promised lifetime utility over the unemployment spell. Similarly, it reduces the value of the employment tax required to smooth consumption in the transition from unemployment to employment.

More recently, Pavoni and Violante (2007) study the optimal design of welfare-to-work programmes. These programmes are a mix of government expenditures on passive policies, such as unemployment insurance and social assistance, and active policies, such as job-search monitoring, training and wage taxes or subsidies, targeted to the unemployed. Most governments in fact use a combination of passive and active policies in dealing with unemployment. There are several novel findings. First, the optimal welfare-to-work programme endogenously generates a permanent policy of last resort, which resembles a social assistance programme. The unemployed worker is given a constant lifetime benefit and is not active in job search or training. Second, optimal unemployment benefits are generally decreasing or constant during unemployment, but they must increase after a successful spell of training. These findings result from the fact that utility conditional on employment decreases with the length of the unemployment spell and increases after job training. The central assumption is once again human capital depreciation over the unemployment spell. Indeed, it is shown that human capital depreciation is necessary for policy transition to be part of an optimal welfare-to-work programme. Pavoni and Violante find that, by providing more insurance to skilled workers and more incentives to unskilled workers, the optimal welfare-to-work programme delivers significant welfare gains with respect to the existing US system.

Concluding remarks

Most studies of optimal social insurance exclude the presence of private insurance contracts. Does the government have a special role in the provision of insurance with private information? The seminal work of Prescott and Townsend (1984) demonstrates that the first welfare theorem holds for a large class of economies with private information. Golosov and Tsyvinski (2007) study an adverse selection economy and allow for private insurance provision. They show that, if all trades are observable and individuals can sign binding contracts with private insurers ex ante, the only effect of public provision of social insurance is crowding out of private insurance. On the other hand, if certain trades are not observable, privately provided insurance is not Pareto optimal and government policies can increase welfare. Bisin and Guatioli (2004) examine a moral hazard economy and show that, if agents’ contractual relationships with competing insurance providers cannot be monitored, the competitive equilibrium allocation is not Pareto optimal.

The observability of trades allows insurance providers to restrict participation in additional contractual relationships with other agents. Absent this, individuals can undo the incentive effects of an insurance contract by purchasing additional insurance or engaging in trades that provide a limited amount of self-insurance. These results suggest that, if exclusivity of private insurance contracts cannot be enforced, government provision of insurance plays a critical role.
I wish to thank Claudia Olivetti, Nicola Pavoni and Bruce Preston for very helpful comments and discussion.

social interactions (empirics)

Yannis M. Ioannides
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Empirical studies of social interactions address a multitude of definitional, econometric and measurement issues associated with the role of interpersonal and social group influences in economic decisions. Applications range from studies of crime patterns, neighbourhood influences on upbringing and conformist behaviour, mutual influences among classmates and keeping up with roommates in colleges regarding academic and social activities, to herding and to learning about social services. The article reviews several instances of successful identification of effects emanating from others’ behaviour as distinct from characteristics of others. Data-sets with increasingly rich contextual information will allow estimation of complex models of economic decisions.

Article

The empirical economics literature on social interactions addresses the significance of the social context in economic decisions. Decisions of individuals who share a social milieu are likely to be interdependent. Recognizing the nature of such interdependence in a variety of conventional and unconventional settings and measuring empirically the role of social interactions poses complex econometric questions. Their resolution may be critical for a multitude of phenomena in economic and social life and of matters of public policy. Questions like why some countries are Catholic and others Protestant, why crime rates vary so much across cities in the same country, why fads exist and survive,
and why there is residential segregation and neighbourhood tipping are all in principle issues that may be examined as social interactions phenomena.

The social context enters in a variety of ways. One is that individuals care not only about their own purely private outcomes – for example, the kinds of cars they drive or the education they acquire – but also about outcomes of others, such as the kinds of cars or the education of their friends. This type of interpersonal effect is known as endogenous social effect (or interaction), because it depends on decisions of others in the same social milieu. Individuals may also care about personal characteristics of others, that is, whether they are young or old, black or white, rich or poor, trendy or conventional, and so on, and about other attributes of the social milieu that may not be properly characterized as deliberate decisions of others. The latter is known as exogenous social or contextual effect. In addition, individuals in the same or similar social settings tend to act similarly because they share common unobservable factors. Such an interaction pattern is known as correlated effects. This terminology is due to Manski (1993).

Emergence of social interdependencies is natural if individuals share a common resource or space in a way that is not paid but still generates constraints on individual action. This is also known as pecuniary externalities. Individuals who try to form expectations about future outcomes of current decisions, like occupational choice, may rely on lessons from the actions of others and therefore end up mimicking their behaviour. Endogenous social interactions are a case of real externalities, a pervasive feature of economic behaviour.

Theorizing in this area must lie in the interface of economics, sociology and psychology, and often is imprecise. Terms like social interactions, neighbourhood effects, social capital and peer effects are often used as synonyms, although they may have different connotations. Empirical distinctions between endogenous, contextual and correlated effects are critical for policy analysis because of the ‘social multiplier,’ as we see further below.

Joint dependence among individuals’ decisions and characteristics within a social milieu is complicated further by the fact that in many interesting circumstances individuals in effect choose the social context. For example, individuals choose their friends and their neighbourhoods and thus their neighbourhood effects as well. Such choices involve information that is in part unobservable to the analyst, and therefore require making inferences among the possible factors which contribute to decisions (Brock and Durlauf, 2001; Moffitt, 2001). The present article focuses on highlighting the significance of key empirical findings and owes a lot to Durlauf (2004), the most comprehensive review to date that examines the methodological basis, statistical reliability and conceptual and empirical breadth of the neighbourhood effects literature.

**Empirical framework**

Let individual $i$’s outcome $\omega_i$, a scalar, be a linear function of a vector of observable individual characteristics, $X_i$, of a vector of contextual effects, $Y_{n(i)}$, which describe $i$’s neighbourhood $n(i)$, and of the expected value of the $\omega_j$’s of the members of neighbourhood $n(i)$, $j \in n(i)$. It is straightforward to incorporate social interactions into economic models in a manner that is fully compatible with economic reasoning, that is, by positing that individuals maximize a utility function subject to constraints and obtain a behavioural equation such as:
where \( \varepsilon_i \) is a random error and \( k \) a constant. Ignore for the moment the fact that individual \( i \) may have deliberately chosen neighborhood \( n(i) \). The assumption that the expectation of \( \varepsilon_i \) in (1) is zero, conditional on individual characteristics, on contextual effects and on the event that \( i \) is a member of neighbourhood \( n(i) \), allows us to focus on the estimation of the model. The critical next step for translating theoretical models into empirical applications is to assume social equilibrium and that individuals hold rational expectations over \( \omega_{n(i)} \). That is, individuals’ expectations are confirmed in that they are exactly equal to what the model predicts on average. So, taking the expectation of \( \omega_i \) and setting it equal to \( \omega_{n(i)} \) allows us to solve for \( \omega_{n(i)} \). Substituting back into (1) yields a reduced form equation, an expression for individual \( i \)'s outcome in terms of all observables:

\[
\omega_i = k + \varepsilon X_i + \alpha Y_{n(i)} + \beta m_{n(i)} + \varepsilon_i
\]

(1)

This simple linear model obscures the richness that nonlinear social interactions models make possible, like multiplicity of equilibria (Brock and Durlauf, 2001). Yet it does facilitate studying other aspects. For example, it does confirm that endogenous social effects generate feedbacks which magnify the effects of neighbourhood characteristics. That is, the effect of a unit increase in \( Y_{n(i)} \) is \( \frac{d}{1 - \alpha} \), and not just \( d \), as one would expect from (1). It also confirms why it is tempting for empirical researchers to study individual outcomes as functions of all observables. Following the pioneering work of Datcher (1982), a great variety of individual outcomes have been studied in the context of different neighbourhoods and typically significant effects have been found. Deriving causal results requires suitable data. Manski (1993) emphasized that the practice of including neighbourhood averages of individual effects as contextual effects, \( \gamma_{n(i)} = X_{n(i)} \), may cause failure of identification of endogenous as distinct from exogenous interactions, that is, to estimate \( J \) separately from \( d \). That is, if the neighbourhood attributes coincide with the neighbourhood averages of its inhabitants’ characteristics, or \( \gamma_{n(i)} = X_{n(i)} \), then regressing individual outcomes on neighbourhood averages of individual characteristics as contextual effects allows us to estimate a function of the parameters of interest, \( \frac{Jc + \phi}{1 - \alpha} \), the coefficient of \( X_{n(i)} \) in a regression according to (2). A statistically significant estimate of this coefficient implies that at least one type of social interaction is present, either \( J \) or \( d \) or both are non-zero. This is known as Manski's
reflection problem, which is specific to linear models: the equilibrium value of the outcome $m_{n(i)}$ is linearly related to the neighbourhood attributes, and therefore its effect on individual outcomes may not be distinguishable from their ‘reflection’.

Complicating the basic model in natural ways, as by assuming correlated effects – like group members sharing group-specific unobservable effects, that is, the performance of students in the same class is affected by the quality of their teacher, which is unobservable, over and above peer effects from classmates – introduces additional difficulties with identification, even if individuals are randomly assigned to groups. Brock and Durlauf (2007) provide an exhaustive analysis of the various possibilities in binary choice situations with unobserved group effects. When more than two choices are available, there may be additional possibilities for identifying choice-specific effects by working with subsets of choices (Brock and Durlauf, 2005). Graham (2006), discussed further below, offers a promising approach for continuous outcomes when individuals are randomly assigned to groups, but is not focusing on the distinction between exogenous and endogenous interactions. Yet more possibilities appear when panel data (that is, repeated observations over time on the same decision-making units) are available. If contextual effects take time to make their impact on the endogenous social effect, the linear dependence is broken and the lack of identification – Manski’s reflection problem – is mitigated.

Sometimes, and depending upon the nature of the data as well, it may be impossible, especially in linear models, to identify social interactions in the presence of unobserved group effects. Moving from linear models to binary and other non-linear choice models improves identification even with cross-section data (Brock and Durlauf, 2007).

If it is plausible to exclude some neighbourhood averages of individual covariates, then identification may be possible. Also, if nonlinearities are inherent in the basic model specification, identification again may be possible, even in the case where the contextual effects coincide with neighbourhood averages of individual characteristics. Nonlinearities may eliminate the reflection problem. A noteworthy case in point here is Drewianka (2003), who studies two-sided matching in the marriage market and finds that it allows identification of endogenous and exogenous social interactions. The logic of the model requires that the two sides of the market contain an additional source of variation: the greater the number of potential marriage partners, the higher is the probability that a match will occur. There is an inherent multiplier effect at work here. One’s prospects of finding a marriage partner depends on the rate at which other people match up, an endogenous social effect. Drewianka’s results show that a ten per cent increase in the fraction of the population that is unmarried causes the marriage rate of never-married men to fall by ten per cent and that of never-married women by seven per cent.

An interesting consequence of endogenous social interactions is the amplification of differences in average neighbourhood behaviour across neighbourhoods. In fact, Glaeser, Sacerdote and Scheinkman (2003) use directly such patterns in the data to estimate a social multiplier. This is defined for a change in a particular fundamental determinant of an outcome as the ratio of a total effect, which includes a direct effect on an individual outcome plus the sum total of the indirect effects through the feedback from the effects on others in the social group, to the direct effect. It is easy to see it as the ratio of the ‘group level’ coefficient, the coefficient of $Y_{n(i)}$ in eq. (2), to the ‘individual level’ coefficient, the coefficient of $Y_{n(i)}$ in eq. (1): $\frac{\frac{d}{1-I}}{\frac{1}{1-I}} = \frac{1}{1-I}$. It follows that a social multiplier greater than 1 implies endogenous social interactions, $0 < I < 1$. This approach must deal, in practice, with dependence across
social interactions (empirics): The New Palgrave Dictionary of Economics
decisions of individuals belonging to the same group, which is implied by non-random sorting in terms of unobservables. It is particularly useful in delivering ranges of estimates for the endogenous social effect and when individual data are hard to obtain.
This is the case with crime data. Glaeser, Sacerdote and Scheinkman (1996) motivate their study of crime and social interactions by the extraordinary variation in incidence of crime across US metropolitan areas over and above differences in fundamentals. If social interactions are present, variations in observed outcomes are larger than would be expected from variations in underlying fundamentals. Glaeser, Sacerdote and Scheinkman (2003) regress actual crime rates against predicted crime rates, which are formed by multiplying percentages of US individuals in each of eight age categories by the crime rate of persons in that category. They perform such regressions at the level of county and state cross-sectionally and for the entire United States over time. Their results imply large social multipliers, which increase with the level of aggregation exactly as their basic theory would predict.
It is possible to modify this basic model in order to study several other areas involving economic decisions akin to social interactions. For example, diffusion of innovations, herding and adoption of norms or other institutions by a population involve ideas that are conceptually related to social interactions. Transmission of job-related information is of particular relevance (see Ioannides and Loury, 2004). Also, $J$, the endogenous social effect, may be negative, as in the case of land development, which is conceivably due to congestion.

Identification of social interactions using observational data on ‘natural experiments’

Several researchers have sought to identify social interactions by exploiting uniquely suitable features of observational data, which are often referred to as ‘natural experiments’. For example, consider outcomes for children from families with several children who share the common influence of unobservable family factors, such as parental values and competence, taste for education and time spent with children, and other unobservables that affect the upbringing of household members living in close proximity. They also share the variation in neighbourhood effects that is produced by families’ residential moves. By using observations on several children from the same family who are separated in age by at least three years, Aaronson (1998) controls for family-specific characteristics. This obviates the need to control for the impact of self-selection in terms of unobservable neighbourhood characteristics. Aaronson uses data from the Panel Study of Income Dynamics and finds large and statistically significant contextual neighbourhood effects, but his models exclude endogenous social effects. His results are robust to changes in estimation techniques and in sample and variable definitions, but are sensitive to the formulation of neighbourhood characteristic proxy. Incomplete specification of family characteristics is an important concern, and its consequences for the robustness of estimated relationships are aptly demonstrated by Ginther, Haveman and Wolfe (2000).

Grinblatt, Keloharju and Ikaheimo (2004) use data for all residents of two large Finnish provinces – amounting to millions of observations – and establish that automobile purchase decisions by close residential neighbours influence one another. The measured endogenous neighbourhood effects are strongest among individuals belonging to the same ‘social class’ (especially if they belong to lower-income classes), or when the cars they purchase are of the same make or even the same model. These findings militate in favour of information sharing rather than ‘keeping up with the Joneses’. We note that
excluding neighbourhood averages of demographics as contextual effects is reasonably plausible in this case: there is no reason why the average age of my neighbours should affect directly my taste in cars. Conceptually related is the study of Aizer and Currie (2004), who use data from more than 3.5 million birth certificates from California to examine ‘information sharing effects’ in the utilization of publicly funded prenatal care. They conclude that it is not information sharing, but is, instead, differences in the behaviour of institutions that explain the established correlations between neighbourhood and ethnic group membership in prenatal care use.

Luttmer (2005) uses data from the US National Survey of Families and Households, augmented with census data from the Public Use Microdata Areas, and examines how self-reported well-being varies with own and neighbours’ incomes and with other characteristics. He interprets his findings as direct evidence that people have preferences regarding their neighbours’ incomes. That is, after an individual’s own income is controlled for, higher earnings of neighbours are associated with lower levels of self-reported happiness on a variety of measures.

Sacerdote (2001) exploits the fact that at Dartmouth College freshman-year room-mates and dorm-mates are randomly assigned, thus producing a natural quasi-experimental setting for studying peer effects. Sacerdote posits that an individual’s grade point average is a function of an individual’s own academic ability prior to college entrance, of social habits, and of the academic ability and grade point average of his room-mates. Sacerdote finds that peers have an impact on each others’ grade point average and on decisions to join social groups such as fraternities. He does not, however, find residential peer effects in other major college decisions, such as choice of college major. He finds peer effects in grade point average at the individual room level – you keep up with your room-mates! – whereas peer effects in fraternity membership occur at both the room level and the entire dorm level – dorms are conformist! These data provide strong evidence for the existence of peer effects in student outcomes, even among highly selected college students who may be otherwise quite homogeneous albeit in close proximity to one another. Peer effects are smaller the more directly a decision is related to labour market activities.

Peer effects in classrooms and schools

Social interactions in classrooms – peer effects – are particularly interesting in understanding schooling as an economic activity and its consequences for inequality of social outcomes. Whether students benefit from classmates with different characteristics and academic performance and whether the effect is different depending upon whether one’s classroom peers are more or less able are important for education policy and the actual functioning of schools. In other words, deciding whether or not students should be ‘tracked’ – that is, administratively segregated in terms of different characteristics – is the sort of policy question which rests on understanding peer effects quantitatively.

Hoxby (2001) posits a relationship between individual academic achievement by a male student in a particular school and grade as the sum of what the mean achievement among males would have been in the absence of peer effects, of a term that is proportional to the percentage of females in the classroom, plus an error. She extends such a relationship to the case of several racial groups, which is particularly appropriate for the Texas Schools Project data that she uses. Her identification strategy involves exploring the panel structure of the data under the plausible assumption that there is natural idiosyncratic variation across successive cohorts in terms of gender, race and other individual attributes. Hoxby finds
that students are affected by the achievement levels of their peers: an exogenous one-point increase in peers’ reading scores raises a student’s own score between 0.14 and 0.4 points. Peer effects are stronger intra-race, and there is evidence of contextual effects: both male and female students perform better in classrooms that are more female despite the fact that females’ math performance is about the same as that of males.

The role of gender is corroborated by research by Arcidiacono and Nicholson (2005), who use data on the universe of students admitted to US medical schools for a particular year. One positive peer effect in US medical schools that they find pertains to female students, who benefit from attending medical schools that have other female students with relatively high scores on the verbal reasoning section of the Medical College Admission Test.

Of particular interest have been studies of the impact of school racial integration in the US on student performance. Consider Boston’s Metropolitan Council for Educational Opportunities (METCO) programme, a voluntary desegregation programme. The programme allows mainly black inner-city kids from Boston public schools to commute to mainly white suburban communities in the Boston area that accommodate them in their public schools. Angrist and Lang (2004) show that, although the receiving districts, which tend to have higher mean academic performance, experience a mean decrease due to the programme, the effects are merely ‘compositional’, and there is little evidence of statistically significant effects of METCO students on their non-METCO classmates. Analysis with micro data from a particular receiving district (Brookline, Massachusetts) generally confirms this finding, but also produces some evidence of negative effects on minority students in the receiving district. METCO is a noteworthy social experiment, which was initiated by civil rights activists seeking to bring about de facto desegregation of schools. Lack of evidence of negative peer effects is particularly useful for informing desegregation policy. Still, there is self-selection in the participants on both sides.

Estimation of social interactions in experimental settings

Experimental data used by social interactions studies come from two types of deliberate experiments: field and laboratory experiments. A well-known field experiment is Project STAR, an experimental programme in the US state of Tennessee that randomly assigned entering kindergarten students into three different class sizes and then randomly assigned teachers to them. A recent study that utilizes Project STAR data is Graham (2006). He seeks to estimate a relationship like (1) by measuring ‘excess’ variance patterns across groups of exogenously given, but varying, sizes of classrooms that are associated with randomly assigned students and teachers in the presence of correlated effects in the form of unobservable group effects. Graham compares excess variance across small and large classrooms and finds social multipliers between 1.07 and 2.31, and 1.05 to 3.07, for math and reading achievement, respectively. Studies of this type aim at distinguishing excess between-classroom variance that is due to social interactions from that due to group-level heterogeneity.

Duflo and Saez (2003), using experimental data, study how social interactions among employees of a large US university may influence participation in a tax-deferred retirement account plan. The experiment more than tripled the attendance rate of those who received a small monetary reward for participating, doubled that of those not thus ‘treated’ but who belonged to the same departments as the treated, and significantly increased participation in the target programme by individuals from treated departments.
departments, and did so by almost as much as those who did not receive direct encouragement. While clearly the effect of social interactions may coexist with differential treatment and motivational reward effects, social interactions are also relevant for the effects of treatment on attendance and of attendance on participation. The authors conclude that the role of social interactions in amplifying the effect of treatment is unambiguous, in spite of the fact that they cannot distinguish unambiguously between the three different effects.

Moving to Opportunity (MTO) is a set of large randomized field experiments that were conducted by the US Department of Housing and Urban Development in several large US cities. The experiments offered poor households (who were chosen by lottery from among residents of high-poverty public housing projects) housing vouchers and logistical assistance through non-governmental organizations for the purpose of relocating to precisely defined ‘better’ neighborhoods. Several studies based on data from these experiments show that outcomes after relocation improved for children, primarily for females, in terms of education, risky behaviour and physical health, but the effects on male youth were adverse. Regarding outcomes for adults, such as economic self-sufficiency or physical health, the picture is more mixed. Kling, Ludwig and Katz (2005) find that four to seven years after relocation families (primarily female-headed ones with children) lived in safer neighborhoods that had lower poverty rates than those of a control group that were not offered vouchers. Unfortunately, there is serious controversy over how to interpret these findings in the context of policy design for large-scale policy interventions (Sobel, 2006).

As for laboratory experiments, a notable study is by Ichino and Falk (2006). The experiment involves workers in pairs stuffing envelopes, with control being provided by subjects working alone in a room. These authors find that standard deviations of output are significantly smaller within pairs than between pairs, that is individuals keep up with their neighbours. They also find that social interactions raise productivity: average output per person is greater when subjects work in pairs. They also show that social interactions are asymmetric: low-productivity workers are more sensitive to the behaviour of high-productivity workers. Their setting does reduce some of the noise associated with ‘natural’ experiments but does not allow for contextual effects.

Identification of social interactions with self-selection to groups and sorting

The presence of non-random sorting on unobservables is a major challenge for the econometric identification of social interactions models. The critical role of local public finance in education in the United States has been studied extensively as a link between sorting into residential communities and socio-economic outcomes. Brock and Durlauf (2001) turned adversity into advantage by recognizing that self-selection itself, that is that individuals choose their neighbourhoods making $n(i)$ in eq. (1) endogenous, may provide additional evidence on identification. That is, if it is possible to estimate a neighbourhood selection rule, then correction for selection bias via the mean estimated bias, the so-called Heckman correction term, introduces an additional regressor in the right-hand side of (1) whose neighbourhood average is not a causal effect. Ioannides and Zabel (2002) implement this method successfully using micro data for a sample of households and their ten closest residential neighbours from the American Housing Survey and contextual information for the census tracts in which these individuals reside.
Endogeneity of the average of one's neighbours housing demands, an endogenous social effect, is instrumented by treating housing demands by a group of close neighbours as a simultaneous system of equations. By choosing neighbourhoods, census tracts in this application, individuals choose desirable social interactions. Ioannides and Zabel work with an otherwise standard housing demand model and find a very significant and large endogenous social effect along with very significant contextual effects in the form of unobservable group effects. Several other studies have sought to use instrumental variables to account for self-selection. Still, the identification of valid instruments is often quite hard and requires deep understanding of the actual setting.

Conclusions

Social interactions are ubiquitous. Interest in estimating their effects is expanding rapidly in numerous areas of economics and is motivating important methodological advances. For econometricians, key challenges include social interactions effects on market outcomes coexisting with feedbacks from the characteristics of individual market participants via their impacts on prices, consequences of self-selection and the attendant role of the presence of individual and group unobservables. Fundamentally, and in the light of ever-improving data availability, social interactions empirics will rely increasingly critically on careful theorizing that involves precise definitions of social interactions and justifies stochastic specification, possibly by calling on psychology and sociology to define appropriate boundaries, and must facilitate use of data from different sources. The likely payoff is enormous: better understanding of social forces in the modern economy, with individuals sharing information while self-selecting into social groups and living and working in close proximity to one another, as in firms and cities, the hallmark of modern economic life, and informed design of policy interventions.

social interactions (theory)

José A. Scheinkman
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Social interactions refer to particular forms of externalities, in which the actions of a reference group affect an individual's preferences. In the presence of strategic complementarities, social interactions help reconcile the observation of large differences in outcomes in the absence of commensurate differences in fundamentals. This article surveys the theoretical literature and discusses different approaches to estimating social interactions.

Article

Social interactions refer to particular forms of externalities, in which the actions of a reference group affect an individual's preferences. The reference group depends on the context and is typically an individual's family, neighbours, friends or peers. Social interactions are sometimes called non-market interactions to emphasize the fact that these interactions are not regulated by the price mechanism. Veblen's (1934) analysis of conspicuous consumption – that is, consumption that signals wealth – is perhaps the first contribution to the economic literature on social interactions. Duesenberry (1949) and Leibenstein (1950) are also among the earliest contributors. Although Veblen's *Theory of the Leisure Class* has had a remarkable impact in the social sciences, Schelling's (1971; 1972) pioneering formal analysis of the influence of social groups in behaviour was particularly important for later developments in economics.
Models of social interaction seem particularly adapted to solving a pervasive problem in the social sciences, namely, the observation of large differences in outcomes in the absence of commensurate differences in fundamentals. Many models of social interactions exhibit strategic complementarities, which occur when the marginal utility to one person of undertaking an action increases with the average amount of the action undertaken by his peers. Consequently, a change in fundamentals has a direct effect on behaviour and an indirect effect of the same sign. Each person's actions change, not only because of the direct change in fundamentals, but also because of the change in the behaviour of his or her peers. The result of all these indirect effects is the social multiplier.

When this social multiplier is large, we expect to see a large variation of aggregate endogenous variables relative to the variability of fundamentals, which seem to characterize phenomena as diverse as stock market crashes, religious differences, and differences in crime rates. In fact, if social interactions are large enough, multiple equilibria can occur – that is, one may observe different outcomes from exactly the same fundamentals. The existence of multiple equilibria also helps us to understand high levels of variance of aggregates.

Social interaction models have implications for the sorting of people and activities across space. As Schelling (1971) demonstrated, when individuals can choose locations, the presence of these interactions may result in segregation across space, even in situations where the typical individual would be content to live in an integrated neighbourhood, provided his group does not form too small a minority. Cities exist because of agglomeration economies which are likely to come from non-market complementarities. In dynamic settings, social interactions can produce $s$-shaped curves which help to explain the observed time series patterns of phenomena as disparate as telephone adoption and women in the workplace. Closely related topics include social learning, where agents learn from observing choices by other agents (for example, Arthur, 1989; Bickhchandani, Hirshleifer and Welch, 1992), and local interaction games (for example, Ellison, 1993; Morris, 2000).

**Schelling's critical mass model**

In Chapter 3 of his *Micromotives and Macrobehavior* (1978), Schelling discusses a critical mass model where he supposes that there is an activity which some individuals will always undertake, others will undertake only if a large enough fraction of the population is engaged in the action, and still others may never undertake. Formally, agents are parameterized by an $x \in [0, 1]$, and can choose between undertaking an action or not. The gain in utility for an agent of undertaking the action is given by $u(x, t)$, where $t$ is the fraction of the population engaging in the action. Schelling assumes that $u(x, t)$ decreases with $x$, that is, agents can be inversely ordered by their gains from undertaking the action. He also assumes that $u(x, t)$ increases with $t$, that is, the gain is larger if a larger fraction of the population is engaged in the action. This assumption is exactly what was later named ‘strategic complementarity’.

Each agent $x$ takes $t$ as given and chooses to undertake the action if and only if $u(x, t) \geq 0$. An equilibrium is a fraction $t^*$ such that $u(t^*, t^*) = 0$. Clearly, for such a $t^*$ every agent $x \leq t^*$ will undertake the action while, if $x > t^*$, agent $x$ would refrain. Schelling constructs a numerical example where multiple equilibria arise and noticed that even when uniqueness prevails such models display a ‘multiplier effect’. In his example, the presence of a smaller number of individuals that would undertake the activity unconditionally would have a more than proportionate effect on the equilibrium level of the
activity. Granovetter (1978) proposes a very similar model to analyse riots and other collective actions. He noted that as parameter changes some equilibria may disappear, leading to drastic changes in the equilibrium outcomes.

Versions of the critical mass model set out in Schelling (1978) have later been used to study a myriad of economic questions, often with a more detailed micro-economic foundation to justify strategic complementarities. Examples include income inequality (Loury, 1977; Durlauf, 1996), social customs (Akerlof, 1980), the big push in industrialization (Murphy, Shleifer and Vishny, 1989), crime (Sah, 1991), education (Benabou, 1993), savings and consumption norms (Lindbeck, 1997), the transmission of culture (Bisin and Verdier, 2000), and the timing of desertion by soldiers (de Paula, 2005). A continuous action version of the same model, where an agent's utility depends on the average action of the population, is used by Cooper and John (1988) to model macroeconomic coordination failures. Much of this work has ignored market responses to the presence of social interactions. Among the exceptions are Becker and Murphy (2000), who produce a systematic analysis of the effect of prices on market behaviour when social interactions are present, and Pesendorfer (1995), who examines how a monopolist would exploit the presence of non-market interactions.

Models inspired in statistical physics

Schelling's (1971) paper sets out a model where individuals occupy discrete points on the line or plane and interact locally. However, most of the developments that followed use the simpler critical mass model. Follmer (1974) was the first to use explicitly a random field model (also known as an interactive particle system) imported from statistical physics to model social interactions. In these models one typically postulates an individual's interdependence and analyses the equilibrium behaviour that emerges. Typical questions concern the existence and multiplicity of equilibria that are consistent with the postulated individual behaviour, and the sensitivity of these equilibria to parameters. Follmer models an economy in which the preferences of an individual depend on the preference of his peers, and shows that randomness in individual preferences may affect the aggregate, even as the number of agents grows to infinity – a failure of the law of large numbers. Blume (1993) and Brock (1993) recognize the connection between models of discrete choice with interaction effects and some random field models. Glaeser, Sacerdote and Scheinkman (1996) observe that crime rates across large American cities seem to vary too much to be explained by the usual socio-economic variables. They construct a theoretical model connecting the structure of social interactions among individuals with the variation of aggregate behaviour across space, providing a framework for investigating the importance of social interactions. They set up a simple model of local interactions inspired by the voter model in the literature on interacting particle systems (for example, Ligget, 1985) and show that the model is able to generate the large observed variance across aggregates from small amounts of variability in the fundamentals. A simple, one-sided version of their model works as follows. Individuals occupy discrete points on a circle and choose between two actions \( \{0, 1\} \). With probability \( \pi \), the individual chooses action 1 with probability \( p \) and action 0 with probability \( 1 - p \). With probability \( (1 - \pi) \) he imitates his predecessor's action. The parameter \( (1 - \pi) \) can be thought of as a measure of the intensity of social interactions. In a population of \( n \) individuals, if we write \( a_i \) for the action of agent \( i \) then
Although the limit average action is always \( p \), the (limit) variance of the normalized average action across groups is a function of \( \pi \). As \( \pi \) converges to zero, this variance becomes arbitrarily large. Social interactions increase the variance of the crime rate across population groups. In a similar vein, Topa (2001) examines the spatial distribution of unemployment with the aid of contact processes (for example, Ligget, 1985), another class of random field models, and shows that social interactions help explain the variation in unemployment rates among Chicago census tracts.

Brock and Durlauf (2001) develop a model that is very much in the spirit of Schelling's critical mass framework. Individuals choose between two actions, and the payoff an individual experiences when taking an action depends on a baseline utility that is common across individuals, on an idiosyncratic preference parameter, and on the distance between his action and the average expected action in the population. By making specific assumptions on the probability distribution of the idiosyncratic preferences, Brock and Durlauf obtain a joint probability measure over choices that is related to that of the mean-field version of the Curie–Weiss model of statistical mechanics. They then show that the model may have one or three equilibria, depending on the values of some parameters. Multiple equilibria are more likely to appear when the baseline utility of the two actions is not very different or when the desire for conformity is strong. Durlauf (1997) and Ioannides (1997; 2006) consider generalizations of the Brock–Durlauf framework with a richer interaction structure that accommodates local interactions. Horst and Scheinkman (2006), who do not use explicitly the language of random fields, also consider infinite systems with arbitrary interaction structures.

Most of this literature is static, but dynamics models, usually involving myopic agents, have been developed, for example, by Blume (1993), Blume and Durlauf (1999), Brock and Durlauf (2001), and Young (1993; 1998), who is especially interested in the evolution of social norms and customs.

The social multiplier

The social multiplier measures the ratio of the effect on the average action caused by a change in a parameter to the effect on the average action that would occur if individual agents ignored the change in actions of their peers. This social multiplier can also be thought of as a ratio \( \frac{\Delta p}{\Delta I} \) where \( \Delta I \) is the average response of an individual action to an exogenous parameter (that affects only that person) and \( \Delta p \) is the (per capita) response of the peer group to a change in the same parameter that affects the entire peer group. Unless an equilibrium selection mechanism is present, the social multiplier is well defined only if the equilibrium average action is unique, but models that exhibit large social multipliers can explain large differences in outcomes across populations with small differences in exogenous variables. If agents have idiosyncratic random preferences, this same multiplier amplifies the differences in realizations of
these preferences across samples. In models with continuous actions but otherwise fairly general interaction structures, Glaeser and Scheinkman (2003) and Horst and Scheinkman (2006) show that moderate social interactions, a condition that limits the effect of the actions by peers on the optimal choice of an individual, is sufficient for uniqueness of equilibrium. They also show that if, in addition, strategic complementarities are present then the social multiplier exceeds one. Typically, the forces that lead to multiple equilibria also lead to large social multipliers. For instance, in Brock and Durlauf's (2001) model, in the region where uniqueness prevails, the social multiplier is bigger when the desire to conform is stronger and when the fraction of agents that are close to being indifferent between the two possible actions is larger (see Glaeser and Scheinkman, 2003).

**Choice of peer group**

In several models (for example, Gabszewicz and Thisse, 1996; Benabou, 1993; Glaeser, Sacerdote and Scheinkman, 1996; Mobius, 2000) the peer group that concerns an agent is formed by geographical neighbours. Mobius (1999) shows that, in a context that generalizes Schelling's (1972) tipping model, the persistence of segregation depends on the particular form of the near-neighbour relationship. Kirman (1983), Kirman, Oddou and Weber (1986), and Ioannides (1990) use random graph theory to treat the peer group relationship as random. This approach is particularly useful in deriving properties of the probable peer groups as a function of the original probability of connections. Another literature deals with individual incentives for the formation of networks (for example, Boorman, 1975; Jackson and Wolinsky, 1996; Bala and Goyal, 2000). (A related problem is the formation of coalition in games; for example, Myerson, 1991.) Benabou (1993) and Glaeser and Scheinkman (2001) use Tiebout's equilibrium approach (see for example Bewley, 1981) to model peer group choice.

**Empirical issues**

Several statistical problems arise in estimating social interactions effects. It is often difficult for a researcher to identify correctly the peer groups. Another problem is that, ideally, one should distinguish between three effects in understanding group behaviour: correlation of individual characteristics, influences of group characteristics on individuals, and the influence of group behaviour on individual behaviour (Manski, 1993). Although the last two effects could both be merged into a social interactions effect, the correlation across individual error terms could remain a problem. This problem does not arise in randomized experiments that allocate persons into different groups. Katz, Kling and Liebman (2001) and Ludwig, Hirschfeld and Duncan (2001) use data generated by the Moving to Opportunity experiment to provide evidence for the existence of neighbourhood spillovers on juvenile crime. Sacerdote (2001) exploits variation in peer groups generated by the random assignment of freshman room-mates at Dartmouth and finds evidence of peer effects on academic effort, grade point average, and fraternity membership. In the absence of randomized experiments, Case and Katz (1991) use peer group background characteristics as instruments for peer group outcomes, which in certain cases yield valid estimates of social interactions. They find some evidence that peer behaviour influences self-reported juvenile crime.
However, as Manski (1993) stresses in the presence of correlations among unobservables, which is particularly likely to arise with sorting, the instrumental variables estimator may overstate social interactions.

Brock and Durlauf (2001) discuss structural identification for their model. In Brock and Durlauf (2000) they provide estimators for the parameters of the model and account for the endogeneity of peer groups. This structural approach leads to a natural behavioural interpretation of the parameters, but it requires individual-level observations and it may suffer from mis-specification.

A less structural approach, proposed by Glaeser, Sacerdote and Scheinkman (1996), is to use the variances of group average outcomes to identify social interactions. Using this methodology they found evidence that social interactions can help explain the large differences in community crime rates. This approach has been formalized further by Graham (2004). Another possibility is to use the logic of the multiplier. The relationship between exogenous variables and outcomes for individuals is compared with the relationship between exogenous variables and outcomes for groups. The ratio is a measure of the size of social interactions. Glaeser, Sacerdote and Scheinkman (2003) apply this method and find evidence of interactions in social group membership in the Dartmouth room-mates data and in crime, and of human capital spillovers at the state and the Public Use Microsample Area (PUMA) level. Yet another alternative is to identify the presence of interactions based on spatial clustering in the behavioural data. (see Topa, 2001; Conley and Topa, 2002). Finally, results in De Paula (2005) suggest that dynamic models might be easier to identify.

social learning

Kaivan Munshi
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Social learning describes the process whereby individuals learn about a new and uncertain technology from the decisions and experiences of their neighbours. Because information must flow sequentially from one neighbour to the next, social learning provides a natural explanation for the gradual diffusion of new technology that is commonly observed. It can also explain the wide variation in the response to external interventions across communities as a consequence of the randomness in the information signals that they receive. Social learning has been associated with the adoption of new agricultural technology, the fertility transition, and investments in education in developing countries.

Article

Since the 1950s, people living in developing countries have gained access to technologies, such as high-yielding agricultural seed varieties and modern medicine, that have the potential to dramatically alter the quality of their lives. Although the adoption of these technologies has increased wealth and lowered mortality in many parts of the world, their uptake has been uneven. Entire communities sometimes stubbornly oppose the use of modern medicine or contraceptives. And while high-yielding crop varieties might have spread widely, it took as long as two decades in some cases for this readily available technology to be adopted.

The traditional explanation for the observed differences in the response to new opportunities, across and within countries, is based on heterogeneity in the population (Griliches, 1957; Mansfield, 1968). An alternative explanation, which has grown in popularity in recent years, is based on the idea that individuals are often uncertain about the returns from a new technology. For example, farmers might not
know the (expected) yield that will be obtained from a new and uncertain technology and young mothers might be concerned about the side effects from a new contraceptive. In these circumstances, a neighbour's decision to use a new technology indicates that she must have received a favourable signal about its quality and her subsequent experience with it serves as an additional source of information. Because information must flow sequentially from one neighbour to the next, social learning provides a natural explanation for the gradual diffusion of new technology even in a homogeneous population. Social learning can also explain the wide variation in the response to external interventions across otherwise identical communities, simply as a consequence of the randomness in the information signals that they received. Early contributions by Banerjee (1992) and Bikhchandani, Hirshleifer, and Welch (1992) gave rise to an enormous theoretical literature on social learning (see Bramoulle and Kranton, 2004, for an excellent summary). This article, however, is concerned with a smaller empirical literature on social learning and economic development that has emerged in recent years.

The adoption of new agricultural technology

Following Munshi (2004), consider a simple model of agricultural investment in which there are two technologies: a new high yielding variety (HYV) and a traditional variety. The yield from the uncertain HYV technology for grower \( i \) in period \( t \) is specified as

\[
y_{it} = y(Z_i) + \eta_{it}
\]

where \( y(Z_i) \) is the yield under normal growing conditions and \( Z_i \) is a vector of soil characteristics and prices. \( \eta_{it} \) is a mean-zero serially independent disturbance term with variance \( \lambda_i^2 \), measuring deviations from normal growing conditions that cannot be observed by the grower. When \( y(Z_i) \) is uncertain, the optimal acreage allocated to HYV by the risk-averse grower is increasing in his best estimate of the expected yield \( \hat{y}_{it} \) and decreasing in the variance of that estimate \( \sigma_{it}^2 \), as well as \( \lambda_i^2 \). Because the grower's expected utility is declining in \( \sigma_{it} \), he will utilize all the information about \( y(Z_i) \) that is available to him to arrive at his best estimate \( \hat{y}_{it} \).

At the beginning of each period the grower receives an unbiased information signal about the value of his expected yield. He combines this signal with his prior to compute his best estimate of his expected yield, which in turn determines the acreage that he allocates to HYV. Subsequently, he observes his neighbours’ acreage decisions, which reveal the signals that they received, as well as all the yields realized in the village. This social information is used to update the grower’s prior for the next period. Under the assumption that the expected yield is constant across growers, the acreage function is additively separable in the expected yield, and that the individual information signals are normally...
distributed, Munshi derives the grower's acreage $A_{it}$ as a linear function of his lagged acreage $A_{it-1}$, lagged (mean) acreage in the village $\bar{A}_{t-1}$, and lagged yields $\bar{y}_{t-1}$:

$$A_{it} = \pi_0 + \pi_1 A_{it-1} + \pi_2 \bar{A}_{t-1} + \pi_3 \bar{y}_{t-1} + \varepsilon_{it}. \quad (2)$$

When information is pooled efficiently within the village, $A_{it-1}$ contains all the information about the expected yield $y$ that was available at the beginning of period $t-1$, specifically the entire history of information signals and yield realizations up to that time. Conditional on $A_{it-1}$ and fixed individual characteristics subsumed in $\varepsilon_{it}$, $A_{t-1}$ represents the new information that was received by the village in period $t-1$ through the exogenous signals. $\bar{y}_{t-1}$, in turn, represents the information that was obtained from the yield realizations in that period.

As Manski (1993) notes, neighbours’ past decisions will be correlated with the grower’s current decision if any determinant of that decision is correlated across neighbours and over time. The prospects for the identification of social learning improve, however, when we focus on the relationship between the current decision and lagged yield realizations. The information signal received by the grower in period $t$, $u_{it}$, determines his acreage decision $A_{it}$ (through his expected yield estimate), and so is subsumed in $\varepsilon_{it}$. Growers are never systematically misinformed, $E(u_{it})=y$, and so $\bar{y}_{t-1}$ and $\varepsilon_{it}$ will be correlated as well.

One solution to this problem is to difference $\bar{y}_{t-2}$ from $\bar{y}_{t-1}$, leaving us with $\bar{y}_{t-1} - \bar{y}_{t-2}$ from eq. (1). The acreage response to yield shocks in the village would then identify the presence of social learning.

By specifying yield to be the sum of a constant term $y(Z_i)$ and an idiosyncratic shock $\eta_{it}$, we implicitly assume that input markets function smoothly and that input and output prices do not change over time. In practice, changes in the yield from period $t-2$ to $t-1$ could reflect changes in prices or access to scarce resources (such as credit) that are unobserved by the econometrician but directly determine the grower's period-$t$ acreage decision. A spurious yield (shock) effect could in that case be obtained.

To provide additional support for the presence of social learning, Munshi exploits differences in the diffusion of information across crops. Although we have assumed that the expected yield is the same across growers, it will more generally depend on the grower’s characteristics. The grower could condition for differences between his own and his neighbours’ observed characteristics when learning from them, but the prospects for social learning decline once we allow for the possibility that some of these characteristics will be unobserved, or imperfectly observed. Take the case where all the neighbours’ characteristics are unobserved by the grower. He could rely on his own information signals and yield realizations, ignoring information from his neighbours, to obtain a consistent but inefficient estimate of his expected yield. Alternatively, he could continue to learn from his neighbours’ decisions and yields, but some bias will then inevitably appear. The testable prediction is that the grower will choose individual learning if the population is heterogeneous and the yield with the new technology is sufficiently sensitive to unobserved characteristics; otherwise he will prefer to learn from his neighbours.
Munshi tests this prediction with farm-level data on wheat and rice cultivation over a three-year period at the onset of the Indian Green Revolution. Rice-growing areas in India are characterized by wide variation in soil characteristics. The early rice varieties were also sensitive to soil characteristics such as salinity, as well as to managerial inputs, which are difficult to observe. As predicted, HYV acreage responds to lagged yield shocks in the village with wheat but not rice. If the view that rice growers were informationally disadvantaged is correct, then these growers should have compensated for their lack of information by experimenting on their own land. Munshi shows that rice adopters allocate more land to HYV than wheat adopters, despite the fact that their farms are smaller and the likelihood of HYV adoption is significantly higher for wheat.

While Munshi assumes that the yield \( y(Z_i) \) is exogenous and uncertain, Foster and Rosenzweig (1995) assume that the grower's objective is to learn his optimal (profit-maximizing) input use \( Z_i \). The point of departure for their work is the target-input model of Jovanovic and Nyarko (1996), but we will see that the signal extraction aspect and, hence, the basic structure of the learning process remains the same across these different models of learning. With a slight change of notation, Foster and Rosenzweig assume that the grower attempts to learn the optimal or target input use on his land \( \theta^* \),

\[
\tilde{\theta}_{ijt} = \theta^* + u_{ijt} \tag{3}
\]

where \( \tilde{\theta}_{ijt} \) is the optimal input use on plot \( i \) for farmer \( j \) in period \( t \) and \( u_{ijt} \) is an i.i.d. random variable with a (known) variance \( \sigma^2_u \). Notice the similarity with eq. (1), where the grower's objective was to learn the value of the (expected) yield \( y(Z_i) \). Previously he collected information on \( y(Z_i) \) from various sources to finally arrive at the optimal acreage. In the current set-up, the grower collects information on \( \theta^* \) from various sources to arrive at his profit-maximizing input level.

Summing the profit over all plots and taking expectations, the grower's expected profit can be expressed as

\[
\eta_{jt} = \left[ \eta_h - \frac{\eta_{ha} H_{jt}}{A_j} - \frac{\sigma^2_{\theta} + \sigma^2_u}{2} \right] H_{jt} + \eta_a A_j, \tag{4}
\]

where \( \eta_a \) is the yield from traditional varieties, \( \eta_h \) is the yield from HYV on the plot most suitable for the HYV technology, and \( \eta_{ha} \) represents the loss from using land less suitable for HYV. \( A_j \) is the total number of plots and \( H_{ji} \) is the number of plots allocated to HYV. The term in square brackets above
represent the yield from HYV, which is declining in two sources of error: $\sigma^2_u$ and $\sigma^2_{\theta_{jt}}$. $\sigma^2_u$ corresponds to $\lambda^2$ in Munshi’s model and cannot be avoided. However, $\sigma^2_{\theta_{jt}}$, which is associated with suboptimal input use and corresponds to $\theta^2_{jt}$ in Munshi’s framework, will go to zero as the grower learns the value of $\theta^*$ from his own and his neighbours’ experiences.

Munshi’s test of social learning is based on the relationship between the grower's current HYV acreage and his neighbours’ lagged HYV yields. In contrast, Foster and Rosenzweig derive implications for the relationship between the grower’s profit (yield) with HYV and cumulative experience with the new technology corresponding to eq. (4):

$$n_{jt} = (\eta_h + \beta_{ot}\delta_{jt} + \beta_{vt}\bar{s}_{jt})H_{jt} + \eta_\alpha A_{jt} + \xi_{jt}$$

where the term in parentheses represents the profit (yield) from HYV, which is increasing in the cumulative experience with the new technology on own land $S_{jt}$ and neighbours’ land $S_{jt}$. The potential sources of spurious correlation that arise in Munshi’s analysis evidently apply here as well; time-varying changes in growing conditions or access to scarce resources would affect current HYV yield as well as $S_{jt}$, $\bar{s}_{jt}$. Once again it is possible to appeal to the restrictions from the theory to provide additional support for the presence of social learning. While Munshi shows that the effect of neighbours’ past decisions and experiences on the grower's current decision will vary across crops, depending on growing conditions and the technology, Foster and Rosenzweig derive predictions for changes in the pattern of learning over time. Foster and Rosenzweig’s learning model generates the predictions that (i) $\beta_{ot}$, $\beta_{vt}$ will be declining over time, and (ii) $\frac{\beta_{ot}}{\beta_{vt}} = \frac{\beta_{ot+1}}{\beta_{vt+1}}$. These predictions are successfully tested, consistent with the presence of social learning.

The fertility transition

In Munshi and Myaux’s (2006) simple model of the fertility transition no one regulates fertility prior to the inception of a family planning programme. While this remains a potential equilibrium, a new equilibrium in which a sufficient fraction of the community uses convenient modern contraceptives to regulate fertility could also emerge. The object of interest in this case might not be the performance of the new contraceptive (or the side effects associated with its use) but the nature of the future social norm. Individuals gradually learn about the equilibrium that will ultimately prevail in their community as they interact sequentially with each other over time. These changes in beliefs can be mapped into changes in actions: the probability that the individual chooses modern contraceptives in period $t$ is determined by her decision in period $t-1$ and the probability that she interacted with a user in that period. With random interactions within the community, this last probability is in turn measured by the
As with the identification of social learning in agriculture, estimation of the individual decision-rule described above is complicated by the fact that lagged contraceptive prevalence in the community could proxy for any unobserved determinant of the contraception decision that is correlated across individuals and over time. However, the model of the fertility transition as a process of changing social norms places additional restrictions on the relationship between the individual's contraception decision and lagged contraceptive prevalence in the local area. In particular, social effects should be restricted to the narrow social group within which norms restricting fertility were traditionally enforced. Contraceptive prevalence outside that social group should have no effect on the individual's contraception decision. Munshi and Myaux test these predictions using data from rural Bangladesh. In their research setting, the traditional norm was characterized by early and universal marriage, followed by immediate and continuous child-bearing. Religious authority provided legitimacy and enforced the rules that sustained this equilibrium. Changes in social norms should then have occurred independently within religious groups (Hindus and Muslims) within the village. As predicted, lagged contraceptive prevalence within the individual's religious group within the village has a strong effect on her contraception decision whereas cross-religion effects are entirely absent, both for Hindus and for Muslims.

Education

A recent paper (Yamauchi, 2007) studies social learning and investment in education with the same three-year farm panel at the onset of the Indian Green Revolution that was used by Foster and Rosenzweig (1995) and Munshi (2004). Schooling levels among the growers in the sample were determined long before the unexpected availability of the new HYV technology and so the returns to schooling can be estimated directly at the level of the village using realized incomes. A positive relationship between schooling enrolment among the children and the returns to schooling in the previous generation is then seen to be indicative of social learning.

The usual problem when testing this prediction is that returns to education in the previous generation could be correlated with returns in the current generation, which directly determine school enrolment but are unobserved by the econometrician. Yamauchi consequently derives testable predictions that provide additional support for the presence of social learning at the level of the village. He shows formally that social learning will be faster when the income variance is lower and when there is greater heterogeneity in educational attainment in the village. This last prediction is not inconsistent with Munshi’s observation that social learning will be slower in heterogeneous populations where neighbours’ characteristics are unobserved or imperfectly observed. Schooling is an easily observed characteristic and Yamauchi’s insight is that more variance in this characteristic leads to more precise estimates of the returns to schooling. Matching these predictions, schooling enrolment among the children is increasing in the returns to schooling in the village in the previous generation and, more importantly, is increasing in the interaction of the returns and the variance in educational attainment in the village.

Conclusion

How important is social learning in the development process? Foster and Rosenzweig report results from
a simulation exercise based on the estimated parameters from their learning model, which compares profits without learning, with learning from own experience, and with learning from own and neighbours’ experience. Profitability from the new HYV was lower than profitability from the traditional variety to begin with, but HYV profits exceed traditional profits after four years of experience without learning. With social learning, this point is reached one year earlier. Similarly, Yamauchi’s simulations indicate that an increase in schooling inequality within the village could increase enrolment levels by nearly ten per cent. Access to social information appears to be readily available in many practical applications, particularly since there is little cost to the individual from providing information to his neighbours. Thus, the value of interventions that provide the seed for the subsequent spread of such information could be quite high. Understanding how best to design such interventions would seem to be an important area for future research.

social multipliers

Mary A. Burke
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Social multipliers can be thought of as indicators of the degree of strategic complementarity among interacting agents. A simple choice model is used to derive a formal expression of the social multiplier. The behaviour of the multiplier is described in relation to various factors, such as the strength of complementarity and topology of social interactions. Social multipliers are shown to help explain behaviours, such as criminal activity and labour participation, which vary greatly across social groups or across time out of proportion to variation in fundamentals. Challenges associated with identification of social multipliers are also discussed.

Article

A social multiplier arises when choices are subject to social interactions that lead to strategic complementarity, whereby an increase in the level of an action among others in a relevant social group leads to an increase in the same action at the individual level. While multiplier effects may arise in diverse contexts, including that of inter-firm behaviour (see, for example, Cooper and John, 1988), the specific notion of a social multiplier refers to the effects of choice interdependence among individuals in social contexts such as families, neighbourhoods, schools, professional associations, or friendship networks, within which individual choices are thought to be influenced by the choices of others directly, rather than via the effect of others’ choices on market variables. Such influences are also referred to as endogenous (social) effects. Under such interactions, a change in fundamentals exerts a direct effect on individual action, with the actions of others held fixed, and an indirect effect in the same direction
representing the complementary response to the fundamentals-induced change in others’ actions.

Around a stable equilibrium, the total effect (direct plus indirect) of a change in fundamentals on the average equilibrium action exceeds (in magnitude) the average partial (that is, direct) effect of the change. The social multiplier can be defined as the ratio of the former effect to the latter effect, and therefore exceeds 1 (around a stable equilibrium) under the assumption of strategic complementarity. (The effects of changes in fundamentals around an unstable equilibrium are discussed below.) Social multipliers have been invoked to explain large differences in behaviour across groups that are not readily explained by variation in group characteristics, as well as improbably large swings over time in social practices.

To illustrate formally, consider a choice model in which each agent in a large but finite group (size \(N\)) chooses the level of an action, \(x_i \geq 0\), according to a reaction function, \(x_i = f_i(p, \theta_i, \bar{x})\), where \(p\) is a common exogenous parameter such as the unit price of the action, \(\theta_i\) is an individual factor such as inherent taste for the action or income (presumed exogenous), and \(\bar{x} \equiv \frac{1}{N} \sum_i x_i\) is the (presumed or expected) average action level in the population. (The individual is included in the population average on the assumption that his influence on average action is negligible; this assumption is relaxed below.) The model is said to involve global social interactions in the sense that individual action is complementary to the average action in the relevant population, rather than depending only on the actions of some subset of the population. Assume without loss of generality that \(\partial x_i / \partial p \leq 0\) and \(\partial x_i / \partial \theta_i \geq 0\); strategic complementarity implies \(\partial x_i / \partial \bar{x} > 0\). Equilibrium is a set of actions, \(x_i^e\), for \(i = 1, 2, 3, \ldots, N\), such that \(x_i^e = f_i(p, \theta_i, \bar{x}^e)\) for each \(i\), and \(\bar{x}^e = \frac{1}{N} \sum_i x_i^e\).

If we evaluate the effects of a price change around a stable equilibrium, the social multiplier is defined by

\[
M = \frac{\partial \bar{x}^e}{\partial p} \frac{1}{\frac{1}{N} \sum_i \frac{\partial x_i}{\partial p}}.
\]

(The existence of equilibrium, stable or otherwise, is not guaranteed under the minimal conditions given here, but we assume existence for simplicity. See Glaeser, Sacerdote and Scheinkman, 2003, for discussion of existence conditions.) It can be shown (Becker and Murphy, 2000) that the multiplier can be expressed as

\[
\frac{1}{1 - \frac{1}{N} \sum_i \frac{\partial x_i}{\partial \bar{x}}}
\]
The last expression shows how the strength of the social interactions, as indicated by the term \( \frac{1}{N} \sum_i \frac{\partial x_i}{\partial x} \), or \( \gamma \) for short, influences the magnitude of the multiplier. For example, if \( \gamma = 0.6 \), then the multiplier \( (M) \) equals 2.5. This means that the equilibrium effect on the average action of an exogenous change in price is two and a half times as great (in absolute magnitude, and in the same direction) as the average partial effect of the price change on individual action. When social interactions are ‘moderate’ in the sense that \( \gamma < 1 \) around the given equilibrium (Glaeser and Scheinkman, 2003), the value of the multiplier exceeds 1 (provided also \( \gamma > 0 \)) and the model exhibits multiplier effects in the intended sense. The consequences of strong social interactions, that is, \( \gamma \geq 1 \), are discussed below.

In the same model, variation in the vector of individual factors, \( \{\theta_1, \theta_2, \ldots, \theta_N\} \), of the population also generates a social multiplier. With some additional assumptions we can define the social multiplier for a change in the average value of \( \theta_i \), denoted \( \bar{\theta} \). Assuming that the partial effects, \( \frac{\partial x_i}{\partial \theta_i} \), are constant and identical across individuals, the effect on the average equilibrium action of a marginal change in \( \bar{\theta} \) does not depend on the composition of the changes in the underlying \( \theta_i \) values, and so is well defined. The social multiplier is now given by the ratio:

\[
\frac{\frac{\partial \bar{x}}{\partial \bar{\theta}}}{\frac{\partial x_i}{\partial \theta_i}}.
\]

Again it can be shown that this ratio equals \( \frac{1}{1 - \gamma} \), where \( \gamma = \frac{1}{N} \sum_i \frac{\partial x_i}{\partial x} \), so the magnitude of the multiplier around a given equilibrium does not depend on the underlying independent variable (\( p \) or \( \bar{\theta} \)). (If the population is small in the sense that a change in any individual \( x_i \) exerts a non-negligible effect on \( \bar{x} \), then a change in any single \( \theta_i \) also sets off multiplier effects. See, for example, Cooper and John, 1988; and Glaeser, Sacerdote and Scheinkman, 2003. This analysis may be seen as applying to small group dynamics such as classrooms.)

A critical implication of social multipliers for policy analysis is that failure to consider multipliers may lead to significant underestimation of the aggregate effects of interventions when these are based on estimates of the effect of the intervention at the individual level. Conversely, elasticities measured at the aggregate level will overestimate the average individual response to a change in a variable affecting that individual alone.

**Behaviour of the multiplier**

Given the formulation that \( M = \frac{1}{1 - \gamma} \), we see that the multiplier increases in \( \gamma \) over the open interval \([0, 1)\), diverging in the limit as \( \gamma \) approaches 1. However, in the neighbourhood of a stable equilibrium,
it can be shown that \( \gamma < 1 \), guaranteeing a finite social multiplier. This latter condition says that, for the average individual, a change in average peer action leads to a less than commensurate change in individual action, *ceteris paribus*.

If social interactions are not moderate (that is, \( \gamma \geq 1 \)) in the neighbourhood of equilibrium, the equilibrium is unstable. In addition, when \( \gamma \geq 1 \) over some or all the domain of mean peer behaviour, multiple equilibria or non-existence of equilibrium may obtain. Comparative statics around unstable equilibria are possible (provided \( \gamma \neq 1 \)), but in such cases the aggregate equilibrium response to a parameter takes the opposite direction from the partial individual response: for example, \( \gamma = 1.5 \) yields \( M = -2 \). Consequently, multiplier effects – defined in the sense that the aggregate equilibrium response reinforces the partial individual response – do not apply. Becker and Murphy (2000) define the social multiplier as the value of \( \gamma \) itself and so do not restrict social multipliers to effects around stable equilibria. However, they too discount the relevance of comparative statics around unstable equilibria, instead invoking instability to help explain phenomena such as fads, which are characterized by explosive growth in popularity followed by precipitous declines in same.

**Applications**

The lesson of social multipliers is that relatively small differences in fundamentals can lead to large differences in outcomes. This insight has been used to help explain large differences in crime rates across cities (Glaeser, Sacerdote and Scheinkman, 1996), in unemployment rates across census tracts (Topa, 2001), in medical treatment rates across hospital market regions (Bell, 2002; and Burke, Fournier and Prasad, 2006), and in stock market participation across social groups (Hong, Kubik and Stein, 2004), among other patterns not readily explained on the basis of the relevant fundamentals.

Conventional wisdom suggests that peer effects may be an important determinant of educational outcomes, and this is the subject of much active research, but conclusive findings on the significance of social multipliers on academic achievement have not yet emerged, given the difficulties of empirical estimation.

Social multiplier effects may accelerate shifts in social norms over time initiated by technological change. Goldin and Katz (2002) link the birth control pill, via direct effects as well as indirect multiplier effects, to the dramatic increases in women's career investment and age of first marriage in the 1970s. Contraception has also been linked to the large increases in out-of-wedlock births since the 1960s (Akerlof, Yellen and Katz, 1996), where the technology's direct impact eventually served, via social interactions, to erode the associated social stigma against out-of-wedlock births. More recently, it has been argued that social multiplier effects have magnified the impact of technological change on obesity rates in the United States in recent decades and led to a larger value of the social norm for body size (Burke and Heiland, 2007).

**Extensions**

Analysis of social interactions under discrete choice has been described extensively in Brock and Durlauf (2001) and Blume and Durlauf (2003). Utility is given a random component in these models, so
that individual behaviour varies probabilistically with exogenous factors, and in general mean behaviour does not vary linearly with mean group characteristics. The magnitude of the social multiplier, as well as the existence and number of equilibria, again depends on the intensity of social influence on individual choice, although the analytic representation of the multiplier is less straightforward than in the linear, continuous choice model (see Glaeser and Scheinkman, 2003). This discrete model framework has been applied extensively in the analysis of qualitative, non-market choices such as dropping out of school and engaging in criminal behaviour, choices that are intuitively viewed as particularly susceptible to social influences. The model has the further advantage of being readily amenable to empirical analysis, as the structural choice equation maps directly into a logistic (or, with modification, probit) specification.

Social multipliers also arise in models of local social interactions, in which individual action is influenced only by the actions of others in some ‘local’ subset of the population as defined within a particular spatial model. For example, individuals could be situated at points on a circle and the influential peer group defined as the neighbours to the immediate left and the immediate right. Under this structure, and on the assumption of symmetric and linearly separable reaction functions under continuous choice, the social multiplier (as defined above) equals \( \frac{1}{1 - \lambda} \), where \( \lambda \) represents the marginal effect of average action among the (local) peer group on individual action. The magnitude of the multiplier therefore reveals the strength of the social interactions but not necessarily their topology. Models on lines, lattices, tori, and other spaces are also possible, as are numerous other specifications of the reference group. Multipliers typically arise, but the specific results derived here do not hold in general. See, for example, Ioannides (2006).

Mean group characteristics, \( \bar{\theta} \), may be a direct source of externalities on individual outcomes. In the presence of such an externality, dubbed an exogenous or contextual effect (Manski, 1993), variation in some mean group characteristic may induce an effect on the mean outcome that exceeds the effect that would be predicted on the basis of the influence of the characteristic at the individual level. For example, if girls tend to have higher test scores than boys, and if an increase in the classroom proportion of girls reduces disruption and so enables higher test scores for all, the total effect on average test scores of an increase in the proportion of girls will exceed the averaged individual gender effects. (However, if girls have lower test scores on average, the two effects of gender composition will oppose each other.) Therefore, even in the absence of endogenous effects, for example even if an increase in mean peer achievement has no effect on individual achievement, exogenous interactions may create the appearance of a multiplier effect. While Manski adopts the stance that social multipliers occur only in the presence of endogenous social interactions, on the grounds that contextual effects are merely additive, Glaeser, Sacerdote and Scheinkman (2003) endorse a broader definition of multipliers that includes the contributions of both exogenous and endogenous social interactions. Although the two types of interactions are analytically distinct, it may be impossible to separate their respective effects empirically. Manski (1993) was the first to note this identification problem. Subsequent progress in distinguishing between exogenous and endogenous interactions in the linear model has been made by Brock and Durlauf (2001) and Cohen-Cole (2006).

The canonical derivation of social multipliers relies on a static decision model. However, recent research shows that results may not extend to dynamic decision contexts. In a life-cycle consumption model with social interactions, Binder and Pesaran (2001) show that the emergence of social multipliers depends on
social multipliers: The New Palgrave Dictionary of Economics

The distribution of patience parameters in the economy. Bisin, Horst and Ozgur (2006) show that multiplier effects may disappear under forward-looking behaviour and that the magnitude of social multipliers (in both static and dynamic settings) depends on the amount of information people have about other people's types. These findings indicate that the empirical relevance of social multipliers is likely to depend not just on the salience of social influences but also on the nature of intertemporal decision-making, both of these factors being the subject of significant ongoing debate within economics.

Measurement

The researcher who seeks to measure social multipliers encounters a number of formidable identification problems inherent in the empirical analysis of social interactions. One of the most pervasive challenges concerns the non-random selection of individuals into social groups, resulting in a spurious correlation of actions within groups based on similarities in underlying traits, some of which inevitably go unobserved (an example of correlated effects, in Manski's terminology). Under such conditions, naive estimation strategies may produce the appearance of a social multiplier where none exists. Even when all relevant sources of correlated effects can be controlled for, it may be possible to identify only the combined effects of endogenous and exogenous social interactions. The attempt to overcome these problems constitutes an area of active research in econometrics. Since identification conditions depend on the nature of the structural model, qualitative research into the empirical context of interest can serve as an important complement to quantitative analysis.

In a model in which individual action depends linearly on mean peer-group action and linear in all other factors, the definition of the social multiplier as a ratio of marginal effects suggests a regression-based estimation strategy. As explicated in Glaeser, Sacerdote and Scheinkman (2003) and Graham and Hahn (2005), the method involves estimating the respective reduced form equations for mean group behaviour and individual behaviour and taking the ratio of the estimated coefficients on mean group characteristics and individual characteristics, using cross-sectional data on groups defined, for example, by geographic boundaries. Under random assignment into groups, this ratio measures the social multiplier at the given level of aggregation. A multiplier value significantly greater than 1 is consistent with the presence of strategic complementarities deriving from endogenous social interactions. However, if exogenous effects of mean group characteristics cannot be ruled out, the measured multiplier captures both endogenous and exogenous effects due to the collinearity of mean characteristics and mean outcomes. In discrete-choice social interactions models, this collinearity does not hold, however, so endogenous and exogenous effects can be identified separately provided social effects in general can be identified (see Brock and Durlauf, 2001; 2007).

Using variants of this ratio method, Glaeser, Sacerdote and Scheinkman (2003) estimate social multipliers on criminal activity in the United States ranging from 1.72 at the county level to 2.8 at the state level and 8.16 at the national level. As the authors acknowledge, the estimates must be viewed sceptically, given that they do not control for sorting on unobservable demographic factors. Although some models predict that multipliers should increase with the level of aggregation, biases due to unobserved factors may also increase with the level of aggregation.

Graham (2006) employs an alternative measurement of social multipliers, also in the linear context, based on ‘excess variance contrasts’ that controls for some types of group-level heterogeneity, in his
example the effects of teacher inputs on student achievement. The method relies on variation in average class size across sets of classrooms, where a Tennessee policy ensured random assignment of students and teachers to classrooms on the basis of size. Graham obtains point estimates of 1.76 and 1.97 for the social multipliers on maths and reading achievement in kindergarten, respectively, and shows that his estimation method will detect (true) multiplier effects in many cases in which standard regression methods would not. However, the method requires random assignment into groups on the basis of size, and does not separate exogenous from endogenous effects.

Although nonlinearities in the structural model may alleviate the problem of isolating endogenous social multipliers from exogenous effects, they do not alleviate the problems caused by non-random group selection. Although selection biases cannot be eliminated with complete confidence, they can be mitigated in a number of ways. In addition to including various fixed effects as data permit, researchers may exploit information about the selection process itself, as in Ioannides and Zabel (2003), or by eliminating selection altogether, as in experimental research (see, for example, Ichino and Falk, 2006) and in research that exploits natural experiments (Hoxby and Weingarth, 2006). In each of these last three examples, the evidence points to significant social multipliers (on housing demand, worker output, and school achievement, respectively). But even in cases of random group assignment results may be questioned: recent evidence based on a simulated interaction environment shows that an estimated social multiplier, when measured among randomly assigned groups, may be biased downward relative to its true value (Arcidiacono et al., 2005).

Research in sociology and economics points to an important role for social networks in labour markets. Social contacts mediate propagation of rich and reliable information among individuals and thus help workers to find jobs, and employers to find employees. Recent theoretical advances show that, for agents connected through networks, employment is positively correlated across time and agents, unemployment exhibits duration dependence, and inequality can persist. Recent empirical findings underscore nonlinearities in social interactions and potentially important effects of self-selection. Socioeconomic characteristics can explain substantial spatial dependence in unemployment.

The use of social networks is widespread both in employers’ recruiting and in workers’ job-seeking. Social contacts help workers to find jobs, and employers to find employees. Indeed, social contacts convey rich and reliable information, which they spread widely and fast throughout the labour market. They thus constitute cost-effective search channels that both enrich the information available to both firms and workers, and enhance its quality.

Formal versus informal information sources

The study of social networks in labour markets highlights the nature of labour market transactions as very different from trading in goods, and reflects the importance of idiosyncrasies. The role of job market search and its dealing with frictions goes at least as far back as Stigler (1962).
experience indicates that access to information is heavily influenced by social structure. Individuals use connections with others, such as friends and social and professional acquaintances, to maintain information networks. Rees (1966) first drew attention to differences among workers in their use of the variety of available informational outlets. In this context, formal sources of information include state and private employment agencies, newspaper advertisements, union hiring halls, school and college placement services and, more recently, the internet (Kuhn and Skuterud, 2000). Informal sources include referrals from employees and other employers, direct inquiries by job seekers and indirect ones through social connections. A recent literature in economics has developed about the details of social interactions that affect the job search process. This literature is complemented by the more extensive sociological analysis of networks. Several sociological works, including notably Granovetter (1974) and Boorman (1975), have been very influential within the economics literature. This article explores the salience within both theoretical and empirical economics research of a social networks approach in the study of labour markets.

Stylized facts

Several stylized facts about labour market networks have been established by empirical work on job information networks (Ioannides and Loury, 2004). The first stylized fact is that there is widespread use of friends, relatives, and other acquaintances in job search, and it has increased over time. The second stylized fact about job information networks is that the use of friends and relatives in job search often varies by location and by demographic characteristics. Differences in using informal contacts by age, race and ethnicity show conflicting patterns that suggest that important subtleties associated with the operation of social networks are at work. This is confirmed by international comparative evidence. Pellizzari (2004) explores the empirical evidence for the countries of the European Union as of 2003, using the European Community Household Panel, and compares with the United States, using the National Longitudinal Survey of Youth (NLSY). Pellizzari documents large cross-country and cross-industry variation in the wage differentials between jobs found through formal methods and those found through informal ones. Across countries and industries, premiums and penalties are equally frequent. Such differences may be attributed to different recruitment strategies by firms and to different institutional and social practices which may compound the impact of differences in the industrial compositions of economies. The third stylized fact about job information networks is that job search through friends and relatives is generally productive. Both employed and unemployed workers who used friends to search for jobs received more offers per contact and accepted more offers per contact than did workers who used other sources of information about job openings. The fourth stylized fact about job information networks is that part of the variation in the productivity of job search through networks by demographic group simply reflects differences in usage. In particular, US data suggest that almost one-fifth of the total difference in the probability of gaining employment between black and white youth resulted from racial differences in the use of social contacts.

Recent theoretical treatments

We crudely distinguish two mechanisms through which social contacts impact on the functioning of the
social networks in labour markets: The New Palgrave Dictionary of Economics

Labour market. First, referrals relay information across the two sides of the labour market, firms and workers. Second, workers’ connections disseminate job information within the supply side of the labour market through word-of-mouth communication.

Hires mediated by referrals reduce employer uncertainty about prospective workers’ productivity, for a number of reasons (Montgomery, 1991). One is that incumbent workers are likely to refer their trusted acquaintances and help them be better informed about their prospective employers. A second reason is that the long-term nature of the relationship between incumbent employees and their employers provides the latter with superior information on the incumbents’ productivity-related traits. It is thus not surprising that evidence shows that referral bonuses bring high returns to firms. Yet excessive reliance on referrals deprives firms and individuals who happen to be outside the social networks of firms’ workers of mutually beneficial matches.

Recent findings have improved our understanding of the supply-side effects of social networks (Calvó-Armengol and Jackson, 2004; 2006). In their models, workers rely both on own search effort and on information exchange with their social circles to find jobs. Information passing across acquaintances can display a variety of real-life features; for example, when connections differ in terms of intensities, information recipients can be ranked so as to reflect these relational preferences. Calvó-Armengol and Jackson's models are the first to explain several important stylized facts about labour markets, which are hard to explain altogether without an explicit social network model. We turn to those next.

First, information passed from employed individuals to their unemployed acquaintances makes it more likely that these acquaintances will become employed. This generates a positive correlation between employment and wages of networked individuals within and across periods. Such positive long-run correlation arises despite the short-run rival nature of job information in the following sense: indirect contacts who are two links away in a network are potential competitors for any job held by any common friend. Second, duration dependence and persistence in unemployment, both of which are well documented, can be understood as social effects: the longer an individual is unemployed the more likely it is that her social environment is associated with unfavourable future unemployment prospects. This explanation for duration dependence complements more common ones, such as unobserved heterogeneity. This effect resembles an externality and is also responsible for stickiness in aggregate employment dynamics. The closer the economy is to very high employment (or unemployment), the harder it is to leave that state. For similar reasons, parts of the economy can experience a boom while simultaneously other parts of the economy are experiencing a bust.

These are implications of exogenous information networks. With an endogenous network that results from agents’ participation decisions, the model’s predictions are the following. Third, the likelihood of dropping out of the labour force is higher for an individual whose social contacts have poor employment experience, or for an individual with few acquaintances. Fourth, small differences in initial conditions of different individuals and of network structure can lead to large differences in drop-out rates. Indeed, when an individual drops out, the prospects worsen for all those who remain, and this generates spillover effects in others’ decisions to participate or to drop out. Differences in collective employment histories combine with differences in network structure to produce sustained inequality of wages and drop-out rates that feed on each other. So history matters and is responsible for producing persistent income inequality for reasons that are very different from those due to inequalities in human capital investments. Because spillover effects work in reverse, selective and targeted (rather than separate) interventions in the labour market that provide incentives for individuals not to drop out are likely to have amplified
Current empirical treatments

Empirical research has yet to employ fully formal network concepts. It relies typically on concepts of association because of geographic or cultural proximity. There is evidence of persistent correlations in patterns of unemployment in US cities. Socio-economic characteristics, and in particular ethnic and occupational distance, seem to explain a substantial component of the spatial dependence in unemployment. Topa (2001) and Conley and Topa (2002) argue that social interactions can indeed explain the spatial correlation patterns present in the data. Weinberg, Reagan and Yankow (2004) show that one standard deviation improvement in neighbourhood social characteristics and in job proximity raises individuals’ hours worked by six per cent and four per cent on average, respectively. Such social interactions have nonlinear effects. The greatest impact is in the worst neighbourhoods. Being in a disadvantaged neighbourhood is more important than the labour activity of one’s neighbours per se. Bayer, Ross and Topa (2005) document that people who live close to each other, defined as being in the same census block – a US census block encompasses 3,500 to 5,000 residents of a contiguous geographical area – also tend to work together, that is, in the same census block. Using data from Dartmouth College (where room-mates are assigned randomly), Marmaros and Sacerdote (2002) find large positive correlations between getting help from fraternity or sorority contacts and obtaining prestigious, high-paying jobs. Still, other research points to self-selection as the likely origin of such effects: Oreopoulos (2003) finds that, when neighbourhoods are not selected, neighbourhood quality plays little role in determining a youth’s eventual earnings, likelihood of unemployment, and welfare participation, while correlations among outcomes for siblings are much higher.

As richer network data become available, further empirical tests of the implications of labour market networks should be developed, which ultimately may call for more elaborate network modelling tools in labour economics. Such research deserves attention.

Abstract

Social network analysis has a long history in sociology, but interest in this topic has broadened dramatically since 1995. This article reviews the origins and key concepts from the sociological literature on social networks, and outlines the network approach to economic behaviour (see Zuckerman, 2003 or White, 2002 for a broader vision of ‘economic networks’ not covered here due to space limitations). The central themes we trace relate to ‘social embeddedness’ and aggregation – how occupying different positions in complex networks enables and constrains action, as well as the resulting properties of global networks that arise from these actions.

Sociology's founding theorists often made use of network metaphors, since the discipline is defined by the study of relations; sociology is the study of positions, rather than persons. Durkheim (1984), for example, focused on the primary role played by the division of labour in the idealized transition from traditional to modern society. In traditional society, labour is divided mostly within rather than between households, so outside the household, economic, political, and social relations are based on similarity (‘mechanical solidarity’). Modern society is characterized by a complex division of labour outside the household, resulting in relations based on complementary differences and dependence (‘organic solidarity’). While Durkheim believed that organic solidarity provided much greater potential for growth and development, he also noted that such systems are more vulnerable to breakdowns in connectivity.

Of the classical social theorists, Georg Simmel made the most explicit use of network foundation in his work. What defines being social for Simmel is the super-individual quality of a collective (Simmel, 1908, p. 123). A group takes on this unique characteristic when its existence cannot be linked to the loss of particular members. When there are only two people involved, there is only one tie, and the group can be dissolved with the loss of either person; so for Simmel, the minimal social group is three persons, and also the first opportunity for structural variation in the ties – a ‘two-path’ or a completed triangle. In his work on tertius gaudens (the ‘third who enjoys’), Simmel explores the unique returns to those who occupy an exclusive bridging role between two others. He argues that power and control are a function of how others are connected to each other, rather than an individual attribute:

The power tertius gaudens must expend in order to attain his advantageous position does not have to be great in comparison with the power of each of the two parties, since the quantity of his power is determined exclusively by the strength which each of them has relative to each other. (Simmel, 1908)

Simmel's work is the foundation for much current research on power and positions in networks (Blau, 1964; Cook et al., 1983; Burt, 1992).
Modern social network analysis focuses on explaining where networks come from and how networks affect outcomes. There are multiple summary measures for network structure that span multiple units of analysis. For nodes, the most basic measure is ‘degree’, the number of ties each node has to others in the network, which aggregates up to the population degree distribution. For dyads, measures can either characterize properties of the dyads themselves (for example, duration and type of relation) or the properties of the two nodes (for example, ‘homophily’, a form of correlation between nodal attributes). Higher-order configurations include triads and other cycles, the size and distribution of connected sets, path lengths and distributions, and many more (see Wasserman and Faust, 1994). Overall network attributes are typically functions of the lower-order properties, and include measures like density, centralization, core-periphery structure and clustering. At each level, researchers ask either ‘what underlying processes produce this network structure?’ or ‘what impact does this structure have on some outcome?’ The endogeneity of some of the implied processes leads to interesting and complicated dynamics, as well as causal ambiguity.

Where do networks come from?

Networks emerge as the result of relationship formation and dissolution. These processes are influenced by several factors: contextual effects (for example, population composition, institutional mediation), individual propensities (for example, expansiveness and attractiveness), dyadic factors (for example, homophily or mutuality), and explicit social rules about relational configurations (such as incest prohibitions or social balance rules for friendship). Real-world social networks almost always display more clustering and heterogeneity than similar-volume Erdos–Reyni random networks; where ties are distributed uniform random across all possible pairs. Why? Part of the answer is propinquity; individual behaviour is organized by social contexts that filter the pool of available partners (Feld, 1981). Preferences for similarity combine with attribute heterogeneity to cluster ties within groups (Blau, 1977). Heterogeneities in individual propensities to send or receive ties also contribute to departures from a random graph. More active persons and groups will account for a disproportionate share of relations, creating hubs or clusters of activity. Recent ‘scale free’ network research has this simple ‘preferential attachment’ mechanism at its core (Barabasi and Albert, 1999).

Most social network research examines processes that operate above the individual level, focusing on the generative mechanisms explicitly governed by dyadic, triadic, and higher order relational norms. One of the first dyadic models proposed for directed relations was mutuality, which captures the commonly observed propensity for out-ties to be reciprocated. Another common dyadic model is ‘homophily’, the preference for similarity in social relations (Blau, 1977). Friendship pairs tend to be similar with respect to socioeconomic status, gender, race, and delinquent behaviour (Cohen, 1977; McPherson, Smith-Lovin and Brashears, 2006) and romantic ties are strongly assortative by age, education and race (Mare, 1991; Morris, 1995). The general term given to this dyadic process is selective mixing – which may be assortative, disassortative or idiosyncratic.

The most famous model for triads is social balance theory. At its simplest, balance theory predicts that a friend of a friend will also be a friend, as enmity among one's friends leads to strain and is avoided (Davis, 1963; Holland and Leinhardt, 1971). The beauty of balance models is that they provide a clear (if endogenous) link between individual action and network structure. Consider the example below in Figure 1, which maps the potential change space for a single unbalanced triad. The initial triad is unbalanced, since actor a's friends (+) are enemies (−) with each other. This pattern is expected to create dissonance and thus each actor has a motive to change relations, any one of which would result in one of the three balanced outcomes. Each change, however, may alter the balance of other triads containing these nodes, resulting in a chain reaction of tie formation and dissolution over time. Figure 1

An example of a balance transition
Unbalanced at time 1
Many triad and higher-order models for generating networks have been explored. Johnsen (1986) generalizes a set of simple balance-like rules to describe complex group-level structures. Moody (1999) demonstrates that a stable macro-structure cannot be assumed from the underlying choice patterns, since triad transitions that create balance from one actor’s position will create imbalance for another. Chase (1980) demonstrates that perfect linear hierarchies require transitive triadic dominance relations, and that empirically (at least among chickens) relation formation rules are more important than individual attributes in predicting domination. Bearman, Moody and Stovel (2004) show that a simple rule prohibiting four cycles in heterosexual networks (the smallest possible cycle, equivalent to swapping partners) can generate romantic networks very similar to those observed among adolescents. Finally, relational rules may also be based on the timing of ties. The most well-known example is the norm of serial monogamy in romantic relations. Monogamous networks are completely disconnected at any time point – they are nothing more than collections of isolated dyads. By contrast, if partnerships can be maintained concurrently, larger connected sets can form, and a giant component emerges quickly, even in the absence of nodes with many partners. This example has been well studied because it has implications for the spread of infection (Moody, 2000; Morris and Kretzschmar, 1997; Morris, Goodreau and Moody, 2008).

What do networks do?

The relations that comprise a network define a set of positions. The positions provide individuals with opportunities for access (a person to call for help) and exposure to diffusion (such as a virus through sexual contact or information about a job). The overall structure determines the population dynamics of social exchange and the evolutionary stability of the system. At the individual level, opportunities for access to resources follow from one's position in the network. The set of direct contacts – called the egocentric or local network – is typically characterized by number, heterogeneity, and strength (Marsden, 1987). Recent work on social capital is in this tradition, building on the strength of ties, questions of trust, and the mix of types of people one is connected to (Lin, 2002). The effect of indirect ties – the partners of one's partners, and beyond – has produced some of the best-known network research, starting with Lee's (1969) *The Search for an Abortionist* and continuing with Granovetter's (1973) classic ‘The Strength of Weak Ties’ on job search. Since the people one is very close to know what one knows, the most profitable information sources come from those connected to other social worlds. While we may be influenced by our local network partners, their opinions are similarly shaped, so, as with balance theory, the system of beliefs (its coherence, polarization and dynamics) co-evolves with network ties. Studies of diffusion over networks have focused on a range of different types of processes, from the spread of information, norms, and innovation, to the spread of infection (Coleman, Katz, and Menzel, 1966; Rogers, 1962; Morris, 2004). Speed, pervasiveness and stability of spread are determined by the variations in the transmission network: density, the length and number of paths, clustering and relationship timing (Pool and Kochen, 1978; Watts and Strogatz, 1998; Moody, 2000; Morris and Kretzschmar, 1997).

The systemic perspective on endogeneous network processes leads naturally to a full game theoretic approach: a set of rules that govern interaction at the micro level which aggregate up to produce complex dynamics at the population level. Topics studied this way include the predominance of matrilateral cross-cousin marriage in classificatory kinship systems (White, 1963), the pervasive spread of unpopular ideas (Centola, Willer and Macy, 2005), and the conditions for the persistence of altruism (Bowles, Choi and Hapfensitz, 2003).

Social networks and economic outcomes

The starting point for most network approaches to economic sociology is Granovetter's (1985) paper on social embeddedness. Granovetter draws a middle ground for economic action between purely autonomous and economically rational actors (‘undersocialized action’) and deeply embedded and largely scripted normative behaviour (‘oversocialized action’). He argues that ‘personal relations and structures’ generate trust, discourage malfeasance and are subject to intentional construction. Here, as always in the network approach, there is both
‘Embeddedness’ refers to the fact that economic action and outcomes, like all social action and outcomes, are affected by actors dyadic (pairwise) relations and by the structure of the overall network of relations. As a shorthand, I will refer to these as the relational and the structural aspects of embeddedness. (Granovetter, 1992, p. 33)

At the dyadic level, the focus has traditionally been on contact strength, with questions turning on issues of trust and exchange in local networks (Uzzi, 1999). At the structural level, the focus is on how larger sets of nodes are mutually reconnected, providing contexts where mutual obligations can be reinforced and behaviour monitored (Moody and White, 2003). The role of networks in shaping economic behaviour is particularly clear in settings where markets are not well developed or where capital resources are low. In China's emerging market economy, for example, firms will often trade with well-trusted associates even if they can find the goods cheaper elsewhere (Keister, 2001). Similar patterns are also found in Western commodity trading markets, however, suggesting there is a benefit to trading with known partners even in well-regulated settings (Baker, 1984; Uzzi, 1996; 1999).

Ron Burt (1992) builds on both Granovetter and Simmel in his research, linking profit opportunities to ‘structural holes’ – the absence of a tie between two persons who have something to exchange. As in Granovetter, information is more likely to accrue to those who connect such disconnected worlds. As in Simmel, those in a ‘middle-man’ position can play each of the actors they are connected to off each other, gaining a control advantage in the network. Structural holes are essentially arbitrage opportunities. As such, in a dynamic setting there are incentives for holes to be closed, which can either shorten the window of profitability, or generate action to protect the advantage.

Conclusion

The history of research on social networks in sociology is broad and deep, ranging from the earliest foundation of the discipline to nearly every empirical area under current research. The general theme of this work is to relate individual network positions or network structures either to generative social processes (when explaining network formation) or to substantive outcomes (when using networks to predict behaviour). For economic questions, a network embeddedness approach allows one to identify social bounds to strategic action based on connections with others. Much of the current research on social networks is computationally intensive. Given the endogeneity inherent in network processes, statistical models cannot assume independence, and dynamic models are not analytically tractable. To analyse network formation, a new class of statistical models is being developed to help distinguish between different mechanisms that lead to similar structural features (Morris, 2003; Handcock et al., 2003; Snijders, 2001; Snijders et al., 2006). The new computational models allow us to examine a wide range of questions without the need for traditional simplifying assumptions. This set of tools promises to put the ‘social’ back into social science research methods.

social norms

H. Peyton Young

Abstract

The function of a social norm is to coordinate people's expectations in interactions that possess multiple equilibria. Norms govern a wide range of phenomena, including property rights, contracts, bargains, forms of communication, and concepts of justice. Norms impose uniformity of behaviour within a given social group, but often vary substantially among groups. Over time norm shifts may occur, prompted either by changes in objective circumstances or by subjective changes in perceptions and expectations. The dynamics of this process can be modelled using evolutionary game theory, which predicts that some norms are more stable than others in the long run.

Article

Social norms are customary rules of behaviour that coordinate our interactions with others. Once a particular way of doing things becomes established as a rule, it continues in force because we prefer to conform to the rule given the expectation that others are going to conform (Schelling, 1960; Lewis, 1969). This definition covers simple rules that are self-enforcing at a primary level, such as which hand to extend in greeting or which side of the road to drive on, and more complex rules that trigger sanctions against those who deviate from a first-order rule. (We express outrage if someone cuts in front of someone else in a queue.) The former are sometimes called conventions and the latter norms (Sugden, 1986; Coleman, 1990; Bicchieri, 2006), but in fact there are numerous gradations and levels of response to norm violation that make this dichotomy problematic. Hence I shall use the term ‘norm’ in its
David Hume (1739) was the first to call attention to the central role that norms play in the construction of social order. Norms define property rights, that is, who is entitled to what. They determine what commodities are accepted as money. They shape our sense of obligation to family and community. They determine the meanings we attach to words. Indeed it is hard to think of a form of interaction that is not governed to some degree by social norms. (For book-length treatments of the subject see Lewis, 1969; Ullman-Margalit, 1977; Sugden, 1986; Young, 1998a; Posner, 2000; Hechter and Opp, 2001; Bicchieri, 2006.)

Norms and equilibria

Norms can be represented as equilibria of suitably defined games; indeed, Hume's analysis of norms can be viewed as one of the earliest examples of game-theoretic reasoning. Nevertheless, not every equilibrium of a game is a norm. First, the term generally applies only to games with multiple equilibria. People can queue for service or they can push. They can use gold coins or glass beads as money. They can drive on the left or on the right.

Second, even if a game has multiple equilibria, they do not necessarily qualify as norms. To illustrate the distinction, consider two individuals who get to divide a dollar provided they can agree on how to divide it. Each makes a demand, and if the demands sum to at most one the demands are met; otherwise they get nothing. This is a coordination game and it has many equilibria. For example, if one person demands 43 cents and the other demands 57 cents, the demands are in equilibrium: no one can gain from a unilateral deviation. But this is not a norm; it is an idiosyncratic equilibrium for these two individuals. Fifty–fifty division, by contrast, is a norm because it is usual and customary in games of this kind, and everyone knows it.

Norm enforcement

Broadly speaking there are three different mechanisms by which norms are held in place. Some are sustained by a pure coordination motive. If it is the norm to drive on the left, I adhere to the norm in order to avoid accidents. If gold is the commonly accepted currency, it would be a waste of time to try to conduct my business with glass beads. These are ‘social’ phenomena, because they are held in place by shared expectations about the appropriate solution to a given coordination problem, but there is no need for social enforcement.

Other norms are sustained by the threat of social disapproval or punishment for norm violations (Sugden, 1986; Coleman, 1990). If queuing is the norm, I will be censured if I try to push my way to the front. If duelling is the proper response to an insult, I will lose status in the community if I do not challenge the one who insulted me. If I am expected to avenge the murder of my brother and fail to carry it out, I may be ostracized by other family members. (Exactly why third parties bother to express disapproval or carry out punishments is a matter of debate, but the evidence suggests that they sometimes do so even at considerable personal cost – Fehr, Fischbacher, and Gächter, 2002.)

A third enforcement mechanism arises through the internalization of norms of proper conduct. If it is the norm not to litter, I will avoid littering even in situations where no one can see me. If I eat a meal in a
foreign city and fail to tip the waiter, I need not fear the consequences because there is no continuing relationship; nevertheless, I may think the worse of myself for having done it. More generally, norms often take on the character of virtuous or right action (Hume, 1739), and departures from a norm can trigger emotions of shame or guilt even when third-party enforcement is absent (Coleman, 1990; Elster, 1989; 1999). This fact is especially useful in large-scale societies, where it may be difficult to monitor others’ compliance with equilibrium behaviour.

Norms and efficiency

It remains to be explained why a dictionary on economics, in contrast to sociology or law, should bother with an entry on social norms. What economic purpose do they serve? The answer is that norms coordinate expectations, and thereby reduce transaction costs in interactions that possess multiple equilibria (Wärneryd, 1994).

This point seems clear enough intuitively; it can also be demonstrated experimentally (Roth, 1985). Consider a game in which two players can divide a pile of chips in any way they like, but if they fail to agree on a division within a specified period of time they forfeit all of them. When all the chips can be cashed in for the same amount of money, the norm is to divide the chips equally; moreover, the great majority of players do in fact coordinate in this manner. Notice, however, that any division of the chips, not just 50–50, can constitute an equilibrium of the one-shot game if both players expect that it will be played. Now consider a variant in which the players get to cash in the chips for different amounts of money (which is publicly known). In this case there are two potential focal solutions – divide the chips equally and divide the money-value of the chips equally – but there is no norm to steer the players’ expectations towards one or the other. As a result, the frequency of disagreement rises substantially. More generally, a norm has economic value if it creates a uniquely salient or focal solution to a coordination problem, thus reducing the risk of coordination failure. In this sense norms are a form of social capital (Coleman, 1987). This does not mean, however, that norms are invariably welfare-enhancing; indeed some norms would appear not to have any direct welfare implications.

Consider norms of etiquette, such as the fine points of table manners. The welfare consequences are so trivial that it is hard to see why anyone bothers with them. No one is harmed, for example, if I wear a hat to dinner or eat peas with my fingers. The fact is, however, that such indiscretions may do serious harm to my reputation. In particular, they signal that I am a person who does not care about social norms, which may lead others to doubt my reliability in more important interactions (Posner, 2000). Complex social rituals allow people to signal their sensitivity to norms in general; they also provide a training ground for learning to follow norms, and for disciplining those who fail to do so.

Even when norms do have direct welfare implications, one cannot conclude that societies will opt for efficient norms. It is doubtful, for example, that norms of retribution are efficient, or that pushing is superior to queuing. Yet these are the operative norms in quite a few cases. The problem is that norms are not ‘chosen’; they arise from historical accident and the accumulation of precedent. Once expectations converge on an inefficient norm, it can be very difficult to dislodge.

Over the longer run, it is conceivable that societies could somehow extricate themselves from inefficient outcomes. One way that this could happen is that societies with superior norms simply displace societies with inferior norms, through growth, conquest, or migration. Another possibility is that societies with
inferior norms imitate the practices of more successful ones (Robson and Vega-Redondo, 1996; Boyd and Richerson, 2002). Yet a third possibility is that norm change comes from within, the result of gradual and almost imperceptible changes in expectations that ‘tip’ the society into a new way of doing things without anyone intending it. I discuss this possibility in more detail below.

Excess uniformity

I have argued that some norms may be inferior from the standpoint of welfare, yet stay in place for long periods of time. Others may have little direct effect on welfare but serve an important signalling function. Another way in which norms can affect economic welfare is by imposing excess uniformity on behaviour. People might be better off if they adapted their actions to their particular circumstances. To illustrate, consider a situation in which a principal and an agent are bargaining over the terms of a contract. To be concrete, think of a landlord bargaining with a prospective tenant over the terms for renting a plot of land. In theory, the optimal contract will depend on a variety of factors that may be idiosyncratic to the contracting parties, including information asymmetries, monitoring costs, and attitudes towards risk (Cheung, 1969). Yet, in practice, contracts often exhibit a high degree of uniformity, and employ ‘usual and customary’ terms that mask idiosyncratic differences (Bardhan, 1984). In late 20th-century Illinois agriculture, for example, more than 50 per cent of the contracts specified fixed shares between tenant and landlord, and of these more than 90 per cent specified the shares 1/2–1/2, 2/5–3/5, or 1/3–2/3 for landlord and tenant respectively (Young and Burke, 2001). The logic of ‘usual and customary’ contractual terms is that they create a focal solution in a situation that has many possible solutions, thereby reducing transaction costs. Such norms are not unique to agricultural contracts: for example, building contractors and architects get customary markups over cost, franchisees pay standard percentages to their parent companies, real estate agents receive customary commissions on house sales, and so forth. While such norms may reduce transaction costs, however, the uniformity imposed by the norm may prevent the contracting parties from fully wringing out all of the potential gains in their particular circumstances. Thus, in evaluating the efficiency of a norm, one must consider both the savings in transaction costs and the costs imposed by excess uniformity.

The evolution of norms

If a norm merely represents one equilibrium out of many, how does society settle on a particular one starting from out-of-equilibrium conditions? We may distinguish three ways in which norms become established and change over time: top-down influences, including official edicts and role models; bottom-up influences in which local customs and practices coalesce into norms; and lateral influences in which established norms from one type of interaction are transferred to related types of interactions. The law, for example, operates partly from the top down: statutes and judicial rulings identify norms of acceptable behaviour in people's relations with others. At the same time, the boundary between acceptable and unacceptable behaviour is constantly in flux due to variations in the way that individual cases are resolved by individual courts (a bottom-up effect). And precedents in one domain can be transferred by analogy to other domains (a lateral effect). An example of the latter is the extension of laws regarding persons to those involving corporations. (For more on the interplay between norms and
As these examples suggest, the evolution of norms is a complex process that involves the interplay of many different forces. One may nevertheless gain insight into the process by examining how small variations in behaviour at the individual level can trigger major norm shifts at the societal level. Consider a symmetric, two-person coordination game $G$ that is played by pairs of agents drawn from a large population. Assume for simplicity that the total number of agents is even, and that in each period everyone is paired with someone else through a random matching process. Each matched pair chooses actions simultaneously and receives the corresponding payoffs in $G$. Assume that each agent makes a ‘trembled best response’ to the distribution of choices in the previous period. Specifically, suppose that for some $0 < \varepsilon, \lambda < 1$, each agent chooses a best response with probability $\lambda(1 - \varepsilon)$, trembles with probability $\lambda$, and chooses the same action as before with probability $1 - \lambda$ due to inertia (Kandori, Mailath and Rob, 1993; Young, 1993a).

This type of learning process has rather striking implications for the social norms that are most likely to emerge and remain in place for long periods of time. To illustrate, consider a competition between alternative forms of money. Suppose there are $m$ different commodities, indexed $1 \leq k \leq m$. Assume that, in a given pairwise interaction, each player's payoff is $a_k$ if both adopt the $k$th form of money, whereas their payoffs are zero if they adopt different forms. It can be shown that this trembled best-response process selects the efficient equilibrium with high probability, that is, when $\varepsilon$ is small the probability is high that, in the long run, almost everyone in the population will be using the form of money with the highest payoff (Kandori and Rob, 1995).

Unfortunately, efficiency may fail when the game does not have the structure of a pure coordination game. Suppose, for example, that a potential form of money generates payoffs in two ways: as a medium of exchange and as a form of adornment. In each pairwise interaction, let $a_k$ be the payoff in each period from using $k$ as a medium of exchange (on the assumption that the other player also uses $k$), and let $b_k$ be the payoff from using it instead as jewellery. When there are just two commodities one obtains the symmetric payoff matrix

$$
\begin{bmatrix}
  a_1 + b_1 & a_1 + b_1 & b_1 & b_2 \\
  b_2 & b_1 & a_2 + b_2 & a_2 + b_2
\end{bmatrix}
$$

Assume that this is a coordination game: $a_1 + b_1 > b_2$ and $a_2 + b_2 > b_1$. Commodity $k$ is efficient if it maximizes $a_k + b_k$. However, the evolutionary process defined above selects the risk-dominant commodity, that is, the commodity $k$ that maximizes $a_k + 2b_k$ (Young, 1998b). The latter criterion gives twice as much weight to the payoffs from adornment (which do not require coordination) as to the payoffs that arise from using the same medium of exchange (which do require coordination). Moreover, this conclusion holds under a wide range of assumptions about the nature of the trembled best-response process (Blume, 2003).

Evolution and fairness norms
The evolutionary framework outlined above has implications not only for the efficiency of norms but for their distributive properties as well. Consider a situation in which a principal and an agent must agree on the form of contract that will govern their relationship. Different types of contracts will have different distributive implications, some favouring the principal, others favouring the agent. Let us restrict attention to just those contracts that leave both parties better off than they would be under their outside options. To illustrate, suppose that just three contract forms are available: A, B, C. Assume a one-shot, take-it-or-leave-it bargaining process in which a given contract is adopted if and only if both parties simultaneously agree to it; otherwise they fall back on their outside options. Without loss of generality one can assume that the outside options have zero utility for both players. Consider the following example:

<table>
<thead>
<tr>
<th>Agents</th>
<th>A</th>
<th>B</th>
<th>C</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>5, 1</td>
<td>0, 0</td>
<td>0, 0</td>
</tr>
<tr>
<td>B</td>
<td>0, 0</td>
<td>3, 3</td>
<td>0, 0</td>
</tr>
<tr>
<td>C</td>
<td>0, 0</td>
<td>0, 0</td>
<td>1, 5</td>
</tr>
</tbody>
</table>

Contract A favours the principal, C favours the agent, and B is a compromise between A and C. (Of course, in reality there may be many more contract forms, but this does not change the analysis in any fundamental way.) Consider an evolutionary process like the one for money conventions, but with two distinct populations – one of principals, the other of agents – that are randomly matched in each period. Assume, as in the previous model, that they play trembled best responses with inertia, where ‘best response’ is defined relative to the frequency of play of the opposite population in the previous period. A contractual norm is a situation in which the same contract is agreed to by everyone. In this example all three norms are efficient: none of them Pareto dominates another. It can be shown, however, that the evolutionary process favours exactly one of them, namely, the compromise contract B. More generally, in evolutionary processes of this sort there tends to be a selection bias toward outcomes that represent a compromise for the two parties, and against extreme outcomes that lie near the boundary of the payoff-possibility set (Young, 1998b). This suggests that norms of fairness may result from evolutionary forces, an idea that is explored by Binmore (1994; 2005) and Young (1998a).

**General implications**

Although evolutionary accounts of norm formation vary in their details, they have several qualitative implications that hold quite generally. One is that different societies often employ different norms for solving the same type of coordination problem. This follows from the fact that norms represent alternative equilibria that can become established through different sequences of chance events. This is known as the local conformity/global diversity effect (Young, 1998a). It has been documented in a
social norms: The New Palgrave Dictionary of Economics

A variety of settings, including agricultural contracting (Young and Burke, 2001), and the manner in which subjects divide payoffs in experimental situations (Henrich et al., 2004).

A second implication is that, due to stochastic perturbations, norms occasionally shift, and these shifts tend to be quite rapid compared with the long periods of stasis when a given norm is in place. This is the tipping or punctuated equilibrium effect (Young, 1998a).

A third implication is that some norms are inherently more stable or durable than others: once established they tend to remain in place for long periods of time even when buffeted by stochastic shocks. These stochastically stable norms depend on the payoff structure of the underlying game, and also on the nature of the stochastic perturbations (Foster and Young, 1990; Young, 1993a; Kandori, Mailath and Rob, 1993; Samuelson, 1997). Irrespective of these details, the important point is that some norms are remarkably resilient under changing circumstances. Due to their longevity, such norms may come to be seen as right and necessary, though in fact they are the product of chance and contingency, and are sustained simply because they coordinate people's expectations about how to interact with one another.

social preferences

Jeffrey Carpenter
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Behaviour in a variety of games is inconsistent with the traditional formulation of egoistic decision-makers; however, the observed differences are often systematic and robust. In many cases, people behave as if they value the outcomes accruing to other reference agents. In reaction, behavioural economists have offered and tested a variety of formulations (such as inequality aversion and reciprocity) that capture the social nature of preferences.

Article

For the longest time economists reacted allergically to preference formulations that allowed for anything but material self-interest (cf. Binmore, Shaked and Sutton, 1985). The reaction was well founded: by adding elements to the agent's utility function, potentially one allows economic theory to explain everything and, therefore, nothing. Any behaviour can be explained by assuming it is preferred. However, this strong position has sometimes made economics seem out of touch with the world economists try to explain. Even economists care about the outcomes achieved by others, in addition to their own outcomes. Moreover, they also care about how those outcomes are achieved. Only in 1982, however, was the weakness of taking material self-interest for granted demonstrated by Werner Güth and his co-authors, who showed that economic theory failed in the simplest of decision settings (Güth, Schmittberger and Schwarze, 1982), the ultimatum game. In this game a first mover offers a share of a monetary ‘pie’ to a second mover who either accepts the proposal, in which case it is divided as proposed, or rejects the proposal, in which case both players earn nothing. Since then this game has become the workhorse of experimenters intent on exploring carefully the extent to which people behave in ways that are contrary to their material self-interest.

While it is interesting to document the fact that people consider the outcomes of others when they make choices in experimental games, there are at least two other particularly compelling aspects of the research that has developed since the 1980s. First, these deviations from self-interest can be replicated, and have been, both inside and outside the laboratory. Replication suggests that these behaviours are not just errors or flukes, and therefore, although self-interest is a convenient modelling assumption, it should not be used as the basis for policy formulation. Second, this research illustrates that there is a difference between theory failing because of a false assumption and its failing because of flawed logic. Research shows that people do use economic reasoning, but that they, or most of them, are not narrowly self-interested.

The original results of the ultimatum game provided the impetus for a large body of research. Initially, some researchers were convinced that the explanation was not a concern for others but simple error (for example, Binmore, Shaked and Sutton, 1985). However, this explanation was soon swept aside by volumes of evidence from a variety of games that suggested that the payoffs of other players entered into the strategic choices of experimental participants (see the reviews of Bowles, 2004; or Sobel, 2005). Despite all this research, a precise definition of social preference has not been settled upon. In most cases, ‘social preference’ is defined loosely as a concern for the payoffs allocated to other relevant reference agents in addition to the concern for one's own payoff. (A largely separate branch of research has focused on altruism and warm glow motives for giving to others, especially in the context of public goods provision. This work is discussed elsewhere in the dictionary.)
social preferences: The New Palgrave Dictionary of Economic

Within the standard outcome-oriented definition, research has focused on identifying the more pro-social preferences for altruism and inequality aversion while considerably less attention has been given to their opposites, spite and eminence. The evidence from the hundreds of ultimatum games conducted since 1982 suggests that, on the second-mover side of the game, few people are willing to accept the low offers associated with the subgame perfect equilibrium prediction. In fact, offers of less than 20 per cent of the pie are routinely rejected, and as offers increase they are more likely to be accepted (Camer, 2003). Turning down positive offers is clearly against one's material self-interest, but it is consistent with aversion to unequal payoffs (inequality aversion). As the stakes increase, the probability of a rejection falls, but even when the pie is as large as three months expenditures the rejection rate is not zero (Cameron, 1999).

Interpreting the motivation of the first mover in the ultimatum game is not as straightforward, though. One hypothesis is that proposers offer half the pie because they are inequality averse. We cannot, however, distinguish this reasoning from that of completely selfish, but astute, proposers who anticipate that low offers will be rejected and offer half because they know it will be accepted. The dictator game evolved to identify the motives of first movers (Forsythe et al., 1994). The dictator game is played just like the ultimatum game except for one very important design change: second movers are passive recipients of whatever they are allocated. In other words, they cannot reject offers. If the enlightened self-interest hypothesis is correct, we would expect to see first movers allocating nothing in the dictator game. This is not the case. Although allocations in the dictator game are susceptible to changes in the presentation of the game (Hoffman et al., 1994; Eckel and Grossman, 1996), it is common for people to allocate positive amounts. In fact, it is common for the behaviour of non-student participants in the two games to be indistinguishable (Carpenter, Burks and Verhoogen, 2005) suggesting that many people prefer equal outcomes.

There is some question as to whether the simple outcome-oriented definition of social preference is sufficient. An example illustrates why. Instead of offers being generated by other participants, imagine second movers in the ultimatum game being assigned offers randomly by a computer programme. If inequality aversion is a sufficient description of the motivations of participants, this change should have no impact on behaviour. However, it does: responders are much less likely to reject computer-generated offers than offers that come from real proposers (Blount, 1995). This indicates that people are also interested in the process and intentions that generate outcomes. The definition of social preference should perhaps be expanded accordingly to a concern for the payoffs allocated to other relevant reference agents and the intentions that led to this payoff profile in addition to the concern for one's own payoff.

Expanding the definition of social preference to include a process component allows us to also classify reciprocity – treating only kind acts with kindness – as a social preference. Pure reciprocity, however, is more elusive than inequality aversion because one needs to show that outcomes and intentions matter. Only a few experiments have been conducted to show that intentions matter, but the results are compelling. For example, imagine two binary choice versions of the ultimatum game (Falk, Fehr and Fischbacher, 2003). In game A, the proposer can decide between claiming the lion's share of a ten-dollar pie (8, 2) and sharing the pie equally (5, 5). In game B, the first option is the same (8, 2) but the second is even worse for the second mover because the proposer demands the whole pie (10, 0). Inequality aversion predicts that the (8, 2) offer will be rejected at the same rate in the two games because the other offer is irrelevant – the decision-maker should focus only on the outcome presented. Reciprocity, on the other hand, suggests that one would be much less likely to reject (8, 2) in game B because it is the kinder of the two offers. Indeed, people are almost five times more likely to reject the (8, 2) offer in game A. An alternative approach is to compare the response of participants to different outcome allocations after another participant has made a kind or unkind act to the response when there is no initial move by another participant (Charness and Rabin, 2002). Reciprocity is identified by the subtraction of the first outcomes and intentions experiment from the second baseline inequality-aversion experiment.

In the trust (or investment) game, a first mover decides how much to send to a second mover. Any amount sent is multiplied by k>1 before it reaches the second-mover. The second mover then decides how much to send back. Because of the multiplication, sending money is socially efficient yet a first mover should send money only if she trusts the second mover to send back at least enough to cover the investment. The standard interpretation is that the first mover must expect the second mover to be motivated by reciprocity before it makes sense to invest in the partnership (Berg, Dickaut and McCabe, 1995). However, one can just as easily invoke inequality aversion to explain the fact that people tend to send back more when they receive more (Cox, 2004). The same problem exists with the related experiments developed to test for the notion of gift exchange in the labour market context (for example, Fehr and Schmidt, 1999).

Other, more indirect, evidence for reciprocity and the more nuanced definition of social preference comes from the experimental literature on voluntary contributions to public goods. In these settings participants are given an endowment and asked to decide how much to contribute to a ‘group project’. The incentives are of a social dilemma; contributing nothing is a dominant strategy but contributing everything is socially efficient. Playing the public goods game in strategic form asks participants to decide how much they want to contribute conditional on the contributions of others. Half the participants are conditionally cooperative in that they generate contribution schedules that are increasing in the contributions of others (Fischbacher, Gächter and Fehr, 2001). The fact that people condition their contributions according to those of others suggests that intentions and reciprocity matter.

To identify reciprocity separately from inequality aversion one may employ a design in which the two forces pull in different directions. Imagine that one can punish free riders in the public goods game: a participant can impose a penalty p at a cost c. In most cases people punish despite it being dominant to free ride on the punishment done by others (that is, punishment is just a second-order public good), and this tends to stabilize contributions (Fehr and Gächter, 2000). However, in most cases p>c, which means cooperators reduce the inequality between themselves and the free rider by punishing. To isolate the role of, in this case negative, reciprocity one can allow p<c, which actually increases the inequality. Although they do it less often, people punish when the sanction delivered is lower than the cost, and this is a nice demonstration of reciprocity (Carpenter, 2007).
Several attempts have been made to organize the evidence on social preferences into parsimonious, but flexible, utility functions. One of the most successful outcome-oriented approaches is the Fehr and Schmidt (1999) specification, perhaps because it is relatively easy to work with. Here the utility of player $i$ increases in her own payoff, $x_i$, but decreases in any difference between her payoff and the payoffs of other relevant players. For two-player games this is just:

$$u_i(x_i, x_j) = \begin{cases} 
    x_i - \alpha_i (x_j - x_i) & \text{if } x_i < x_j \\
    x_i - \beta_i (x_i - x_j) & \text{if } x_i \geq x_j
\end{cases}$$

where $\alpha_i$ is player $i$'s degree of inferiority aversion and $\beta_i$ is her degree of superiority aversion. It is natural to expect $\alpha_i > \beta_i$.

While this utility function is a good first approximation because it has been shown to be consistent with much of the experimental data (if one is willing to make assumptions about the distribution of $\alpha$'s and $\beta$'s in the population) it is limited in two ways. First, as one can see in Figure 1, the predictions can be coarse. It is not hard to graph the indifference curves associated with the Fehr–Schmidt specification, but if one superimposes a budget constraint on the indifference mapping there are just two predictions: keep it all or give away half unless the constraint has exactly the same slope as the indifference curve, in which case any amount between nothing and half is possible.

The fact that intentions play no role is a second problem faced by all the outcome-oriented approaches. A trade-off does, however, exist because incorporating intentions makes the specifications considerably harder to work with. The outcome- and process-oriented specifications evolved from the notion of *psychological games*, which posits that utility will
depend on both outcomes and beliefs (Geanakoplos, Peurce and Stacchetti, 1989). Beliefs are important because emotional responses are often triggered by expectations about how one should be treated. Perhaps the specification that is easiest to work with is the Charness–Rabin utility function, which incorporates a term $\theta q$ to capture reciprocal motivations:

$$u_j(x_i, x_j) = (\rho r + \sigma s + \theta q)x_j + (1 - \rho r - \sigma s - \theta q)x_i.$$ 

The parameters $r$ and $s$ indicate which of the two players has the advantage ($r=1$ if $x_i > x_j$, $s=1$ if $x_j > x_i$ and $r=s=0$ otherwise) and the parameters $\rho$ and $\sigma$ represent outcome-oriented preferences (Charness and Rabin, 2002). To recover the Fehr–Schmidt specification we simply assume $\sigma < 0 < \rho < 1$ and $\theta = 0$. Reciprocity and intentions are at work if $\theta > 0$ because we set $q=-1$ if player $j$ has misbehaved and $q=0$ otherwise.

Why should economists care about social preferences? By ignoring social preferences, economists have incompletely characterized many important interactions (Fehr and Fischbacher, 2002). Because many people are motivated by notions of fairness and reciprocity, social preferences can hinder the dynamics of competition that are assumed to drive equilibria, especially in the context of labour markets. For example, wages may never fall to the competitive equilibrium level because bosses understand that workers are reciprocally motivated. By lowering the wage, the boss also lowers morale and productivity (Bewley, 1999). Likewise, the economic theory of collective action is only narrowly applicable because it fails to realize that most people are predisposed to cooperate, but hate being taken advantage of (Andreoni, 1988). Designing incentives is ultimately more challenging when one accounts for the heterogeneity of social motivations identified in economic experiments.

Future research on social preferences is likely to extend in a number of interesting directions. Experimenters have begun to move from the laboratory to the field to identify the preferences of more representative samples and to investigate the external validity of these preferences (that is, what important behaviours and outcomes do social preferences correlate with?). Within the laboratory it will be interesting to better isolate the role of outcomes versus the role of intentions, to examine the co-evolution of preferences and institutions, and to examine the difference between social preferences and social norms. Is it the case, for example, that norms dictate how one should treat others regardless of whether the prescribed behaviour is consistent with one's underlying preferences?

Social Security in the United States

Selahattin •mrohorol•lu

Abstract

Social Security is a pay-as-you-go US federal government programme that provides pensions for retirees and their surviving family members. It is a public annuity that insures against longevity and stock market risks. The payroll tax that finances it discourages private saving and work effort. The projected aging of the US population will strain the programme and necessitate either a reduction in benefits, an increase in payroll taxes, partial privatization, or some combination of these policy reforms, by 2030.

Article

Social Security is a US federal government programme that provides retirement, survivors, and disability benefits for eligible workers and their dependents. It is largely a pay-as-you-go (PAYG) tax-financed system; current workers are taxed and these revenues are used to finance the old age, survivors (widows, widowers, surviving divorced spouses, surviving children, and parents of deceased qualified workers), and disability insurance payments. Health insurance for the elderly is administered separately in another federal programme called Medicare. Retirement, survivor and disability benefits are financed by Old Age, Survivors, and Disability Insurance (OASDI) taxes, and Medicare is financed by Health Insurance (HI) taxes. In addition to the Social Security Disability Insurance, there is Supplemental Security Income that pays benefits based on financial need. Health insurance for the poor, regardless of age, is called Medicaid, and this is financed jointly from general federal tax revenues and the states.

Eligibility and coverage
As of 2007, nearly 150 million US workers and their dependents are covered by this compulsory system. (Among the few workers who are exempted from Social Security are federal civilian workers hired prior to 1984, some state and local government workers, and household, agricultural, and self-employed workers whose earnings are too low.)

There are about 40 million retirees and survivors drawing benefits from the system. Eligibility for full retirement benefits typically requires working for ten years, although early retirement at age 62 is possible with reduced retirement benefits. The normal retirement age is currently 66, set to rise to 67 by the time the 1960 cohort retires with full benefits in 2027. Retirement benefits are about 40 per cent of lifetime average earnings of a median wage earner. High-wage earners get less than this average replacement rate and low-wage earners get more than 40 per cent. Up to an additional one-half of the retired worker's full benefits may be paid to a spouse if the spouse has not worked or has low earnings. Under certain conditions, a divorced spouse can also get benefits if the marriage lasted at least ten years. If there are children eligible for Social Security, each receives up to 50 per cent of full benefits, with a maximum of 150–80 per cent of a worker's own benefit payments as a family limit. (For details and the separate Disability Insurance program, see http://www.ssa.gov.)

The tax rate for OASDI in 2007 is 12.4 per cent, paid equally by the employer and the employee (or entirely if the individual is self-employed). There is no tax on earnings over $90,000 in 2005 dollars, with this maximum rising every year by the national average wage index. (The HI tax rate is 2.9 per cent on all earnings.)

A private retirement fund is typically invested in a portfolio of stocks, commercial paper, and government bonds. Social Security is largely a PAYG system with current taxpayers paying for current retirees’ benefits. Since the mid-1980s, Social Security has collected more in taxes than it pays in benefits. This surplus is loaned to the US Treasury in return for special-issue Treasury bonds that are used to finance other federal government expenditures. This Trust Fund stood at $1.8 trillion at the end of 2006. Although this sum seems quite large, it is actually quite small compared with the annual OASDI benefits which amounted to $461 billion in 2006. (This sum does not include Disability Insurance payments, which amounted to $91 billion in 2006.)

A short history of social security

In 1889, Germany became the first country to provide old-age insurance on a large scale. Designed by the Chancellor, Otto von Bismarck, the German system required mandatory participation, taxed the employer and the employee, and used government taxes to provide retirement and disability benefits. The retirement age was 70, though it was lowered to 65 in 1916.

In the United States, the German system was viewed as a model. In 1935 The Social Security Act, which covered workers in commerce and industry, was signed by President Roosevelt. The original proposal and draft legislation, the Economic Security Act, was a three-tiered social pension programme: (a) old-age welfare payments, (b) mandatory, contributory old-age retirement programme, which evolved into what is now called Social Security, and (c) voluntary annuity sales through which the federal government would sell certificates to workers who could, upon reaching the retirement age, convert them into monthly annuities to supplement their basic compulsory retirement benefits. However, the Congress rejected this third proposal by President Roosevelt, which was the earliest attempt to allow for

a private saving programme for retirement with mandatory annuitization at retirement.

Since 1935, many changes were made to the original 1935 act. In 1937, workers were required to pay two per cent of their payroll to support the Social Security system. In 1939, the programme started to cover dependents and survivors. In 1950, coverage was extended beyond commerce and industry, the tax rate was raised to three per cent and benefits were also raised. In 1956, the tax rate was raised to four per cent and disability insurance was introduced. Early retirement for women was permitted in 1956 and for men in 1961, when payroll taxes were raised to six per cent. In 1972, cost-of-living-adjustments (COLAs) were introduced, automatically indexing benefit levels to inflation, and payroll taxes were raised to 9.2 per cent. In 1977, the tax rate jumped to 9.9 per cent.

In 1983 the National Commission on Social Security Reform was formed to suggest ways to deal with the actuarial imbalance of the system. The commission proposed (a) a phased-out increase in the retirement age from 65 to 67, (b) an increase in the self-employment tax, (c) partial taxation of benefits to upper income retirees, and (d) expanding the coverage to include federal civilian and non-profit organization employees. The tax rate was raised to 10.8 per cent. The payroll tax rate was raised to 11.4 per cent in 1985 and to 12.4 per cent in 1993. In 1996 the Social Security Trustees (1996) reported that the Social Security system would start to run deficits in 2012, and the trust funds would be exhausted by 2029. They predicted that, in order to keep the benefit levels unchanged, the tax rate would have to rise to 18 per cent.

The simple economics of social security

A simple textbook treatment will be presented here. For a more rigorous treatment of social security and overlapping generations models, the reader should see the seminal papers by Samuelson (1958) and Diamond (1965). For a recent and thorough coverage, see Ljungqvist and Sargent (2005).

Consider a simple overlapping generations model in which individuals live for two periods. Their earnings are $y$ when young, and 0 when old. They face a social security tax $\tau > 0$ when young and receive a retirement benefit $b$ when old. They earn interest on their saving, $s$ at the rate $r$. There is no uncertainty. The economy is assumed to have perfectly functioning credit markets that allow individuals to borrow any amount at the market rate of interest $r$. Population grows at the rate $n > 0$, and productivity (and hence real income) grows at the rate $g > 0$. The lifetime utility function of the individuals is given by

$$\log(c_1) + \beta \log(c_2)$$

(1)

where $c_1$ and $c_2$ are consumption when young and when old, respectively, and $\beta > 0$ is the subjective discount factor. The budget constraints faced by the individuals are given as

$$c_1 + s = y$$

(2)

We can write the lifetime budget constraint facing the agents in present value form

\[ c_1 + \frac{c_2}{(1 + r)} = y + \frac{b}{(1 + r)}. \]  

(4)

The social security system is unfunded, which requires that taxes collected from the young equal benefits given out to the retirees at each period:

\[ b = (1 + g)(1 + n)\tau y. \]  

(5)

The Lagrangian for the individuals' optimization problem is given by

\[ L = \log(c_1) + \beta \log(c_2) + \lambda \left[ y + \frac{b}{(1 + r)} - c_1 - \frac{c_2}{(1 + r)} \right], \]  

(6)

where \( \lambda > 0 \) is the Lagrange multiplier. The first-order conditions for maximizing the Lagrangian with respect to the choice variables \( c_1 \) and \( c_2 \) (and \( \lambda \)) yield optimal lifetime consumption quantities as

\[ c_2 = (1 + r)s + b. \]  

(3)
The second-order conditions are satisfied given our choices of functional forms and parameter restrictions. Using eqs (2), (3) and (8), we obtain the individual's private saving under social security as

\[ c_1 = \frac{(1 + r)(1 - \tau) y + b}{(1 + r)(1 + \beta)}, \quad \text{and} \]

\[ c_2 = \frac{\beta(1 + r)(1 - \tau) y + \beta b}{(1 + \beta)}. \]

Equations (9) and (10) show that the introduction of an unfunded social security system reduces private saving. The productive capital stock in an economy is determined to a large extent by private saving, and therefore an unfunded social security system results in a lower capital stock and per capita consumption. (If factor prices were determined by the capital–labour ratio, then the general equilibrium effect would be to mitigate the reduction in private saving as the return to capital would rise in response to the decrease in private saving. However, the direction of the change in saving is still the same, and, in quantitative versions of the life cycle model, the magnitude of this effect is quite large. Also, if labour were endogenous, one could show that a public pension system with no linkage between contributions...
What is the impact on the individual's lifetime welfare? To address this issue, we need to compare the lifetime consumption values with and without social security. Substituting eq. (5) into eqs (7) and (8) yields

\[ c_1^{ss} = \frac{(1 + r) \gamma - \tau \gamma[(1 + r) - (1 + g)(1 + n)]}{(1 + r)(1 + \beta)}, \]

(11)

\[ c_2^{ss} = \frac{\beta(1 + r) \gamma - \beta \tau \gamma[(1 + r) - (1 + g)(1 + n)]}{(1 + r)(1 + \beta)}, \]

(12)

where \( c_1^{ss} \) and \( c_2^{ss} \) denote young- and old-age consumption under social security. Imposing \( \tau = 0 \) and \( b = 0 \), and using \( c_1^{lf} \) and \( c_2^{lf} \) to denote young- and old-age consumption under laissez-faire, eqs (11) and (12) become

\[ c_1^{lf} = \frac{(1 + r) \gamma}{(1 + r)(1 + \beta)}, \]

(13)

\[ c_2^{lf} = \frac{\beta(1 + r) \gamma}{(1 + r)(1 + \beta)}. \]

(14)

Given our assumptions on the parameters,
In other words, unfunded social security yields lower young- and old-age consumption to the individual if the rate of return on capital, $1+r$ exceeds the rate of growth of the economy, $(1+g)(1+n)$. Historically, the annual growth rate of the US economy has been just under three per cent on average, whereas the return on capital has exceeded this amount significantly, by about two to five percentage points, depending on alternative definitions of the capital stock. (The condition presented in eq. (15) is known as the condition for dynamic efficiency. If the reverse were true, then a reduction in saving would reduce the dynamic inefficiency – or capital overaccumulation – in the economy and improve welfare by raising consumption in both periods.) In fact, reform proposals in the early 21st century to partially privatize social security aim to exploit this return differential in order to build up private retirement funds for old-age consumption.

Pros and cons of unfunded social security

As the previous section demonstrates, the most important welfare cost of an unfunded social security system is that it discourages private saving and the accumulation of capital. There are other social costs associated with a PAYG system, as well as several social benefits. In this section, these costs and benefits will be listed and the empirical evidence about their quantitative importance will be evaluated.

Welfare costs

1. Unfunded social security discourages saving. Young workers with high marginal propensities to save are taxed, and these resources are given to retirees, with low marginal propensities to save.
2. It discourages work effort since the payroll tax paid by the worker has less than perfect linkage, if any, with the retirement benefit that the worker will receive. The labour supply in the economy is adversely affected and so is the demand for labour as firms are reluctant to create new jobs.
3. It distorts the retirement decision and encourages early retirement.
4. It imposes a hardship on workers and companies that are facing borrowing and credit constraints. Removing the high payroll taxes devoted to this mandatory retirement system would bring welcome relief to a large number of households and firms.

Welfare benefits

1. Unfunded social security provides longevity insurance. If an individual lives longer than expected, an annuity that provides for old-age consumption is welfare-enhancing. (Yaari, 1965,
showed that in a simple two-period overlapping generations model rational individuals without an altruistic motive would find it optimal to annuitize all their wealth. However, the annuity markets in the United States are thin. Indeed, Friedman and Warshawsky, 1990, and Mitchell et al., 1999, document that private annuities are unattractively priced in the United States and that the adverse selection problem likely contributes to the low volume of these contracts. See also Feldstein, 2005, for an excellent survey of issues surrounding social security.

2. 2. It provides insurance against (privately uninsurable) income shocks over the life cycle.
3. 3. It serves as a partial substitute for a commitment device for individuals with time-inconsistent preferences.
4. 4. It insulates the individuals to a large extent against aggregate shocks such as stock market risks.

Empirical evidence

Auerbach and Kotlikoff (1987) presented one of the earliest attempts at using a large-scale overlapping generations framework to address fiscal policy effects in a calibrated, general equilibrium setting. In their model, social security did not have any potential benefit and it imposed a deadweight loss on the society. Hubbard and Judd (1987) introduced the longevity insurance aspect of social security, but still the negative impact of social security on saving outweighed this potential benefit. mrohoro lu, mrohoro lu and Joines (1995; 1999) consider variations of the earlier quantitative models but they arrive at the same conclusion.

Diamond (1977) and Feldstein (1985) argue that a fraction of the population might lack the foresight to save for retirement. However, mrohoro lu, mrohoro lu and Joines (2003) use Strotz’s (1956) time-inconsistent preferences to evaluate the welfare benefit of an unfunded social security system in a quantitative model that includes most of the costs and benefits of social security listed in the previous section, and find that social security is a poor commitment device and that individual’s welfare is not increased unless for relatively high (and implausible) degrees of short-term discount rates.

Despite the widespread quantitative evidence on the inefficiency of social security, the institution seems resistant to reform. One reason may be due to potentially large transitional costs of privatizing the system. For example, Conesa and Krueger (1999) find large transitional costs, with a majority of the currently alive population suffering welfare losses, and thus blocking any reform proposal. Fuster, mrohoro lu and mrohoro lu (2007), on the other hand, argue that these transitional costs are easily paid for by a growing economy with strong bequest motives and flexible labour markets. Cooley and Soares (1999) and Boldrin and Rustichini (2000) study the political-equilibrium considerations that allow the introduction and maintenance of an unfunded social security system. Krueger and Kuebler (2006) introduce aggregate uncertainty in the form of ‘investment risk’ but still find that the capital crowding-out effect dominates and social security reduces welfare.

The future of social security

Notwithstanding the economic burden of PAYG systems, as the previous section summarizes, the future
holds much worse predictions for OECD countries. Without exception, all social security programmes are facing financing difficulties, due to significant increases in longevity and the decline in fertility. Most European countries and Japan are aging very rapidly. The United States is not far behind. The ratio of the number of retirees to the number of workers, the so-called dependency ratio, was near 20 per cent in 2000, but is expected to rise to almost 50 per cent in 2060, meaning only two workers per retiree.

To get an idea of how much of a strain the aging of the US population puts on the current pension system, consider the following two findings from De Nardi, •mrohorolu and Sargent (1999). First, responding to a proposal to index retirement age to the increases in longevity so that the dependency ratio is held constant at the current level of 20 per cent, they calculate that the retirement age has to eventually rise to 76. Second, maintaining retirement benefits at their current levels when the population is aging (and the costs of medical services are rising) requires an increase in the Social Security payroll tax rate from its current level of about 10 per cent to an eventual 40 per cent. If a reform is not undertaken, even these high tax rates will not be enough to pay for pensions in the future.

Social status is a social reward that affects the incentive structure facing individuals. If status is provided to educated people, more people will obtain an education. The choice of occupation is affected by the social status associated with different occupations, establishing a link between social status, the equilibrium wage structure and the allocation of workers among occupations. When status is not directly observed, people try to signal it by changing their consumption choices or behaviour. The narrow paradigm of *homo economicus* should be extended to include social status among the basic motivations for economic decisions.

People are social animals who care about their standing in society and about what other members of society think about them. Stated differently, people care about their ‘prestige’ or the ‘respect’ that they are accorded by individuals with whom they interact. Many people would gladly pay large sums of money for a knighthood. Similarly, the value of the Nobel Prize lies not entirely in the monetary prize itself; hence, we would not be surprised to find that many people might actually be willing to pay to obtain this prize. These observations on human nature are far from new. Hobbes, for example, wrote that: ‘Men are continuously in competition for honour and dignity’ (cited in Hirschman, 1973, p. 634). While the focus of traditional economics has been on the monetary rewards that are exchanged through a market mechanism, sociologists have stressed social status and other social rewards as important motivations for human behaviour. The term ‘social status’ was first introduced by Max Weber as ‘an effective claim to social esteem in terms of negative or positive privileges’ (Weber, 1922, p. 305).
One of the important factors that distinguishes societies and determines their success is the form of the incentives they provide to their members. Generally speaking, there are three broad types of such incentives: (a) private monetary rewards, such as wages and profits; (b) social rewards including status and prestige; and (c) rules, laws and regulations that enforce certain types of behaviour while penalizing others. Societies may differ in the mix of incentives and rules that they employ. This mixture has a significant effect on economic performance. Social status is thus part of the incentive structure provided to individuals in every society. These incentives affect an individual's choice of actions, occupation, education level and so forth. They thus are of significant economic importance (see also the review in Weiss and Fershtman, 1998).

If prizes, knighthoods and other status symbols were up for sale like any other commodity, their value would be deflated. The value of a medal, award or title will be small if it were obtainable by many people. Thus, the value of status symbols depends on the allocation rule that determines who is eligible to receive a particular symbol, who is excluded from eligibility, and the number (and certainly the identity) of its recipients. This property distinguishes social status from economic rewards. Giving a medal to one individual (may) reduce the medal's value for another individual. Social status may thus be viewed as the ranking of individuals, or groups of individuals, in society. This ranking may be based on personal attributes, actions, occupations or group affiliations. Yet, by definition, if someone climbs up in rank, someone else climbs down.

Ranking matters only if people agree on how ranking is established. For social status to matter, a society must generally agree about the relative position of its members. The crucial feature of social status is that it ‘rests on collective judgement, or rather a consensus of opinion within a group. No one person can by himself confer status on another, and if a man's social position were assessed differently by everybody he met, he would have no social status at all’ (Marshall, 1977, p. 198). An interesting – and relatively unexplored – issue is the role of social status in a multicultural society where every group maintains its own ranking, each of which may be affected by different characteristics. Fershtman, Hvide and Weiss (2006) have shown that the gains made from (social) trade in a culturally diverse society can be translated into higher output and wages.

The categories comprising social status are diverse. We can distinguish between ‘status group’ and ‘individual status’. In the first category, originally conceived by Weber, social status is obtained by affiliation with a group, be it a social class, profession, club, and so on. Members of the status group share a similar status. In the second category, social status is obtained through individual attributes or actions. One should also distinguish between status that is acquired through specific actions or group affiliation and status that has been inherited. People may have social status simply by being born into an aristocratic class. The specific structure for gaining and maintaining status thus plays an important role in determining its effect on the economy.

One of the major problems in incorporating social status into economic models is that it is not directly observed. How do we measure status? How do we identify the ranking that determines who is perceived as important and who is not? And how do we quantify this ranking? Another task necessary for modelling is identification of the variables that affect social status. What determines social status in different societies? Conducting surveys by asking people to rank occupations according to their ‘prestige’ or to state which of the individual's attributes affects his or her social status has been the accepted method for responding to these questions. Treiman (1977), for example, found that the ranking of occupational status is stable over time and similar in different societies. Moreover, status rank has
social status, economics and - The New Palgrave Dictionary of Economics

been found to be systematically dependent on occupational attributes; that is, occupations requiring high levels of education and providing high income also confer high social status.

Social status and consumption

Individuals may use consumption choices to signal that they have properties that affect their social status. The most familiar form of such signalling is ‘conspicuous consumption’, a signal relevant whenever relative wealth is a factor in determining social status. Yet the quest for social status may affect other consumption choices as well. For instance, individuals may buy and display books or go to the theatre to signal the level of education they have obtained. They may join clubs, buy a house or hire a maid if such actions signal their desired status.

The concept of ‘conspicuous consumption’ was first introduced by Veblen (1899), who argued that individuals often consume highly attention-getting goods and services in order to signal their wealth and thereby achieve greater social status. ‘In order to hold the esteem of men it is not sufficient merely to possess wealth or power. The wealth and power must be put in evidence, for esteem is awarded only on evidence’ (Veblen, 1899, p. 36). The extreme form of such behaviour is known as the ‘Veblen effect’, witnessed whenever individuals are willing to pay higher prices for functionally equivalent goods (for a discussion, see also Leibenstein, 1950, and Frank, 1985a, 1985b). The Veblen effect may indeed be empirically significant in some luxury good markets (see Creedy and Slottje, 1991; Heffetz, 2004).

Veblen distinguished between (a) ‘invidious comparison’ – whenever an individual from a higher class consumes conspicuously to distinguish himself from an individual from a lower class, and (b) ‘pecuniary emulation’ – whenever an individual from a lower class consumes conspicuously to imitate a member of the upper class. Bagwell and Bernheim (1996) used a signalling model to investigate the conditions under which the Veblen effect may result from the desire to signal wealth (see also Ireland, 1994).

Conspicuous consumption may lead to excessive consumption and suboptimal saving but this conclusion depends on the specific details and timing of the ‘conspicuous consumption race’. As Corneo and Jeanne (1996) have shown, if the signalling is typically done late in the life cycle, conspicuous consumption may actually encourage saving.

Letting social status be determined by relative wealth may help to explain some of the puzzles we observe in human behaviour. The empirical evidence indicates that saving continues in old age and hardly declines with wealth. These observations imply that saving behaviour cannot be explained solely by consumption motives. Status concerns derived from relative wealth may provide some explanation of this phenomenon.

It is important to note that the striving for social status is not the only explanation for conspicuous consumption. Such behaviour may also signal professional success or ability. Simply think about a situation in which you need to choose a lawyer without any knowledge about the candidates’ ability. Often a lawyer's dress, the car she drives or how her office is decorated may affect your choice whenever these items may signal ability or success.

Status and the labour market

Some professions enjoy higher status than others. For example, in most countries, being a physician yields a higher status than being a butcher. In such cases, simply belonging to a profession, and not the individual’s characteristics, is rewarded by the relevant professional status. Consequently, individuals choose their occupations not just according to the wages they will be paid but also according to the status associated with that occupation. However, at equilibrium, wages are also affected by the quest for status. Adam Smith, in *The Wealth of Nations* (1776), was the first to state the argument of compensating wage differences by pointing out that: ‘Honour makes a great part of the rewards of all honourable professions. …The most detestable of all employment, that of a public executioner, is, in proportion to the quantity of work done, better paid than any common trade whatever’ (Book I, ch. X). Still, no empirical evidence has been found supporting the phenomenon of high status being associated with low wages, because to do so one would need to control for ability, which is not directly observable. Status concerns may also explain some degree of wage rigidity. Unemployed individuals are often reluctant to accept temporary but low-paid jobs because doing so implies a loss of status (see Blinder, 1988). On the other hand, immigrants are less reluctant to apply for low-status jobs; they tend to stress wages over occupational status partly because their reference group is new immigrants and not the wider society.

The workplace itself is a venue for social interaction. Relative wages may be important in forming ‘local’ status at the firm level. The willingness of workers to exert effort may be affected by social rewards. When workers are concerned with their ‘local’ status, wage inequality across firms will tend to exceed wage inequality within firms. Within each firm, productivity differentials will exceed wage differentials as some reward is derived from higher status (see Frank 1984a, 1984b; for empirical and experimental evidence for the relevance of wage comparisons, see Clark and Oswald, 1996, and Zizzo and Oswald, 2001).

**Social status and growth**

The great variability in growth across different economies is a major puzzle for economists. While most of the literature offers an economic explanation for this phenomenon, others claim that some of the variation can be attributed to cultural factors. Social status affects growth primarily by affecting individuals’ choices of occupation, investment and education. For example, it has been argued that contempt for entrepreneurs and the high status of the idle gentleman in 19th-century England were the main causes for its economic decline during that period (see Wiener, 1981).

A common feature of recent growth models is the existence of externalities associated with human capital or certain occupations. Each worker, when choosing his level of schooling or occupation, ignores the impact of his choice on overall economic performance. Whenever social status is attached to such activities or occupations, it can be perceived as a corrective mechanism. Baumol (1990) emphasizes the role of social status or social prestige associated with ‘non-productive’ (rent-seeking) activities versus ‘productive’ activities. The implications are simple: a status structure that awards higher status to ‘productive’ activities is conducive to growth. Fershtman and Weiss (1993) used a simple general equilibrium model in which wages and social status are determined endogenously to show that changes in the demand for status, triggered by changes in preferences, may affect growth rates. But status has a collective nature and may be determined endogenously by the type of people who
choose each occupation or profession. The drive for status may thus be counter-productive and induce an inefficient allocation of talent among the different occupations. A large emphasis on status may encourage the ‘wrong’ individuals – those with low ability and great wealth – to choose a ‘productive’ occupation or acquire schooling, thereby forcing workers with high ability but little wealth to leave growth-enhancing occupations. This crowding-out effect may, by itself, discourage growth (see Fershtman, Murphy and Weiss, 1996).

Social status as a corrective mechanism

It has long been recognized that activities that generate externalities but cannot be priced are not efficiently regulated by private rewards. It was Arrow (1971) who initially suggested the role of social rewards as a mechanism designed to resolve the inefficiencies arising from externalities (see Elster, 1989, for a critical view for this approach). According to Arrow, an individual who chooses an action or occupation that produces positive externalities is appreciated by other members of the society and obtains social status, whereas an individual who produces negative externalities is treated with contempt (or a negative social status). The use of such a social mechanism is appealing as it implies that the problem of market inefficiencies due to externalities can be resolved or diminished. On the other hand, the use of social rewards is limited in itself and as a corrective mechanism. As mentioned previously, a profusion of medals reduces their value – a property that limits the scope of their use.

Social status and the evolution of preferences

While most economists are sympathetic to the idea that the concern for social status is an important aspect of human decision-making, they remain reluctant to incorporate this variable into mainstream economic modelling. The ruling paradigm of *homo economicus* is that of an individual whose utility depends on his consumption bundle and who makes employment decisions based on the wages to be received for performing a particular job. For sociologists, the dominant paradigm is that of people who, as social animals, wish to maximize their standing in society.

The reluctance to incorporate status concerns into the utility function is rooted in the assumption that models including this variable often allow too broad a range of behaviour and thus ultimately display little predictive power (for more on this view see Postlewaite, 1998). The debate centres on whether status concerns are a ‘direct effect’, reflecting the fact the people are (also) social animals, or an ‘indirect effect’, meaning that people care about social status because status affects the goods and services that they and their children will consume (for an illustration of the indirect approach, see Cole, Mailath and Postlewaite, 1992).

Incorporating preferences for status as ‘hard-wired’ into the utility function raises the question of why people (or other animals) have ingrained preferences for social status. One approach to dealing with the issue, common in economics, is not to deal with the formation of preferences. Social biologists have adopted a different approach. They argue that feelings and social concerns are hard-wired in human actors; moreover, concerns that increase fitness tend to be more common. Fershtman and Weiss (1998a; 1998b) applied an evolutionary approach and showed that caring about social status can be part of stable evolutionary preferences.

Abstract

The article deals with the related, though distinct, notions of a social welfare function due to A. Bergson and P. Samuelson on the one hand and K.J. Arrow on the other. After introducing the two formal concepts, it gives a brief outline of Arrow’s well-known impossibility theorem, considers some alternative intuitive interpretations of the notion of a social welfare function, and discusses the informational bases of social welfare judgements.

Article

The concept of a social welfare function is central in welfare economics, the branch of economics that explores the implications of various ethical criteria for deciding what promotes social welfare, what public policies the society should choose, and so on. It was first introduced by Bergson (1938), and was subsequently elaborated by Samuelson (1947). A related, though not identical, notion with the same name was introduced by Arrow (1951); as we shall see below, Arrow's interpretation was different from Bergson's earlier concept. The technical literature on the social welfare function is large. The following discussion will, however, focus mainly on conceptual issues relating to the social welfare function.

The basic notation

Consider a given society consisting of individuals 1, 2, …, n, with X a given set of alternative social
social welfare function: The New Palgrave Dictionary of Economics states. For our purpose, a social state can be thought of as a complete description of all ‘relevant’ aspects of the state of affairs prevailing in society, but one can also use more limited interpretations of a social state. An element of $X$ can be thought of as a vector, each component of the vector representing some particular feature of the state of society. The elements of $X$ will be denoted by $x, y, z$, and so forth. Each individual $i$ is assumed to have a preference ordering (‘at least as good as’) defined over $X$ (an ordering over $X$ is defined to be a binary relation $T$ over $X$ such that $T$ is reflexive (for all $x$ in $X$, $xTx$), connected (for all distinct $x$ and $y$ in $X$, $xTy$ or $yTx$), and transitive (for all $x, y$, and $z$ in $X$, if $xTy$ and $yTz$, then $xTz$)). Such a preference ordering will be denoted by $R_i$, $R'_i$, and so on. An n-tuple of preference orderings over $X$, with the preference ordering of each individual figuring exactly once in the n-tuple, will be called a preference profile. For all social states $x$ and $y$, and for every individual $i$, $[xP_iy$ if and only if $xR_iy$ and not $yR_ix]$ and $[xI_iy$ if and only if $xR_iy$ and $yR_ix]$. Intuitively, $P_i$ denotes the strict preference relation for individual $i$ and $I_i$ denotes the indifference relation for individual $i$. $R, R'$, and so forth will denote social weak preference relations (‘socially at least as good as’) over $X$. Thus, $xRy$ will denote that $x$ is at least as good as $y$ for the society. Given a social weak preference relation $R$, one can define $P$ (‘socially better than’) and $I$ (‘socially indifferent to’) in terms of $R$ in the same way as $P_i$ and $I_i$ are defined in terms of $R_i$.

The Bergson–Samuelson social welfare function

The Bergson–Samuelson social welfare function (SWF (BS)) is a function $W$ that specifies exactly one real number, $W(x)$, for each social state $x$ in $X$. The intended interpretation is this: for all $x$ and $y$ in $X$, $W(x) \geq W(y)$ denotes that $x$ offers at least as high a level of social welfare as $y$, and similarly for $W(x) > W(y)$ and $W(x) = W(y)$. $W(x)$, $W(y)$, and so on are thus ordinal indices of social welfare attached to social states. What determines the form of the function? For example, what determines whether $x$ should be assigned a higher number than $y$ or $y$ should be assigned a higher number than $x$? This, as both Bergson (1938) and Samuelson (1947) pointed out, will depend on the value judgements that we use. It is not surprising that very little can be done with the mathematical notion of an SWF (BS) at this level of generality. Even then, the abstract notion, by itself, makes one thing clear: if one wants to say anything specific about social welfare, one must introduce explicit value judgements.

Specific conclusions emerge from the Bergson–Samuelson social welfare function as one introduces additional value judgements that restrict the form of the function. Thus, assuming that each individual has an (ordinal) utility function $U^i$ defined over $X$, Samuelson considers an ‘individualistic’ form for SWF (BS) where the social welfare indices attached to social states depend exclusively on the individual utilities, so that one can write the SWF (BS) as

$$W = F(U^1, \ldots, U^n) \quad \text{(1)}$$
Assuming further that social states are simply allocations (a specification of the quantity of each commodity figuring in each consumer's consumption bundle and the quantity of each commodity figuring in each producer's production plan), $F$ is increasing in $U^1, U^2, \ldots,$ and $U^n$, and each consumer's utility depends only on her consumption bundle, Samuelson (1947, pp. 229–49) derived conditions for the maximization of social welfare subject to the relevant resource constraints and technological constraints of the society.

**Arrow's social welfare function**

Arrow (1951) introduced a somewhat different concept of a social welfare function (SWF (A)). An SWF (A) is a functional rule $G$, which, for every possible preference profile, $(R_1,\ldots,R_n)$, belonging to a non-empty class of preference profiles, defines exactly one ordering $R$ over $X$. Thus, we write

$$ R = G(R_1, \ldots, R_n) \quad \ldots $$

(2)

The intuitive interpretation of $R$ figuring in this definition is that it represents the society's weak preference relation over social states, $R$ being constrained to be an ordering. Thus, an SWF (A) gives us a (unique) social ordering of all social states once the individuals’ orderings over the social states are given.

What is the relationship between the notion of an SWF (BS) and that of an SWF (A)? Suppose an SWF (BS) has the form given by (1), and suppose the utility functions $U^i (i = 1,2,\ldots,n)$ are ordinal so that they have no more significance beyond just the orderings that they, respectively, represent (recall that the Bergson–Samuelson social welfare indices are also ordinal). Then noting that, for every profile of real valued utility functions over $X$, we have Bergson–Samuelson social welfare indices for social states, such that the ordering implied by the social welfare indices does not change with a change in the profile of utility functions so long as the orderings implied by the utility functions do not change (see Samuelson, 1947, p. 228), we would have a unique social ordering over $X$ for every profile of individual orderings over $X$ and, hence, an Arrow-type social welfare function. Thus, underlying an SWF (BS) as given in (1), there is always an SWF (A). (The converse is not necessarily true since the social ordering $R$ of Arrow may not be representable by a real valued function over $X$.)

**Arrow's impossibility theorem**

If Arrow did not impose any restrictions on an SWF (A), then the definition, by itself, would be of no more substantive interest than just the definition of an SWF (BS) without any specific assumptions about the properties of the SWF (BS). Arrow, however, proceeded to introduce specific restrictions regarding the form of an SWF (A). He postulated that an SWF (A), $G$, must satisfy the following properties.

- **Universal Domain (UD):** the domain of $G$ must include every possible preference profile.
**Weak Pareto Criterion (WP):** for every profile of individual orderings, \((R_1, \ldots, R_n)\), in the domain of \(G\) and for all \(x\) and \(y\) in \(X\), if \(xP_iy\) for every individual \(i\), then \(xPy\).

The weak Pareto criterion, which is a weak version of the familiar Pareto principle, just says that, if every individual strictly prefers social state \(x\) to social state \(y\), then the social ordering must rank \(x\) higher than \(y\).

**Independence of Irrelevant Alternatives (IIA):** Consider any two profiles of preference orderings, \((R_1, \ldots, R_n)\) and \((R'_1, \ldots, R'_n)\), in the domain of \(G\) and any two social states \(x\) and \(y\). If, for every individual \(i\), \(xR_iy\) if and only if \(xR'_iy\) and \([yR_ix\) if and only if \([yR'_ix]\), then \([xRy\) if and only if \([xR'y]\) and \([yRx\) if and only if \([yR'x]\) where the social orderings \(R\) and \(R'\) correspond to the preference profiles \((R_1, \ldots, R_n)\) and \((R'_1, \ldots, R'_n)\), respectively.

IIA requires that, if the individual orderings change but everybody's ranking of a pair of social states remains unchanged, then the social ranking of those two social states must remain unchanged though the social ranking over other pairs of social states may change.

**Non-dictatorship (ND):** there does not exist any individual \(k\) such that for all social states \(x\) and \(y\) and for every profile of individual orderings \((R_1, \ldots, R_n)\) in the domain of \(G\), if \(xP_ky\), then \(xPy\).

ND just says that there should not be any individual such that, whenever she strictly prefers any social state \(x\) to any other social state \(y\), \(x\) must rank higher than \(y\) in the social ordering, irrespective of other people's preferences.

Arrow's (1951) famous impossibility theorem tells us that, if there are at least three social states in \(X\), then there does not exist any SWF (A) that simultaneously satisfies WP, IIA, and ND. The result has the flavour of a paradox since, prima facie, the properties postulated by Arrow for his social welfare function seem plausible. It may be useful to consider two examples to illustrate how Arrow's theorem 'works'. Consider first the simple majority rule (SMR) which says that, for every preference profile, \((R_1, \ldots, R_n)\), and for all \(x\) and \(y\) in \(X\), \(xRy\) if and only if the number of individuals who consider \(x\) to be at least as good as \(y\) is greater than or equal to the number of individuals who consider \(y\) to be at least as good as \(x\). While the SMR satisfies WP, IIA, and ND, it does not yield a social ordering for every preference profile. Thus, if we have three individuals, 1, 2, and 3, and three alternatives, \(x\), \(y\), and \(z\), then, for the preference profile such that \((xP_1y \& yP_1z \& xP_1z)\), \((yP_2z \& zP_2x \& yP_2x)\), and \((zP_3x \& xP_3y \& zP_3y)\), the SMR gives us \((xPy \& yPz \& zPx)\) which is not an ordering (this, in fact is the well known 'voting paradox'). Let us take a second example, the Borda rule, which for every preference profile specifies the social ordering as follows. On the assumption that \(X\) has \(m\) elements, if an individual places a social state \(x\) in the first position in his preference ordering, then \(x\) gets \(m\) points from him; if an individual places \(x\) in the second position in his preference ordering, then \(x\) gets \(m - 1\) points from him; and so on. (In stating the Borda rule, I have ignored the case where an individual may be indifferent between two social states. For a complete specification of the Borda rule, however, the assignment of points in such cases needs to be specified. A social state \(a\) is considered to be socially at least as good as a social state \(b\) under the Borda rule if and only if the sum of all the points received by \(a\) from all individuals is greater than or equal to the corresponding sum for \(b\). The Borda rule satisfies all the conditions of Arrow excepting IIA. To see that it violates IIA, let us consider the case where we have two individuals (1 and...
social welfare function: The New Palgrave Dictionary of Economics

2), three alternatives \((x, y, \text{and } z)\), and two preference profiles, \((R_1, R_2)\) and \((R'_1, R'_2)\) as follows:

\[
xP_1 y \& yP_1 z \& xP_1 z; \quad zP_2 y \& yP_2 x \& zP_2 x; \quad xP'_1 y \& xP'_1 z \& xP'_1 z; \quad zP'_2 x \& xP'_2 y \& zP'_2 y.
\]

Given the profile \((R_1, R_2)\), each of \(x\) and \(z\) receives a total of four points, and, hence, we have \(xI_z\), but, given the preference profile \((R'_1, R'_2)\), \(x\) receives a total of five points while \(z\) receives a total of four points, and hence, we have \(xP'\ z\). This violates IIA since the social ranking of \(x\) and \(z\) changes when we go from \((R_1, R_2)\) to \((R'_1, R'_2)\), though the ranking of \(x\) and \(z\) has remained the same for each individual.

An impossibility theorem such as Arrow's (1951) compels us to think what has gone ‘wrong’, which of the requirements are unreasonable, and which of the restrictions need to be discarded or modified to provide a way out of the impasse. In this brief article, I shall not explore these questions, which have been discussed in great detail in the large literature that followed Arrow (1951). Instead, I turn to some basic issues about how one is to interpret the notion of the social welfare function itself.

**Alternative intuitive interpretations**

Some important questions have been raised by a number of economists (see, for example, Bergson, 1954; Little, 1952; and Sen, 1977a) about the interpretation of a social ranking of social states, such as the social ordering yielded by Arrow's social welfare function and the ordering implied by the welfare indices given to us by a Bergson–Samuelson social welfare function.

It has been claimed by both Little (1952) and Bergson (1954) that the social ordering \(R\) figuring in Arrow's definition of a social welfare function is the result of an aggregation procedure or ‘constitution’ that aggregates a given profile of individual preference orderings reflecting the individuals’ judgements or opinions. In contrast, as Bergson pointed out, the welfare indices that come from his social welfare function were intended to reflect a given individual's personal value judgements about what was good for the society (in a somewhat similar fashion, Sen, 1977a, makes a distinction between committee decision and social welfare judgements). Arrow (1963) agreed that he did intend his social welfare function to be a constitution or a rule for aggregating people's opinions, but he claimed that such aggregation was, indeed, the central issue of welfare economics.

An example may be helpful in clarifying the distinction. Suppose someone, say, individual \(i\), says that a complete ban on smoking in all public places is better than a prohibition of smoking only in a few designated public places. Suppose, when asked to give the reason why he thinks so, he gives us as the reason the fact that 99 per cent of the population in the society have the opinion that a complete ban on smoking will be better for society. This may be a good enough reason if \(i\)'s original statement is a statement about how society should rank the two policies for the purpose of social action, given the existing opinions or judgements of the people. It is, however, possible that individual \(i\) made his original statement as his personal judgement about what would promote society's welfare. In that case, we would find his response to the request for justification a little strange: we would feel that he should give ‘independent reasons’ for his statement rather than referring to the judgements of other people.

Typically, in aggregating people's opinions or judgements through a ‘constitution’ or a committee decision procedure, we do not look into the basis of people's opinions; we take them as given and simply try to find out what will be a reasonable way of reconciling different opinions. In contrast, in forming
our personal social welfare judgements, typically we do not aggregate individuals’ opinions or judgements (in fact, we often question the basis of other people's judgements when they do not conform to our ethical beliefs), though we do take into account other people's well-being. Also, in our personal judgements about social welfare, we often compare the welfare losses or gains of one person with those of another, while, in aggregating opinions or judgements, we rarely take into account the strength with which one individual favours \( x \) over \( y \) with the strength with which another person favours \( y \) over \( x \) (see Sen, 1977a, p. 159).

Arrow (1963) sees the basic purpose of welfare economics as that of analysing procedures for aggregating individual opinions so as to arrive at social decisions. Therefore, he interprets the social ordering that results from such aggregation as the basis of social action, the aggregation procedure being his social welfare function. Nevertheless, as he pointed out, ordering \( R \) in the definition of an SWF (A) could also be interpreted as reflecting the social welfare judgement of a given individual, say, \( i \). In that case, the SWF (A) would reflect the rule(s) by which \( i \) derived his personal social welfare judgement regarding social states, given the preferences of the individuals in the society. If, however, we adopt this interpretation of the SWF (A), then it will be appropriate to interpret the preference orderings that constitute the arguments of the SWF (A) as reflecting the individuals’ welfares rather than their value judgements or opinions since it is not clear why a person would use other people's judgements to form his own social welfare judgement.

Both the interpretations of a social welfare function would seem to be important for welfare economics conceived in a broad fashion. In some ways, the analysis of personal judgements about social welfare and the aggregation of the opinions of the individuals in society correspond to two distinct phases that can often be discerned in a democratic process. The first stage is the stage of deliberation where people engage in ethical debates about each other's personal social welfare judgements. The second stage is the stage of voting or aggregation of people's judgements, where people's opinions or judgements, as they emerge from the debates and deliberations of the first stage, are taken as given, and attention is focused on arriving at a ‘reasonable compromise’ on the basis of these judgements (see Little, 1952; and Pattanaik, 2005).

The informational basis of social welfare judgements

Arrow's analytical structure does not permit us to consider certain types of information, which, intuitively, we often regard as important for forming our social welfare judgements. I note two such informational constraints.

**Cardinal utility and interpersonal comparisons of utilities**: the SWF (A) defines social ordering as a function of the individuals’ preference orderings over \( X \). Thus, social ordering does not use any cardinal feature of individual welfare, and interpersonal comparisons either of the levels of individual welfare or of individual welfare gains and losses does not play any role in the determination of Arrow's social ordering. The same is also true of the ‘individualistic’ Bergson–Samuelson social welfare function (see (1)), given Samuelson's assumption that the individual utility functions are all ordinal. Such complete eschewal of cardinal notions of individual welfare and all interpersonal comparisons of individual welfares goes counter to our intuition when one interprets the Arrow's social ordering as reflecting someone's social welfare judgement rather than simply as the result of aggregating opinions through a
social welfare function: The New Palgrave Dictionary of Economics

As I have noted earlier, in forming our social welfare judgements, we typically take into account the welfare of individuals. In doing so, we also often resort to interpersonal comparisons of individuals’ welfare levels or changes in their welfare. The SWF (A) would not allow us to do this. For example, consider two allocations \( x = (98, 2) \) and \( y = (97, 3) \) of 100 units of some desired resource between two individuals, 1 and 2. Suppose someone wants to say that a move from \( x \) to \( y \), involving a redistribution in favour of 2 will improve social welfare because, at \( x \), 1 has a higher level of utility than 2, and, even after redistribution, 1’s welfare continues to be higher than 2’s welfare. This justification cannot be given in the Arrow framework since the framework does not permit such interpersonal comparison of welfare levels. Nor can the person justify his social welfare comparison of \( x \) and \( y \) in the framework by saying that individual 1’s utility loss from the switch from \( x \) to \( y \) is outweighed by 2’s gain of utility since Arrow’s framework permits neither cardinal individual utilities nor interpersonal comparisons of utility differences. In the literature that followed Arrow (1951), a series of important contributions (see, for example, Harsanyi, 1955; Sen, 1970b, 1977b, 1979; d’Aspremont and Gevers, 1977; and Gevers, 1979) have explored social welfare judgements based on much richer utility information incorporating cardinal and interpersonally comparable individual utilities, and have demonstrated that Arrow-type impossibility results often lose their bite in this expanded analytical structure.

Non-utility information: Sen (1977b) demonstrated that, though the definition of an SWF (A), by itself, does not rule out the possibility of using non-utility information, such as the information contained in the description of social states, in making social welfare judgements, a somewhat stronger version of WP, together with IIA, does rule out that possibility. The stronger version requires that, for all social states \( x \) and \( y \) and for every preference profile \( (R_1, \ldots, R_n) \), [if \( x R_i y \) for all individuals \( i \), then \( x I y \)], and, further, [if \( xR_i y \) for all individuals \( i \) and \( xP_i y \) for some individual \( i \), then \( xPy \)].

Individual rights based on the notion that an individual should be able to make free choices in affairs relating to his or her private life is an important example of an ethical value based on non-utility information. The concept of an individual's private life, which John Stuart Mill (1859) considered so important, cannot, however, be articulated in terms of individual utilities alone. While \( i \)'s religion may cause just as much disutility for his neighbours as his playing loud music in early hours of the morning, Mill (1859) would have considered \( i \)'s religion, but not his playing loud music in early hours of the morning, to be an aspect of \( i \)'s private life. Sen (1970a) investigated the implications of granting individuals the right to make free choices with respect to their private affairs irrespective of how others feel about their choices. In his celebrated result on the impossibility of the Paretian liberal, Sen (1970a) demonstrated that respect for such individual rights clashes sharply with WP, even if one discards IIA and replaces the Arrow requirement that the social weak preference relation \( R \) be an ordering by the much weaker requirement that \( R \) be reflexive and connected and \( P \) be acyclic (\( P \) is said to be acyclic if and only if there do not exist \( x_1, x_2, \ldots, x_n \) in \( X \) such that \( x_1 P x_2 \) & \( x_2 P x_3 \) & \( \ldots \) & \( x_{n-1} P x_n \) & \( x_n P x_1 \)). While Sen departed radically from the Arrow format by introducing individual rights that have non-utility information as their basis, he still retained one basic feature of the Arrow format. His analysis was in terms of a social weak preference relation specified by a function of individual orderings over the social states. Sen's formulation of an individual's right to make free choices in his own private life was introduced as a restriction on this function, the restriction being contingent on the individual's preferences over social states that differed only with respect to some features of his private life. An
alternative version of Sen's theorem uses the notion of social choice rather than social preference. The point under consideration applies to that version as well. Given any set of feasible social states, social choice from that set is still a function of individual preference orderings over social states, and the rights of an individual are formulated as restrictions on social choices, the restrictions being contingent on the individual's preferences over certain social states.

Several subsequent writers (see, for example, Sugden, 1985; and Gaertner, Pattanaik, and Suzumura, 1992), who argued for a formulation of individual rights in terms of game forms, had to abandon Sen's format altogether, given their conception of an individual's right as the individual's freedom to choose any of the actions or strategies permissible under the right rather than in terms of constraints imposed on social weak preferences (or social choice) by the individual's preferences over certain types of social states. (See, however, Pattanaik and Suzumura, 1996, for an attempt to put the problem of social choice of a rights structure, viewed as a game form, back in the framework of an Arrow-type social welfare function.)

To conclude, it will perhaps be fair to say that, while the concept of a social welfare function has been a powerful analytical tool for investigating implications of value judgements relating to social welfare, the individualistic version (see (1)) of the Bergson–Samuelson formulation, as well as Arrow's formulation of the concept, had certain limitations and that some important developments in welfare economics have their origin in attempts to overcome those limitations.

socialism (new perspectives)

Abstract

In the Marxian tradition socialism means the end of expropriation of surplus value from labour by capitalists. If markets are needed more to coordinate economic activity than to provide incentives to workers and managers, socialism could be achieved by more equal distribution of share ownership with restrictions on cashing in shares. Social homogeneity may be a necessary condition for the democratic implementation of egalitarian programmes through redistribution, if the welfare state is motivated by either a purely redistributive or an insurance function. Hence the challenge to implementing socialism posed by multiculturalism.

Marxian theory

In the Marxian theory of historical materialism, the ruling class in each mode of production has its special method for extracting the economic surplus from the direct producers; that method follows from the characteristic property relations under the mode. Under the slave mode, the surplus produced by slaves is forcibly appropriated by the slave owner; under feudalism, the lord extracts surplus serf labour
through the corvée and various forms of taxation. Capitalism, Marx argued, was the first mode in which surplus extraction was not obviously coercive: no capitalist owns his workers or forcibly takes their product. Indeed, under capitalism workers and capitalists form contracts in which labour power is exchanged for a wage. The capitalist keeps the product of the worker's labour.

Indeed, Marx wished to explain capitalist surplus extraction as a process that would emerge under competitive contracting in which workers and capitalists bargain; in the end, competitive markets set the terms of labour exchange. (As Makowski and Ostroy, 1993, have written, prices are what appear after the dust of the competitive brawl has cleared. It is incorrect to think of prices as directing trade; rather, bargaining among many pairs of individuals reaches an equilibrium summarized by a price.)

Why is it that capitalists end up getting the better part of the deal – that is, why do they end up with the surplus while the worker ends up with his wage, which in the Marxian view was only enough for him to subsist upon? The answer lies not in the fact that the capitalist is more clever or has the police on his side; it is that capital is scarce relative to the available supply of labour, and workers must bid for the right to use that scarce capital, which provides them with a wage. Were labour scarce, then capital would have to bid for labour, and profits would be bid down to a minimal level at which capitalists were indifferent between continuing to own capital and becoming workers. Why capitalism seems to have been characterized, throughout its history, as a situation of capital scarcity is not fully understood. Marx argued that capitalists as a class, perhaps represented by the state, undertook strategies to guarantee a ‘reserve army of the unemployed’ in order to maintain the imbalance. Indeed, the proletarianization of the agricultural periphery is an important process by which labour abundance has been maintained until the present (see Rosa Luxemburg, 1913). Keynes and Schumpeter envisaged a time when capital would cease to be scarce, bringing about the euthanasia of the capitalist class.

Thus, the fundamental source of the accumulation of wealth in the hands of a small class, through profits created in production, is the fact that abundant workers must bid for the ‘privilege’ of using their labour power on privately owned productive assets that increase its productivity immensely. This provides them with a wage greater than they could have earned in the non-capitalist sector (back on the family farm, so to speak, or selling apples from a street cart), and also produces an additional amount that, according to the labour–capitalist bargain, belongs to the capitalist. Capitalists consume a part of this surplus product, and invest the rest in other profit-making activities.

Some writers have argued that capitalism is a system that extracts the surplus from workers coercively; they point to the struggles between workers and bosses at the point of production. It is, I believe, important to point out that capitalist accumulation could transpire, in principle, if capitalists were competitive and if coercion at the point of production of the worker by the capitalist and his agents did not occur. That coercion, upon which many have focused as a central evil of capitalism, exists only because labour contracts are incomplete and not costlessly enforceable. Imagine that the worker and capitalist could contract about every eventuality that might occur during production. If, in addition, the contract were costlessly enforceable (imagine an omnipotent arbitrator who is to hand to deal with any disagreement), then there would be no petty coercion at the point of production: capitalists would not try to speed up assembly lines, force workers to work overtime, cheat them of their wages, discipline them in demeaning ways, and so on. I believe that Marx thought that the essence of capitalism was the accumulation of capital even under such conditions. That actual capitalism is not perfectly competitive, that contracts are incomplete, and that capitalists and workers will haggle over who is to do what when a situation not described in the contract comes up, is something which makes capitalism more unpleasant.
Marx (1867) believed that the property relations of each mode of production would last only so long as they succeeded in inducing production in an efficient way. ‘The water mill gives us the feudal lord, the steam engine, the industrial capitalist.’ He believed that eventually productive forces would develop to such an extent that the capitalist mode of extracting economic surplus would no longer be effective. Indeed, the next stage in economic history, Marx conjectured, would be socialism, a period in which the means of production were collectively owned and the economic surplus thereby became the property of the workers.

We must define exploitation in the Marxian sense. Marx said that workers were exploited because the labour required to produce the goods they could purchase with their wages – including the labour needed to reproduce the capital stock used up in that production – was smaller in quantity that the labour expended by workers for which they received those wage goods. The ‘surplus’ labour, the difference between these two quantities, became embodied in goods which, according to the contract, are owned by capitalists and which they sell for profit. Why does the worker put up with this situation? Because he has no access to the means of production; the surplus labour he supplies is, so to speak, the rent he pays the capitalist for access to those means.

Exploitation is defined as the fact that workers labour for more hours than are ‘embodied’ in the goods they receive as the real wage. Note that, although Marx insisted the wage was one of subsistence, this is entirely unnecessary for the argument. All that must be the case, for exploitation to exist, is that the hours of labour embodied in goods which wages purchase are fewer than the hours worked by workers. Marx viewed socialism as the system that would end capitalist exploitation in this sense. There are, however, at least prime facie, several ways of ending exploitation short of collectivizing ownership in the means of production, and hence in collectivizing the product they produce above what workers receive as wages. One is syndicalism, in which groups of workers own their factories collectively; another is people's capitalism, a system in which firms are privately owned by citizens, each of whom owns a small share of all firms. Syndicalism would quickly generate a system with highly unequal ownership of productive assets, so some groups of workers would ‘exploit’ others through trade, not to speak of hiring contract labourers. Designing a people's capitalism in which Marxian exploitation was eliminated is possible in the abstract, but it would be difficult to implement in actuality. One should note that the distribution of shares in firms to citizens that would abolish exploitation could not be an equal one. Consider the situation of a person who does not work out of choice (a ‘surfer’) but collects dividends: he would be exploiting others, in the Marxian sense, because the amount of labour embodied in the goods he can purchase with his income is greater than the labour he expends. Indeed, for exploitation to be abolished (in the sense that the labour accounts balance) those who choose not to work should receive zero shares of the capital stock. It is in fact possible to design a system of share ownership so that, when individuals choose their labour supply to maximize their preferences over labour and income, the income they receive from wages and their dividends is precisely enough to purchase goods embodying exactly the labour they expended and, in addition, the allocation of labour and goods is Pareto-efficient. This arrangement, called the proportional solution by Roemer and Silvestre (1993), solves an interesting intellectual problem, but it has little importance as a way of solving the problem of capitalist exploitation because of the difficulty of actually computing the shares of firms citizens should receive, when information about preferences is asymmetric. (The proportional solution, however, may be used by a small community – for example, of fishermen – who collectively
Moreover, as we shall see below, it is not necessarily ethically desirable if workers are significantly heterogeneous in skill.

Socialism, then, became identified with collectivization of the means of production. Workers would produce more goods than they consumed (nobody claims that investment should be zero under socialism), but the existence of a surplus product would not constitute exploitation because it would be owned by all. This presumably meant that the state, which represented the working class, would decide upon its use. Whether this would be the case because workers obtain the suffrage and vote in a party to represent them, or because a party proclaiming itself to represent the working class takes power by non-democratic means, is another question.

A terminological point is in order. Some advocates of socialism define it as a system in which everyone reaches his full potential, racism and sexism vanish, and citizens view each other as brothers. This is a mistake. To be true to the theory of historical materialism, socialism should be defined as a nexus of property relations that eliminates capitalist exploitation. Whether such a system possesses other nice characteristics in consequence is a scientific question, one that cannot be settled by definition.

A special word must be said about equality. If workers are highly heterogeneous in skills, eliminating capitalist exploitation does not eliminate inequality in incomes. Nevertheless, there has been a tradition of viewing socialism as a system of quite equal incomes. This is partly due to the level of abstraction of Marx's thinking, in which he often viewed capitalism as characterized by a mass of homogeneous workers struggling against a small elite of homogeneous capitalists. It is, however, also due to the belief that many of the inequalities in workers' skills come from unequal opportunities fostered by capitalism and, were capitalism to be eliminated, workers would therefore become more equal in skills. I believe this view of what socialist transformation, in the sense of Marx, would accomplish is too optimistic – on which more below, when we return to the conception of socialism as equality.

**Social democracy**

In the event, the world saw two major kinds of socialist experiment: one, initiated by the Bolshevik revolution, was brought to power by a communist party which ruled undemocratically, and shunned the use of markets, which, it feared, would bring with them the old capitalist mentality, whereby traders tried to accumulate capital and hence to exploit others. The other was social democracy, in which parties representing workers won state power through democratic means, and attempted to tax profits for the purpose of investment and augmenting workers' consumption (the so-called social wage). The social democratic path did not as a principle abolish private ownership of capital assets, although some firms were nationalized.

In principle, both of these techniques could abolish the kind of exploitation associated with capitalism. If communist parties were perfect agents of their collective principal, the working masses, they could set the rate of accumulation at that level desired by workers (there is a problem here of how to aggregate workers' disparate preferences over that rate), and then invest the surplus in the way that would best meet the interests of workers (another preference aggregation problem). And under social democracy, private capital could be taxed at a rate sufficiently high that, although rates of exploitation would not be zero, they would be small. To keep capital from fleeing to more profitable venues, under that situation, workers would have to be sufficiently skilled so that, even under such a regime, capitalists' profits
would be sufficiently great. Thus, guaranteeing highly skilled labour would appear to be a part of the social-democratic formula if capital is freely mobile.

With regard to equalizing the distribution of income, both the Soviet-type economies (the Soviet Union and eastern Europe) and the Nordic social democracies did an excellent job. (Indeed, at least in the Soviet Union, it is arguable that skilled workers contributed more labour, in efficiency units, than they received back in goods.) The major difference was that the Soviet economies equalized incomes at low levels, while the social democracies did so at high levels. To what was due the failure of the Soviet economies? We still do not have a completely satisfying explanation, but it seems as if their abrogation of markets was an important factor.

Although the Soviet-type economies used markets from time to time, beginning with Lenin's introduction of the New Economic Policy in the 1920s, they were never allowed to operate with the kind of freedom that would have fostered technological innovation, and by the 1960s it was the lack of innovation that was largely responsible for the low level of living standards. (Of course, when the state acted to concentrate talent in one sector, such as the space industry, it was able to achieve impressive results, but the Soviet economy never succeeded in fostering innovation across the board.) These problems were foreseen much earlier, however, in the debate around market socialism that began in the 1930s, with Oskar Lange's argument that markets could in large part replace central planning in a socialist economy. Lange (1936) proposed that central planners announce to industrial managers prices for their inputs and outputs, and require the managers to report back with the amounts of inputs they would demand and outputs they would produce at those prices, if they were to equate the prices to marginal costs (a necessary condition for Pareto efficiency). The planners would then sum up, observe the discrepancies in the supply and demand of each commodity, announce a second set of prices, raising those for goods in excess demand and lowering those for goods in excess supply, and go through the exercise again, hoping to eliminate the imbalances. Lange believed this process would converge rapidly to an equilibrium; then the planners would post the equilibrium prices and instruct firms to produce accordingly.

Lange also suggested that each household receive a certain fraction of the firms’ profits, perhaps allocated according to family size.

Lange did not deal properly with the demands of consumers. But, even if we assume that these could be incorporated into the scheme, what is the point of his kind of planning? Why not simply let the market run autonomously? Lange had no convincing answer: he did say that the central planning bureau (CPB) would be able to achieve equilibrium much faster than the market, avoiding the disequilibrium phase that he considered to be socially costly. (Today, this seems to be a quaint view, given the millions of commodities that are produced in a complex economy. Indeed, economic theory still has no full explanation of how the market ‘finds’ the equilibrium, and there are theorems that the kind of ‘tâtonnement’ Lange proposed would, with high probability, not converge.) Perhaps Lange thought that the CPB would control economic activity through setting interest rates of various kinds, thus directing firms to invest in the directions the planners desired.

Friedrich Hayek (1940), however, offered a critique of another type. He wrote that it was an illusion to believe that managers could respond with their input demands, facing prices announced by planners, because they did not know their production functions, and therefore could not compute marginal costs. Capitalist firm managers, he said, learn how much they can produce with given inputs by the discipline of competition. It is the competitive brawl that teaches managers how to cut costs and produce
efficiently, and to suppose that managers would know how to do so in the sterilized situation envisaged by Lange was wrong. Indeed, how would the CPB deal with innovation, with new commodities? The secret of real markets, Hayek argued, was that they provide incentives and a mechanism for people (entrepreneurs) with local information about needs and production possibilities to realize their ideas. Thus fixing the set of managers \textit{ex ante} was already dooming the system to conservatism and inefficiency.

It is interesting to note that Hayek never wrote that socialist managers would be opportunistic or self-serving – that they would lie to the CPB in order to influence their allotment of inputs. Hayek postulated that managers were ‘loyal and capable’. This is in sharp contrast to the critique of socialist management that emerged after 1970 among Western capitalist economists, when the principal–agent problem was formulated, and ‘shirking’ and opportunism became central issues.

### Markets, incentives and coordination

Indeed, this raises a critical question about the failure of centrally planned socialism: was it due to \textit{lack of incentives} or to \textit{lack of coordination}? Markets perform two functions: they provide incentives for workers and entrepreneurs to improve their skills and discover new commodities so as to increase their income, but they also coordinate economic activity. It may not be simple theoretically to distinguish precisely these two functions, but they are clearly different. Matching of workers to firms, for example, occurs in large part by observing wage offers; firms shop for inputs by observing price offers. Of course, the system does not work perfectly, but there is doubtless a strong element of coordination engendered by a competitive price system. (Price systems do not coordinate some things properly, such as control of externalities and the supplies of public goods, and therein lies a major liberal justification of state intervention.)

The history of the Soviet economy is replete with stories of poor incentives and poor coordination: we do not have a complete account of the relative importance of these two failures in the lacklustré performance of centrally planned economies in their late period. One also reads, however, of how hard Soviet workers worked, and how ingenious they were at making do with poor inputs (see, for instance, Burawoy and Lukacs, 1985). I believe it is important to answer the question posed above, for upon it may rest the possibility of a future for socialism.

Suppose markets are needed mainly to generate incentives to work hard, to form skills, to invent, and so on. This implies that it will be difficult to use markets \textit{and} to redistribute income in a relatively equal manner through taxation. After all, if workers form skills in order to increase their incomes, but then their incomes are taxed away, why form skills? But suppose that markets are needed mainly to coordinate economic activity: then in principle wage income (which would adjust competitively to reflect marginal value products) could be taxed to produce an income distribution of equality without harming production. In the second case, workers would form skills and innovate because they enjoyed doing so, or felt valued for their social contributions.

I suspect the coordination problem is relatively more important in the failure of centrally planned economies, and the incentive problem relatively less important, than most currently believe. Many economists, especially, assume that the opportunist kind of behaviour so prevalent in the theory of \textit{homo oeconomicus} is a deep aspect of human nature, and therefore that it must have been rampant in the Soviet Union.
Markets are essential in any complex economy, at least for coordination and perhaps for incentives. But, as we have seen in the Nordic countries, tremendous accomplishments with respect to income distribution can be achieved with taxation and ‘wage solidarity’. One might say that the future of socialism lies in emulating the Nordic social democracies. They may, however, not be easy to emulate, as the solidarity of their citizenries may be due to their homogeneity – linguistic, religious, and ethnic. Perhaps welfare states of that magnitude cannot be achieved in highly heterogeneous societies.

A future for socialism may still, then, require an alternative to conventional private ownership of firms with significant redistribution through taxation, because the solidarity necessary for democratic approval of that degree of redistribution may not evolve in large heterogeneous societies. If firms are not to be privately owned, as they are in the Nordic model, then a central question concerns the way that accountability of firm management is achieved. There is a principal–agent problem between the firm manager (agent) and the shareholder–citizens (principal). How do the latter keep the manager from running off with the profits and even the assets of the firm? The classical solution is that firm ownership must be highly concentrated, so that a small number of shareholders stand to gain huge amounts by carefully monitoring the management. In this view, distributing shares of firms equally to all citizens would destroy management accountability, resulting in unbridled corruption and inefficiency.

Recently a second theory has been proposed: that the guarantor of firm accountability is the corporate raider. When the raider sees the price of a firm's stock fall, because the firm is not performing well (perhaps due to management corruption or lack of imagination), he will buy a majority of shares and reorganize the firm to be efficient, thus increasing its stock price and providing him with a large capital gain. Here, too, if credit markets are imperfect, we need wealthy individuals to keep firms running well. If these two mechanisms of accountability exhaust the possibilities, then market economies in which firm profits are distributed in a relatively equal manner to citizens are impossible. An apparent alternative, however, exists in Germany and Japan, where firms are monitored by boards of directors consisting largely of officers of banks that have a relationship to the firm. It is beyond my scope to describe this mechanism here: suffice to say it provides an alternative to relying upon hugely wealthy individuals for guaranteeing firm accountability. If market socialism has a future, it may well be with this kind of arrangement: firms will be monitored by bankers from the public sector, whose reputations and careers depend upon doing a good job, or they may be monitored by other stakeholders of the firm.

Another alternative (proposed by Roemer, 1994), with no present real-world examples, is a system in which firm ownership is distributed to citizens in an initially equal way but ownership rights are circumscribed. An owner will collect dividends from the firms in her portfolio, and even trade equity shares on a stock market, but she may not liquidate her equity holdings for cash. This would be accomplished by denominated corporate shares in a special unit of account. The values of shares in that unit would oscillate according to supply and demand, reflecting traders’ views about the future profitability of firms, as in a standard stock market. At death, a citizen's portfolio would escheat to the Treasury, and young adults, at the age of 21, would each receive their endowment of shares. Some inequality in the values of shareholdings would emerge as a consequence of differential luck and skill in the stock market during a lifetime, but that equality would not be passed on to descendants. In other words, this scheme is a method by which the nation's profit income could be distributed in a relatively equal manner to citizens, while the virtues of a stock market, with respect to the valuation of shares, and the disciplining of management are retained.

There are surely possibilities for undermining the intentions of such a system. If there are also
individuals (such as foreigners) who are allowed to invest in these firms, then possibilities arise for citizens to capitalize their holdings, to cash out their shares. Old citizens will want firms in which they hold shares to sell their assets and pay out the entire value of the firm as dividends. Whether regulation could make the system workable is an open question.

Finally, there is the possibility of state ownership of firms. We do not as yet have a definitive experiment to test whether state ownership can work, for the Soviet-type experiments also involved lack of democracy; it is logically possible that democratic accountability could keep state-owned firms running efficiently. There are, however, problems here as well: politicians, to whom state-owned firm managers ultimately report, have their own interests that do not always coincide with those of the public. The electoral mechanism is probably too crude a tool to force politicians to monitor firms in the public interest. (Indeed, state-owned firms often pay their workers too much, to garner their political support.) I conjecture that non-state ownership of firms will be significant in any future socialist experiment.

We return finally to the relationship of socialism to equality. Do socialists believe that an economy which implements ‘from each according to his ability, to each according to his work’, which by definition eliminates Marxian exploitation, is desirable? Most socialists probably desire more equality than this, at least in societies where workers are highly heterogeneous in skills. Thus, socialists have come to be, and perhaps always were, more egalitarian than the Marxian definition would imply. Popular usage suggests that socialism should be defined as a regime of income equality, a departure from the Marxian tradition.

The proposals we have discussed above are all concerned with the allocation of profit income. But is the allocation of profits so important with regard to equalizing the distribution of income? In contemporary advanced economies, profits (including interest and rents) comprise at most one-quarter of national income; even if this part were distributed in an egalitarian manner to all households, and remained of the same size, the distribution of income would still, in most advanced countries, be quite unequal. Should, then, the difference between socialism, popularly conceived, and capitalism lie mainly in the distribution of wage income or of the role of redistributive taxation of labour income?

Rather than trying to define at what Gini coefficient a society becomes socialist, one can be satisfied with ordering regimes in the world with respect to their degree of socialism. The central instruments for socialist implementation then become, as well as the redistribution of profit income, intensive investment in education, with a bias towards rectifying the disadvantages children suffer due to being raised by poorly educated parents, in order to equalize market-determined labour incomes, and redistribution of labour income through taxation. The channel of intensive investment in education of the disadvantaged is important because the provision of skills has value to persons for reasons other than the instrumental one of providing income: education renders life more meaningful and fruitful. But if the education channel alone turns out to be too costly, or too ineffective, to engender the changes in income distribution which are desirable, then other methods must be used as well. The issue of feasible socialism, therefore, will hinge upon the package of reforms that are effective and can be realized through democratic means.

Feasible socialism: immigration and unemployment

How politically feasible is socialism – that is, to what degree can we expect democracies to implement the reforms that move societies further along the socialist scale? Here the most hopeful historical
The New Palgrave Dictionary of Economics

evidence is provided by the Nordic and north European countries. Two problems seem to be paramount for the continuation of the socialist trajectory in these economies: those of immigration and unemployment.

The welfare states of the north European countries, as mentioned earlier, evolved during the period when their populations were largely homogeneous, along ethnic, linguistic, and religious dimensions. Homogeneity may be a necessary condition for the democratic implementation of significant redistribution if the welfare state is motivated by either a purely redistributive or an insurance function. For, with respect to the insurance function, it is not in the interest of highly educated and high-wage natives in, let us say, Denmark, to pool their risks with poorly educated, low-wage immigrants. And with respect to the purely redistributive function, ethnic, linguistic and religious heterogeneity reduce solidarity, to put it mildly, which must be the motivation of purely redistributive taxation.

Unemployment is a problem not only for the deleterious welfare effects its victims suffer but because it is a severe form of economic inefficiency. If ‘socialist’ countries have high unemployment levels, and ‘capitalist’ countries low levels, eventually the inefficiency of the former may well reduce per capita income significantly below that of the latter, and populations of the socialist countries will begin to find the higher incomes offered, on average, by the capitalist regimes an attractive alternative. If we assume that, in the coming century, the United States (and, let us say, China) continue to offer low-unemployment, low-taxation, high-growth regimes, but with relatively little redistribution, then democratic polities in Europe and the rest of the world may be reluctant to move further along the socialist spectrum. This, of course, assumes that there is some sacrifice in economic growth entailed by redistributive institutions, a point that I have not defended here but have taken for granted, and which may be incorrect. Indeed, a growing literature asserts that equality increases productivity (see Bardhan and Bowles, 2000).

It is perfectly natural for fertility rates to fall when social insurance replaces the family as the source of income in old age: and smaller families, probably more than anything, entail the liberation of women. (They are also, of course, an effect of that liberation.) But European fertility rates now necessitate either a significant flow of immigrants from poorer countries, or a sharp decline in per capita incomes in Europe for retired workers, or an increase in the length of working life (which itself would exacerbate the unemployment problem). So lower fertility renders the progress towards socialism more complex at least, if not infeasible.

Consequently, the issue of multiculturalism becomes a key intellectual problem for socialists. What degree of integration or assimilation of immigrants is necessary for democratic European polities to be willing and interested to continue and perhaps expand their welfare states? (Recall, we refer here not simply to the redistributive motive but to the risk-bearing motive of natives wishing to pool risks with immigrants.) We do not, I think, yet know the answer. And will this degree of assimilation, whatever it turns out to be, be acceptable to poor Southerners or Easterners who are contemplating migration to the North or West?

Socialism, in the sense of equality of incomes, with a democratic implementation requires either a selfinterested insurance motive or a selfless solidaristic motive among the majority of voter–citizens. We can hope that, as national populations come to experience more equality, they would come to have a deeper preference for it: socialists, at least, believe that solidaristic preferences can intensify with the experience of equality because equality is a public good, a fact that will be appreciated when it is experienced. (Indeed, we have not, in this article, discussed the negative externalities that socialists...
believe accompany a regime with a highly concentrated ownership of private firms, in which corporate and even state policy is set to further the interests of only the wealthiest sliver of society.) But the initial transitions along this path, taken by relatively self-centred voters, must come from the insurance motive. Here, then, is an important problem for progress towards socialism in our time.

Abstract

A society may be defined as socialist if the major part of the means of production of goods and services is in some sense socially owned and operated, by state, socialized or cooperative enterprises. The practical issues of socialism comprise the relationships between management and workforce within the enterprise, the interrelationships between production units (plan versus markets), and, if the state owns and operates any part of the economy, who controls it and how. ‘Feasible socialism’ would take the form of a mixed economy, with enterprises large and small, many if not most self-managed or cooperative, and some privately owned.

Article

It is said that the word ‘socialism’ was first used by Pierre Leroux, a supporter of Saint-Simon, in 1832, and was quickly taken up by Robert Owen. The word has meant many different things to different people. It has been used as a synonym for communism, i.e. as a bright vision of a future in which there are neither rich nor poor, neither exploiters nor exploited, in which, to use an expression borrowed from Charles Taylor, ‘generic man is harmoniously united in the face of nature’. It is by definition the solution of most if not all economic problems, the end of ‘alienation’. As such it has religious overtones: Man was at one time in harmony with society, and will become so once again. For others, these utopian-sounding aims are either meaningless or a vague ideal, the higher stage of communism. ‘Socialism’ is,
so to speak, here on earth, and can be seen (according both to Soviet doctrine and to right-wing critics) in the ‘really existing socialism’ of countries in the Soviet sphere, who claim to be on the way towards a communist future. Still others criticize this ‘really existing socialism’ from the left, declaring it not to be socialism at all; their criteria for what constitutes socialism are not always very clear, some using the marxist vision as their point of departure, others laying stress on the lack of democracy, the hierarchical nature of society, and other departures from what, in their view, ought to be. The term ‘socialism’ is also used, or misused, to describe the aims and programme of the British Labour party, or the state of affairs actually achieved under a series of social-democratic governments in Sweden. The term at one time had an appeal to moderates. Thus the moderate-reforming party of the Third Republic in France chose to call itself Radical-Socialist, though its leaders, such as Edouard Herriot, had no aims which could qualify as socialist. Then, at the extreme right of the political spectrum, Hitler's party was self-described as national-socialist.

So one should proceed at an early stage to a definition, or rather to exclusions. Not Hitler, obviously. Nor Herriot either. If one were to adopt a definition which corresponds with Marx's vision of socialism (of which much more below), there is the evident danger of adopting an impossibly rigid criterion by which to judge any real-world society: thus, whatever reasons there may be to criticize or condemn today's USSR, it would be rather pointless to ‘accuse’ it of not having ensured the withering away of the state, or not having ‘surmounted’ (aufgehoben) the division of labour. Let us provisionally accept the following as a definition of socialism: a society may be seen to be a socialist one if the major part of the means of production of goods and services are not in private hands, but are in some sense socially owned and operated, by state, socialized or cooperative enterprises. ‘The major part’ is enough. Just as any non-dogmatic socialist would accept that most ‘capitalist’ countries contain sizeable state and cooperative sectors but still deserve the label ‘capitalist’. This leaves three big questions unanswered:

1. (1) What are the relationships between management and workforce within the enterprise?
2. (2) How do the production units interrelate? (i.e. by plan, by contractual or market relations, or some combination of both).
3. (3) If the state or other public bodies own and operate any part of the economy, who controls the state, and how. One remembers the remark attributed to Engels, that if state ownership is the criterion of socialism, the first socialist institution was the regimental tailor.

If the world ‘socialist’ was coined in 1832, the idea of socialism long preceded it. Among the first to put forward principles which contain strong socialist elements was Gerard Winstanley, representing the Levellers of Cromwell's time. They believed in equality, wished property to be held in common, opposed concentrations of private wealth. During the French revolution Babeuf denounced inequalities of wealth and advocated the overthrow of the government, which he saw as representing property-owners. Robert Owen could be described as a paternalist, in that he believed in good treatment of his employees (as can be seen even today in the housing he built for his workers in New Lanark), but he also envisaged what would now be called producers’ cooperatives. As essentially a practical man, he can be distinguished from those ‘utopian socialists’ who, before Marx, have painted a series of pictures of imaginary socialist-type societies. Leszek Kolakowski (1981) analyses the ideas of men like Fourier, Saint-Simon, Proudhon, and notes certain elements of similarity with those of Marx, and also some essential differences. They have in common, inter alia, a hate for the ‘bourgeois’ order, a society based
upon greed, profit, the mercantile spirit. The French revolution substituted plutocracy for aristocracy. Unlike Marx, they did not consider this to be a progressive stage in the history of mankind, but, like Marx, they stressed the ugly features of capitalist industrialism and wished to do away with it, substituting a new harmony, cooperation, the reassertion of the true rights of Man. They rejected Adam Smith's basic idea that common good is generally attained through the competitive profit-making process. As, for instance, was asserted by Saint-Simon, the basic cause of human misery is free competition and the anarchy of the market. The so-called utopians varied in their approach to the issue of equality: thus in Fourier’s ‘phalansteries’ the means of production were held in common, children were to be brought up together, the family would dissolve, there would be provision of subsistence for all, but Fourier would encourage individual enrichment through work (though not the inheritance of riches or unearned incomes). Some advocated violent revolution to achieve their objectives, others hated violence and hoped to persuade their fellow-citizens to adopt freely the ideas of the good and just society of their imagination.

As will be argued later, Marx differed from his predecessors not because he conceived of a realistic alternative to capitalism: there was much that was utopian in his ideas too. However, firstly he did not go into detail as to how a future society would function; nothing in Marx is similar to such notions as phalansteries, or radiant cities of 1800 persons with 810 different human characteristics, or the idea that dirty work that needs doing will be done by boys, who, as everyone knows, like dirt; Marx favoured the emancipation of women, but he did not follow Fourier in drawing up a ‘table des termes de l'alternat amoureux’.

Secondly, and more important, he provided a set of powerfully argued historical reasons as to why the desired state of affairs must come to pass. As Engels said at his graveside: ‘Just as Darwin discovered the law of development of organic nature, so Marx discovered the law of development of human history.’ The class struggle, the growth of monopoly capitalism, the proletarianization of the petty bourgeoisie (peasants, shopkeepers, small businessmen of all kinds), the growing misery of the masses, the growth of class-consciousness, the logic and consequences of large-scale industry, the belief that, having spectacularly developed the forms of production, the bourgeois-capitalist relations of production act as fetters on the further development of productive forces, all these things will lead inexorably towards socialism. Ever-deepening crises, the falling rate of profit, the refusal of the poverty-stricken masses to accept their lot, i.e. the accumulation of capitalist contradictions, will bring the system down. The proletariat, having overthrown the bourgeoisie, would inaugurate the classless society. In the marxist tradition there are various interpretations of the relative importance of historic necessity (i.e. inevitableness, a march towards a predestined goal) and voluntariness (deliberate human action designed to achieve the goal). These two principles coexist uneasily, and they can be seen as mutually inconsistent, but they can be reconciled. To take two examples, it is meaningful to assert that, should a professional soccer team play a school side, the professionals would ‘inevitably’ win. The same would be (was) true of a conflict between the Germans and say the Luxemburg army. However, the outcome requires human action, on the part of the footballers and the German soldiers respectively. This calls for two kinds of comments. One relates to the interpretation of history, the other to the utopian elements of so-called scientific socialism.

It hardly needs stressing that capitalism has not evolved in the manner foreseen by Marx. He himself stressed, in a famous passage, that no mode of production passes from the historical scene before its productive potential is exhausted. He believed that capitalism was reaching exhaustion already when he
was writing *Das Kapital*. Over a hundred years later it is still not exhausted, and ever-new technological revolutions, while certainly presenting new problems and dilemmas of which we shall speak, continue to enlarge the productive potential of capitalist society. It is also clear that the concept of ‘proletarianization’ was wide of the mark. Yes, great concentrations of ‘monopoly-capital’ do exist, but so do very large numbers of small businesses and a far larger number of ‘professionals’ of all sorts and grades who are, or consider themselves to be, middle class. This fact has given rise to much debate among Marxists, typified by the argument between Poulantzas and Erik Wright (see for example, Wright, 1979). We need not go into this argument, which turns on who could or could not be considered to be working class. The political and social fact remains that a large and growing proportion of the citizenry of developed countries do not own the means of production and are emphatically not class-conscious proletarians.

Furthermore, the development of the forces of production has made possible a substantial improvement in the living standards even of those who in any definition are workers. Clearly, they do not have ‘nothing to lose but their chains’. It is neither original nor amusing to say that men who have ‘nothing to lose’ except a three-bedroomed house, a car, a video-tape machine and a holiday in Spain are not very likely to be revolutionaries, or indeed particularly interested in socialism. It is true none the less. Marx himself, and some of his followers, when willing to recognize that living standards could rise, insisted that this does not remove the essential antagonism between labour and capital, the existence of exploitation and alienation. In a sense this is so, though one must avoid an oversimplified zero-sum-game approach; situations arise in which both profits and wages can rise together, as they have done in successful capitalist countries in the twenty-five years that followed the last war. Nor is there any necessary correlation between the depth of human misery and the spirit of revolt. None the less, the lack of support for the socialist alternative in developed countries cannot be treated as merely a temporary aberration. It is also true that revolutions, whatever their merits or necessities, impose grave hardship upon people, notably the masses. The association of the word ‘socialism’ with revolution is therefore an important reason for many ‘proletarians’ not to support the socialist idea, at least in developed countries. ‘Underdeveloped socialism’ is a different question, to be tackled later.

Now to the utopian nature of Marx’s ‘scientific socialism’. The key points to make are:

1. **Abundance.** Here Marx reflects the optimism of his century, yet natural resources are not inexhaustible. Human needs and wants increase – as indeed Marx himself recognized. Conservationist and ecological socialism can be strongly defended, but this is precisely because resources (even the air we breathe, the water we drink) are finite. It is not the case that the problem of production has been ‘solved’, and that socialists will not require to take seriously the question of the allocation of scarce resources. I define ‘abundance’ as a sufficiency for all reasonable requirements at zero price.

2. **The non-acquisitive ‘new man’**. His (and her) appearance surely presupposes abundance. Marx himself was perfectly clear that a share-poverty ‘socialism’ would reproduce ‘the old rubbish’. Men do not become good by being so persuaded, or by reading good books. If there is enough for everyone, then there is no need to strive to keep things for oneself, one’s family, one’s locality, one’s institution. If there is scarcity, therefore opportunity cost, therefore a situation in which there are mutually exclusive alternatives, then conflict on priorities of resource allocation is inevitable. This does not in fact require any assumption about individual egoism. Even unselfish
persons tend to identify the needs they know with the common good. Indeed, in a complex modern society there is no generally accepted and objectively based criterion as to what ‘the common good’ is. Nor can any individual apprehend the multitude of alternative uses potentially available for the resources he or she desires, either for him/her self or for the given township, library, orchestra, football team, industry or whatever.

3. **The political assumptions.** These are linked with (1) and (2), above. The state withers away, not only because it is assumed that its ‘essential’ repressive functions are not needed when no ruling class imposes its will on the masses, but also because, to re-cite Charles Taylor, Marx assumed a ‘generic man harmoniously united in the face of nature’. Consequently there would be no need for legal institutions, coercive powers, police, indeed any politics as we know them. Civil society and individuals will have merged, the task of the ‘administration of things’ would not be undertaken by political institutions, would be merely technical. There is no marxist political theory of socialism.

4. **The economic assumptions.**

1. (a) **Value theory and economic calculation.** The suppression of the market, of commodity production, of money, seems to involve the ‘withering away’ of the law of value. What is to replace it? Presumably it will continue to be important to use resources economically to provide the goods and services desired by society. How are calculations to be made? On this Marx is almost totally silent. Engels, in *Anti-Dühring*, speaks of assessing use-values and relating them to the labour-time required to provide for them. This runs at once into several rather evident problems. First is the theoretical one that Marx most emphatically (at the very beginning of the first volume of *Das Kapital*) asserted that different use-values were not comparable, so could not be added up or subtracted. A pen, a cup, a book, a skirt, a light-bulb (to take a few examples at random) satisfy different needs. The one thing they have in common, apart from satisfying various needs, is that they are the products of labour. How, in any case, are Engels’s use-values to be computed, by whom, on the basis of what criteria? In a book wholly devoted to marxian use-value (*valeur d’usage*), G. Roland (1985) goes at length into the basically unsatisfactory treatment by Marx of use-value, due apparently to his anxiety to distance himself from subjective value theory. This has created some awkward problems for Soviet pricing theory, or at the very least does nothing to help. The dogmatists insist that Marxian labour-values ought to underlie Soviet prices, or alternatively that these be modified into the equivalence of ‘prices of production’, but both of these share the characteristic of being based on effort, on cost. This not only fails to give due weight to utility (or user preferences), but also runs into yet another problem, or rather two interlinked problems; measuring labour inputs, and the failure to take into account other scarcities. A few brief remarks are appropriate on each of these points. Can one actually identify the labour content, including the labour embodied in machine and materials, and the ‘share’ in joint overheads, of hundreds of thousands or even millions of different goods and services? This is a hugely difficult if not impossible task, even if one calculated only in hours of labour. But then what of skilled labour? How is it to be ‘reduced’ to simple labour? Marx does not handle this ‘reduction’ satisfactorily in discussing value in capitalist society, and in the end one is left with actual wage ratios as the only usable criterion, which is unhelpfully circular. And then can one
treat labour as the only scarce factor? What of land, oil, timber, what of time (not labour-
time, but, say, delay in construction)? Novozhilov remarked that the most modern
equipment would be scarce even under full communism unless it be assumed that
technical progress ceases. Space forbids further remarks about other deficiencies of the
labour-theory inherited from Marx. (Thus demand or price must affect labour-content if
there are economies or diseconomies of scale, or if relative prices influence choice of
techniques.) And if the purist retorts that Marxian value theory is not supposed to apply to
socialist economies at all, then he or she must be asked: ‘What is your alternative?’.
This has (so far) usually taken the form of some surrogate labour-theory (such as hours of
human effort), with all the deficiencies of such an approach.

2. (b) ‘Simplicity’. The lack of interest – until comparatively recently – of Marx and marxists
in the question of economic calculation under socialism is explicable by a grave
misunderstanding, i.e. by the belief that the complexities of modern industrial society are
a consequence of commodity production and ‘commodity fetishism’, which conceal
relations which, as Marx said, were inherently ‘clear and transparent’. ‘Everything will be
quite simple without this so-called value’, said Engels. Planning under socialism ‘will be
child's play’, said Bebel. ‘To organize the entire economy on the lines of the postal
service, … under the leadership of the armed proletariat, this is immediate [sic]
task’ (Lenin, in 1917), and so on. But evidently in a modern industrial society with
hundreds of millions of people, hundreds of thousands of productive units, millions of
products and services (if disaggregated down to specific items, there are millions), it is a
hugely complex task to discover exactly who needs what, and to identify the most
effective means of providing for needs, especially if one bears in mind that any output
requires the acquisition (or allocation) of dozens or more of inputs. Barone (in his path-
breaking ‘Ministry of production in a collectivist state’) pointed this out in 1908, but
failed to get a hearing from the socialists of his time. It is nonsense to talk of labour under
socialism being ‘directly social’, in the sense of being applied with advance knowledge of
needs – contrasting with ex post validation through the market under capitalism. This can
only be so if perfect knowledge and foresight were assumed, and the need to test ex post
for possible error assumed to be unnecessary. All socialists (rightly!) reject theories which
assume perfect foresight, perfect markets, perfect competition, when put forward by
neoclassical model-builders. So, apart from problems of value theory, there is the sheer
complexity of marketless, quantitative planning, the formidable obstacles in the way of
identifying requirements and providing for their satisfaction.

3. (c) Political-social implications. Lest the above be seen as ‘merely technical’, and so
remediable by computers, the objective requirements of marketless planning in a complex
industrial economy are centralizing (who but the centre can identify need and ensure the
allocation of means of production?), hierarchical, bureaucratic, and concentrate immense
power over both people and things in the hands of the state apparatus. The importance of
political democracy is undeniable, but the officials (who else?) who plan the output and
allocation of sheet steel, sulphuric acid and flour are taking decisions unconnected with
democratic voting – save in the sense that such voting should affect broad priorities. There
were moments when Marx, Engels, Lenin, showed that they understood the inevitability
of hierarchy: thus Lenin saw the socialist economy as a sort of ‘single office, a single factory’, with ‘a single will linking all the sub-units together’ to ensure the parts of the economy fitted together ‘like clockwork’ (Lenin, 1962, pp. 157). But whereas clockwork functions automatically (i.e. is not unlike the ‘hidden hand’, or maybe the hidden pendulum), in a marketless economy the parts have to be moved by human beings charged with the purpose. The contrast between ‘the administration of man’ and ‘the administration of things’ (a phrase borrowed by Marx from Saint-Simon) is a false contrast: I am quite unable to ‘administer’ this piece of paper, but I can persuade a secretary to type it, a postman to deliver it to the publisher, and (hopefully!) the publisher decides to tell the printers to print it! All Soviet experience underlines the political and social consequences of the high concentration of hierarchically organized economic power.

5. Division of labour and ‘alienation’. There is, and must surely be, a division of labour between productive units (those that produce sulphuric acid, steel or hairdressing services are unlikely also to be making hats, computer software or music). Marx's notion of a universal man, who fishes, looks after sheep and writes literary criticism, without being a professional fisherman, shepherd or critic, makes no sense, other than in the (sensible but weaker) form of aiming at a greater degree of job interchangeability. Thus the author of these lines was once a soldier, then a bureaucrat, then a university teacher, but could not be all of these at once. The vertical division of labour (e.g. between management and those managed) could also be modified by some system of rotation or election, but management is also a skill, and human intelligence is not of itself a guarantee of tolerable administrative ability: we all know of good specialists who could not (and would not wish to) administer anything well. One is then struck by the inherent unreality of such books as by I. Mészáros (1972). Mészáros fully and correctly sets out Marx's view, and he does state that ‘the political road to the supersession of alienation and reification’ is a long one and success is not guaranteed. But he still sees the ‘transcendence of alienation’ as a meaningful goal, as if separation of Man from his product, his subordination to outside forces, the division of labour, can be overcome through the elimination of private ownership. And Kolakowski (1981, p. 172) is surely right when he notes that for Marx ‘the fundamental premise of alienation is already present as soon as goods become commodities’, and that ‘the division of labour leads necessarily to commerce’. So alienation appears to be the inescapable consequence of an inescapable division of labour, so how can it be aufgehoben? Private ownership represents a particular manifestation of ‘outside’ control, and it is an important part of any socialist programme to give to labour a greater influence over the work process. But what can one make of Bettelheim (1968), when he criticizes Yugoslav-type self-management enterprises for what is surely the wrong reason: that they are controlled not by the workforce but by the market. It ought to be clear that production is for use, and that what is produced ought in the last analysis to conform to user needs, i.e. to be controlled by a force outside the production unit itself. This could be the market, in which bargaining takes place between producer and user. It could be a planning agency, who informs the production unit what is should be doing. Tertium non datur.

6. Labour, wages, ‘the proleteriat’. Several distinct points need to be made.

1. (a) The end of the wages system. This is not what real workers want. Money wages give freedom of choice, including the choice of hiring the services of each other (to repair the
Marx's idea of tokens denominated in hours of labour (‘which are not money and do not circulate’) makes very little sense, and not surprisingly has not been applied. If goods are distributed free, this usually limits consumer choice: you take what you are given.

2. (b) Labour direction is the sole known alternative to material incentives or other forms of inequality. This was understood by Kautsky, Trotsky and Bukharin, when they discussed this question. The term ‘labour market’ has an opprobrious sound, reminiscent perhaps of a slave market. Yet workers are freer, have greater choice, more possibility to bargain, than under direction of labour, necessarily exercised by officials with power over persons.

3. (c) The proletariat as redemptor humanis is essentially a religious concept, unrelated to the qualities and desires of the real working class. Eloquent words on this subject have been written by Andre Goroz: ‘No empirical observation or actual experience of struggle can lead to the discovery of the historic mission of the proletariat which, according to Marx, is the constituent of its class being’ (Gorz, 1980, p. 22). Rudolf Bahro wrote that ‘the proletariat, the collective subject of general emancipation, remains a philosophical hypothesis in which is concentrated the utopian element of marxism’, and he added, rightly, that ‘the immediate objectives of subordinate classes and strata are always conservative’ (sind immer Konservativ) (1977, p. 174). But if one accepts these and other similar arguments, it follows that, as Lenin said, the working class left to itself will limit itself to ‘trade union’ types of demands, and so it is the task of the revolutionary intelligentsia to provide the revolutionary theory. This in turn leads to what has been called ‘substitutionism’, i.e. a party dominated at the top by non-workers, which in its turn dominates society, an outcome prophesied by Bakunin well over a hundred years ago. It is clearly not the case that, to cite Marx's letter to Weydemeyer in 1852, ‘the class struggle leads necessarily to the dictatorship of the proletariat’, which ‘is but a transition to the withering away of classes’ (letter dated 5 March 1852, Marx, 1962, p. 427).

Marxists may now be impatiently protesting that the above analysis is a vision of full communism, that no one, certainly not Marx himself, expected this to be realized quickly, or even certainly. The much-used words ‘socialisme ou barbarie’ show a recognition that barbarism can be an outcome if the socialist idea fails. Trotsky spoke often of a ‘transitional epoch’ during which money, markets, commodity production, are indeed indispensables. Soviet discussions refer to the indeterminate length of time required to move from ‘socialism’ (i.e. Soviet reality, which they define as socialism) to full communism. For example, a book devoted to the subject and published for the fiftieth anniversary of the revolution duly lists the characteristics of communism (abundance; from each according to his ability, to each according to needs; the elimination of commodity money relations, and so on), but goes on to stress that communism must be preceded by the lower ‘socialist’ phase, and that to try to overleap that phase is ‘a harmful utopia’ (Gatovski, et al (eds), 1967, p. 9, p. 43).

Marx himself used ‘socialism’ and ‘communism’ almost as interchangeable terms. Whether ‘really existing socialism’ should be seen as a transitional society or as socialist is to some extent just a terminological question. In either case it is supposed to be evolving towards fully fledged socialism or communism. But does it? Should it? What are the signs by which such an evolution can be identified? Bettelheim has good evidence for his view that, for Marx and Engels, when the workers acquire the
means of production, ‘there will be in socialist society, even at the beginning, no commodities, no value, no money, and consequently no prices and no wages’ (Bettelheim, 1968, p. 32). Equally strongly, the French critic Cornelius Castoriadis roundly asserts that ‘Marx knew nothing of transitional societies infinitely contained within each other like Russian dolls or Chinese boxes, which Trotskyists later invented’ (Castoriadis, 1979, p. 299). Marx did specifically say, in the *Grundrisse*, that ‘nothing is more absurd than to imagine that the associated producers’ would choose to interrelate via commodity production, exchange, markets. We have already noted that, in his *Critique of the Gotha Programme*, Marx envisaged an immediate conversion of wages into tokens denominated in hours of labour, not despite but *because* society will still bear the stigmata of pre-socialist attitudes. In the 1920s in the Soviet Union it seemed obvious to the party comrades that reducing the area of market relations was in some sense the equivalent of an advance towards socialism. Indeed those who forced 25 million peasant households to join so-called collective farms thought that this was part of the class struggle, though the effect was to turn independent ‘petty-bourgeois’ households, who did to a considerable degree control their own means of production and their product, into something akin to a new sort of state serfdom. If socialism is to do with the liberation of the ‘direct producers’, then surely this was a march in the wrong direction.

Similarly, can we say that the Hungarian or Soviet reformers of today are wrong in advocating an extension of ‘commodity-money relations’? And if the point is made that such a judgment would be premature, but that communism is still an aim to pursue when circumstances are propitious, it is legitimate to ask: what circumstances can be imagined in which communism/socialism in Marx’s sense *could* come about? No wonder the Soviet orthodoxy of today is to speak of ‘mature socialism’ as a long-term stage, with communism seen as a remote objective of no short-term operational significance. There were also socialist alternatives to Marx, during and since his lifetime. William Morris combined some ideas derived from Marx with ethical socialism and devotion to arts and crafts. Others further developed Christian socialism of various kinds, and indeed much could be made of the contrast between Christian ideals and the mercantile spirit, the ‘dark satanic mills’ (‘and we will build Jerusalem in England’s green and pleasant land’). The British Labour party in its origins and for many decades afterwards was heavily influenced by Christian beliefs, especially those based on Methodist and other nonconformist creeds (thereby attracting some contemptuous remarks from Lenin). The Fabian society (Shaw, the Webbs and others) by contrast, preached non-religious (and non-violent) socialism, opposed extremes of inequality, and advocated industrial democracy. However, though they too influenced the Labour party, the Society remained a small intellectual group, with a tendency to believe that an elite (themselves), or even a strong dictator, would show the way. It is perhaps no accident that both Shaw and the Webbs lived to express an admiration for Stalin – even though they themselves would recoil from cruelty and killing. Mention must also be made of G.D.H. Cole and ‘guild socialism’, with decentralized decision-making by producers’ associations.

On the continent, social-democracy nominally retained its allegiance to Marxism. However, already in 1899 Edward Bernstein advocated a non-revolutionary revision of many of Marx’s theories. While the leaders of German social-democracy, men like Bebel and Kautsky, rejected Bernstein’s ‘revisionism’, it was in fact rooted in the considerable improvement of the workers’ living standards, the weakening of revolutionary spirit. In the end, while retaining marxism as their nominal creed, German and other continental social-democrats (notably the ‘Austro-marxists’, such as Otto Bauer) adopted a non-revolutionary position which differed little from Bernstein’s and became a party of moderate reform.
within capitalist society.
In Russia, side by side with the growth of marxism (initially preached by men such as Plekhanov and Zieber) there arose other and non-marxist socialist currents, sometimes labelled ‘populist’. They believed that a Russian road to some form of socialism could be found, perhaps based on traditional communal institutions, which would enable capitalism to be by-passed. These ideas came from men such as Mikhailovsky and Vorontsov. As we shall see, Marx himself did not reject this possibility. There were also some influential anarchist socialists, owing inspiration to Bakunin, of which Prince Peter Kropotkin was a colourful example.

Since 1945 European social-democrats have tended to abandon their already tenuous allegiance to Marx and Marxism, and it may be hard to discern the extent of commitment to socialism of any sort in the programme and policies of the German and French parties. By contrast, the recent evolution of the Italian communist party has put it close to a social-democratic, evolutionist position. Opinions vary within the British and the Scandinavian Labour parties. Further change may well depend greatly on what happens to contemporary capitalism.

Of course the future may reserve surprises for us all. While material resources may be finite, the scientific-technical revolution may enable us to economise labour on a big scale. The resulting high level of unemployment may be a chronic disease. True, by freeing factory and office labour, we could, in a more rational society, greatly enlarge labour-intensive forms of providing a higher quality of life. But precisely this is opposed, and successfully so, by the New Right, by the ‘Chicago’ ideology, which is vehemently against public expenditures. Yet we may already be reaching a stage in which the profitable (privately profitable) use of labour can cover only a portion of those available for work. A possible reading of Marx places emphasis on equating the realm of freedom with freedom from work (i.e. from necessity), with a much shorter working week, and Gorz too sees freedom as a situation where one can undertake handicrafts and other hobbies. This would be a paradoxical reversal of the view that the one scarce factor of production is labour, since then it would be the abundant factor, the problem being how to share it out. This would not be the era of abundance. To cite an example, fish could be caught by modern trawlers using fewer fishermen, but dangers of over-fishing would compel a strict limitation on numbers caught. This brings one back to the idea of an environment-preserving, ecologically conscious, employment-sharing socialism as an attractive alternative to capitalism. But this was not Marx’s alternative.

A case for socialism can be made, not only along the ‘ecological’ lines mentioned above. In the developed world, massive resources are devoted to persuading people to buy trivia, to keep up with the Joneses. Unemployment is a scourge which is a threat to public order. External diseconomies (and external economies too) frequently cause the pursuit of private micro-profit to conflict with more general interest. The ‘quality of life’ may not be readily quantifiable, but several economists (for instance Kuznets, Tobin) have noted that conventional measures of economic growth by GNP can conceal real losses, or indeed count real costs of urban living as a net addition to welfare. The inequalities of income and property-ownership have all too often no visible connection with the contribution to society or to production of the individuals concerned. Schumpeter (cited in Brus, 1980) rightly pointed out that no social system ‘can function which is based exclusively on free contracts … and in which everyone is guided only by personal short-term interest’. Furthermore, fanatics of the New Right are engaged in reducing essential public services, disintegrating where possible the welfare state, cutting back public transport, pursuing dogmatic monetarism, in the naive belief that primitive laissez-
faire is the best of all possible worlds. It may turn out that the grave-diggers of capitalism will be those ultra-'liberal' ideologists who fail to understand how modern capitalism really works, that the so-called imperfections (price and wage stickiness, administered prices, oligopoly and so on) are preconditions for the functioning of the system. On the assumption of perfect competition, perfect markets, perfect foresight, there is no role for the entrepreneur, no reason for firms to exist, and logically enough profits tend to zero in equilibrium. The idea that rational investment decisions are possible when we face so many inflationary uncertainties (what will the rate of the dollar, or the rate of interest, be in a year's time?) is somewhat far-fetched, to put it mildly, and inconsistent with meaningful ‘rational expectations’. The belief that all markets clear, that unemployment is ‘voluntary leisure preference’, curable by freeing the labour market, will sound very odd to future generations.

No socialist should deny the need for economic calculations. With no price mechanism it is not possible to calculate or compare cost, or to measure the intensity of wants. Microdemand cannot be derived from voting or from clamour, nor should there be ‘dictatorship over needs’, to cite the title of a critique of East European socialism (Feher et al., 1983). There really is no alternative to allowing choice, i.e. to ‘voting’ with money. Choice necessarily involves competition between actual and potential suppliers. Yet the limitations of the price mechanism also require to be clearly seen. As the Hungarian economist Janos Kornai (1971) has pointed out, major decisions are not and cannot be taken on the basis of price information alone. The currently fashionable ‘methodological individualism’ goes far to deny the very existence of the general interest, distinct from that of individuals composing the society, confining ‘public goods’ to defence and lighthouses. (Yet it is not even true that the interests of a firm are only the sum total of that of the individuals composing it!)

Socialism as an idea lays stress on the general interest, but has not always avoided overstressing this at the expense of the individuals, for otherwise the dangers of totalitarianism (albeit of a paternalist kind) may loom ahead. The notion that Man is at the mercy of blind forces he cannot control, or of mighty and remote corporations (faceless, sociétés anonymes, or worse still, inhuman computers) sets up a search for a ‘socialist’ alternative, more human, fairer, and not necessarily less ‘efficient’ in terms of human welfare. Acquisitiveness and competitiveness may be unavoidable, must indeed be utilized, but do not require to be encouraged. Individualist profit-seeking as the dominant purpose in life, can be regarded by socialists as inhuman and ultimately destructive of society. A greater – not exclusive, but a greater – emphasis on caring for others may be a precondition for survival. More directly destructive would be nuclear war. There was a long-standing attachment of the idea of socialism with that of peace. This can be less confidently argued today, alas (when Chinese and Vietnamese soldiers shot at each other, could they both be ‘socialist’?). Experience does show that states aiming to be socialist can commit aggressive acts, and accumulate immense stores of destructive weapons. None the less, the autonomous role of the arms lobby and of hate-propaganda may be particularly associated with militant capitalism.

Socialist ideas in the Third World raise some specific problems. While it is dangerous to generalize about so heterogenous a group of countries, in many of them the logic and spirit of capitalism is rejected. There too, to re-quote Bahro, ordinary people are ‘immer konservativ’, and it is capitalism which is new, which threatens traditional ties and attitudes. The effect may or may not be to provide mass support for socialist slogans: we have had such phenomena as Khomeini and Moslem fundamentalism by way of reaction. But socialist ideas do attract many, in places as far apart and as different as Chile, India, Egypt, Zimbabwe. Of course many blunders have been committed in the name of pursuing socialist policies, not least in relations with the peasantry. But there are many examples
which demonstrate that there are countries where free-market capitalism, far from being associated with free and democratic institutions, requires repressive police-state measures. Pinochet's Chile is but one such example.

The relationship between socialism and economic development is a subject in itself, on which volumes could be written. It has often been pointed out that, paradoxically, marxist-inspired revolutions have occurred in relatively backward countries. Indeed, the Russian Empire in 1917 was in no sense ‘ripe’ for socialism. The preconditions were absent, and the Mensheviks considered themselves to be orthodox marxists when they denounced the Bolsheviks for trying to overlap the predestined historical stages. Lenin, on the contrary, believed that it was possible, indeed essential, to seize power when opportunity offered and then to create the preconditions, with (he hoped) the help of revolutions in developed industrial countries. Some of the less agreeable features of the Soviet system can be ascribed to isolation in a hostile world, or to ‘socialism in one country’, though it would be wrong, in the light of later experience (such as the evolution of the relations between the USSR and China) to regard this one factor as decisive. But, true enough, backward countries seeking to introduce ‘socialism’ introduce backward ‘socialism’. It becomes an industrializing ideology, mobilizing the masses and imposing sacrifices for the goal of modernization, of industrialization, with a substantial admixture of nationalism. Whatever may have been their conscious aim, a strong case can be made for the proposition that Lenin and Mao re-established their respective empires, after a period of breakdown and disintegration, which in China’s case lasted almost a century.

Marx's attitude to the socialist transformation of backward countries was by no means clear-cut. While his basic model did point to a socialist revolution occurring in highly industrialized capitalist countries, his correspondence with Vera Zasulich showed that he had great difficulty in applying his ideas to Russia. Theodor Shanin has edited a lively and (in the best sense of the word) provocative volume (Shanin, 1984), which does show Marx's perplexity, his partial recognition that there would perhaps be a road which by-passes capitalism. This was far from the view of Russian marxists, and the correspondence with Zasulich remained unpublished until 1924. However, on other occasions Marx took a different view, as when he regarded British rule in India as progressive, in the sense of introducing capitalist relations into a traditionalist society.

Any analysis of ‘really existing socialism’ would have to take account of the major role of nationalism, though this at least would have astonished Marx. It influenced Soviet internal and foreign policies, it surely played a key role in the split between Russia and China, it may be seen in the treatment of the Hungarian minority by the Romanians. The Soviet author Vasili Grossman, in his major novel *Life and Fate* (1985), put into the mouth of one of his characters the thought that the battle of Stalingrad completed the process of transforming Bolshevism into National-Bolshevism (needless to say, the book was not published in the Soviet Union). We are very far from the idea that ‘the workers have no fatherland’, and the proper translation of the Soviet official doctrine of ‘proletarian internationalism’ is ‘acceptance of the leadership of Moscow on all important questions’.

There is one aspect of ‘backward socialism’ which has profound political and social significance. In the USSR, in China, and in many Third World countries, the peasantry formed a large part of the population and there was a sizeable petty bourgeoisie. Far from having exhausted its potentialities, the ‘marketization’ of the economy was still in its early stages. In Marx's model the bulk of the petty bourgeoisie has been eliminated by monopoly capital. But in these countries, in the name of the class struggle, it was destroyed by coercive state policies, i.e. by police measure. Indeed, the police has to be
ever-watchful in case the banned private activities are reborn. This is one reason, among others, for there being socialist police states, which have only a remote connection with Marx's 'dictatorship of the proletariat'.

Much could be said about socialist analyses of underdevelopment, and such names as André Gunder Frank, Samir Amin and Arrighi Emmanuel come to mind. How far was underdevelopment due to capitalism and to links with the world capitalist market? Do socialist remedies require a break with that market? Is the poverty of the Third World due to ‘unequal exchange’ and exploitation? Is there any operational meaning in the so-called transfer of values? Thus if (say) Zaire buys a machine from the United States and a precisely similar machine at the same price from India, are ‘values transferred’ in the one case and not in the other?

If Amin is to be believed, such a deal would actually impoverish Zaire if the purchase is from the United States, for presumably the machine would contain much less labour than the similar machine bought from India, or than whatever Zaire exports to America in exchange for it. Yet frankly this is nonsense. Which by no means excludes the possibility, or even the likelihood, of unequal gains from trade.

It is of interest, in the light of some socialist theories of development, to compare the experience of various countries which follow widely different models. In doing so it is evidently important not to select countries which suit a prearranged roman à thèse. Thus Cuba's record on literacy, health, the poor, compares favorably with (say) Guatemala, its economic performance is outshone by South Korea and Singapore, but it would be far-fetched to imagine that Cuba under another Batista would have equalled such countries as these; many factors are involved other than the economic system. More to the point would be to compare South Korea with North Korea: same people, same historical experience until 1945. In this instance South Korea undoubtedly out-performs the North. In Africa the free-market orientated Côte d'Ivoire has done better, even for its poor, than those of its neighbours who have opted for socialist-type solutions, but again, some African countries have achieved an appalling mess for reasons very far removed from socialism: Ghana and Uganda can serve as examples.

Those who assign to capitalism, or the links with the world market, the responsibility for income inequality, unemployment, regional underdevelopment, etc. should be made to study China. China also illustrates the correctness of the idea advanced by Arthur Lewis: the general level of wages in a given country depends not on the relative productivity of specific workers: thus an Indian or Chinese driver of a five-ton truck is probably as ‘productive’ as his American or British equivalent. It is determined by what he called opportunity-cost, notably (in predominantly peasant countries) the very low productivity and rewards available in agriculture. Thus wages in Shanghai, even in the modern industrial sector, are very low indeed. Were China a capitalist country, this would be the effect of the enormous ‘reserve army of labour’ constituted by 800 million peasants, whose income is much lower than that of Shanghai workers. In China it is a matter of public policy that urban wages be not too excessively far above the levels in rural areas. The effect is not dissimilar.

True enough, any comparison between China and India must note the great inequalities of income in India, and also the fact that the lowest strata of the poor in India are very poor indeed, compared with China. However, as was pointed out by Amartya Sen, India since independence has found it politically indispensable to avoid mass famine, while China suffered acutely from the politically imposed effects of the Great Leap Forward: millions died.

Nor should one ignore the big regional disparities in China, or the very considerable inequalities which existed even before Deng's reform policy was adopted. Also Yugoslavia's regional inequalities persist.
Of course in both these instances there are historical and geographic explanations. All that can be said is that these matters resist speedy solutions under all systems.

To return to the developed world, the Soviet model has come to serve as a negative factor, and Western socialists, and indeed Eurocommunists, have tried to distance themselves from it.

The negative influence of the Soviet example is partly due to the revelations about the Stalin terror and Gulag. But, paradoxically, it was the Stalin period which, with all its horrors, did show a high degree of dynamism, high growth rates, evoking some enthusiasm and commitment from many Soviet citizens as well as foreign observers. It was brutal, it was crude, but they were forcing through a huge industrialization programme, preparing for war, fighting it, eventually winning it. There is, unfortunately, some Stalin-nostalgia in the Soviet Union today, analysed vividly by the emigré Viktov Zaslavsky (1982). ‘Really existing socialism’ has become grey, dull, undramatic, inefficient, more than a little corrupt. The ruling stratum under Stalin was young and faced sizeable risks of purge and execution. People could find little to enthuse about under the Brezhnev gerontocracy; the privileged abused their privileges without fear of punishment, shortages and poor quality contrasted with official claims of successes. Of course, under Stalin, things were in fact much worse. There were indeed horrors, but they were little understood outside the Soviet Union. (Thus the brutalities of collectivization and the famine that followed it were fairly successfully concealed from view.) The result was that the Soviet Union and the ‘socialism’ it represented became for a time a pole of attraction for millions. ‘I have seen the future, and it works’, ‘Soviet communism – a new civilization’, to cite two contemporary judgements. Today the Soviet model no longer impresses or convinces. It is not in chaos, it is not about to fall apart, but it is no beacon, can inspire nobody either in or out of the Soviet Union. And this despite the fact that much has gone wrong in the capitalist West. We will see if the new generation of leaders can restore the lost dynamism.

A few left-wing intellectuals transferred their allegiance to Mao. As was the case with some Western admirers of Stalin's Russia of the Thirties, this allegiance or admiration was based on misunderstanding, on ignorance. The ‘Maoists’ simply did not know about the real Great Leap Forward and its millions of victims, or just what the ‘Great Proletarian Cultural Revolution’ was really about. The post-Mao reaction brought them to their senses. The Yugoslav self-management model too has had its admirers, and indeed its principles are attractive, and will be looked at below. However, grave economic problems have hit Yugoslavia. By no means all of them are connected with the self-management model, but the fact remains that the negative aspects now tend to predominate in observers’ minds. Then there was Poland. The ‘Solidarnosc’ story, in the present context, is one which not only highlights governmental economic ineptitude, but more important, makes spectacular nonsense of the communist claims to represent the workers, or to be the advance-guard of the proletariat.

So, to summarize, socialism is not, at present, a politically attractive slogan, and this despite the quite vigorous efforts of the New Right to destroy ‘consensus-capitalism’. Worse, the immediate political programme of (for instance) Labour's left in Great Britain may be a sure recipe for trouble, reminiscent of the tragic errors of the Allende regime in Chile (which I had the sad experience of witnessing: price control, import controls, large wage increases, the disruption of the normal functioning of the market with no coherent idea of how to replace it).

Democratic socialism, however defined, can come only if the majority of the people are convinced that the old order has outlived itself, that major changes in a socialist direction are urgently needed. In a perceptive analysis, S.C. Kolm has noted a repeated tendency: a left-wing government is elected, and its
economic policies begin to hurt those middle strata (or middle-class, or left-centre parties) whose votes brought this government to power. The result is a rightward shift of opinion, and either the loss of the parliamentary majority (as in France, in 1937–8, for example) or a successful right-wing coup, as in Chile. Some draw far-reaching conclusions about there not being any democratic road to socialism (although, for example, in Chile there was no left-wing majority in Congress, Allende having been elected on a ‘reformist’ programme and with some support from left-wing Christian Democrats).

Whatever may be the actual or anticipated resistance of the powers-that-be, one can only repeat that democratic socialism requires the support over a prolonged period of the democratic majority – and right now this is not available – except for Swedish-style welfare state social-democracy (which has again won an election in Sweden on a welfare-state programme).

Perhaps Sweden is in fact the model we should study, if what we seek is a programme which a moderate, non-revolutionary, democratic-socialist party ought to ‘sell’ to the electorate. Yes, it is a high-tax solution, but one which the electorate, at least in Sweden, can be persuaded to prefer to any Swedish translation of Thatcherism. In my book on *Feasible Socialism* (Nove, 1983), I rejected the notion that Sweden is a socialist republic (‘and not only because it is a monarchy’), and of course there is a large ‘capitalist’ sector. But there is no serious current of opinion in Sweden which would support a policy of nationalizing the privately owned enterprises, or other drastic changes of existing arrangements. So if this is in fact the practical policy recipe of moderate-socialism or social-democratic parties in Western Europe, then this might be seen as a medium-term objective. Leaving the term ‘socialist’ as a distant perspective, just as the official Soviet propaganda now views full communism. Just as the Soviet government does not tell people that they actually intend at any particular date to abolish wages and prices, so a Western socialist party should not be committed to ‘the introduction of socialism’ as a policy for today. But there should be a longer-term objective. What objective?

For reasons already examined at length, it cannot be the socialism/communism foretold by Marx. Then what can it be? Let us examine this subject, bearing in mind the three points made earlier: what relationship between management and workforce; how do productive units interrelate; and what sort of state can be envisaged – bearing in mind that a state there would and must be, with important functions to perform.

So let us look at self-management. Why has its Yugoslav version lost much of its attractiveness? As already suggested, some of the reasons have little to do with the self-management model as such: centrifugal tendencies in a multi-national state with a relatively weak central authority; unwise policies on interest rates (which have been negative in real terms) and on foreign exchange; lack of any effective control over bank credits, to cite some examples. However, certain lessons can none the less be drawn. One is that self-management is not necessarily desired by the workforce, in the sense that many wish to spend long hours sitting in committee-rooms or studying the firm's accounts. However, the formal responsibility of management to the workforce is an important principle, as is the right of participation, which can be exercised when something goes wrong or feelings run high.

A second point relates to the lack of interest of much of the workforce in the longer term. This is a consequence of that fact that the capital assets do not belong to them, and when they leave they have no saleable asset to dispose of. Their only interest is in the income they can earn. This inclines them to a short-term view, to a desire to increase current income rather than invest in the future. One effect is to increase inflationary pressure.

Thirdly, neither the workforce nor the management has any real responsibility for investment decisions,
past or present. Suppose they prove disastrous, who is to blame? If indeed the initial investment decision (to set up the firm) was mistaken, and it was taken before there could be a workers’ council or the election (appointment) of a manager, why should management or labour be penalized? This is one aspect of a wider problem: that of how to cope with failure under socialism (other than be assuming that it will not occur!).

Fourthly, by making the workforce's incomes dependent on the given enterprise's financial results (subject, to be sure, to a legal minimum), one ensures unequal pay for equal work, and thus a chronic source of tension and discontent. Thus suppose citizen A and citizen B both drive five-ton lorries from Zagreb to Split, but A works for a more successful enterprise than B; they may well receive very different pay. The resultant pressure for higher pay in the financially less successful enterprises is yet another source of inflationary pressure.

Fifthly, Yugoslavia suffers from unemployment. Yet material incentives based upon dividing net revenues among the existing labour force builds in a reluctance to employ extra labour, whenever such employment would diminish the sum represented by net (distributable) revenue per head. In choosing between investment variants, there is for the same reason a tendency to choose the more capital-intensive variant, in comparison with the profit-orientated capitalist or the ‘plan-fulfilling’ Soviet manager.

For what should be obvious reasons, self-management requires a market. The self-managed units decide what to produce by reference to market criteria, and purchase their inputs by freely negotiating contracts with suppliers. Charles Bettelheim was quite right when he wrote that ‘commodity production’ (i.e. for exchange) must exist so long as units of production are autonomous and not wholly integrated into the plan. Yet he criticizes Yugoslav-type self-management: the workers do not really control their means of production and the product – the market does. This presupposes the existence of some unrealizable alternative, in which what is done and the acquisition of means to do it are controlled by no outside force at all. Yet needs have to be conveyed somehow, if not through negotiating contracts then via instructions from a superior authority.

Another significant moral to draw from Yugoslav experience relates to regional questions. In a country which, for historical and geographical reasons, has a relatively highly developed north and a backward south, measures to correct these disparities have had little success. Experience elsewhere shows that such matters defy solution in very different systems (for instance, compare Italy's mezzogiorno, or the megalopolis problem in such countries as Mexico and Brazil). However, the combination of autonomous ‘self-managed’ units and centrifugal forces, with the centre in a relatively weak position, tends to perpetuate or even reinforce regional inequalities. Indeed – and Soviet experience with sovnarkhozy (regional economic councils) points in the same direction – one might conclude that regional power over enterprises is very likely to result in irrationalities. The reason is clear: a local authority has information about the needs of its locality and, unless prevented, will tend to give them priority to the detriment of other localities, with duplication of investments as yet another undesirable consequence. In other words, if one were to imagine a modern industrial society with complex interregional links, there are two possible logical solutions: central control or enterprise autonomy (the ‘enterprise’ could, in some circumstances, be large or even, in such cases as electricity supply, a centrally controlled monopoly). If power over resources were given to an authority covering one area, it would divert resources for its own purposes, with potentially disruptive effects.

Finally, one must refer to the very considerable literature, of which Ward's fascinating excursion into...
‘Illyria’ is the original example (Ward, 1958), which appears to prove that self-managed enterprises, in which the workforce’s income depends on that enterprise's net revenue, are of their nature inefficient. Some of the conclusions are irrelevant to the real world. Thus Ward's model shows that it would ‘pay’ the firm to reduce output if prices rose, but this would only be so under the assumption of so-called ‘perfect competition’, in which such considerations as real competition do not enter. For example, in real competition one is concerned not to lose customers to one's competitors, who might not be regained if prices fall, as in future they might. Nor are self-managed enterprises likely to dismiss fellow-workers without some extremely strong reasons. None the less, as already noted, they may choose labour-saving, capital-intensive investment variants even when unemployment is a major social problem. It may be necessary (and it surely is possible) to devise fiscal means to counteract this tendency. As for efficiency, this depends (inter alia) on the attitude of the workforce. Would the sense of participation increase commitment and loyalty, and so the quality of the work effort? These considerations seldom figure in economic analysis (with Albert O. Hirschman an honourable exception). Some unimaginative model-builders would doubtless also conclude that the reluctance of Japanese firms to shed labour is ‘inefficient’, yet any loss can be counterbalanced by the sense of ‘belonging’ that goes with security of employment. A recent study of Israeli kibbutzim noted that one finds no resistance there to labour-saving innovations, which can be encountered in private firms, because such innovations do not threaten loss of jobs.

There are lessons to be learnt from the experience of the Mondragon cooperatives in northern Spain. Unlike the Yugoslav enterprises, they pay wages, so that there is an identifiable profit. They also ensure that the workforce has shares in the business (if necessary lending them the money to acquire them), and this also gives them a longer-term stake in its prosperity. It is, however, worth recalling that the Mondragon enterprises function in an area of strong local loyalties, just as the kibbutz members are committed volunteers. The outcome may be different with different human material.

Socialists must be aware that there are bound to be problems connected with property ownership and long-term responsibility, involving also risk-taking and the consequences of failure. Where uncertainty exists – i.e. in any conceivable situation – there must be the possibility of failure. A capitalist can go bankrupt, but what of ‘socialist bankruptcy’? One cannot ‘solve’ this question simply by assuming either perfect foresight or perfect planning. The existence of genuine autonomy of decision-making is surely an aim desirable in itself, and freedom necessarily involves both uncertainty and freedom to err, to act in ways not necessarily consistent with the general interest or the national plan.

What, then, could a ‘feasible socialism’ be like? Should the word be redefined? Surely a non-utopian definition of socialist values should be counterposed to the crude laissez-faire ideology of the New Right. Some of the traditional slogans associated with socialism have become deservedly unpopular. There are good reasons to associate nationalization with bureaucracy, satisfying neither the workforce nor the customers. It is in a review in Radical Philosophy (Spring 1985) that one can read: ‘A regime devoted to equality in its literal sense would have to be authoritarian, ready to crush inequalities whenever they reasserted themselves, as they inevitably and constantly would.’ The New Right's view of ‘liberty’ may be distasteful, but one must recognize that the aims of equality and freedom can conflict with one another. Socialism cannot be happy with a purely acquisitive society. Indeed such a society would fall apart, for why should civil servants, judges, police officers, not be crude income-maximizers, i.e. behave as most doctors seem to do in America? Yet acquisitiveness is not a value to be disparaged, the vast majority of citizens do have material aspirations. Thus a conscientious doctor does his best for
his patients, even if they cannot pay an economic fee, but he or she is also not averse to acquire a country cottage and go on holiday to Greece. Furthermore, at least since the days of Adam Smith it has been rightly noted that there are worse ambitions than making money: the men who, in the process of competing for power, sent their comrades to be shot in cellars were not seeking to maximize profits. What is to be sought is a balance between (enlightened) self-interest and a sense of social responsibility. Inevitably this differs as between individuals.

Individuals also differ greatly in what might be called ‘producers’ preferences’. Some like to be independent innovators, others prefer routine. Some gladly take responsibility, others prefer to avoid it. Some opt for life in a commune or kibbutz, others would be very unhappy there. While Marx's vision of a universal Man is a fantasy, it is not at all a fantasy to provide both for variety and for the opportunity to change one's specialization if the spirit so moves one. A socialism based on one economic model might be a sort of procrustean bed for a sizeable part of the population. (Imagine, for example, compulsory communal living!) Hence it seems desirable to redefine ‘socialism’ as a mixed economy: enterprises large and small, many if not most self-managed or cooperative, with some private enterprises too. If the private sector does not play a dominant role, its existence should be consistent with a sensibly defined socialism; otherwise its suppression would be the constant task of a ‘socialist’ police (unless, of course, it proves not to be needed, in which case ‘privateers’ no more require to be banned than to outlaw private water-carriers when everyone has tap water). A major objective would be not only to ensure variety of choice of occupations, but also work for all, when unemployment is in danger of becoming a major social curse. Only in ideological textbooks of economics do labour markets automatically clear. One must anticipate the need to take job-creating action. One must also anticipate that freedom to organize involves freedom to form not only political parties but also interest groups which will press for additional resources. Since money will undoubtedly continue to exist, it would be possible to issue too much of it in the face of pressures, so inflation (and some species of monetarism) will not just go away. Freedom of choice implies both a market and competition, both in consumers’ goods and producers’ goods and services, though there must also be some large-scale natural monopolies (such as electricity, water, public transport), where responsibility of management to the users is as important as its responsibility to its workforce.

Mises, Hayek, and later on also Friedman, have argued that efficiency in resource allocation is impossible under socialism. At a formal level they were answered by Lange, Lerner, Dickinson, but there were and are major practical obstacles in realizing their socialist models, which are anchored (as are so many of the neoclassicals’) in static equilibrium assumptions, and it is unclear why either the central planning board or the managers in Lange's model should act out their parts in the prescribed manner. It should be admitted that the absence of (or severe limits on) a real capital market can cause inefficiencies, that rewards for risk-taking and innovation may well sit uneasily with social or state ownership of capital assets. Nor is this all. Kornai, in his Dublin lecture (Kornai, 1985) pointed to contradictions between the requirements of efficiency and socialist ethics. But the world is full of contradictions, and one usually arrives at some species of compromise; ‘maximization’ in terms of just one objective function can seldom be encountered in really existing societies (a fully fledged and devoted ‘profit maximizer’ would probably suffer a nervous breakdown, if not already dead of cardiac arrest). Mises and company are right to insist that economically meaningful prices are needed, wrong to assert that socialist prices cannot be meaningful (though today's Soviet prices are indeed irrational, reflecting neither use-value nor relative scarcity). But it must be emphasized how far the contemporary
Western system is from the free-market model of the textbooks. Thus in his challenging ‘Profits without production’, Seymour Mellman notes and deplores the narrow concentration on short-term profits, by executives who have no long-term commitment to their corporation (on average they move to another one within five years or so). Current uncertainties about prices, interest rates, inflation, are hardly conducive to ‘rational’ long-term investment decisions. Too often critics of socialist economics (with its imperfections) implicitly compare it with a Chicago utopia, which is in its own way as unreal as a marxist one. Perfect markets and perfect plans are equally utopian.

But in the end much will depend on the ability of contemporary capitalism to surmount its many problems, not least that of mass unemployment and ecological decline (acid rain, deforestation, over-fishing, etc.). The masses will not opt for a different system unless faced with the bankruptcy of the existing one. To repeat, it was Marx who wrote that no mode of production passes from the scene unless and until its productive potential is exhausted. With Soviet-type socialism seen as obsolete, in contradiction with the forces of production, it offers no alternative model. A great deal remains to be done to revive socialism as an aim worthy of effort and sacrifice.

Article

The calculation debate centres on two issues. First, is it possible for a socialist society, with common ownership of the means of production, to use planning to replicate the performance of a capitalist society, with private ownership of these means of production? This is the ‘replication’ thesis. Second, is it possible to do ‘better’ than replication? This is the ‘improvement’ thesis. Both theses were widely accepted by economists until shortly before the planned economies passed into history with the demise of the Soviet Union (Lavoie, 1985).

We state the problem in terms of possibility in order to emphasize an ambiguity in the debate. What do we conclude when we observe a centrally planned economy that is unlike any known capitalist economy? Has the replication thesis failed? Not necessarily. Confronting such a situation, Drewnowski.
The calculation debate was launched in 1920 by a brief article in which von Mises challenged socialist economists to apply their arguments against market economies to their own systems. On the assumption that the collectivist state would allow private ownership of consumer goods, and thus private exchange, von Mises saw no particular problem with the allocation of consumer goods in such a setting (von Mises, 1920, pp. 90–2). The problem comes with collective ownership without exchange, since there

Von Mises on Mill

The calculation debate was launched in 1920 by a brief article in which von Mises challenged socialist economists to apply their arguments against market economies to their own systems. On the assumption that the collectivist state would allow private ownership of consumer goods, and thus private exchange, von Mises saw no particular problem with the allocation of consumer goods in such a setting (von Mises, 1920, pp. 90–2). The problem comes with collective ownership without exchange, since there
will then be no prices. If prices do not reflect opportunity costs, no ‘rational’ economic system is possible.

Von Mises's 1920 paper cites a small number of socialists, none of whom he respected. That situation changed in Socialism: An Economic and Sociological Analysis (German editions 1922 and 1932; English edition 1936), in which he draws the reader's attention to John Stuart Mill's thoughts on socialism:

The writer who has occupied himself most thoroughly with this problem is John Stuart Mill. All subsequent arguments are derived from his. … They have provided for decades one of the main props of the socialist idea, and have contributed more to its popularity than the hate-inspired and frequently contradictory arguments of socialist agitators. (Von Mises, 1936, pp. 154–5)

It is here that von Mises confronts the second model of economics, the model of socialism that Mill made for people of the future, somewhat like us only a little more sensitive to the opinion of others. Mill explained how a successful communal system must rely upon a different motivational package from that which characterizes market economies. The problem of the commons was central to classical political economy. T.R. Malthus's 1798 Essay on Population had addressed William Godwin's proposal of replacing private property with commons. Malthus asked why individuals would renounce or defer marriage and childbearing if someone else were to support them in case of difficulty. For Mill, a workable commons would require a great deal of motivation from the desire for approbation. For a system of equality to hold, the commoners must know that they cannot support each other's children without mass misery. They must understand the self-restraint that characterizes a market economy and, without any incentive other than a desire for praise and an aversion for blame, act on the basis of that understanding (Mill, 1848, II, p. 1, § 3). When embodied in the public understanding, the model must be self-motivating. We will return to the question of self-motivating models below.

Von Mises (1936) surmised that Mill failed to link material rewards with effort in a market economy because he wrote before the advent of marginal productivity theory (1936, p. 155). Von Mises acknowledged the problem of workers who are not paid by the piece – the partial basis of Mill's defence of socialism – and suggests this is the fault of the worker:

Doubtless the individual working for a time wage has no interest in doing more than will keep his job. But if he can do more, if his knowledge, capability and strength permit, he seeks for a post where more is wanted and where he can thus increase his income. It may be that he fails to do this out of laziness, but that is not the fault of the system. (Von Mises, 1936, p. 155)

To deal with public opinion motivation, von Mises denies Mill's hypothesis that human nature might alter and claims instead that motivation will be the same under both settings:

It is not impossible that under Socialism the public spirit will be so general that disinterested devotion to the common welfare will take the place of self-seeking. Here
Mill lapses into the dreams of the Utopians and conceives it possible that public opinion will be powerful enough to incite the individual to increased zeal for labour, that ambition and self-conceit will be effective motives, and so on.

It need only be said that unfortunately we have no reason to assume that human nature will be any different under Socialism from what it is now. And nothing goes to prove that rewards in the shape of distinctions, material gifts, or even the honourable recognition of fellow citizens, will induce the workers to do more than the formal execution of the tasks allotted to them. Nothing can completely replace the motive to overcome the irksomeness of labour which is given by the opportunity to obtain the full value of that labour. (Von Mises, 1936, p. 157)

Von Mises continues to suggest that 20th-century socialists object to this argument by pointing to heroic acts as counter-examples. He confesses that he does not understand heroes, people who are ready to die for their principles, driven purely by their ‘union of will and deed’ (1936, p. 158). He acknowledges that the fate of civilization itself depends on the heroic (1936, pp. 157–8) – but for the purposes of economic analysis, he is content to deal with the ordinary. Although von Mises was disinclined to pursue the heroic as a motivational force under socialism, there is an important sense in which the Soviet Union seems to have attempted to function on the basis of the heroic: the Stakhanovite (someone who joyfully over-fulfils the production quota), a Soviet-era concept of consequence (Kotkin, 1995, pp. 207–15), deserves attention.

Mill, too, was concerned with the character of the majority in any institutional setting; hence, to learn about social transformation one needed to apply the inverse deductive method, Mill (1844, VI, p. x, § 4). The idea that people might develop over time was ruled out of consideration by Hayek (1935a) in his summary of the history of the discussion:

John Stuart Mill, in his autobiography, numbered himself among the socialists, because he believed that certain ideas would be realized in the distant future. In this connection Cairnes pointed out that true socialism does not consist of a body of ideas which can only be realized if human nature and the conditions of human life are radically transformed. Socialism subsists in the recommendation of certain modes of action and in the utilization of the authority of the state for particular purposes. This appears to me also as the correct view. (Hayek, 1935a, p. 47)

The replication thesis

Fred Taylor's 1928 Presidential Address to the American Economic Association sets the stage for market socialism. He starts with a model of the private market economy:

First, on the basis of a vast complex of institutions, customs and laws, the citizen adopts a line of conduct which provides him with a money income of greater or less volume. Secondly, that citizen comes on the market with said income demanding from those
persons who have voluntarily assumed the rôle of producers, whatever commodities, he, the citizen chooses. Thirdly, the producers promptly submit to the dictation of the citizen in this matter, providing always that said citizen brings along with his demand entire readiness to pay for each commodity a price equal to the cost of producing that commodity. (Taylor, 1929, p. 1)

The ‘correct general procedure’ for market socialism is to maintain consumer sovereignty. Taylor thus argues that the planners must use the market model in the new institutional setting:

(1) the state would assure to the citizen a given money income and (2) the state would authorize the citizen to spend that income as he chose in buying commodities produced by the state – a procedure which would virtually authorize the citizen to dictate just what commodities the economy authorities of the state should produce. (Taylor, 1929, p. 1)

To implement this under socialism, Taylor proposes ‘trial and error’. The idea is that the planners start somewhere, and then if managers have an algorithm which implements the market model of capitalism, they adjust factor valuations on the basis of shortage or surpluses (Taylor, 1929, p. 8). Equilibrium follows. In H.D. Dickinson's judgement, Taylor's statement of the replication thesis withstood later criticism:

Taylor has the distinction of being the first writer to point out the way to answer Professor Mises's attack on socialists. Moreover, he answers in anticipation the later criticisms of Professors Hayek and Robbins, that had not been published when his paper first appeared. (Dickinson, 1938, p. 532)

The improvement thesis

Although market socialism literature took off from Taylor, Barone had earlier described an iterative solution to the problem of maximizing consumer surplus, for example, ‘maximum collective welfare’ (Barone, 1908, pp. 270–2), and he discussed the problem of how to determine productive coefficients experimentally (1908, pp. 287–8). Further, with his argument that one can do better than replicate the capitalist solution in the case of multiple prices, he announced the improvement thesis:

Hence, when the first area is larger than the second it is possible that multiple prices may be consistent with increase welfare for the community. And as such a proceeding is more possible when production is socialized, this is in reality a sound argument in defence of socialized production, in certain cases, when such conditions are proved to exist. (Barone, 1908, p. 283)

As the literature developed, the Taylor solution concept was refined and extended by a host of authorities. Responding to von Mises and developing Taylor's ideas without knowledge of Barone, H.D.
Dickinson (1933, p. 29) added that socialist markets would eliminate or reduce the divergence between private and social costs. For Dickinson, the improvement thesis was made in the welfare metric of orthodox economics characterized by consumer sovereignty (Hutt, 1940).

Maurice Dobb (1933), who had previously supported market socialism entailing consumer sovereignty, abandoned this position in 1933 (1933, p. 591). Instead, Dobb (1933) asked whether the state might actually create tastes (1933, p. 532) and why the rules of equating at the margin would apply to a state which can create technical progress (1933, pp. 596–7). There followed one of the most interesting and important contributions to the debate, Abba Lerner's defence of market socialism. Lerner mentions half a dozen mistakes in Dickinson's algorithm and counters that those in power do not wish to reconcile markets with socialism:

The cautious guardians of socialism are for retaining the superior strategic fastnesses of simple faith. The heresy must be eradicated. Against the ‘Dickinson’ thesis is the raised the antithetical slogan: ‘The categories of capitalist economy are inapplicable to the socialist society.’ (Dobb, 1933, p. 52)

Hayek entered the debate at this point with his edited collection Collectivist Economic Planning, which contained translations of Barone's and von Mises's original papers, as well as Hayek's summary of the discussion and his restatement of the issues in terms of the dynamics of the problem. Here the questions posed were: supposing that a solution were found to a static problem, what incentives does the socialist management have to solve the problem correctly? Why would the model have motivational force? (Hayek, 1935b)

Hayek also noted the ambiguity in the notion of ‘impossible’ in his discussion of Taylor and Dickinson. In his account, their papers were directed to show that on the assumption of complete knowledge of all the relevant data, the values and the quantities of the different commodities to be produced might be determined by the application of the apparatus which theoretical economics explains the formation of prices and the direction of production in a competitive system. Now it must be admitted that this is not an impossibility in the sense that it is logically contradictory. But to argue that a determination of prices by such a procedure being logically conceivable in any way invalidates the contention that it is not a possible solution, only proves that the real nature of the problem has not been perceived. (Hayek, 1935b, pp. 207–8)

The great step in algorithm development was then taken by Oskar Lange (1936), with comments and corrections from Lerner (1936). The market algorithm now improved upon the competitive equilibrium by solving for a social optimal in which the same consumer preferences pertained as in the capitalist economy. Market socialism became the Lange–Lerner model.

Hayek's (1940) review of the market socialism advanced by Taylor, Dickinson, and Lange questioned the details of the algorithm, pointing out many gaps in the explanations. Hayek's puzzle as to whether an
algorithm based on a model of price-taking competitive equilibrium was appropriate would later blossom into perhaps the most influential single article in the debate, his 1945 ‘Use of Knowledge in Society’ paper. The problem for the capitalist economy was reformulated as a division of knowledge. Prices reflect the decentralized knowledge possessed by all the participants in a market economy. Markets were now viewed in terms of information aggregation. Hayek also notes the importance of the socialist market economists, singling out Lange and Lerner for particular praise, and suggesting that the political aspect of the debate is now at end, leaving only methodological issues to resolve.

The entire focus of the calculation debate was challenged again in 1961 when Drewnowski revived Dobb’s position and asked why a socialist economy would wish to mimic or modestly improve upon a market. Why would not the planned economy find a political optimum as distinct from the consumer sovereignty constrained optimum? Indeed, if one looked at existing socialism in the Soviet Union, very little attention was paid to consumer wishes.

Proving the algorithm correct

The line of defence on the replication thesis consisted in taking a model of a private market economy and turning it into an algorithm that might be given to various functionaries of a planned economy. The defences differed on the basis of the model itself, or the algorithm, and in the latter instance the issue of possibility came into play. The question that emerged next was whether the solution of the model and algorithm would be the same. Specifically, would the agents in the model of capitalism make the same choices as those in the planned economy if, in fact, the incentives facing them differed under the two institutional settings?

The debate now moved from theoretical issues of information generation to understanding behaviour in socialist economies in the light of the incentives facing the socialist agents. In 1936, Durbin discussed the responsibility of economists to get things right, arguing that the economist certifies the model’s correctness, but not the algorithm’s correctness. There is no guarantee that it will be executed as ordered. That is someone else’s responsibility:

“The calculations will not be made.” “The mobile resources will be unwilling to move.” “The production units that ought to expand will refuse to do so.” All these criticisms may or may not be true. They may or may not be the real problems of policy. But they are not problems that the professor of economic theory is competent to discuss. They are problems of social behaviour. They can only be resolved, if they can be resolved at all, by a comprehensive sociological and principally psychological analysis. (Durbin, 1936, p. 678)

Later, reviewing the Taylor and Lange contributions, Dickinson points out the weakness in the algorithm. He focused on whether agents in the socialist algorithm would behave the same way as agents in the capitalist model:

Mr. Lange … speaks of rules that the Central Planning Board would have to impose on the managers of socialist enterprise. But what guarantee would there be that these rules
Is market socialism incentive compatible?

For capitalism and socialism to be described by one model, we require common technology, common preferences and common incentives. At the simplest level we require all three to have a price system. Could a strongly planned economy actually move to the pseudo-planning of market socialism? Eucken (1948) asked whether Lange's solution is incentive compatible in a centrally administered state:

Would it not perhaps have been possible to graft prices on to the controlling mechanism of the centrally administered economy in the following way? The central administration would have distributed consumption goods by rationing, as well as fixing prices. With regard to consumption goods, demand and supply would have been equated by rationing. But with regard to the factors of production, there would have been no rationing. Entrepreneurs would have applied for these to the state authorities. The factors would have been priced, and then these prices adjusted according to the extent of demand. By this adjustment of prices would not demand and supply have been possible? In this way, the German authorities would have been proceeding in accordance with proposals outlined by, for example, O. Lange. Wouldn’t it have been possible to follow this proposal? (Eucken, 1948, p. 93)

Not surprisingly, given what we know today, his answer was an emphatic ‘no’:

This method of control was out of the question for the central administration, for it would have meant to some extent letting the control of the means of production – in this case leather or iron – out of its hands.

Competition means the end of central authority:

Competition can be used to improve efficiency, but as a mechanism of direction for an important section of the economy it cannot be applied without abdication of the central authority. (Eucken, 1948, p. 94)

Eucken claimed that the outcomes, as well as the language used to describe outcomes in the two institutional settings, will differ. The critical term is ‘unemployment’. In an institution-free, Post-Keynesian economic model, one could draw a single production possibility curve for any society. Without unemployment, all would attain the frontier (for example, Samuelson, 1948, p. 20). Eucken notes that Keynesian unemployment, which is both privately and socially costly, would not be a problem
in a centrally administered economy:

every worker can be taken on regardless of costs. In an exchange economy, workers are dismissed because there exists a measure of scarcity with regard to single units … Workers are dismissed if the return resulting from their employment does not cover the costs. … even it is estimated that the costs of employing several thousand workers on road construction are not covered, the central administration does not have to cut the work short. In these conditions full employment is always attainable. (Eucken, 1948, p. 179)

But without prices to allocate resources, we revert to barter. Here is Eucken and Meyer's (1948) description of the barter economy that will emerge in the centrally administered economy:

In dirty, overcrowded, and unlighted trains they travel into the farm areas which are a hundred miles away in order to get from the farmers some food in exchange for part of their city rations, part of their wages in kind, if they receive such, or simply for other possessions which they still retain. They collect beechnuts from the forest and leftover ears of grain and potatoes on the harvested fields. In their free time or during their vacations they cut peat, collect wood in the forests, cultivate a small vegetable plot, or search for rabbit food. Housewives spend uncounted hours in lines before stores, in lines before distribution offices for ration coupons, and in lines before various other government offices. (Eucken and Meyer, 1948, pp. 56–7)

The economic consequence of barter is ‘misery’ and risks ‘death by starvation’:

From the economic point of view, such extra work is senseless waste. From the point of view of the individual German, however, it is exceedingly important because it saves him from ultimate misery and frequently even from death by starvation. (1948, pp. 56–7)

What puts society in this interior of the production possibility set? The ‘unemployment’ problem in capitalism maps to the ‘barter problem’ in planned economies because a move from planning to markets is not in the interests of those who hold state power.

The consequences of the calculation debate

The major principles textbooks of the post-Second World War era (Elzinga, 1992) drew from the planned economies’ lower consumption–income ratio the inference that they were growing faster than market economies. In doing so, they supposed that ‘unemployment’ had the same meaning in both systems (Samuelson, 1970, p. 3; Lipsey and Steiner, 1975, p. 899; McConnell, 1963, p. 751). As a consequence, his insight was temporarily obscured. The realization that planning entailed barter led to the abolition of the German centrally administered economy, but this insight was lost until the Soviet economies were near collapse. Then it became all too obvious that the disequilibrating prices and
pervasive shortages were the result of planners’ pursuit of private self-interest as opposed to the public good (Levy, 1990; Shleifer and Vishny, 1992).

Learning from the Soviet failure

The surprising collapse of the Soviet economies occasioned a useful series of discussions that attempted to understand both the failure of the Soviet economies and the failure of Western economists. It is appropriate that von Mises's and Hayek's works were re-read with considerable care by those on all sides of the debate.

The heroic in the Soviet economy

As noted above, von Mises rejected the possibility of socialism motivated by public opinion. The fact that heroic motivation is a puzzle for him may reflect the fact that economists have lost contact with the classical economists’ discussion of sympathetic motivation and the desire for approbation (Peart and Levy, 2005). For Mill, the strength of sympathetic motivation measures a civilization. The willingness of Americans to die because of their obligation towards the enslaved indicated to him the superiority of American civilization (Peart and Levy, 2005). For Mill, the desire for approbation is sufficiently strong that anti-social behaviour is attenuated because an individual wishes to avoid the disapproval that follows when he or she imposes a cost on society. Socialism on a small scale is then unproblematic to the extent that a socialist community has tight consensus concerning costly behaviour. If one disagrees with such proscriptions, one can leave that society. Mill’s dissent from large-scale socialism arose from his concern that it would be inconsistent with diversity of opinion: there would be no place to go to. Scholars have asked why the Soviet political authorities ignored the advice of expert engineers to insist upon the heroic. A belief in the efficacy of heroic motivation might explain the political appeal of the gigantic Soviet engineering failures such as the Great Dnieper Dam, the Steel City of Magnitogorsk and the White Sea Canal (Graham, 1993; Kotkin, 1995). When his engineers asked the authorities to consider what was feasible, Stalin is quoted as having responded: ‘There are no fortresses that Bolsheviks cannot storm’ (Graham, 1993, p. 42).

In his study of Soviet engineering failures Graham puzzles over why the political leadership gave up the feasible and risked the certainty of the ordinary for a chance at the heroic. Such a choice makes no sense if one is thinking of the incentives of a market economy with a democratic government. But if socialism itself is justified by risking the seemingly impossible, then the political calculus seems inescapable.

Had all the costs, social and economic, of the Dnieper dam been considered more carefully, and had the benefits of a single enormous hydroelectric power plant been weighted against those of several small ones, including thermal power plants, a different decision probably would have been made. These alternatives, now quite obviously more desirable, were outlined by Russian engineers during the early planning stages. The final decision to go ahead with the giant dam was based not on technical and social analysis but on ideological and political pressure. Stalin and the top leaders of the Community Party wanted the largest power plan ever built in order to impress the world and the Soviet
If industrial development is viewed as if it required wartime heroics then, on the basis of American experience of the Civil War, one might well expect a mix of volunteers and conscripts. And this, of course, was observed:

One of the characteristics of industrialization under Stalin was the coexistence of volunteer and forced labour, of heroic self-sacrifice and violent coercion. (Graham, 1993, p. 59)

Heroic motivation also provides some insight into the speed of the Soviet collapse. If people chose socialism over ordinary capitalism with the hope or expectation of the heroic, then, when the ‘heroic’ was revealed as a sham, there was no reason to believe that the public opinion that supported the system would hold. Events like the explosion at Chernobyl – ‘a product of the standard Soviet industrialization policy that emphasized gigantic projects over smaller ones’ (Graham, 1993, p. 90) – could no longer be hidden.

The ‘impossibility thesis’?

At the beginning of this article we distinguished between the ‘replication’ thesis and the ‘improvement’ thesis to identify the source of ambiguity in the question ‘Is socialism possible?’ Let us return to that theme in the context of a very simple question. Was it possible for the Soviet system to create projects which could have been deemed efficient *ex post* by the standard calculus? Let us be precise and define the heroic as something valued for its own sake. Soviet engineering for instrumental, non-heroic projects, for example military hardware, certainly passes any market test for efficiency. But when the political incentives were such as to view the project as an end in itself then, even when the *ex post* efficient projects were feasible from an engineering point of view, they were not selected by the political authorities. Thus, although efficient projects were possible, in the sense that anything feasible is ‘possible’, they were not observed and never existed. The debate between Caplan (2004) and Boettke and Leeson (2005) over the ‘impossibility’ of socialism struggles with this ambiguity, with the question of whether the Soviet Union failed because of the ‘impossibility’ of calculation or because of the perverse incentives of its rulers.

There is another way in which the ‘impossibility’ of socialism is ambiguous. Von Mises's argument asserts that a socialist economy cannot replicate the performance of a market economy. From this, can we infer that socialist economies could not exist with the consent of the participants? Surely not. There may well be benefits from socialism that over-compensate the material losses. This would seem an odd reading of von Mises if one supposes, as both sides of the Caplan–Boettke and Leeson debate do, that von Mises is engaged in an argument with Marx and his followers. It is not so odd if he is arguing with Mill's socialism.

Is socialism robust?
The attractions of socialism to disinterested scholars are evident in Roemer's efforts to re-imagine a socialism that can be defended after the fall of the Soviet Union. In a remarkable display of historical rethinking, Roemer works through the Lange–Hayek argument giving Hayek the better of each question (Roemer, 1994, p. 30). This is not just on technical economic grounds.

Hayek claims that Lange never justifies disallowing market determination of industrial prices in his proposal along with consume goods’ prices and wages. Indeed, Lange actually does but the justification seems weak if not wrong. He says that disequilibrium in industrial prices is very costly in the economy, since these prices determine the prices of all other goods, and that the CPB [Central Planning Board] can find the equilibrium faster than the market can. I am puzzled by this. It seems that perhaps Lange feared that, were he to allow the market to determine all prices in his model (except the interest rate), he would be giving up too much. As Hayek notes … the Lange proposal already makes great concessions to those who opposed pervasive planning, perhaps Lange believed it would not have been politically wise to go further. (Roemer, 1994, pp. 30–1)

Roemer identifies the problem with the Soviet Union as the incentives of the principal–agent sort (Roemer, 1994, pp. 35–9) and he argues that this can be attenuated by allowing democratic competition (Roemer, 1994, pp. 39–40). A model of the political process is proposed in which equilibrium brings with it a weighted average of the utilities of the poor and the rich (Roemer, 1994, p. 65). To deal with investment decisions, Roemer (1994) proposes the creation of institutions akin to the Japanese *keiretsu* (a group of interrelated companies, both in terms of products and owners, which is centred around a bank) sufficiently independent of the state so as not to allow politician–manager interactions (1994, p. 74).

Roemer's model of the political process is not the only one available. A long line of formal voting models worry about the results of changing the sequence of votes. If an agenda-setter can control the voting sequence he is able to force the results (for example, McKelvey, 1979). Faith in the performance of *keiretsu* may have declined somewhat from the early 1990s. Perhaps we should give some thought as to what can go wrong with a model of socialism as compared with a model of capitalism (Levy, 2002). If modellers are putting forward proposals out of sympathy for extra-scientific goals (Peart and Levy, 2005), then the arguments about model uncertainty in the context of least favourable priors take on a new urgency (Brock, Durlauf and West, 2007).

Eucken's argument that moving from a planned economy to market socialism is not incentive compatible does not, of course, preclude moving from a capitalist economy to market socialism. The question is whether that is where society would stay. If market socialism were to be judged a failure, would we return to market capitalism or move to less liberal institutions (Levy, Peart and Farrant, 2005)?

**soft budget constraint**

Gérard Roland
Edited by Steven N. Durlauf and Lawrence E. Blume

**Abstract**

The concept of ‘soft budget constraint’ was first proposed by Janos Kornai to explain the pervasiveness of shortages under socialism. It has subsequently been understood mostly as a dynamic incentive problem whereby an investor would like to commit not to bail out an agent but ends up deciding on a bailout *ex post*. The concept has had a large number of applications in the transition literature but more broadly in economics as it can shed light on important episodes of bailouts.

**Article**

The concept of ‘soft budget constraint’ was coined by János Kornai in his famous book *Economics of Shortage* (1980). In that book, Kornai developed a comprehensive theory of the socialist economy (completed in 1992 by *The Socialist System*). The starting point was that in the socialist economy firms had soft budget constraints as opposed to the hard budget constraints firms face under capitalism. ‘The classical capitalist firm had a hard budget constraint. If it is insolvent, it will sooner or later become bankrupt. •…• As opposed to this, the budget constraint of the traditional socialist firm is soft. If it works with a loss, that does not yet lead to real bankruptcy, i.e. ceasing operations’ (1980, p. 29). Kornai used the concepts of mainstream economic theory to contrast the situation of the capitalist firm and that of the socialist firm. Interestingly, in standard microeconomic theory only households have a budget constraint, not firms. The latter do not face any financial constraint and are only maximizing profits. Also, a budget
soft budget constraint: The New Palgrave Dictionary of Economics

The soft budget constraint thus seemed intriguing. It reflected indeed a very important observation about the environment that the managers of socialist firms were facing as compared with the environment faced by the managers of capitalist firms. It immediately implied differences in the incentives managers were facing in the two economic systems, and one could understand that these different incentives had economy-wide consequences.

The basic observation that socialist firms had soft budget constraints and could count on continued financial support in case they were making losses led Kornai to develop a general theory of shortage in the socialist economy. Since the budget constraints of firms under socialism are not binding, one understands that they must necessarily meet a resource constraint, that is, experience shortage. This is, however, only an equilibrium implication. Shortage, or hitting the resource constraint, was thus achieved via the effect of soft budget constraints on the demand behaviour of firms.

Soft budget constraints had indeed a major effect on the demand behaviour of socialist firms. Demand for labour, input and capital tended to be in general higher than what it would be if firms had hard budget constraints. Moreover, demand was hardly responsive to price variations. Shortage tended to aggravate this phenomenon as it led to a hoarding motive in demand that tended to further aggravate shortages. Shortages were thus ubiquitous. Kornai developed a comprehensive theory of firm behaviour under shortage based on the premise of soft budget constraints. As of 2007 this is the most complete theory of the socialist economy that has been published, and most probably it will never be superseded. It is impossible in this short article even to summarize the exhaustive analysis Kornai made of firm behaviour and its general consequences for the economy. The interested reader is strongly encouraged to read the original analysis.

Like many general theories, Kornai's theory has led to extensions, refinements and also criticisms. Several papers (for example, Kornai and Weibull, 1983; Goldfeld and Quandt, 1988; 1990; 1993; Magee and Quandt, 1994) have examined formally the link between soft budget constraints and the supply and demand behaviour of socialist firms. Gomulka (1985) emphasized that households had hard budget constraints under socialism. In that case, the price system should have been able to eliminate shortages for consumer goods. Firms were, however, not responsive to signals from consumer goods markets under socialism since they were themselves resource-constrained on their supply side.

Why did firms in the socialist economy have soft budget constraints? Kornai related this to paternalism: ‘Paternalism is the direct explanation for the softening of the budget constraint’ (1980, p. 568). While Economics of Shortage was written while Kornai was still living under the socialist regime, this explanation remained partial for obvious reasons of self-censorship. In The Socialist System, he came back to the question at more length and explicitly defined causal mechanisms from the undivided power of the Communist Party to the dominance of state ownership, the preponderance of bureaucratic coordination to the environment of firms, including softness of budget constraints.

The soft budget constraint as a general incentive problem

While debates on soft budget constraints, their causes and consequences, were mostly confined to economists studying the socialist economy, it was recognized that the soft budget constraint syndrome had broader applications than in the context of socialist firms. Bail-outs of large firms and banks occur repeatedly under capitalism. Kornai’s concept of the soft budget constraint was widely popularized by a now famous article by Dewatripont and Maskin (1995) in which the soft budget constraint problem was formalized within the context of contract theory. Dewatripont and Maskin formulated the soft budget constraint as a rather general dynamic commitment problem within the framework of contract theory. Specifically, a principal can decide to invest in a project but would like to commit to not refinancing the project if its return is low. However, if he or she cannot commit not to refinance the firm, there are conditions under which they end up bailing out the firm in order to cut its losses. One would thus observe projects that are on the whole unprofitable but that nevertheless get refinanced: in other words they are loss-making firms with soft budget constraints. The reason for this dynamic commitment problem is that the initial funds spent on the firm are sunk costs and only the net return to refinancing is taken into account in the bail-out decision. Dewatripont and Maskin thus showed the soft budget constraint to be a very general incentive problem, not necessarily one to be related only to the context of socialism or government ownership.

The Dewatripont–Maskin model considers the following adverse selection problem. The government faces a population of firms, each needing one unit of funds in initial period 1 in order to start its project. A proportion $\alpha$ of these projects are of the ‘good, quick’ type: after one period, the project is successfully completed, and generates a gross (discounted) financial return $R_g > 1$. Moreover, the manager of the firm (possibly also workers) obtains a positive net (discounted) private benefit $E_g$. In contrast, there is a proportion $(1 - \alpha)$ of bad and slow projects which generate no financial return after one period. If terminated at that stage, managers in the firm obtain a private benefit $E_t$. Instead, if refinanced, each project generates after two periods a gross (discounted) financial return $\pi_b^*$ and a net (discounted) private benefit $E_b$. Initially, $\alpha$ is common knowledge but individual types are private information. A simple result easily follows: if $1 < \pi_b^* < 2$ and $E_b > 0$, refinancing bad projects is sequentially optimal for the government, and bad entrepreneurs who expect to be refinanced apply for initial financing. The government would, however, be better off if it were able to commit not to refinance bad projects, since it would thereby deter managers with bad projects from applying for initial financing, provided $E_t < 0$.

Termination is here, by assumption, a disciplining device that allows the uninformed investor (creditor) to turn away bad types and only finance good ones. The problem is that termination is not sequentially rational if $\pi_b^* > 1$: once the first unit has been sunk into a bad project, its net continuation value is positive so that, in the absence of commitment, the soft budget constraint syndrome arises. In this set-up, because irreversibility of investment is such a general economic feature, the challenge for theory is more to explain why hard budget constraints prevail rather than why budget constraints are soft in the first place.

Dewatripont and Maskin considered the soft budget constraint problem within a banking set-up. They found that centralized banking was more prone to the soft budget constraint problem than decentralized banking. In particular, to the extent that decentralized banking makes refinancing more costly because of incentive problems between multiple investors, it tends to favour hard budget constraints (see also

Indeed, when refinancing is more costly, investors are less willing to bail out and more willing to terminate projects, thereby changing the incentives of enterprise managers. While the dynamic commitment aspect of the Dewatripont–Maskin model of the soft budget constraint coincides with Kornai’s formulation, differences appear when it comes to explain the cause of the soft budget constraint problem. Indeed, Kornai emphasized the paternalism of government as the cause of soft budget constraints for the socialist firms. Paternalism plays no role in the Dewatripont–Maskin model. The main driving force is the sunk cost of investment combined with asymmetric information and inability to commit. These apparent differences in the explanation of soft budget constraints are, however, related to the fact that both explanations are located at different levels of abstraction and also related to different concepts of scientific explanation. Indeed, Dewatripont and Maskin develop a logical explanation of soft budget constraints deriving sufficient conditions for soft budget constraints. This logical explanation can then be applied to different empirical and institutional set-ups such as the one they discuss, namely, the comparison between centralized and decentralized banking. From that point of view, one can claim that paternalism is neither a necessary nor a sufficient condition for soft budget constraints. However, it would be misguided to take this as a criticism of Kornai’s explanation, which is situated at a different level. His concept of soft budget constraint is an abstraction destined to capture an empirical regularity rooted in the behaviour of socialist firms. The explanation of soft budget constraints by paternalism is an explanation based on empirical plausibility rooted in the institutional context of the socialist economy. Because these are explanations at different levels (pure logic on one hand, a concept grasping an empirical regularity on the other hand), they should not be seen as contradictory and mutually exclusive. Kornai’s explanation gives us crucial insights into the mechanisms of the socialist economy and the transition process, while Dewatripont and Maskin give us logical conditions that may be applied to different institutional contexts.

The Dewatripont–Maskin model has made the soft budget constraint concept an integral part of mainstream economic theory. It has also been recognized as a general incentive problem that has played a role in diverse banking crises that have occurred since the 1980s, including the 1997 east Asian crisis.

**Models of soft budget constraints under socialism**

Soft budget constraint models following the seminal model of Dewatripont and Maskin have been developed in a wide variety of contexts. First, beyond the models cited above that look mostly at the consequences of soft budget constraints, models were developed to understand various aspects of the socialist economy. For example, Qian (1994) developed a model showing that in the context of the socialist economy, shortages were a good way of alleviating some of the negative consequences of the soft budget constraint. Indeed, he showed that price caps that lead to shortages could be beneficial in terms of somewhat reducing soft budget constraints. Indeed, shortages reduce the likelihood that bad projects will be refinanced. This therefore reduces the incentive to submit poor projects. *A contrario*, with flexible prices and soft budget constraints, enterprises will bid for scarce resources, leading to price inflation and crowding out of consumers who face hard budget constraints. This explains why in many socialist economies, partial price liberalization as in the Soviet Union under President Gorbachev or in Poland, Hungary and China, and even advanced price liberalization as in the former Yugoslavia, led to strong inflationary pressures.
soft budget constraint: The New Palgrave Dictionary of Economics

Other models by Wang (1991) and Debande and Friebel (2004) showed similarly that reforms giving more autonomy to socialist enterprises, by relaxing the monitoring of enterprise activities, tended to exacerbate the soft budget constraint phenomenon. Qian and Xu (1998) developed a model to explain how soft budget constraints had a negative effect on innovation under socialism. This is an important theme since the inferiority of the socialist economy to capitalism in generating innovation is one of the main reasons for its demise. Knowing that firms had soft budget constraints, central planners were very cautious in approving investments with innovations. Indeed, the return to innovations is uncertain and it is important to be able to stop innovations that turn out to be disappointing. The market economy is able to do that quite well because firms have hard budget constraints; but this was not the case in the socialist economy. The caution of central planners in approving investments was relatively greater in areas where innovation was riskier and science was relatively new, precisely in the areas where returns to innovation were greater. This was for example the case for the computer industry where socialist firms were considerably behind capitalist firms. In industries where science was older and where risk was likely to be smaller, the centrally planned economy fared better. This was the case for the aerospace industry.

Dewatripont and Roland (1997) developed a model to analyse the links between the soft budget constraint and another incentive problem that was present in the socialist economy: the ratchet effect. The term ‘ratchet effect’ was coined by Berliner (1952) in his analysis of management behaviour in Soviet-style firms. In such firms, managers were given what appeared to be strong incentives to fulfil their production plans. Indeed, they had inducements to overfulfil the plans: each percentage point over the target was rewarded by additional bonuses. Nevertheless, managers tended to pass up the opportunity for these bonuses and instead were conservative in their plan overfulfilment, rarely exceeding two per cent over target. Berliner's explanation for this conservatism was that managers feared that next year's target would be ‘ratcheted up’ (that is, made more demanding) if they exceeded this year's goal. By producing at 110 per cent instead of 102 per cent, their bonus would be higher today, but so would their target tomorrow. Dewatripont and Roland show that the ratchet effect and the soft budget constraint could be interrelated in the sense that the need to bail out weaker firms gave central planners a stronger incentive to ratchet up the plans of the better-performing firms.

Models of soft budget constraints under transition

The issue of soft budget constraints, which was initially fundamentally neglected in the early transition from Communism, especially by the advocates of the Washington consensus and the big-bang approach to transition (apart from some mention here and there), became an increasingly important issue in trying to understand the restructuring process of firms and of banks. First, the transfer of ownership from the state to the private sector changed the incentives to bail out firms but did not automatically eliminate soft budget constraints. Indeed, by using the Dewatripont–Maskin model, it is easy to understand (see for example Kornai, Maskin and Roland, 2003) that privatization, by shifting the financing of firms from the government to the private sector, and in particular to private banks, changes the motive for bailing out firms from ex post care for employment and the welfare of those working inside firms to ex post profit maximization. However, this only reduces the extent of soft budget constraints since the logic of Dewatripont–Maskin does not require state ownership to generate soft budget constraints. What is
important is the sunk cost nature of investment that would lead an investor to refinance ex post a firm even though it would want to commit not to do so ex ante.

Complementary to the changes in ownership, there are other institutional changes during the transition process that would tend to harden budget constraints. Several models were developed along those lines. Segal (1998) examined the role of demonopolization and the development of competition in the hardening of budget constraints. The argument is that demonopolization and competition both increase entry of firms and reduce their profits. The reduction in profitability reduces the incentive to bail out but the increase in entry reduces the likelihood of any single firm of being bailed out. The argument requires a certain amount of excess capacity of firms in the market at any moment in time which is consistent with competition between firms.

Berglöf and Roland (1998) advanced a slightly different argument about the entry of new firms. If newly entering firms have a sufficiently high expected return in a competitive market economy, then the expected return to lending to those firms might be higher than the expected return to bailing out existing firms. This would then yield hard budget constraints as firms with poor projects would know that they were unlikely to be bailed out. However, for the argument to be valid, the expected return of the newly entering firms should be significantly higher than that of older firms. Indeed, with an expected return that is only marginally higher than for old firms, soft budget constraints will still be present. The reason is that the competition for funds is tilted against the newly entering firms because initial investments in older projects are sunk costs. Therefore, the comparison between the return to bailing out existing firms and financing entering firms does not count the initial funding of existing firms, so giving the latter an advantage in the competition for funds. The upshot is that, if the rhythm of innovation in the economy is not sufficiently strong, that is, if newly entering firms do not have an expected profitability that is significantly higher than existing firms, then soft budget constraints may persist.

Yet another argument related to firm restructuring was made by Perotti (1993) and Coricelli and Miles-Ferretti (1993). This is basically an argument about the negative externalities of soft budget constraints. Here, the hardening of budget constraints depends on the existing firms’ links with their chains of suppliers and clients. The idea is that banks may be reluctant not to bail out firms if closing the operations of those firms creates financial difficulties for the more healthy firms who do business with the weaker firms. The softness of banks may in turn dull the incentives of firms to restructure. From that point of view, it is harder to restructure an enterprise operating in a business network where budget constraints are very soft. Firms setting up new business networks in an environment with hard budget constraints will then face hard budget constraints themselves.

Another key institutional variable affecting the hardness of budget constraints is the degree of decentralization of banking. This is what the original Dewatripont–Maskin model was about. The general idea is that under decentralized banking renegotiating initial loan contracts is more difficult because it involves more inefficiencies and it thus more costly than under centralized banking. The particular mechanism in the model is the following: if the initial bank is liquidity-constrained and refinancing must involve another bank, the initial bank has less incentive to monitor the firm to ensure a higher return to refinancing than would be the case under centralized banking. Indeed, it must share the returns to monitoring with the other bank, which is assumed to have less experience with the existing project and thus is unable to monitor the use of its money. Because the bank that monitors does not reap the full returns from monitoring, it has less incentive to monitor. Other mechanisms would deliver the same result. Povel (1995) examined a model in which a project is financed from the outset by two banks.
Suppose that an agreement on a restructuring plan is necessary to refinance a poor project and that each bank's assessment of the continuation value of the project is private information. The asymmetric information between banks can give rise to a delay in their negotiating an acceptable restructuring plan. However, if the value of the project declines over time, this delay may render refinancing unprofitable. Huang and Xu (1999) studied a related model in which two banks (investors) agree to lend jointly to a project but have conflicting interests concerning how to organize the project should it be refinanced. This conflict may make it too costly to reach an agreement on a strategy after bail-out. Huang and Xu apply this argument to illuminating the east Asian crisis of the late 1990s. They note that the Korean jaebeols were subject to centralized financing and suffered from lack of financial discipline and soft budget constraints. By contrast, Taiwan's economy was characterized by dispersed financial institutions and decentralized banking. In the event, Taiwan suffered much less from the crisis than Korea (even though it, too, was attacked by speculators).

Decentralization of government, under federalism, may also have the effect of hardening budget constraints under certain circumstances, as argued by Qian and Roland (1998) on the basis of the transition experience in China. Decentralization of government was an important feature of Chinese reforms. Among other features, it led local governments to compete with each by investing in infrastructure investment other than to attract capital in order to boost growth in their province or region. This form of fiscal competition leads to overinvestment in infrastructure because the return of infrastructure investment to a province is higher than the return to society as a whole, as local governments do not internalize the effects of attracting capital away from other provinces. A positive side effect of this fiscal competition, however, can be that local governments prefer now to put their money in infrastructure investment rather than in bailing out loss-making enterprises. While decentralization of government can harden the budget constraints of enterprises that are controlled by local government, it can lead to soft budget constraints for local governments. Indeed, local governments can always structure the composition of their expenditures in such a way as to coax additional funds from the central government. Say that local governments are responsible for hospitals: they can strategically underfund hospitals and spend their budget on other items so as to obtain additional funds from the central government to improve hospital services. Zhuravskaya (2000) found evidence in the case of Russia that is consistent with such a story, using a data-set from 35 large cities in 29 regions of the Russian Federation between 1992 and 1997. She found that any increase in own revenues by local governments tends to be offset by a decrease of nearly one to one of shared revenues, which is consistent with soft budget constraints. Moreover, weaker fiscal incentives (a negative correlation between shared revenues and own revenues) tend, everything else equal, to decrease spending on education and health. There is also a negative impact on the quality of health and education, as measured by infant mortality and evening school attendance by children due to crowded schools. This is consistent with the idea that local governments have an incentive to distort their expenditures by neglecting health and education so as to try to attract more grants.

The soft budget constraint phenomenon has been analysed not only in the context of enterprises or local governments. It has been studied in the context of banks. Mitchell (1998), for example, built a model of bank passivity where banks fail to liquidate bad projects because they themselves expect to be bailed out by government. Similarly, Berglöf and Roland (1995) show that banks may strategically exploit the government's concerns for jobs in loss-making firms to extract government subsidies to refinance firms,
in effect forcing the government to pay part of the refinancing of firms. Policies of bank monitoring and recapitalization may help to eliminate soft budget constraints of banks, but policies of recapitalization face incentive problems of their own (see Aghion, Bolton and Fries, 1999).

Other visions of soft budget constraints

Interpretations of the soft budget constraint different from the Dewatripont–Maskin model are also present in the economics profession. Boycko, Shleifer and Vishny (1996), for example, do not identify soft budget constraints as a dynamic commitment problem where the principal would prefer not to commit to bailing out but ends up doing so. They see soft budget constraints as a deliberate choice of a governmental body to subsidize an enterprise in order to prevent management from laying off workers. According to this interpretation, soft budget constraints are not an inefficiency but rather the consequence of government preferences. This interpretation has had some following partly because the Dewatripont–Maskin view of soft budget constraints has often been associated too narrowly with bank–enterprise relationships and because, in reality, soft budget constraints occur more often in government–firm or government–bank relationships.

More recently, Robinson and Torvik (2006) have proposed a political economy theory of the soft budget constraint in a framework where politicians cannot commit to electoral promises. In this context, soft budget constraints, while resulting from an inability to commit to not bailing out a project, can be seen as commitment devices to redistribute transfers to particular constituencies of voters and to secure re-election and create an incumbency advantage. In other words, it emerges as a kind of political patronage.

Empirical work on soft budget constraints

It is very difficult to do empirical work measuring soft budget constraints as ex post bail-outs that were not desired ex ante. Seen in this light, soft budget constraints must be distinguished from other forms of funding that do not have these features. Moreover, the behaviour of firms is based on expectations of bail-out that are not easy to measure either. It is therefore not surprising that much of the empirical work surrounding soft budget constraints has been about using proxies that can find some justification but are necessarily quite noisy. The empirical work has often been quite detached from the theory. Various studies have looked at tax arrears as a proxy for soft budget constraints (Claessens and Peters, 1997; Schaffer, 1998; and Coricelli and Djankov, 2001). Others have looked at open subsidies (Djankov and Nenova, 2000; Grigorian, 2000) or tax concessions (Alfandari, Fan and Freinkman, 1996; Brown and Earle, 2000; and Shleifer and Treisman, 2000). Other studies have looked at payment arrears of firms and the tendencies of state-owned banks to lend to distressed enterprises (Cull and Xu, 2000; Gao and Schaffer, 1998; Coricelli and Djankov, 2001; Claessens and Djankov, 1998; and Schaffer, 1998).

There have nevertheless been a few serious attempts to study soft budget constraints empirically in line with existing theoretical models. Petterson-Liblom and Dahlberg (2005), for example, have made such an attempt and tried to measure the effect of soft budget constraints on the borrowing behaviour of Swedish municipal governments between 1974 and 1992. They find that, if a municipality expects to be bailed out with certainty, as opposed to a situation where it is not bailed out, it will increase its debt level...
by 30 per cent. Bail-out expectations obviously cannot be measured directly. However, instead they use observed bail-out as a noisy measure of bail-out expectations and use an instrumental variable approach to get consistent measurement using as instrument observed bail-outs in neighbouring municipalities. A comprehensive survey of the literature on soft budget constraints can be found in Kornai, Maskin and Roland (2003).

Born in Linz, Austria, on 1 June 1930 and died in Heidelberg, Federal Republic of Germany, on 8 March 1977. He was educated at the Universities of Vienna, Kansas and Tübingen, and at the Massachusetts Institute of Technology, from which he received a doctorate in economics in 1958. He taught economics at Yale University from 1958 to 1961, at the University of Saarlandes in Saarbrücken from 1961 to 1969, and at Heidelberg University from 1969 to his death. Sabbatical leaves were spent at the University of Minnesota in 1963–4, and at the Smithsonian Institution in Washington, DC, in the spring of 1975.

Sohmen played a significant part in the 1960s in making the case for flexible exchange rates respectable. He wrote widely on the subject, attacking the Bretton Woods system and insisting that free floating would produce exchange rates that approached equilibrium continuously, as opposed to fixed-rate systems with their encouragement of speculation, wide departures from equilibrium and ultimate necessities for parity changes. With the adoption of floating rates in 1973, he turned his attention to other problems in economic theory with emphasis on competitive markets.

Solow, Robert (born 1924)

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Robert Solow is a leading theorist of economic growth. In one of his two pioneering papers he argues that, with labour fully employed, the long-run economic growth rate is independent of the saving rate. In the other, he argues that only a minority of economic growth can be explained by increases in labour and capital inputs; the residual, which presumably reflects technological innovation, accounts for the majority. He also argues that new capital is more valuable than old capital because it embodies more up-to-date technology. He has made contributions on fiscal policy and wage bargaining as well.

Robert Merton Solow was born in Brooklyn, New York, in August 1924, so he was just five years old when the Great Depression began in the United States and, depending on how it is dated, about 16 years old when it ended. The timing is significant. He has characterized himself as part of ‘the generation of economists that was moved to study economics by the feeling that we desperately needed to understand the Depression’ (1990, p. 183). The search for answers about what makes the macroeconomy tick, and why it occasionally goes badly off track, has been the touchstone of his illustrious career.

Solow was educated in the New York City public schools at a time when that was a great place to be educated – a time and place that produced, among others, Kenneth Arrow, William Baumol and Robert Fogel. (That's just in economics; the number of distinguished scientists is legendary.) Graduating at age 16, he became the first person in his family to attend college when he enrolled at Harvard in 1940. But with the Second World War raging, Harvard did not hold his attention for long, and he volunteered for the US Army in 1942, serving for three years in North Africa and Italy – an experience which, he has written, ‘formed my character’ (1988).

Once back at Harvard, and now married to the love of his life, Barbara, Solow decided to specialize in economics and was fortunate to have Wassily Leontief assigned as his tutor. This happenstance probably also changed his life – and that of the economics profession – forever; for while economics at Harvard may not have been very inspiring at the time, nor particularly modern, nor at all mathematical, Leontief was a shining exception. He took the brilliant young student from Brooklyn under his wings and, six years later, Solow won the first of what were to be many accolades: the coveted David A. Wells Prize for the best Harvard Ph.D. dissertation. The thesis, which Solow never published because ‘I thought I could do it better’ (1988), was a highly original application of the then-novel theory of Markov processes to model the size distribution of wage income in the United States. (I actually read this fine piece of work, in typescript, while writing my own dissertation on the size distribution of income at MIT about 20 years later.)

Solow's first and, in a real sense, only job was at MIT, where he was an assistant professor and then an associate professor of statistics in what was then the Department of Economics and Social Science from 1950 to 1958. It was during that period that he wrote his two classic papers on the theory and empirics of economic growth (described below), which must have made it easy for MIT to promote him to professor of economics in 1958. Fifteen years later he was designated an Institute Professor, a post he held until his (de jure, not de facto) retirement from MIT in 1995. In 1979 he served as president of the American Economic Association. In 1987 he was awarded the Nobel Prize in Economic Science. And in
1999 he was honoured with the National Medal of Science—one of only seven economists ever to have won that distinction. Since 2000 Solow has divided his time between MIT and the Russell Sage Foundation in New York, where he is the foundation’s only permanent fellow.

In terms of research publication dates, the years 1956–61 in Solow’s career were probably as outstanding a quinquennium as any economist has ever had. (The research production dates, one guesses, were probably two years or so earlier.) His two most famous papers, of course, came in 1956 and 1957: ‘A contribution to the theory of economic growth’, Quarterly Journal of Economics (1956), and ‘Technical change and the aggregate production function’, Review of Economics and Statistics (1957). These two papers, which introduced what came to be called ‘the Solow model’ and ‘the Solow residual’, respectively, are still, almost 50 years later, among the most widely cited papers in all of economics, despite the fact that they are so much a part of the corpus of modern economics that citations are often omitted. At this point the Nobel Prize, had there been one at the time, was in the bag. And indeed, when his Nobel award was announced, these were the two papers principally cited.

The two landmark growth papers were followed by the classic book Linear Programming and Economic Analysis (with Paul Samuelson and Robert Dorfman, 1958), which included, among other things, the first turnpike theorem. Next, in a 1960 paper titled ‘Investment and technical progress’, Solow introduced the important—and probably realistic—idea that new technology might have to be ‘embodied’ in new capital. (After all, a vintage 2000 computer does not develop new and more powerful chips just because Intel invents them.) This theoretical innovation opened the door to a new and rich (though more complicated) class of ‘vintage’ models, which then proliferated in the literature. Finally, in collaboration with Arrow, Hollis Chenery, and B. S. Minhas, he invented the constant-elasticity-of-substitution (CES) production function in their paper ‘Capital-labor substitution and economic efficiency’ (1961). This clever functional form has proven to be both a theoretical and an empirical workhorse.

This remarkable burst of intellectual activity and creativity clearly established Robert M. Solow, by then aged 37, as the major figure in what was then the sub-field of economic theory that was attracting the most attention (growth theory). And it won him the American Economic Association’s John Bates Clark Medal, which is awarded every second year to the most outstanding economist under the age of 40, in 1961. But along the way he also found time to collaborate with Samuelson in bringing the Phillips curve to America in their, ‘Analytical aspects of anti-inflation policy’, American Economic Review, 1960. Whew!

The Solow model

Now back to 1956. Why is the Solow model so important in the history of economic thought? Prior to Solow’s ‘Contribution’ and the contemporaneous paper by Trevor Swan (1956), growth theory was stuck in an awkward position. Roy Harrod (1939) and Evsey Domar (1946), noting the long-run (relative) fixity of the capital-output ratio, had posited a fixed-proportions technology:

\[ Y_t = fK_t \]  
\[ (1a) \]

\[ Y_t = gL_t \]  
\[ (1b) \]

where \( f \) and \( g \), two constants, are the reciprocals of the capital-output and labour-output ratios. Equating investment \( \frac{dK_t}{dt} \) and saving \( S_t \), and assuming that saving is proportional to income yields:

\[ \frac{dK_t}{dt} = S_t = SY_t \]

\[ (2) \]
and appending an exogenously growing labour force,

\[ L_t = L_0 e^{nt}, \]

leads to the simple Harrod–Domar growth model. The model is easily solved for a so-called balanced growth path in which output, capital, and labour are all growing at the same rate, so that ratios like \( Y = \frac{Y}{L} \) and \( K = \frac{K}{L} \) are constant. By (3), that common growth rate must be \( n \)—or \( n+\mu \), where \( \mu \) is the rate of technical progress, in the presence of exogenous technological progress. (In that case, \( L \) must be measured in efficiency units.) By (2), the growth rate of capital is

\[ \frac{1}{K} \left( \frac{dK}{dt} \right) = s \left( \frac{Y}{K} \right) \]

which, by (1a) is just \( sf \). So the fundamental Harrod–Domar equation equates the so-called natural rate of growth, \( n \), to the so-called ‘warranted’ rate of growth, \( sf \): \n
\[ sf = n. \]

Output in an economy with a labour force growing at rate \( n \) can therefore grow at that same rate indefinitely as long as \( sf \) is equal to \( n \). But therein lies the problem that bothered Solow. The product \( sf \) is a number, which is equal to \( n \) only by coincidence. What if they are unequal? If \( sf > n \), \( K \) will grow faster than \( L \) forever; if \( sf < n \), it will grow slower – also forever. The economy therefore seems to be poised on a knife-edge between explosive growth of \( y \) and \( k \) and implosive contraction. Only if \( sf \) happens to be equal to \( n \) is it capable of supporting steady growth.

To Solow, the child of the Depression, this was a most unsatisfactory state of affairs in modelling, because real economies do not behave that way. The Great Depression was such a noteworthy event precisely because it was so unusual. History teaches us that capitalist economies do not often either implode or explode. Something approximating steady growth is much more normal. Could all this really be the result of coincidence? Solow thought not.

Furthermore, he had long been interested in production theory and viewed factor proportions – at least at the aggregate level – as more variable than fixed. So he proposed making just one change in the Harrod–Domar model: replacing the fixed-coefficients technology (1) by a more conventional neoclassical production function:

\[ Y = F(K, L) \]

which, under constant returns to scale, can be written:

\[ \frac{Y}{L} = F \left( \frac{K}{L}, 1 \right) \]

or

\[ Y = f(K). \]
Now the solution looks the same as in the Harrod–Domar model because saving (=investment) per head is $sf(k)$, which is constant along a steady-state growth path (defined as a path with constant $\frac{k}{l}$). The growth rate of the capital stock is therefore $\frac{1}{k} = \frac{sf(k)}{k}$, and equating this to the growth rate of labour ($n$) leads to the famous Solow equation:

$$sf(k) = nk.$$  

(7)

This resembles the Harrod–Domar equation, (4), and in fact, if $f(\cdot)$ is a linear function, the two are identical. But by making $f(\cdot)$ concave, Solow eliminated the bothersome knife-edge. Now no coincidence of constants is necessary to allow steady growth; instead, $k$ will adjust to guarantee it, as illustrated by the famous Solow diagram (see Figure 1). Figure 1
Many complications can be and have been added to the basic Solow model – some of them present already in Solow's original 1956 paper. But the two most essential and important lessons are extremely robust. First, the economy's growth path is most likely stable, not perched on a precarious knife edge. Consider the growth rate of $k = \frac{K}{L}$ which, in steady-state equilibrium, is zero. Out of equilibrium, it is:

$$\left(\frac{1}{k}\right) \frac{dk}{dt} = \left(\frac{1}{k}\right) \frac{dK}{dt} - \left(\frac{1}{L}\right) \frac{dL}{dt} = \frac{sf'(k)}{k} - n,$$

so that $\frac{dk}{dt} = sf'(k) - nk$.

Thus $k$ will be increasing whenever $sf'(k) > nk$ and decreasing whenever $sf'(k) < nk$. A glance at Figure 1 (or taking the derivative of equation (8) with respect to $k$) shows that the dynamic model is stable – the reverse of the Harrod–Domar conclusion – as long as $sf'(k) < n$ (see again Figure 1.) Thus this new wrinkle achieved Solow's modelling objective: the economy normally stays on track.

But the Solow model accomplished more. Contrary to what had been common intuition until 1956 (and is still common intuition among those not schooled in the Solow model), the model shows that the **economy's growth rate** ($n$ in this case, or $n+\mu$ with exogenous technical progress) **is independent of its saving rate** ($s$). How can that be true when, in the model, saving is the same as investment? The answer, which was surprising at the time but is now a commonplace, is that a society's propensity to save affects its **level of output**, as shown by equation (7), but not its steady-state **growth rate**.

Of course, this lesson can be learned too well. Figure 2 shows what happens if a Solow economy manages to **increase** its saving rate, from $s_0$ to $s_1$. The steady-state level of capital per head will eventually rise from $k_0$ to $k_1$, raising output per head from $f(k_0)$ to $f(k_1)$. Thus societies that save more will be richer, just as expected. But Solow pointed out that they **will not grow faster** in steady state; in fact, the growth rates are identical in the two equilibria shown in Figure 2.
However, we should remember that the transition from one steady state to another can take a very long time (see Atkinson, 1969). During the adjustment period from point A to point B, which may last for decades, the high-saving society will indeed grow faster than the low-saving society. It's just that diminishing returns to capital eventually catch up to it, bringing the growth rate back down to \( n \). Furthermore, what later came to be called ‘endogenous growth theory’ argued that capital deepening (which often meant knowledge capital or human capital) can boost the growth rate forever, if returns are not diminishing.

The Solow residual

Solow's famous 1957 paper picked up on the diminishing returns point. It had two main purposes: to verify that, as an empirical matter, returns to capital are in fact diminishing; and to estimate the relative contributions of technological progress and capital deepening (rising \( k \)) to growth. He began by adding what we now call ‘Hicks-neutral’ technical progress to the production function (5) to get:

\[
Y = A_t F(K_t, L_t).
\]
Under constant returns and assuming marginal productivity pricing of factor inputs, Euler's theorem implies that:

\[
\frac{1}{Y_t} \frac{dY_t}{dt} = \frac{1}{A_t} \frac{dA_t}{dt} + \beta \frac{1}{K_t} \frac{dK_t}{dt} + (1 - \beta) \frac{1}{L_t} \frac{dL_t}{dt},
\]

where \( \beta \) is capital's factor share. Subtracting the growth rate of labour from both sides leads to the 'other' famous Solow equation:

\[
\frac{1}{Y_t} \frac{dY_t}{dt} = \frac{1}{A_t} \frac{dA_t}{dt} + \beta \frac{1}{K_t} \frac{dK_t}{dt},
\]

where \( \frac{1}{A_t} \frac{dA_t}{dt} \) is what came to be called the Solow residual, that is, the portion of the growth of labour productivity that is not accounted for by capital deepening. As an empirical matter, Solow (and those who have followed in his tradition) solved (10) for the residual:

\[
\frac{1}{A_t} \frac{dA_t}{dt} = \frac{1}{Y_t} \frac{dY_t}{dt} - \beta \frac{1}{K_t} \frac{dK_t}{dt}.
\]

Since everything on the right-hand side of (11) is directly measurable, this equation can be used to compute a time series on the growth rate of \( A \). Doing so for the years 1909–1949 led Solow to the conclusion that only about one-eighth of the advance of \( Y = \frac{Y}{L} \) over those 40 years could be attributed to capital deepening, leaving about seven-eighths to 'the residual'. This surprising (at the time) conclusion has, of course, changed numerically over the years as Solow's technique was refined (by, for example, Edward Denison, 1962 and others) and replicated on newer data. But the qualitative finding that technological change is far more important than capital deepening has held up extremely well.

What about the shape of the aggregate production function (9)? Does it really display the curvature implied by diminishing returns? By using his synthetic time series on \( A_t \), it was a simple matter of arithmetic to compute a time series on \( f(k) = \frac{Y_t}{A_t} \) (which is not constant in the real world) and then to inspect the shape of the \( f(k) \) function. Eyeballing the scatter plot gave Solow 'an inescapable impression of curvature, of persistent but not violent diminishing returns' (1957, p. 318). And his regression estimates of a variety of nonlinear functional forms, including the Cobb–Douglas, rejected linearity. (In the Cobb-Douglas case, his original estimate of \( \beta \) was 0.35, not far from current estimates.)

One footnote to the history of economic thought is of interest here. Solow's empirical work included the years of the Great Depression and the Second World War, in contrast to the modern proclivity to omit those years. He noted that the data points for 1943–49 fell noticeably above the smooth estimated \( f(k) \) function, however. Solow commented on that fact, hazarded a few guesses as to why the war years might have been abnormal, but ended up confessing that 'I leave this a mystery'. Honesty pays. Shortly thereafter Warren Hogan (1958) found a computational error in Solow's original paper and showed that, once the error was corrected, those seven data points were no longer aberrant.

I will be much briefer about some of Solow’s other major works.

In a famous paper presented at the December 1959 meetings of the American Economic Association, Samuelson and Solow (1960) not only brought the Phillips curve to America but noted how what we now call a wage-Phillips curve can be transformed into a price-Phillips curve, and offered some reasons why that curve might not represent a stable menu of policy choices. Shortly thereafter, Solow joined the ‘New Frontier’ as a staff member of President Kennedy’s original Council of Economic Advisers in 1961–62 and continued as a consultant through the Kennedy-Johnson years. That was quite a staff, including the likes of Kenneth Arrow and Arthur Okun. As Solow put it years later, ‘What I cherish about that experience was the conscious effort to use macroeconomic theory to interpret the world and, in a small way, change it’ (1990, p. 192).

In 1973 Solow and I co-authored ‘Does fiscal policy matter?’ (1973), a widely discussed contribution to the then-raging monetarist-Keynesian debate. The article established several counterintuitive implications that stem from the so-called government budget constraint, one version of which is:

\[
\frac{dM}{dt} + P_s \frac{dB}{dt} = G + \mathbb{E} - (Y + \mathbb{B}),
\]

(12)

where \( M \) is the money supply, \( B \) is the number of government bonds (paying interest rate \( i \) and selling for price \( P_b \)), \( G \) is government (non-interest) expenditure, and \( T(\cdot) \) is the tax function. (While Blinder and Solow, 1973, used a fixed-price model, Tobin and Buiter, 1976, soon established parallel results for a full-employment model with a variable price level). The right-hand side of equation (12) is the budget deficit, and the left-hand side is the value of the money and/or bonds that must be issued to cover it. In steady-state equilibrium, neither \( M \) nor \( B \) is changing; so the budget must be balanced:

\[
G + \mathbb{B} = T(Y + \mathbb{E}).
\]

(13)

Blinder and Solow used a dynamic IS-LM model with wealth effects to prove the following surprising results:

- The model is always stable under money financing of deficits; but it can be either stable or unstable under bond financing of deficits, depending on parameter values.
- If the model is stable under debt financing, then bond-financed deficits are actually more expansionary in the long run than money-financed deficits, in stark contrast to standard teaching in macroeconomics. (Remember, monetarists were arguing at the time that bond-financed deficit spending had no effects on aggregate demand.)
- An open-market purchase that creates more money is expansionary in the short run (for the usual reasons), but will be cancelled out in the long run by the government budget constraint.

While the first result is purely technical, the other two have interesting intuitions behind them. Other things equal, more wealth, whether in the form of \( M \) or \( B \), leads to higher output. (This assumes that government bonds are net wealth to the private sector.) In the short run, money creation is more expansionary than bond creation for the usual reasons. But for that very reason the budget deficit closes more slowly (and therefore with more cumulative wealth creation) under bond financing, leading ultimately to a larger multiplier (provided the system is dynamically stable), which is the second result.

A similar dynamic adjustment explains the third result, which anticipated parts of the message of both Sargent and Wallace’s ‘Unpleasant monetarist arithmetic’ (1981) and the so-called fiscal theory of the price level. Start from an initial steady-state equilibrium with a balanced budget. An expansionary open-market operation, which raises \( Y \), brings in more tax revenue, thereby creating a budget surplus. Under pure money financing \( \frac{dB}{dt} = 0 \), so (12) implies that the surplus leads to money destruction. And (13) assures us that, with unchanged fiscal policy, the process of money destruction must continue until all of the new money has been withdrawn. Thus, in a real sense, the government budget constraint renders conventional monetary policy (an open-market operation) impossible in the long run.

In 1981 Solow teamed with Ian McDonald to produce a widely cited model of wage bargaining. The paper offered a fresh approach to a question that dates back to the earliest days of
the Keynesian period: why, over business cycles, does employment fluctuate so much while real wages fluctuate so little? So-called implicit contract theories tend to predict that both employment ($E$) and real wages ($w$) will be stabilized; but empirical observation shows clearly that $E$ is quite cyclical. McDonald and Solow used bargaining theory to explain the phenomenon of highly variable $E$ combined with relatively stable $w$. Their arguments are lengthy and technical, and defy brief summarization. Suffice it to say that each of several specifications of how efficient bargaining might be conducted points toward this conclusion.

No summary of Robert M. Solow's contributions can be limited to reviewing his research, for Solow has also been a 'good citizen' par excellence. He has given his name, his wisdom, and his precious time to all manner of worthy causes and organizations, ranging from the Institute for Advanced Study to the Sierra Club. These include the National Academy of Sciences, the Manpower Demonstration Research Corporation, the Center for Advanced Study in the Behavioral Sciences, the Woods Hole Oceanographic Institution, the National Science Board, and the German Marshall Fund. There are many more.

Perhaps even more important are his remarkable achievements as a teacher of economics, particularly Ph.D. students. During the 1950s and early 1960s Samuelson, Solow, and a few of their friends created what came to be considered the world's pre-eminent economics department at MIT, an institution that had no great tradition in the subject. Generations of America's and the world's best graduate students came to study at MIT largely because Samuelson and Solow were there. While there are no objective measures of such things, Solow's clarity, wit, and mastery of a variety of subjects surely made him one of the finest teachers of economics who ever lived.

Perhaps for this reason, he was also the dissertation adviser of choice for scores of MIT's most promising graduate students over a period of time spanning 45 years. The list of Solow dissertation students, particularly in the 1960s, reads like an all-star team. In the two years 1966 and 1967 alone (based on completion dates), he supervised the Ph.D. dissertations of (in alphabetical order) George Akerlof, Robert Gordon, Robert Hall, William Nordhaus, Eytan Sheshinski, Joseph Stiglitz, and Martin Weitzman. Extending the time span back to 1956 and forward to 1971 brings in (now in chronological order) Alain Enthoven, Ronald Jones, Ronald Findlay, Peter Diamond, Ray Fair, Avinash Dixit, Jeremy Siegel, and the present author. More recently, Olivier Blanchard and David Romer were added to the list. It is a remarkable collection, for both its quality and its intellectual diversity. And probably every person on that list came to idolize Solow.

For most leading scholars, a list of students even half that extensive and distinguished would probably be considered their most enduring legacy. But in Robert M. Solow's case the research accomplishments are so fundamental, and have been and will be so enduring, that they eclipse even his amazing accomplishments as a teacher.

Sombart, Werner (1863–1941)

B. Schefold

Edited by Steven N. Durlauf and Lawrence E. Blume

Article

Sombart was born in Ermsleben (Germany), the son of a well-to-do National Liberal member of the Prussian Diet. He studied economics, history, philosophy and law in Berlin, Pisa and Rome. In 1888 he received his Ph.D. from the University of Berlin and became an officer of the Bremen chamber of commerce. Two years later he was appointed extraordinary professor of political economy at the University of Breslau; in 1906 he became full professor at the Handelshochschule in Berlin and in 1917 transferred to the University of Berlin.

Sombart started his career as a left-wing advocate of social reform, influenced by Marxian theory. This was the reason why for a long time he could hold only second-rate positions within the German university system.

His dissertation on the economic and social conditions of the Roman campagna (1888) was brilliant and much less controversial than his later works.

An important work was his description of the German economy in the 19th century (1903). His outstanding study on the historical genesis of modern capitalism from its medieval origins to modern times (1902) may be considered Sombart's magnum opus. The really important edition was the second, published between 1919 and 1927, which differed completely from the first. Its three volumes treated three stages of capitalist development: early capitalism (Frühkapitalismus), high capitalism (Hochkapitalismus) – beginning with the industrial revolution in the 1760s – and late capitalism (Spätkapitalismus), starting with the First World War. The scope of this study was extremely broad. The reader is confronted with an amazing richness of facts. However, the data that Sombart presented were mostly second-hand and contained many speculative notions. Still, this work of ‘unsubstantial brilliance’ was ‘highly stimulating even in its errors’ (Schumpeter).

In the course of his research on Der moderne Kapitalismus Sombart published several special studies on the psychology and spirit of capitalism, on the Jews, on war and on luxury. In an outstanding study of
the bourgeois individual in general and the entrepreneur in particular he analysed the emergence of a certain economically oriented mentality and psychology, the ‘Wirtschaftsgeist’ (economic spirit), for the development of capitalism (1913a).

In a voluminous work on the role of the Jews in economic life (1911) he described the Jews much along the lines of Max Weber's analysis of Puritanism, as the most dynamic part of the population, introducing ‘capitalist spirit’ into commerce and industry. At this time, Sombart was not anti-Semitic: on the contrary, he perceived the Jews’ contribution to the rise of capitalism positively, regarded them as one of the most valuable ‘species’ of mankind (1912, p. 56) and was in favour of Zionism as the national renaissance of the Jewish people. However, the foundations for his later anti-Semitic turn were laid: his description of the characteristics of the Jews treating them as a ‘species’ was full of prejudices and exaggerations and included a discussion of their ‘race’ and ‘blood’ peculiarities.

Sombart further analysed the development of luxury consumption, which he connected in a very original way with the erotic, and its economic importance as a creator of new markets and industries (1913b, vol. 1). In a similar way Sombart treated war as a creator of new markets due to the services and goods required by the military (1913b, vol. 2). Two years later, during the First World War, Sombart wrote a chauvinistic, strongly anti-English book, which glorified war and militarism (1915). The best way to observe his political views is to follow his discussion of Marx: Sombart was never a Marxist. But when the third volume of Capital appeared, he praised Marx as an outstanding thinker and described his theory in a very positive way (1894), which in turn was warmly welcomed by Engels. Also, in the first edition of his famous work on socialism and social movements (1896), he discussed Marx from a sympathetic point of view. Its tenth edition, now titled Der proletarische Sozialismus (Marxismus) (1924), was violently anti-socialist and full of hatred and personal insults against Marx. However, this did not hinder Sombart from stating three years later that his Der moderne Kapitalismus was written in the Marxian spirit and that he regarded it in a certain way as the conclusion of Marx’s work (1927, p. xix).

What had occurred was an evolution in Sombart's assessment of capitalist development. While he still appreciated Marx as a historian of capitalism, he now disliked the latter's optimistic view of the future, his regard for capitalism as the creator of the better world to come (1927, p. xx). Marx had been an admirer of technical progress and of the historical forces which fostered it. Sombart no longer believed that industrial development was automatically beneficial and he realized its destructive potential. He contrasted the uniformity and ugliness of modern civilization with the cultural variety of the pre-industrial past.

This enmity towards industrial development and what he called the ‘economic age’ was the reason why Sombart sought to ally himself with right-wing anti-capitalism and temporarily turned to fascism. When the Nazis came to power he made a contribution towards a programme of German (National) Socialism (1934). Contrary to proletarian socialism, which accepted the industrial society and only intended to redistribute its surplus, Sombart perceived German socialism as rejecting the industrial age (1934, pp. 160–8). Beside the corporative state, the Führerprinzip (leader principle), a state interventionist regulation of the German economy, autarky and a partial re-agrarianization of Germany, he advocated state planning and, as a key idea, control of technological development based on what would now be called technology assessment (1934, pp. 263–7). However, his proposals were not welcomed by the Nazis, who, as Sombart was later to realize, intended to use the most advanced technologies available in order to win political hegemony.
It is not easy to regard Sombart as member of an economic school. He first rejected and then accepted the deductive method. Although he claimed that *Der moderne Kapitalismus* bridged the gap between the abstract-theoretical and the empirical-historical method (1927, p. xvi), there is no doubt that this book lacked an analytical framework and, though not without theory, was mainly a historical description of a large mass of facts. Sombart even ‘out-Schmoller’d Schmoller’ (Schumpeter) and had to be regarded as belonging to the younger, or, as Schumpeter called it, the ‘youngest’ historical school. Sombart himself, however, would certainly not have admitted that. He distinguished between three kinds of political economy (1930): the ‘richtende Nationalökonomie’ (judging economics), which was intended to decide what was right and wrong, and whose scientific character Sombart denied; the ‘ordnende Nationalökonomie’ (ordering or systematizing economics) that tried to apply quantitative exact methods, and, finally, the ‘verstehende Nationalökonomie’ (understanding or interpretative economics), which should be a ‘Geistwissenschaft’ (science of social mind) and was both theoretical and historical and tried to grasp the motives of economic life. It goes without saying that Sombart regarded his own work as being in the tradition of the latter.

Sombart extended his claims to being a theorist beyond economics. He also perceived sociology as a ‘Geistwissenschaft’ and developed a new type of sociology, which he called ‘Noo-Soziologie’, which was supposed to be a general theory of culture (1936).

He remains one of the most brilliant and interesting personalities of the German economics profession, being a gifted writer with profound historical insights. While many works of the Historical School are boring collections of facts, the best of Sombart's books are sparkling and still make fascinating reading.

Sonnenfels was born of Jewish parents who shortly afterwards converted to Catholicism; the family moved in 1744 from Moravia to Vienna, where the father taught oriental languages. Joseph first served in the army from 1749 to 1754, when he began to study law and literature at Vienna University. A prominent member of the Enlightenment literati, he was in late 1763 appointed to the newly founded chair in ‘Police and Cameralistic Sciences’ at the University of Vienna. Until his death he was prominent in constitutional reform, also engaging in a campaign for the abolition of torture and of usury. The textbook which he wrote for his own teaching, the *Grundsätze der Polizei Handlungs- und Finanzwissenschaft* (1765, 1769, 1776), remained the official text in the Austrian Empire until 1848, running to eight editions and several abbreviated teaching editions. The *Grundsätze* devotes a volume each to police, commerce and finance. The leading idea running through all three is the importance of a large population gainfully employed for the general welfare of the state. Coupled with this is a conception of the accumulation of wealth as the ‘multiplication of means of subsistence’, governed however by the necessity of maintaining equilibrium in the society, which is the task of police. The functioning of police is therefore tied less directly to economic welfare than is the case with Justi, to whom Sonnenfels makes reference. The treatment of commerce owes a great deal to Forbonnais’ *Elémens du commerce*, who also laid emphasis on the advantages of a large population and the need for proportion within it. But while Sonnenfels takes much from Forbonnais, he remains more concerned with general political order than the economic structure of an advancing society.

South Sea bubble

Hans-Joachim Voth
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The South Sea bubble resulted from an equity-for-government debt swap that had gone wrong, and occurred in England in 1720. Prices of South Sea Company stock rose sharply following the announcement of the scheme, and collapsed eight months later. Frequently cited as an example of investors’ folly, the factors driving the sharp rise and fall of South Sea Company share prices have remained controversial. The so-called Bubble Act of 1720, passed before the bubble peaked, restricted the development of a vibrant market in publicly traded companies for a century.

Article

The South Sea Company was founded in 1711, in the expectation that peace between Spain and England after the end of the War of the Spanish Succession would produce profitable trading opportunities with the ‘South Seas’ (that is, Spanish America). The company’s trading activity remained intermittent and unprofitable throughout the 1710s. In 1719, a new scheme was launched – the conversion of government debt into equity of the South Sea Company. Debt-holders of the 1710 lottery loan were offered the option to convert their holdings into company shares. The government agreed to make interest payments to the company instead of to debt-holders. As old (and illiquid) loans were swapped for liquid company shares, debt-holders gained. The government negotiated a lower rate of interest, and the South Sea Company made a modest profit. The 1719 equity-for-debt swap is generally seen as Pareto-improving.

The 1720 conversion scheme differed in important ways. Key elements included (a) the absence of a fixed conversion ratio – higher prices of South Sea stock meant that more debt could be bought with each share, (b) issuance of new stock on instalment, with only a small down payment required, (c) massive lending against shares, and (d) a high degree of corruption in the awarding of the contract. The South Sea conversion also shared important characteristics with John Law’s Mississippi scheme in France, which produced a similar run-up (and crash) of prices half a year earlier.

Both the Bank of England and the South Sea Company competed for the contract to convert government bonds into equity. After bribes to MPs, ministers, and members of the court (of about £1.3 million), the South Sea Company won the right to perform the conversion in March 1720. By this time, the price of its shares had increased to 255, from 128 at the beginning of the year. The share prices of other companies moved up and down in parallel with South Sea stock, but less sharply (see Figure 1). The company proceeded to issue fresh shares in four subscriptions, and offered to convert debt into shares on (modestly) generous terms. By late June, prices had risen to 765, and forward prices during the summer rose as high as 950. When regular trading resumed, prices began to weaken, but the fourth subscription was still strongly oversubscribed. In September, prices fell quickly. By the year end they had almost declined to their January level.

Figure 1

Since Mackay's classic *Extraordinary Popular Delusions and the Madness of Crowds*, the South Sea bubble has often been cited as a prime example of irrational investor behaviour. In contrast, Peter Garber (2000) argued that the share prices increased in line with ‘changing view(s) of market fundamentals’. If the scheme had succeeded in improving economic conditions in England as a whole (as John Law's logic would predict; Verde, 2004), the firm's large capital base might have allowed it to pursue profitable ventures. Yet most of these remained vague, and the company had no track record of successfully making money from anything other than financial transactions. It is doubtful whether future profits could ever have been high enough to justify the company's market capitalization in the summer of 1720. Even Garber accepts that prices above 400 are hard to square with reasonable expectations of future profits. Easy credit, investor preferences for lottery-like payoffs (as a result of shares being sold with only a small down payment), and restricted free float (caused by company lending against its own shares) may have contributed to the start of the bubble.

Recent work has focused on the reasons why the bubble, once under way, could have expanded greatly. Dale (2004) argues that apparent mispricing of subscription receipts proves investor irrationality, while others have argued that the gap can be explained by the option-like nature of receipts. Temin and Voth (2004) examined the trades of a goldsmith bank, Hoare's, which made large profits buying and selling South Sea stock in 1720. They argue that the bank was aware of the overpricing, but invested in South Sea stock regardless. Predictability of investor sentiment made it rational to 'ride' the bubble, and to sell out with a profit as soon as it began to deflate. This strategy is similar to hedge fund behaviour on Nasdaq in the late 1990s (Brunnermeier and Nagel, 2004). If other large investors faced similar incentives, the lack of a coordinated early attack becomes easier to understand. The role of market microstructure imperfections was probably limited, as opportunities to sell short were abundant. However, the nature of the settlement process and the artificial reductions of free float engineered by the company may have contributed to the bubble.

**Consequences**

The rise and crash of share prices in 1720 had few direct economic consequences. As prices declined, former debt-holders demanded compensation. Parliament investigated the scheme in which it had played such an important role. Directors had most of their assets expropriated. In contrast to the resolution of the Mississippi bubble in France, those who had tendered government bonds for company shares received partial compensation in the form of fresh government debt. The political consequences were possibly more formidable than the immediate economic repercussions. Leading politicians who had taken bribes, such as the Chancellor of the Exchequer, John Aislabie, were forced out of office and incarcerated. Robert Walpole, sometimes referred to as England's first prime minister, distinguished himself both through his opposition to the scheme and competent handling of its fallout. He succeeded Aislabie at the Exchequer and remained in power until 1742. The collapse of the South Sea bubble is sometimes seen as a factor behind the Bubble Act. This appears to be erroneous, as the Act was passed before the bubble deflated (Carswell, 1993). Its passage and rigorous enforcement after the summer of 1720 probably owed more to the company's efforts to support its own sagging share price. Because of the Act, new equity issues became very rare for almost a century. The Act was repealed only in 1825.

sovereign debt

Kenneth M. Kletzer
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The liabilities of sovereign states are not directly enforceable, for example by court-imposed transfer of collateral. Sovereign borrowing must be sustained by the prospect that indirect sanctions follow default. The credibility of sanctions for default and the roles of third parties and reputations for motivating repayment are discussed. The interaction of sovereignty and externalities between creditors complicates the renegotiation of sovereign debt. The importance of the collective action problem for debt restructuring is reviewed.

Article

A straightforward definition of sovereign debt is simply that it is debt issued by a sovereign state. Sovereignty conveys supreme legal authority within the geographical boundaries of the nation, giving national authorities autonomy over the regulation of economic activity inside the country through legislation, administration, and judicial enforcement. This means that foreign governments cannot interfere with economic activities within sovereign boundaries and cannot enforce contractual relationships without the cooperation of national authorities. Sovereignty denies creditors the right to reach inside national borders to confiscate assets or attach sources of revenue, public or private, to satisfy outstanding debts.

The importance of sovereignty for international capital markets is evidenced by the frequency of sovereign debt crises and defaults in history. Over the last century, debt crises have been associated with
default on international debt by governments in emerging market economies, but between the 16th and 19th centuries, sovereign default was similarly frequent in Continental Europe (Reinhart, Rogoff and Savastiano, 2003, survey the history of default). Although international debt is at the centre of recent crises, the economics of sovereign debt apply to debt issued in either international or domestic markets held by either foreign or domestic residents.

**Repayment incentives**

The first concern of the analytical literature on sovereign debt is what motivates borrowers to repay. When the terms of a debt contract cannot be enforced directly by a court, a sovereign debtor can be expected to honour its debts only if it faces adverse consequences for default. The literature focuses on the possibility of sanctions for debt repudiation or default which include the disruption of international trading opportunities by foreign governments or private market participants. For example, a repudiating debtor could face a trade embargo, suspension of trade preferences or loss of access to international capital markets. Each is a case of reduced access to international trade, whether trade takes place contemporaneously or across time.

A consequence of the observation that indirect sanctions provide the incentive to repay debt is that lending to sovereigns is constrained by the willingness of the debtor to repay rather than by its ability to repay. The concept of willingness to pay was first applied to sovereign debt in an analytical model by Eaton and Gersovitz (1981) following its use in earlier writings (for example, by Wallich, 1943). Eaton and Gersovitz emphasize that repayments are made out of the enlightened self-interest of the borrower and that debt limits are determined by the expected present value of the cost to the debtor of sanctions that will be imposed if debt is repudiated. They demonstrate two versions based on punishments given by disruptions of commodity trade and credit embargoes, respectively. Some immediate implications of the Eaton and Gersovitz model are that credit is rationed in equilibrium and that more severe sanctions increase loan supply.

It is helpful to compare lending sustained by the threat of indirect sanctions to conventional domestic lending with collateral. The use of collateral relies on a legal system to enforce debtors’ property rights in collateral assets and to transfer the ownership of these assets to creditors in specific events. Under a collateralized loan, the debtor repays to avoid losing collateral, and a solvent debtor should do so only if the value of the collateral exceeds the required repayments. The value of loan collateral determines a non-sovereign debtor's willingness to pay. In a time-consistent equilibrium, lenders should not lend more than the discounted present value of the assets that secure the loan.

Sovereign borrowing is analogous to legally enforced borrowing with collateral if the imposition of sanctions subsequent to default is exogenous. In the first version of the Eaton and Gersovitz (1981) model, static trade sanctions are imposed exogenously. One insight of the paper is that indirect penalties such as the disruption of commodity trade require the cooperation of third parties. Lenders, public or private, can count on repayment only if sovereign nations impose barriers to a recalcitrant debtor's trade. Eaton and Gersovitz consider how repayment incentives might arise within the credit relationship itself using the threat of a credit embargo in response to debt repudiation. Lending and repayment are derived as perfect equilibrium outcomes in an extensive-form game in which a risk-averse borrower with random income seeks to smooth consumption over time. The borrower repays if the net gain from future credit access is at least as large as the utility cost of the current repayment. The gains from credit access
Sovereign debt: The New Palgrave Dictionary of Economics

Depend on the amount that creditors will lend which in turn depends on the expected future repayments by the borrower. Perfect equilibrium is sustained in this model by the threat of permanent loan autarky. The strategies of creditors are restricted so that this punishment is imposed after a borrower defaults in any amount. Therefore, borrowers either repay in full or repudiate their entire debt. The restriction to a simple choice between full repayment and debt repudiation is one drawback of the basic model. If the gains from international trade or credit market access are stochastic, then allowing state-contingent repayments can raise welfare for borrowers or lenders. Grossman and van Huyck (1988) argue that default and debt renegotiation may result from an implicit state-contingent contract guided by a standard loan contract with fixed repayments. Several authors model debt renegotiation as the outcome of an implicit state-contingent contract with stochastic gains from trade.

Bulow and Rogoff (1989a) analyse a repeated model of bargaining over repayments supported by the threat of trade sanctions. By making an initial loan, a creditor acquires the right to invoke a trade embargo if the debtor fails to repay. Each period the creditor and debtor bargain over the amount paid by the debtor to avoid an embargo. This provides a foundation for the exogenous penalty in the first version of the Eaton and Gersovitz model. The repayment is a price paid by the debtor to purchase the right to impose sanctions from the creditor for one period at a time. The enforcement of property rights is essential to this model. The sovereign initially has the right to free trade which it sells for the price of the loan to the creditor. The creditor then rents access to free trade back to the sovereign debtor. Thus, the Bulow and Rogoff model parallels lending with collateral in that it requires the enforcement of property rights by disinterested parties.

The possibility that lending to sovereigns might be enforced by market participants themselves by denying credit market access to defaulting borrowers is addressed by several authors. Bulow and Rogoff (1989b) question the force of reputations-based punishments for sovereign default and argue that official imposition of sanctions or enforcement of creditor rights is necessary. In particular, they argue that permanent loan autarky as proposed by Eaton and Gersovitz in the consumption-smoothing model of debt does not deter sovereign default when debtors can accumulate foreign assets. They assume that a sovereign borrower can purchase a foreign interest-bearing deposit which it can draw against in default. Under this assumption, a sovereign borrower raises its welfare by defaulting and saving the amount it would have repaid in a foreign deposit. In this model, international capital flows are sustainable in perfect equilibrium, but only if the sovereign lends rather than borrows. An interpretation of Bulow and Rogoff is that reputations alone cannot sustain sovereign borrowing. This result received a fair amount of attention because it implies that sovereign borrowing cannot be self-enforcing and that earning a reputation for default is insufficient to deter opportunistic debtor behaviour. The special assumption of the paper is that foreign financial obligations to a government are enforceable while its financial obligations are not. The foreign creditors can commit to make future payments to the sovereign even when it is not in their self-interest to do so as events unfold. Contrary to the interpretation of Bulow and Rogoff, the capacity to commit requires exogenous enforcement by another sovereign state.

Kletzer and Wright (2000) model capital flows for smoothing a sovereign borrower's consumption in the absence of any exogenous means of contract enforcement and show that asymmetric commitment is essential for the conclusion of Bulow and Rogoff (1989b). The paper demonstrates self-enforcing equilibrium in an economy that treats both sides of the market as sovereign supported by punishments.
proof to renegotiation. Permanent credit embargoes are not credible threats because the gains from risk-sharing that motivate lending in the first place give incentives for forgiveness and new lending. Kletzer and Wright prove that sovereign borrowing is sustainable with free entry by new counterparties, as envisioned by Bulow and Rogoff, so that reputations alone are sufficient to enforce repayments. The general result is that credit markets are possible under the anarchy that characterizes international relations between sovereigns.

Kletzer and Wright show that the equilibrium is implemented by one-period loan contracts with state-contingent repayments that are not negative. State-contingent repayments are interpreted as the outcome of an implicit contract guided by non-contingent loan contracts following Grossman and van Huyck (1988) and Bulow and Rogoff (1989a). Non-commitment is exactly the assumption that any net payment (a new loan) made by a lender to the sovereign is voluntary. Introducing one-sided commitment allows conventional insurance, while the absence of commitment is consistent with renegotiation of conventional loans. Kletzer and Wright show that the opportunistic acceptance of defaulting borrower's deposits can only eliminate sovereign borrowing if international insurance contracts are exogenously enforced by other sovereigns.

A different approach to demonstrating the self-enforcement of sovereign borrowing through reputations is taken by Cole and Kehoe (1998). In a model with asymmetric information, actions reveal information about the borrower to counterparties in other financial and trading relationships. The borrower then cares about reputational spillovers to these other relationships (this possibility is noted by Bulow and Rogoff, 1989b). They demonstrate equilibrium repayment in the presence of one-sided enforcement of the sovereign's own foreign loans.

Sovereigns may enforce contractual obligations of domestic borrowers to foreigners because they recognize national benefits from doing so. Sovereign states set the rules inside national borders so that enforcement of private obligations is at the discretion of the sovereign. Until the 1950s, sovereign immunity applied with respect to assets held abroad. A commercial creditor could not pursue legal remedies against a sovereign debtor without its consent in either the United States or UK. By the mid-1970s both countries adopted more restrictive legal theories of sovereign immunity that allow private parties to seek remedy in home courts if the dispute concerns commercial transactions (Brownlie, 2003). Contemporary emerging market bond issues are overwhelmingly issued under the governing law of a few financial centres (primarily, New York and London) and incorporate waivers of sovereign immunity, thus voiding one-sided commitment opportunities.

Insights about the credibility of sanctions can be gained from the historical experience of sovereign default. Although trade sanctions were imposed on some sovereign defaulters before the 1930s, creditor nations appear reluctant to interfere with the international trade of countries in default (see, for example, Eichengreen and Portes, 1989). Ozler (1993), Lindert and Morton (1989) and others find that historically default had limited impact on loan terms for sovereign debtors, suggesting that credit market sanctions may be weak. Short-lived punishment or exclusion from borrowing while existing debts are renegotiated and settled, however, is consistent with credible punishment. Esteves (2005) studies debt renegotiation between 1870 and 1913 and finds that capital market access was disrupted during renegotiation but regained after resolution was reached. Many recent financial crises and debt restructurings conform to this pattern.
Debt renegotiation and restructuring is central to achieving gains from international risk sharing with limited financial instruments. The protracted and costly process of sovereign default resolution and debt restructuring remains the subject of policy concern and debate (for a review, see Eichengreen, 2003). The difficulty of achieving the acquiescence of a large number of creditors to a sovereign debt restructuring agreement has been repeatedly demonstrated for more than a century.

Tirole (2002) identifies the interaction between problems of common agency in lending and debtor sovereignty with inefficiencies in international capital markets that produce crises. He observes that debtor sovereignty impedes solutions adopted in domestic financial markets to the externalities between various creditors due to common agency in lending. With legal enforcement of contracts, bond and loan covenants can establish property rights across heterogeneous creditors in the event of default so that individual creditors internalize the impact of their actions on other creditors. In corporate debt markets, the power of the sovereign can be used to mitigate moral hazard on the part of both the debtor and its creditors, in contrast to the case of sovereign debt.

One of the problems associated with common agency in sovereign lending is the difficulty of achieving collective action among creditors for resolving default. In default or bankruptcy, an important role of court proceedings is to aggregate various debts and resolve conflicting claims between creditors to reach completion of financial restructuring. For a sovereign debtor, creditors who accept reduced repayments in default increase the value of debt held by creditors who do not participate. Free-riding of this type is related to the public goods nature of the capacity to impose sanctions. Any debt rollover, reduction or exchange can be prone to hold out creditors prolonging and contributing to crises. A minority of creditors can also interfere with a debt restructuring by exercising their legal rights under the governing law under which bonds were issued.

The collective action problem for sovereign debt renegotiation (and, hence, lending to sovereigns) has been addressed in various ways over time. Prominent approaches include the formation of bondholder committees, representation of creditors by banks, and official sector intervention. In recent years, two approaches, neither new, have received considerable attention. One of these concerns contractual innovation. An example of the issue is the ability of individual creditors to block debt swaps under unanimous consent clauses required for US corporate borrowing. Collective action clauses allowing less than unanimous consent to restructurings were included in major sovereign debt issues in the United States after active encouragement. An analysis of these clauses is given by Eichengreen, Kletzer and Mody (2004), and the possibility of voiding benefits for hold-outs under unanimous action clauses is discussed by Buchheit and Gulati (2000). The other approach is statutory innovation which may challenge debtor sovereignty. Although such proposals have been advanced over the years, the prospects for an international debt restructuring mechanism are diminished for now in favour the pursuit of market-based innovation.

Soviet and Russian research, development and innovation

Julian Cooper

Abstract

For its level of economic development, the Union of Soviet Socialist Republics (USSR) possessed a research and development (R&D) system that was impressive in terms of personnel and funding, yet the country's achievements in technological innovation were, with the partial exception of military industry, unimpressive. Following the collapse of Communism, the R&D system substantially contracted in scale. After a decade of post-Communist transformation in Russia, funding began to recover but the new market conditions did not prove conducive to successful innovation on a significant scale. The National Innovation System of present-day Russia is still marked profoundly by the Soviet legacy.

Understanding the functioning and performance of the Soviet R&D system and the innovation-averse character of the planned economy has posed a challenge to economists and science policy specialists since the 1950s. It was the ‘sputnik’ shock of 1957 that triggered serious analysis of the Soviet R&D system. Initial research (De Witt, 1961; Korol, 1965) focused on its scale in terms of personnel and on its basic organizational and behavioural characteristics, a landmark being the 1969 Organisation for Economic Co-operation and Development (OECD) report on science policy in the USSR (Zaleski et al., 1969). This report highlighted the organizational separation of research from production, the dominant role not only in basic research but also in much applied work of the USSR Academy of Sciences, which played a central role in the overall science policy of the country and occupied a position of prestige in society, and the relatively modest role in R&D of the higher educational sector. Later works contributed
By this time there was an appreciation that, notwithstanding the scale of the R&D system, somewhat overstated by Soviet official statistics, overall innovative performance was poor. A pioneering attempt to analyse the economics of innovation was that of Joseph Berliner (1976). For Berliner, Soviet industry was characterized by an all-pervasive lack of responsibility, risk aversion and weak incentives for successful innovation, coupled with mild penalties for failure in the absence of competition. Attempted economic reforms had achieved little to improve the situation, and Berliner was not optimistic that any major structural change would boost innovative performance. The outcome of inadequate innovation was the focus of work undertaken by researchers at the University of Birmingham (Amann, Cooper and Davies, 1977). This demonstrated that from the mid-1950s to the mid-1970s in many sectors of the economy there had been no diminution in the technological gap between the Soviet Union and leading industrial economies. It was found that the rate of diffusion of major new technologies tended to be slower than the rates typical of advanced market economies. Further research into industrial innovation (Amann and Cooper, 1982) built on the findings of Berliner, but with more attention to the specific historical conditions in which particular industrial sectors developed. While the Soviet economic system was by its nature averse to innovation, some sectors showed better performance than others, above all the defence industries, where high-level political intervention and priority resource allocation to some extent overcame the inertia of dysfunctional economic institutions. That these institutions and their implications for the development of science and technology had deep roots was shown by the pioneering work of Bailes (1978) and Lewis (1979). Further insights into poor performance in the adoption of innovations was later provided by the application of a principal–agent framework, notably by Dearden, Ickes and Samuelson (1990).

In the late 1960s and 1970s, recognizing the limits of the domestic civil R&D and innovation systems, the Soviet authorities attempted to boost technological progress by importing the latest technology from the West, with the automobile industry as a pioneer (Holliday, 1979). The results were disappointing. As shown by Hanson (1981), the Soviet system was unable to reap the productivity gains potentially available and was incapable of reproducing the technology itself to diffuse the achievements more widely.

Soviet R&D was heavily militarized. At various times the authorities attempted to harness the resources and skills of the military sector to boost performance in the civil economy. However, ‘spin-off’ from the defence sector was modest; and when a policy of ‘conversion’ was pursued in the final years of the Soviet regime under General Secretary Gorbachev the practical results were modest because of organizational barriers, inadequate incentives and a marked quality gap between the military and civilian sectors.

In terms of personnel and spending, the USSR had a research system of significant size. However, appreciation of its true scale and the productivity of Soviet science was complicated by data problems. According to Soviet official statistics, in 1990 expenditure on science was five per cent of national income. However, this figure was inflated by double counting. Researchers of the Centre for Science Research and Statistics (CSRS), Moscow, concluded that for Russia in 1990 the actual share was two per cent of GDP. Similarly, official data overstated the number of R&D personnel, partly because
employment was not expressed in terms of full-time equivalents.

In the USSR the innovation process was always understood, implicitly by government officials and often explicitly by economists, as a linear process; that is, new products and processes were developed on the basis of ideas and inventions originating in basic and applied research, and then development, after which they were ‘introduced’ into the sphere of production and then diffused more widely. Only in the very final years did some analysts become aware of the work of Chris Freeman and other Western science policy specialists who challenged the linear model and argued for a richer understanding involving feedback relationships. However, in present-day Russia the linear model is still widely met and increased spending on science often presented as the principal means of promoting innovation. Since the collapse of the USSR, there has been no attempt by either Russian or other scholars to revisit the Soviet R&D and innovation system in a comprehensive manner. However, the work of Harrison (2003; 2005) has provided some additional insights into the system during the Stalin era, with a focus on principal–agent problems and incentives. The analysis undertaken before the end of the system drew upon the theoretical advances of Janos Kornai (1980; 1992) only to a limited extent (for example, Hanson and Pavitt, 1987), in particular Kornai’s analysis of the role of soft budget constraints. The pioneering work of the late Yurii Yaremenko, perhaps the most innovative of all economists working in the USSR in its final 20 years, was also disregarded (in particular, Yaremenko, 1981). Yaremenko analysed the Soviet economy in terms of a hierarchical, multilevel system, with each level having access to resources, human and material, differentiated by quality. The qualitative heterogeneity of resources became firmly institutionalized. An individual enterprise, or entire branch of production, could rise up the hierarchy and secure access to higher-quality resources only by a policy decision of the political–economic authorities. Lower-level sectors habitually deprived of high-quality resources compensated for their lack by resort to larger quantities of lower-quality inputs. At the upper levels, occupied by defence industries and some priority civil sectors, higher-quality resources permitted the use and development of more advanced technologies, but innovations possible in these privileged conditions were unsuited to diffusion to lower levels of the economy lacking an appropriate resource environment for their successful application.

The collapse of Communism at the end of 1991 had a profound impact on Russian R&D and innovation. Positive factors included the end of ideological controls and censorship, as well as a new freedom for scientists to travel abroad. But for most of the 1990s negative factors predominated: funding collapsed, the number of researchers contracted sharply, many institutes of the Academy of Sciences and industry developed non-research activities in order to survive, and many talented younger scientists found work abroad (Glaziev and Schneider, 1993; Schneider, 1994; Gokhberg, Peck and Gács, 1997). A comparison of the situation in Russia in 2004 with that of 1990, after 15 years of transformation, shows the following principal features: R&D expenditure as a percentage of GDP was 1.35 compared with 2.03, although it reached a low point of 0.74 in 1992; in real terms R&D spending was 42 per cent of the 1990 level; and the number of researchers had fallen to 401,425 compared with 992,571, the decline moderating but still under way. In 2004 almost 50 per cent of all researchers were 50 years old or more, compared with 35 per cent in 1994 (CSRS and Roskomstat data). A landmark was the OECD (1994) review of Russian science, technology and innovation policies, which remains, with its background report, an important source on the system and problems of transition. This argued that post-Communist economic transformation in the prevailing circumstances of Russia would inevitably entail a substantial
contraction of the scale of the R&D effort and set out measures designed to convert the Soviet-era legacy into a coherent market-oriented National Innovation System. Research undertaken by Russian and Western economists and science policy specialists reveals that, notwithstanding reform measures, the Russian R&D system as of 2006 still retains many Soviet characteristics (Dezhina and Saltykov, 2005; Radosevic, 2003). There is still organizational fragmentation, with the majority of R&D organizations being remote from the business sector; a large proportion of research organizations remain in state ownership; budget spending predominates, with only a modest contribution from the private sector; higher education plays a limited role in R&D, the Academy system still absorbs a large share of total expenditure; and the military share of R&D remains substantial, almost as large as in Soviet times. The inertia is such that it cannot be said that Russia possesses a National Innovation System, understood as a coherent set of interrelated institutions promoting innovation as a natural outcome of their day-to-day functioning. This situation has arisen in part because strong vested interests within the Academy of Sciences and industry have pursued their own survival strategies, resisting the government's reform initiatives.

Innovation activity in Russia's market economy remains relatively weak. Explanatory factors include weak competition, inadequate managerial skills, underdeveloped technological capabilities at the company level, weak demand for new products and processes, inadequate finance, with little long-term bank lending and a lack of venture capital, and modest foreign direct investment in manufacturing (OECD, 2006; World Bank, 2006). Russian government initiatives to improve the situation include the creation of special economic zones and the formation of venture capital funds. The domestic intellectual property rights regime has been improved but enforcement remains weak. For Russia, promoting a more effective R&D system and improved innovative performance is becoming a policy priority in the face of competition from other dynamic emerging economies, in particular China and India (Cooper, 2006). Notwithstanding relative strength in human capital and the possession of a large research system in terms of personnel, the Soviet past still hampers Russia in the field of research, development and innovation, and for economists this represents an interesting case of the costs of institutional inertia.

Soviet economic reform

Vladimir Kontorovich
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

‘Soviet economic reform’ refers to repeated failed attempts from the 1960s to the 1980s to introduce market-inspired institutions into a command economy. These reforms aimed to increase the discretion of enterprise managers and give them incentives to use local information in executing commands while also attending to customers’ demand. Reform arrangements, such as reduction in the number of commands and stress on profit and sales, clashed with the vital functions of the command mechanism, impaired performance, and were eventually reversed, only to be reintroduced later with similar consequences.

Article

Lively organizational churning took place in the Soviet economy behind the façade of ideologically mandated institutional immobility. A command economy was introduced in 1918, gave way in 1921 to a market socialism-type system known as the New Economic Policy (NEP), and was re-established in the late 1920s and early 1930s. In the remaining 60 years of its existence it was subject to three types of organizational change: the reordering of the command hierarchy; the adjustment of the border between the command core of the economy and the peripheral sectors where the market was allowed to operate; and the introduction of market-inspired institutions into the command core itself, which we call ‘economic reform’ and which is the subject of this article.

The Soviet economy was organized like a pyramid, with party and government leadership at the top, enterprises at the bottom, and ministries for particular sectors in the middle. Its organizational chart was regularly redrawn as ministries and enterprises were merged or split, enterprises were transferred from one ministry to another, and functions were redistributed among staff and line departments. These
changes usually came with less fanfare than economic reforms and attracted relatively little interest from researchers, and their effects on economic performance have not been documented.

Administrative allocation of resources in the core of the Soviet economy (industry, transport and communications, construction, distribution of producer goods, foreign trade, part of agriculture) coexisted with market or quasi-market allocation at the interface between these sectors and households, as well as among the households. The boundary between market and command economy was repeatedly adjusted, as when rationing of consumer goods alternated with their sale at fixed prices in state stores. Institutional changes in this category had immediate perceptible effects on consumer well-being, as attested to by contemporaries.

Output commands and input quotas in physical terms never covered all the activities of enterprises. Because of the strains on the planners’ information-processing capacity, some commands were formulated in aggregate terms, and some production activities were left out of the central plan. Actual physical details of aggregate commands, as well as decisions on the provision of some goods and services, were left for the producers and users to work out. Also, the command allocation of resources was shadowed by monetary flows. Enterprises paid each other for supplies at centrally fixed prices, kept accounts in monetary terms and received plan targets for cost, total value of output, and other monetary magnitudes.

In the classical Soviet system, enterprise managers’ discretion in production decisions was limited to low priority goods. Money circulating in the command sector was meant to passively track planned direction of resources, playing merely the accounting role. Financial targets ranked low in the enterprise plans. The thrust of economic reforms was to make these subordinate features of the economy, which served as props for the command mechanism, at least as important as the latter. Enterprise discretion, the influence of users on suppliers, and reliance on monetary plan targets were all intended to increase. Economic reforms attracted far greater attention than the other organizational changes because they arguably represented a retreat from the Stalin-era ideological orthodoxy and held out hope for systemic change, fuelling, for example, theorizing on the convergence of socialism and capitalism (Ellman, 1980, p. 200).

The prototypical reform

The first Soviet economic reform was announced in 1965. It replaced the main indicator of performance, namely, gross value of output, with sales, so as to bring the users’ evaluation to bear on the producers’ performance. To unshackle the initiative of the enterprises, the number of output targets for specific products in physical terms was reduced, and some other targets, including cost reduction, labour productivity, the number of employees, and the average wage were abolished. The volume of profit and its ratio to the enterprise's assets became binding targets. Enterprises were allowed to undertake small-scale investments on their own, and for this purpose to create a development fund financed out of profit, depreciation charges, and proceeds from selling unneeded equipment.

Pecuniary incentives built into the economic mechanism, working automatically, were to play an equal, if not greater, role than specific commands from superiors in guiding enterprises. A substantial bonus fund and a fund for residential construction and social development were created to replace the tiny fund that previously served these purposes. Inspired by the Western experience of profit sharing, reformers
made enterprise profit the source of financing for the funds. While previously the evaluation of performance and rewards and punishments were all tied to the degree of plan fulfillment, the size of the funds was tied to the actual growth of profit or sales and to the ratio of profit to assets through a formula. The coefficients of the formula were to be fixed for a number of years, rather than changed by the ministry at its discretion every plan period.

Another element of stable rules of the game for the enterprises was to be provided by firm five-year plan targets. Before, these were changed annually, if not more often, at the discretion of the supervisory body. Enterprises always paid for labour and intermediate inputs, but got their plant and equipment free as a result of centralized investment decisions. The reform introduced a capital charge, a fixed percentage of the value of fixed and working capital to be remitted to the state budget. The intentions to supplant input rationing by wholesale trade in intermediate products and to allow enterprises themselves to determine their wage bills were announced.

Reform was introduced gradually and by 1970 applied to almost all of industry (Schroeder, 1971, p. 38). However, in the process many reform measures were reversed or modified in ways subverting their initial intent. By the early 1970s, commands for production of specific goods had returned to the pre-reform level of detail, and targets for labour productivity and cost reduction were brought back (Iasin, 1989, p. 100). Funds for decentralized investment were first restricted and then used as just another source for financing centrally planned projects (Dyker, 1981, p. 139). Rules for incentive fund formation and for awarding bonuses were changed repeatedly, making the latter dependent on meeting a number of plan targets, rather than on the growth of profit (Ellman, 1984, pp. 87–9). Trade in intermediate goods and operational five-year plans for the enterprises never got off the ground or were realized only on a small scale.

Because of the eventual reversal of so many reform provisions, arguments about their effects are limited to the period of 1966–70, when they were still being implemented. According to the official Soviet data, industrial output continued to grow through this period at the same rate as in the previous five years. The recalculation by the US Central Intelligence Agency (CIA) shows a marginal slowdown in industrial growth (US Congress, 1982, pp. 191–2), and some of the estimates using the CIA data detect a pickup in total factor productivity (TFP) growth or a slowdown in its decline in 1966–70. To be able to attribute it to the effects of reform, one would need a thorough growth accounting exercise, which has not been undertaken for lack of data. Thus, changes in capacity utilization in industry help explain part of the variation in TFP in the 1970s. Capacity utilization in the late 1960s was increasing for reasons unrelated to the reform, though the extent of the increase, and hence its impact, is unknown (Kontorovich, 1990, pp. 44, 46).

There may have been one-shot gains as enterprises strove to qualify for the new incentive rules by assuming more ambitious targets, selling unneeded equipment, and drawing down inventories (Schroeder, 1971, p. 44). Over the longer period, qualitative evidence on the micro level shows the persistence of enterprise behaviour patterns which the reform intended to modify – hiding resources from the planners, meeting plan targets in ways that sacrifice the customers’ needs and waste resources, and neglecting the tasks that the planners had not specifically ordered. The reform also had several unintended ill effects on performance. Greater discretion in choosing product mix and enhanced interest in value of output measured in administrative, cost-plus prices led enterprises to shift product mix in the direction of more intermediate input-intensive items, irrespective of customers’ needs (Kushnirsky,

1982, pp. 16–17; Iasin, 1989, p. 99). The relationship between the dynamics of output in physical and in value terms shifted, and planners, who did not acknowledge the shift in their calculations, were led to make more wasteful allocation decisions (Khanin, 1991, pp. 41–9).

The treadmill of reform

The expression ‘treadmill of reform’, coined by Schroeder (1979), refers to the post-1965 Soviet attempts at reform followed by retreats. The treadmill appears even more daunting if one considers Soviet history and the collective experience of command economies. A prominent official in charge of heavy industry briefly attempted to do away with rationing of producer goods within his sector as early as 1932, with disastrous results (Davies, 1984, pp. 213–14).

In the late 1940s, as an element of Communist rule, a command economy was imposed on eight east European countries, some of which were the first to try economic reform after Stalin's death in 1953. Most of the elements of the Soviet 1965 reform had been formulated and tried by its east European neighbours in the previous decade, with similar results. In Hungary in 1954, the number of commands issued to the enterprises was reduced, and the intention was announced to promote decentralization through the use of incentives and delivery contracts. The number of commands soon crept back up. In 1956, half a dozen enterprises were experimenting with greater independence and use of profit as the success indicator (Kornai, 1959, pp. 218–21, 234). New incentives based on profit sharing were introduced in the late 1950s, and a capital charge in 1964. These measures proved, in the official estimation, to be ineffective (Bauer, 1987, p. 135; Berend, 1990, pp. 108–9).

Reforms in Poland starting in 1956 included the reduction in the number of commands, provisions for decentralized investment by the enterprises, and creation of a substantial bonus fund, both to be financed out of profit. These changes were rolled back in 1959–60 (Montias, 1962, pp. 294–307, 320–4). In Czechoslovakia in 1958, profit was made the main success indicator for the enterprises, with the latter also given the right to decide on some investment projects and finance them internally. These reforms were reversed in 1960–2 (Myant, 1989, pp. 82–4; Teichova, 1988, p. 148).

By the time the USSR embarked on its first economic reform in 1965, these and other east European countries were already on their second round, to be followed by further retreats, modifications, and new attempts too numerous to list here. Only Hungary escaped from the treadmill, having established a market socialist economy after 1968. The Czechoslovak reform of 1967 and the Polish reform of 1982 had similar aspirations, but the former was aborted after the Soviet invasion of 1968 and the latter was unsuccessful.

Decrees on ‘improvement of the economic mechanism’ adopted in 1979 aimed to correct some of the ill effects and reaffirm some of the neglected planks of the previous attempt. To curb the enterprises’ manipulation of product mix in favour of more material-intensive products, the main target was changed from sales to a variant of net product, and bonus payments were made conditional on fulfilling delivery obligations in terms of volume, assortment, quality and timeliness. The use of fixed rates, rather than ministry discretion, in planning wages, profit distribution, and other financial and physical targets for the enterprises was to be broadened. The intention to make five-year plans operational and to make ministries self-financed was reiterated. An internal investigation of the effects of this reform found that it had no positive impact on performance due to its piecemeal nature (Ellman and Kontorovich, 1998, p.
Though reforms are discussed as discrete events dated by the year of their announcement, each one was implemented in stages over a number of years, with amendments, modifications, and reversals to follow. This, combined with the redrawing of the organizational chart, such as the merger of enterprises into larger associations initiated in 1973, assured that Soviet industry was in the process of almost continuous administrative upheaval. The tempo of reorganization reached a fever pitch in the system's final years.

In 1984 a ‘large scale experiment’, again attempting to cut the number of commands to the enterprises, and extending and strengthening some of the provisions of the 1979 decree, was introduced in five industrial ministries. By 1987 it covered the whole of industry, but in the summer of that year a ‘radical reform’ was announced, to be implemented in 1988.

Its most radical provision was the election of the enterprise managers by their employees. Plan targets for total value of output, profit, and most other aspects of enterprise performance became mere recommendations. Obligatory targets, rechristened as state orders, were kept for output of major products and commissioning of production capacity. They were supposed to cover only a small share of the enterprises’ output. Producers were free to dispose of the output over and above the state orders however they saw fit, though most prices remained fixed. All investment by enterprises was to be financed from their own revenue. Uniform stable long-term rates were to determine the distribution of profit among payments into the state budget and contributions to the investment, bonus, and social development funds, with enterprises retaining a greater share than before. The ministries were forbidden to issue any commands not on the government-approved list, a practice common during the previous reform attempts. Now the enterprises could go to court to overturn such commands and demand compensation for damages they caused.

The effects of the last reform on overall economic performance were drowned out by those of the collapsing political system and of severely misaligned fiscal, monetary, and investment policies. The reform increased financial resources at the enterprises’ disposal, and these were used to boost employee remuneration and decentralized investment, aggravating already significant shortages of consumer and investment goods. Faced with compulsory targets for only part of their output, enterprises reduced production of non-compulsory items and shifted their product mix towards higher-priced items. This disrupted the flow of inputs and made other enterprises unable to meet their obligatory output targets, contributing to an output contraction in many sectors in 1989 and economy-wide in 1990–91 (Krueger, 1993).

The elections of managers were repealed in 1990. The rates governing enterprise profit sharing were manipulated to rein in the growth of employee remuneration. In order to combat supply disruptions, centralized distribution of non-centrally planned products was authorized in mid-1988. While the official objective of curtailing the share of state orders in the output was regularly reiterated, by the end of 1991 only 14 percent of producer goods distribution officially went through non-administrative channels.

Amended and revised, the 1987 reform defined the formal economic mechanism of the Soviet economy until its very end. Western experts were both urging Hungarian-type market socialism on the USSR and predicting its imminent adoption (Schroeder, 1979, p. 340). While proposals for such a transformation were floated in the country's final years, they were never realized.

**Reasons for the failure of reforms**
The evidence of failure consists of the record of reform decrees modified and overturned; proclaimed intentions never realized in practice; the treadmill, with its repeated attempts to implement the same changes over and over again; and qualitative evidence that reform planks actually implemented failed to effect intended changes in enterprise behaviour, and often had negative unintended consequences.

**Politics**

Most Western research focused on the Soviet reform of 1965, and the prevailing interpretation attributed its failure to self-interested sabotage by ministry and other middle-level officials (Schroeder, 1979, p. 324). Resistance from the state and party bureaucracy was also seen as a formidable obstacle to the next serious reform. Such an explanation was consistent with the view of Soviet politics that became predominant in Western academia in the 1970s. The totalitarian model, with the top ruler being the sole unchallenged political actor, had been abandoned in favour of a pluralist model with politics propelled by interest-group rivalry.

The ‘bureaucratic resistance’ explanation of reform failure was incomplete at best, for the formal repeal of reform decrees could be done only by the top political authority. It implied the capitulation of the rulers in the face of interest-group pressure. But this would be highly unlikely given the record of Soviet economic history. In 1921, Lenin thought up and introduced his market-socialist NEP, to the dismay of much of the party, which nevertheless did not mount effective resistance. In 1957, Khrushchev abolished ministries, to the unhappiness of officialdom, but without resistance (Berliner, 1983, p. 383). Gorbachev dismantled or emasculated every economic bureaucracy in the space of a few years. Sectoral ministries were merged, had their staffs cut, and lost their power over the enterprises. The planners themselves carried out the abolition of the central planning when ordered to do so. The Central Committee and the regional party committees gave up their economic functions in an equally disciplined fashion. The military-industrial complex, the sector alleged to have the most political power, was ordered to convert to civilian production and complied (Ellman and Kontorovich, 1998).

A more plausible political explanation of the failure of 1965 reform is that the top political echelon was divided, with the General Secretary being less than enthusiastic about it from the beginning (Baibakov, 1998, p. 171). Fear of political destabilization in the wake of the Czechoslovak ferment of 1968 is thought to have further soured the rulers on the reform and brought it to an end.

**Systemic incompatibility of reforms**

Political explanations imply that the reforms as designed were effective, and their failure was due to faulty implementation. Yet the provisions of the Soviet 1965 reform that were faithfully implemented did not achieve their objectives and produced harmful side effects, some of which are described above. The uniform ineffectiveness and the unintended negative consequences of reforms implemented in different countries over a long period of time suggest flaws in their conceptual foundation, namely, the implanting of market-like institutions into a command economy.

Economic reforms were an exercise in imitation, their intuitive plausibility deriving from the appeal to the workings of competitive markets. Trying to make money, prices, and profit that already existed in the command economy perform some of their market economy functions, the reformers fell into a

linguistic trap, committing the equivocation fallacy. Enterprise profit from centrally ordered transactions, calculated in terms of administratively set prices in an economy with passive money, had, despite the name, different properties from profit in a competitive market, and could not perform the latter's functions. There is no reason why the pursuit of this profit would lead enterprises to efficient decisions, or why the stress on the volume of sales would make them sensitive to the wishes of their customers.

While market-type institutions in the command economy context lack the efficiency properties of their market economy namesakes, they also interfere with the vital function of central planning. A modern industrial economy, with its narrow specialization, depends for survival on the regular flow of intermediate goods and services from producers to users. In the absence of market, the task of balancing, or assuring a tolerably smooth flow of inputs, falls on the economy's administrators. The complexity of the problem (the large number of products and producers, and continuous shocks to supply) overwhelms the planners' information-processing capabilities. If balancing is done poorly enough, the economy may come to a halt. Because of the difficulty and importance of balancing, it received the lion's share of attention of planners and ministry officials, and economic institutions were moulded so as to make their task easier (Grossman, 1963). Despite all that, the degree of balancing remained a grave problem in the functioning of the Soviet economy.

Most of the economic reform measures, if implemented, endangered the regular flow of supplies (Kontorovich, 1988, pp. 312–13). A reduction in the number of output commands and an increase in the level of their aggregation meant abandoning the balancing of some products, or making it less precise. Tying incentives to growth rather than to plan fulfilment deprived the officials of one of the tools of ensuring that certain quantities of goods were produced and shipped to users at designated intervals (Litwack, 1990). Abiding by stable long-term profit-sharing coefficients and other norms required the planners to give up their discretion to adaptively adjust the plan as its imbalances were being revealed (Litwack, 1991, p. 262). Developing long-range plans with the degree of detail that would make them operational defied the planners' capabilities, already strained by constructing a balanced annual plan. Enterprise investment funds, when effective, diverted inputs from the uses designated by the planners (Dyker, 1981, pp. 136–9; Ellman, 1984, pp. 95–6).

The recognition of systemic incompatibility sheds a different light on the role of bureaucratic resistance. Reforms forced the middle-level economic officials, who were responsible for balancing, to surrender many of the tools for accomplishing the task on which they were being evaluated. Faced with contradictory demands, they procrastinated, violated reform decrees, and exerted informal pressure on the enterprises in order to perform the function that was vital for the economy. To the degree that they succeeded, their actions protected the economy from the harm that systemically incompatible change would have inflicted on it (Kontorovich, 1988, pp. 313–14; Litwack, 1991, p. 264). The formal reversal of reform decrees occurred when the top officials recognized their ill effects.

**Reasons for the treadmill**

Repeated introduction and abandonment of a policy or an organizational change may result from efficient adaptation to changing circumstances, the shifting outcomes of interest group struggles, or changing ideas or ideology. However, all of these explanations are predicated on the effectiveness of
recurring change (Siegmund, 1997, pp. 372–4). The treadmill of reform can be explained, in the spirit of North (2005), by considering the rulers’ beliefs about the economy. The evidence, centring on the last and most aggressively reformist General Secretary, suggests that they were not aware that the reforms were unworkable. Memoirs of Gorbachev’s aides and advisors, as well as his own pronouncements, show that he came to power with the intent of improving the workings of the system and with a belief in its ability to be reformed. This reflected a persistent strand in the Soviet thinking, which viewed the economy as highly malleable, as manifested in the overwhelmingly normative slant of Soviet economics and in much of economic policy.

Gorbachev (1995, p. 117) attributed the failure of the 1965 reform to bureaucratic resistance at the intermediate level of hierarchy, and blamed saboteurs for everything that went wrong with his own reforms. Even after having smashed the system and all its institutes, Gorbachev would insist that ‘Sectoral bureaucrats could eat alive anyone, including the Chairman of the Council of Ministers and even the General Secretary’ (Abalkin, Medvedev and Kotkovskii, 1995, p. 123). If sabotage was seen as the reason for the previous failure, then trying again, and harder, made sense. The experts on whom the rulers relied for the elaboration of the content of reforms shared this outlook. Some of the best Soviet economists argued that the 1965 reform had a strong positive effect on the economy. They viewed bureaucratic resistance as the main obstacle to a reform's success, as in Zaslavskaia's sensational ‘Novosibirsk paper’ from 1983 (Hanson, 1992, p. 59). The 1987 reform, incorporating the planks that had been tried and proven unsuccessful over the preceding 30 years, embodied the best the Soviet economists had to offer at the time.

The belief in reformability of the command economy was maintained against long odds. The Soviet rulers had rich experience in supervising large, complex, long-term projects for the creation of weapons systems. With the best domestic experts in charge, every available bit of foreign scientific information was utilized, prototypes were tested experimentally, and failed designs were set aside, while successful ones were developed, resulting in a formidable arsenal. The preparation of reforms outwardly followed the pattern that proved successful in the technical fields: a more or less public discussion among the economists, managers, and officials; blueprints prepared by committees including the representatives of these groups; and experimental trials preceding broad implementation.

Soviet reformers could also draw on foreign expertise, specifically, the east Europeans’ evaluation of their own countries’ experiences, as well as the work of Western Sovietologists. Thus, Kornai (1959, p. 225) argued that central planning is a coherent system, and piecemeal changes to it, such as less detailed plans or more discretion given to the enterprises, are bound to hurt performance. Granick (1959, p. 123–4) noted that even the minimal use of money and quasi-market institutions in the classical Soviet economic model conflicted with central planning. Grossman (1963, p. 119) demonstrated that the ‘command principle’ could not coexist with the market mechanism in a stable way, and correctly predicted the fate of the 1965 reform as it was being initiated (Grossman, 1966, p. 54). The Western analysis of reform failures was based on information from Soviet publications.

One would expect the Soviet economists to learn about the futility of reforms from the experiments, or from the experience of their implementation, or from east European and Western publications, and eventually to convey this conclusion to the rulers (though Western analyses from the 1970s and 1980s, stressing bureaucratic resistance, could be read as confirming Soviet domestic misconceptions). This is what happened to the east European economists, who started from the same level of understanding as
their Soviet colleagues in the 1950s (Kornai, 1959, pp. xiii–xxv). The Hungarian 1968 market reform and the aborted Czechoslovak one in 1967 were preceded by public discussions among economists with a level of sophistication that was not achieved in the USSR until after 1987.

The different pace of learning appears to reflect tighter political constraints in the USSR than in some of its east European satellites. Unlike in the development of new weapons, the rulers had preferences not just over the results of economic reforms, but also over their methods. At various times, they considered particular reform measures to be unacceptable for reasons of political stability and ideological propriety. This not only forestalled public and professional discussions but also created disincentives for individual research. Trying to learn from the results of countries with laxer political constraints simply did not pay in terms of professional advancement. Ideas that were not allowed to be articulated just did not occur to people, at least not to those who might ever be asked for advice. Conversely, the reforms which the rulers did accept could not be undermined by negative experimental results. Economic experiments were ordered by the political authorities and conducted by lower-ranking officials. The latter understood the experiment to embody the official policy and did what they could to make it a success. Choosing the better-performing enterprises to participate in the experiment or affording special treatment to the participants usually assured the result.

In the late 1980s, as political and ideological constraints on acceptable economic advice were being removed, economists’ learning greatly accelerated, and proposals for a transition to a market economy were publicly announced. The demise of the command economy, weakened as it was by the final round of economic reforms, came not through the implementation of these radical proposals but as a result of the disintegration of the underlying political system.

Soviet growth record

Gur Ofer
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The Soviet Union initiated and implemented a heroic social experiment that included a rapid and fairly successful, albeit rather distorted, process of modernization and growth. It culminated more than 70 years later in a dead end that required a difficult and costly ‘transition’ in order to join the main road to modern economic growth and a market system. After presenting the record of Soviet economic growth and structural change, this article describes and analyses its particular strategy of extensive growth, its strengths and weaknesses, its relation to the Communist political regime, and the reasons for its non-sustainability and, hence, demise.

Article

The end of 1991 saw the collapse of the Communist regime, which was created 74 years earlier following the October Revolution of 1917, and with it the disintegration of the Soviet Union into 14 newly created independent states. In this way one of the most heroic social experiments of modern times came to a close. That experiment failed to provide a sustainable alternative social order to that offered by the capitalist model of different mixes of market mechanisms and government interventions, and of
different variants of democratic and free political regimes. The Communist alternative, as presented by the Soviet model, was composed, on the economic side, of central planning and public ownership of most means of production, and of an authoritarian regime on the political and social sides; and both built on the foundation of the political economy teaching of Karl Marx as modified by Vladimir Lenin and his fellow-Bolsheviks. This Communist alternative claimed to be more equitable and just, and at the same time also more efficient, than the capitalist alternative. Specifically, it claimed to achieve faster economic growth, and thereby the potential to catch up with and overtake the capitalist market economies.

The end of the Communist system, indeed its demise from within, provides proof that the system as a whole was not sustainable, and very probably that economic factors had a role to play. This, however, was not the accepted view by everybody during the Soviet period. Throughout that era, more so during its earlier years, the Soviet system presented in the eyes of many an economic challenge (in addition to a military one) to the developed West, the threat of ‘taking over and surpassing’, and an alternative, possibly superior growth strategy to developing countries. This economic challenge, including its military implications, aroused great interest and thereby generated academic and intelligence input into the study of the Communist economic model and development strategy and the resulting outcomes in terms of economic growth, efficiency and equity. This input became all the more difficult, for both Soviet and Western scholars, because of the veil of secrecy that was imposed by the Soviet authorities on all sorts of information and statistics, and the distinct, though in many cases obscure methodology underlying the economic information and data that were published. Often the published data were biased in order to present a rosier picture than the Communist reality.

A survey of Western attempts to estimate the Soviet growth and efficiency record and to evaluate and explain it was prepared by this author during the last years of the Soviet Union (Ofer, 1987). It included, among others, mainstream estimates as well as some of the main debates and disagreements over these estimates and the methodologies used to compile them. Even though some of the figures presented turned out to be somewhat biased in favour of the Soviet record (in the light of data and analysis that became available in later years), the main observations and conclusions regarding the Soviet experience seem to have survived the test of time: among other things, they showed that, following a period of relatively rapid growth and successful industrialization and modernization, the pace of growth slowed down over time up to a virtual stop; that, overall, Soviet growth lagged behind that of many Western and other countries; that Soviet growth was achieved with a greater use of labour and investment resources per unit of output, and a lower contribution to improved productivity, that is, at lower efficiency levels and also with much greater human sacrifice, economic and otherwise; and that the Second World War, the Cold War and imperial ambitions came at a price in terms of lower growth and standards of living. Furthermore, the record showed that Soviet growth was achieved also at high costs of mortgaging future resources and capabilities, thereby making future growth and the transition, at least for a while, even more difficult. There was some degree of greater economic equity among the majority of the people, but it was bought at the cost of lower standard of living and the denial of freedom.

In this article I re-examine the Soviet growth record in the light of new information that became available since the collapse of the Soviet Union, including insights gained from the collapse itself, which was not predicted by most commentators, and from experience gained to date during the transition period. As will be seen, a fair amount of new research and thinking has emerged since the collapse. In most cases the data and analysis in Ofer (1987) and, even more important, the long list of references
there will serve as a kind of benchmark for further discussion and, to save space, discussed only briefly here.

The growth record revisited: the basic figures

The Communist revolution took place in 1917, but only in mid-1928 was the Communist economic system and growth strategy put into place. Collectivization of agriculture was combined with a rapid industrialization drive, all organized under a command system of nationalization and central planning. The first decade following the revolution was devoted to taking control of the economy and government, reconstruction following the devastation caused by the First World War, revolution and civil war, and to experimentation and debates over the appropriate economic strategy, integrated with the struggle for political control. It is generally established that by 1928 the GDP in the Soviet Union regained approximately the level of 1913, while GDP per-capita (GDPPC) lagged by at least ten per cent behind. This followed a sharp decline due to war and revolution, reaching a low by 1920 and 1921. Most estimates for the Soviet period start in 1928. The growth record therefore captures performance during the era of the ‘Soviet model’.

Economic growth and productivity can be measured in a number of ways. For growth we will concentrate on the levels and rates of the growth of GDP per capita. Total GDP and various segments thereof will be used when appropriate. The levels and growth rates of productivity will be represented mostly by ‘total factor productivity’ (TFP), that is, output per unit of combined inputs, usually labour and capital. In what follows we use as a base mostly data assembled and estimated by Angus Maddison (1995; 2001) derived from what he considered (and we concur) the best and most reliable sources. For the Soviet Union Maddison relied mostly on the work of Abram Bergson (1961), who put together the most comprehensive body of Soviet national accounting using the same methodology as the CIA (Maddison, 1995, pp. 141–2). In both cases there were more recent adjustments, as explained below. Maddison’s monumental work Monitoring the World (1995) includes the additional advantage that it provides comparisons of the growth record of many countries, through a uniform methodology and units of accounts. Estimates of variables not included in Maddison’s work are presented following a check of their basic consistency with the lead estimates. Remaining disagreements and the underlying alternative estimates will be presented and discussed.

The rate of growth of GDP per capita over the entire 1928–90 period was 2.6 per cent per annum, a fivefold increase. This growth record puts the Soviet Union in the group of fast developers and separates it from a large number of countries, mostly in the Third World, that failed to take off or that started much later. Over that period the Soviet Union transformed itself from a predominantly agricultural economy, but with a considerable industrial base, into a modern industrial and urban economy. Soviet growth also achieved a modest degree of catching up with the US economy and other developed countries. The relative level of GDPPC of the Soviet Union grew from nearly 21 per cent of the US level in 1928 to almost 30 per cent in 1990. Somewhat higher ratios for 1990 are estimated by others. However, similar or better achievements are shown for many advanced countries as well as for a number of developing countries, especially in east Asia (Maddison 1995, Tables 1–4, p. 25). At the same time many countries, mostly of the Third World, remained far behind.

The average growth rate shown above is made up of significantly higher rates up to 1970, of between
three and four per cent a year (if the First World War is disregarded) followed by steeply declining growth trend thereafter, down to half of one per cent per year during 1985–90. Some decline in growth rates and sustained growth, following a faster take-off, is considered normal. The Soviet record raises the question of whether growth along the Soviet model was sustainable in the future. Likewise, it is observed that, after reaching the highest relative level of GDPPC of 37.5 per cent of that of the United States in 1970, up from 21 per cent in 1928, the Soviet economy retreated below that level, even below most other developed countries. It is this break in the trend, from catching up to retreat, which started at an early stage that sounds the alarm bell over the merit of the Soviet model and its long-term sustainability.

The trends in the rates of growth of total GDP are similar, with relatively high rates up to around 1970 and sharply declining ones thereafter. The difference between the trends in GDP and GDPPC represents a trend of declining population growth, indeed a very sharp ‘demographic transition’, and declining fertility on top of the heavy losses associated with the collectivization drive and famine, other atrocities by Stalin, and then with the Second World War (see more on this below).

The figures on growth mentioned above are somewhat lower than those calculated by the CIA and accepted by most scholars during the period before the fall of the Soviet regime. The downward adjustments were made, including by the CIA itself (Noren and Kurtzweg, 1993), on the basis of more information that came out from the Soviet Union during the 1980s, of criticism of the then existing estimates by émigré and Soviet scholars, most notably Igor Birman (1989), and on the basis of parallel efforts by others, most notably the International and the European Comparative Projects (Summers and Heston, 1991; Heston, Summers and Aten, 2002; United Nations, 1999 and earlier years) projects of estimating and comparing the national accounts of many countries and their structure, based on the purchasing power parity methodology. The CIA revisions were mostly a result of downgrading the quality of Soviet goods and services and of the productivity of providers of public services below previous estimates, and from higher estimates of hidden inflation rates (especially of military production). Based on these downward revisions, affecting mostly estimates since about 1970 during the last two decades, and the adding of 1985–90 to the series, the 1928–90 annual rates of growth were reduced by about half a percentage point, from 4.2 to 3.7 per cent for total GDP and from 3.0 to 2.6 per cent for GDPPC. The adjusted estimates also revealed an even steeper decline following the break near 1970. The new estimates also reduced the relative standing of the Soviet economy by 1990 and before: the Soviet Union/United States ratio for GDPPC for 1990, estimated previously by the CIA at 0.43 per cent, was adjusted down 0.30–0.34 (the higher figure is from United Nations, 1999, ECP96). While these are quite significant adjustments, they do not change the basic picture of the overall growth record or the declining trend. As we shall see, the factors responsible for these trends also remain pretty much the same.

During the years just before and immediately following the fall, an avalanche of estimates reduced the relative standing of the Soviet economy and its growth record much below the adjustments cited above. These were supported by the economic crisis in the Soviet Union, Russia and the former Soviet states, before and then following the collapse, and included sharp declines in output during the early transition period. Some claimed that the observed fall in measured output after the collapse reflected, among other things, an artificial overestimation of the level of output before the collapse (see, for example, Åslund, 2002, pp. 21–39). Some of the arguments supporting this claim were incorporated into the adjusted
estimates mentioned above. However, in some cases such observations were based on a failure to distinguish between the level of output and consumer welfare. First, most of the fall in estimated GDP was due to sharply reduced investment and military expenditure and only a smaller decline in consumption. Second, the price liberalization and the creation of markets reduced shortages and queues, and in this way improved consumer welfare. Finally, the production and consumption preferences of the Russian society shifted from that of the Communist leadership to another, determined by the people, who valued consumption much more and investment and military spending much less. In the eyes of the people, the former GDP was evaluated so much lower. It took a few years until more balanced views on the size of the Soviet GDP returned, and estimates of overall Soviet growth, including the downward adjustments, were generally accepted (Hanson, 2003, p. 249; see also Åslund, 2002, p. 34).

This is, however, not yet the case regarding Soviet growth during 1928–37 (or 1940). Here the gaps among scholars seem to have widened rather than converged since the fall of the Soviet Union. Two Russian economists, Vasili Selyunin and Grigori Khanin, produced an estimate of Soviet growth, with much lower estimates for 1928–40 (Harrison, 1993). These estimates reinforced similar estimates for the same period by Naum Jasny, estimates that were the focus of an older dispute, unearthed in a recent article by Howard Wilhelm (2003). *Per contra*, a recent book by Robert Allen (2003) challenges the entire established view of Soviet growth, based mostly on an upward revision of rates of growth, of GDP and of consumption, also during 1928–37 (Allen, 2003, and Wilhelm, 2003, Appendix A, pp. 212–22). Maddison's figures for that period are taken from Moorstein and Powell (1966, p. 361) which are somewhat higher than the final estimate by Bergson (1961, p. 48).

The estimates by Bergson and by Moorsteen and Powell are calculated with 1937 prices as weights. Given the sharp structural changes, and that of the accompanying relative prices, the choice of price weights, according to the notorious theory on ‘price index relativity’, makes a great difference. In particular, the use of 1928 prices as weights produces significantly faster growth during 1928–37. Allen claims, correctly, that in such cases a geometric average of the two measures or a similar ‘compromise’ is more appropriate. This argument was well known to Bergson and all other scholars working on Soviet growth. Bergson justified his decision to stick to 1937 prices by claiming that the 1928 prices were not free-market prices and extremely distorted. This observation is supported also by Hunter and Szzyrmer (1992, ch. 3 and pp. 305–11), who substituted in their calculations for 1928 a set of ‘equilibrium calculated prices’. When these prices were used as weights the rate of growth of GDPPC during 1928–37 turned out to be similar to that based on 1937 prices (see more on Allen's position below). Let us point out in conclusion that any upward adjustment for 1928–40 will have to come at the expense of future growth, of both GDPPC and consumption, thus making the declining trend even steeper. Indeed, despite the above, Allen seems to agree with the overall estimates for GDPPC presented by Maddison (Allen, 2003, pp. 220–2).

A few words have to be added on the changing industrial structure of the Soviet Union. The general patterns of change were similar to those associated with modern economic growth: there was a decline in the share of agriculture, a marked increase in the share of manufacturing and related industries, construction and transportation, combined together as the M sector, and some rise in the share of services – all in terms of shares of the labour force and of GDP. The intensity of the changes was marked during 1928–37 and much less during the period since 1970. The increase in services was slower than normal in market economies, explained by the absence of markets, the view that services were ‘non-
productive’, and the policy of requiring households to supply many services during their non-working hours. The decline in the shares of agriculture was somewhat slower than ‘normal’, especially of the labour share, reflecting low labour and general productivity, due to the inefficiency of collectivization and low investment. Regarding manufacturing, and the M sector, there was the bias in favour of producer goods at the expense of consumer-good industries. This bias was reflected in the emphasis on investment and defence at the expense of consumption. The Soviet economy, as well as those of other Communist countries, was characterized as ‘over-industrialized’ in comparison with market economies at similar levels of development.

The growth strategy: extensive and capital-led growth

Growth strategy

What was the growth strategy of the Soviet Union, and how successful was its implementation? What explains the initial take-off and acceleration, and the eventual decline? How do the Soviet growth mechanisms and patterns compare with those in other countries in nature and in effectiveness? Following intensive and prolonged debates during the 1920s, the Soviet leadership opted for a strategy of rapid growth and industrialization based on high rates of investment, mostly in heavy industry and the producer-goods industries – sector ‘A’, according to the Marxian jargon. It rejected the other option of industrialization along with more ‘balanced growth’ between the various branches of the economy (Erlich, 1960; Hunter and Szyrmer, 1992). The chosen strategy followed the Marxian doctrine of ‘expanded reproduction’, as articulated at the time by a growth model developed by G.A. Fel'dman (Allen, 2003, pp. 53–60). It demonstrated that an initial high rate of investment can provide for rapid growth and, after some delay, also an overall higher level of consumption. On the ground this strategy was translated into maximization of capital investment through forced savings and maximum mobilization of the labour force, including of women, while consumption levels were kept at the minimum sustainable level. Both became possible only through the power of the authoritarian regime and the ‘command economy’, not to mention the merciless rule of and atrocities committed by Stalin. The rates of gross investment climbed over time to over 30 per cent of GDP. Such rates allowed the capital stock to grow much faster than in most other countries, and contributed the lion's share of total growth. The high share of investment left a mere 55 per cent of total output to household consumption, a share that declined further towards the end of the regime to below 50 per cent of GDP, 15–20 per cent below common levels in market economies. The most extreme version of this growth model was manifested during 1928–40, when the industrialization effort drew millions of people from agriculture and rural areas to monumental construction sites in old and newly created cities, and when consumption levels failed to increase, according to the accepted view, or even declined or increased modestly according to dissenters on both sides. There is no doubt, however, that the accompanying human losses and suffering during that period kept personal welfare at extremely low levels. The Second World War added to the losses and suffering, and only during the early 1950s did private consumption levels start to rise to a moderate level. By 1990, consumption per capita in the Soviet Union stood at just a quarter of that in the USA as compared with about a third for GDPPC (investment per capita stood at 55 per cent of that in the USA). While over the Soviet period there was some catching up towards the US level in terms of GDPPC, there was probably very little in terms of private consumption. It can be concluded
that, while the first part of the Soviet growth strategy, emphasizing investment, was fully implemented, the subsequent rise in consumption was very modest, and failed to arrive at the ‘promised land’. A major reason for this, as is demonstrated below, is the failure of the Soviet system to generate enough productivity growth through technological and other efficiency improvements.

An increasing share of the remaining GDP was devoted to defence and to ‘public consumption’ on education and health care, among other areas. The increase in defence spending, eventually up to about 15 per cent of GDP, is explained by the perceived outside threats, first from Germany and then from the West, and by the ambition of the leadership to build an empire and become a world power (see more below). Investments in human capital through education and health services were extremely important for the industrialization drive. However, they also improved the welfare of the population, typically to a higher degree than in other countries with similar levels of economic development. Especially noteworthy here is the encouragement of women to enrol in professional and higher education.

**Extensive growth**

Economic growth in general is generated mainly by two sources, inputs, or factors of production, namely, capital and labour, and by increasing productivity in the use of inputs, getting more output per unit of input. Among the factors increasing productivity are technological innovations, improvements in the organization of production, increasing returns to scale, greater effort, and structural shifts from less to more productive activities (such as from agriculture to manufacturing). The common way to account for the contribution of each factor to total growth is through a ‘Cobb–Douglas’ production function, which assumes constant returns to scale. It is estimated as output produced by capital and labour, and at a per capita level. The residual growth left after the contributions of all inputs are accounted for is ‘total factor productivity’ (TFP). Inputs are combined according to their relative weights in the production process.

The Soviet growth model and record described above are commonly characterized as involving ‘extensive’ growth or as ‘inputs-led’ or even ‘capital-led growth, driven mostly by increasing contributions of the main inputs and much less by greater productivity. The alternative, ‘modern’ economic growth as defined by among others Simon Kuznets (1966) is characterized in most developed countries as ‘intensive’, whereby productivity growth accounts for a larger share of total growth and the bulk of per capita growth.

But although the mobilization of inputs was fundamental to the Soviet growth strategy, there was no strategic intention to neglect ‘productivity growth’; on the contrary, much was invested in R&D, in quality manpower, material resources and institutional support. Technological innovation and productivity growth were targets of multiple incentives. Yet the outcomes were rather disappointing. While during 1928–40 TFP contributed 1.7 per cent a year to GDP growth, nearly half the per capita growth, this declined to about 0.5 per cent during the 1950s and 1960s and then moved to negative territory for the rest of the period, thereby contributing significantly to the decline in the rates of growth. The higher contribution of TFP during the early period is explained by the dissemination of readily available technologies, and by major structural changes and initial industrialization, advantages that were exhausted later.

The poor outcomes in productivity during the entire post-Second World War period are explained by attributes of the system that limit its capability to generate new technologies and other improvements in
productivity, by the priority allotted to the military sector, and by systemic barriers to the diffusion of innovations and general TFP measures across the production sector. Other TFP failures resulted from the interaction between the input-driven growth and the systemic nature of central planning. A study by Joseph Berliner (1976) contains a detailed analysis of the technological weaknesses of the Soviet system. There are two major clusters of factors, strongly intrinsic to central planning, that are responsible for the low rate of TFP: first, the rigidity of the system and the high cost of flexibility and change; and second, the strong reliance on quantity and quantitative rather than qualitative achievements and incentives.

The hierarchical, top-down and command character of central planning discourages initiatives from below and suppresses competition: both are believed to be essential generators of innovation. Central planning is also a rigid system that minimizes flexibility in production and supply networks. The high costs of reliable information flows across long hierarchical command ladders provide a great advantage to routine, and to inertia in regard to change, to ‘planning from the achieved level’ as against adopting flexible and innovating plans, and to stable supply networks as against shifting ones – which are needed when new materials or new markets are to be preferred. All are barriers to innovation and dissemination. Control under central planning is so much simpler – indeed only possible – on the basis of quantitative performance measures of output, inputs, supply flows, than on the basis of qualitative performance measures, better or new products, new production materials and processes, and greater labour efficiency. For these reasons, incentives under central planning reward first of all quantitative performance. Production plans are tight, in order to eliminate hidden production reserves and to encourage growth, and incentives to managers are mostly based on plan fulfilment. This also helps to assure smoother supply flows among producers. It comes at the expense of quality, of productivity and of setting aside time and inputs for improvements and innovation. Tight plans create shortages and a seller's market that severely limits the power of buyers to control for quality. There are incentives to innovation, but they are mostly dominated by those for quantitative plan fulfilment. The emphasis on quantity also explains the almost complete absence of exit of inefficient enterprises with obsolete equipment. Their contribution to the fulfilment of branch plans cannot be dispensed with. They are kept alive through the mechanism, termed by Janos Kornai, of the ‘soft budget constraint’, the pumping of additional resources into enterprises that create bottlenecks in the flow of output. On balance, enterprise managers refrain from the introduction of improvements and innovations, whose dissemination across the economy is thereby severely restricted. The extensive nature of the growth strategy as described above also contributed to the bias in favour of quantity over qualities and of inertia over change.

The process of innovation and technological change suffered also from the autarkic nature of the economy, which limited the free flow of advanced technology and production processes from the West. Huge effort and resources were invested in ‘reverse engineering’ of Western technology, and in other cases in ‘reinventing the wheel’, both costly and wasteful alternatives. Civilian innovation also suffered from the high priority accorded to military R&D and to military production in general. Military R&D took the lion's share, by some estimates up to two-thirds or more, of the entire Soviet R&D effort, and on top of this only very limited spillover of military innovations was allowed to benefit civilian production. Furthermore, in order to assure the prompt fulfilment of military production plans and to secure its proper quality, an entire body of priorities was granted to the military at the expense of the civilian sector: in quality of human resources and material inputs, in quality control, in price discrimination and in supply. The superior military and space technological achievements of the Soviet
The Soviet Union became possible partly by the imposition of a heavy burden on the civilian sector, and an even heavier burden on civilian R&D and on Soviet TFP.

Part of the relatively high TFP during the 1950s and the decline thereafter can be explained by the process of reconstruction following the devastation caused by the Second World War. However, another part of the TFP decline over time is to be blamed on some of the factors listed above as negatively affecting TFP, such as the increasing difficulty over time in incorporating new and more complex technologies. Another important factor is the increasing complexity of the economy, imposing a heavier burden on the planning process, on the flows of information and on the supply networks. It was expected that at some point the computer revolution may have eased those difficulties, but this did not really happen, partly due to the slow development of information technology (IT) in the Soviet Union, but probably more to the growing complexity of the economy such that even much more advanced IT would not be able to simulate.

In addition to external autarky the Soviet economy also suffered from what may be called ‘internal autarky’, the segmentation of the economy along vertical lines corresponding to the planning hierarchy, with very limited horizontal networking. This structure was amenable to the development and dissemination of sector-specific technologies, but was an obstacle to economy-wide ones. This is one explanation of the slow development of IT of all types, including in computing, and other advanced general-purpose technologies. The internal segmentation of the economy also delayed the dissemination of new technologies across branch lines. This is why central planning failed to seize an advantage over the market economy, where the dissemination of innovations is delayed by patent protection. Finally, declining TFP may also have been caused by the trend of deteriorating discipline and work motivation and enforcement during the post-Stalinist era.

After the death of Stalin the Soviet Union became engaged in endless attempts at reform, directed mostly towards partial decentralization, in order to increase flexibility and reduce the cost of change. Most such attempts failed and were abandoned, and gave way to recentralization. The more radical, though still partial, reform measures initiated by President Gorbachev during 1985–91 increased the level of disorganization of the economy and contributed to the disintegration of the centrally planned system.

The above discussion of the low and declining level of TFP fits well the Cobb–Douglas production setting, in the sense that the listed factors affected the entire production process in a neutral way. There were, however, two attempts to link the low productivity performance of the economy to the high rates of capital investment and the nature of this investment. The more notable study, by Martin Weitzman (1970), estimated a constant elasticity of substitution (CES) production function for the Soviet economy and found that, while the level of productivity growth was quite respectable and constant over time, the elasticity of substitution (ES) between capital and labour was very low. Later estimates repeated this finding for the entire post-war period (Easterly and Fischer, 1995). Low and declining ES is consistent with low and declining capital productivity. Low ES focuses on the increasing technological and organizational difficulties in keeping up with the fast trend of capital deepening that resulted from the growth strategy, especially when the rate of growth of the labour force declined over time (see below). This resulted in a fast decline in the marginal productivity of capital. While the substitution of capital for labour is normal along the path of modernization and industrialization, the level and pace of the needed substitution, dictated by the high rate of investment, were too demanding for Soviet planners and innovators. Soviet sources reported thousands of fully equipped work stations with no workers to
operate them. Low ES is therefore one important argument supporting the non-sustainability in the long run of capital-led growth. But the sources of low ES seem to be very similar to the explanations for low TFP in general listed above.

An interesting interpretation of the same phenomenon is offered by Vladimir Popov (2007). His argument is that it is much easier for the central planners to build and install new enterprises and plants than to re-innovate and replace production lines in existing ones, as was shown above. Accordingly, high rates of growth of output were achieved during the 1950s and early 1960s, when a new generation of enterprises was built. These rates declined later when the production lines aged and the authorities encountered organizational and technical difficulties in replacing them. The outcome was continued use of old equipment for long periods of time, well beyond its normal age in market economies, with very high maintenance and labour costs and long stoppages. The reluctance to retire obsolete enterprises resulted also from the pressures to meet tight production plans, as mentioned above (see Ickes and Ryterman, 1997). In later years, continued investments in new plants, albeit at lower rates, faced extreme labour shortages. This stage arrived during the late 1970s and 1980s, and contributed further to declining marginal utility of capital and to low ES.

The low and declining rates of TFP growth, or for that matter of any ‘residual’ beyond the contribution of capital and labour, made the Soviet growth pattern more and more ‘extensive’, that is, dependent almost exclusively on increasing amounts of labour and capital. At the same time, there are limits to the potential growth of both inputs, and therefore ‘extensive’ growth is bound to decline and eventually stagnate (Bergson, 1973). In order to keep the rate of growth of capital at high levels, under conditions of no or little growth of TFP, and with normally lower growth of labour inputs (see below), the share of investment in GDP must increase constantly, first reducing the share of consumption, and later also its absolute level. In addition to the negative effects on incentives and morale, this eventually becomes also politically unsustainable, even under an authoritarian regime. This danger forced the planners during the 1980s to reduce the rates of growth of material capital, from the previous eight to nine per cent per year to six per cent and below.

The rate of growth of labour inputs, however measured, declined during the post-Second World War period from more than 1.5 per cent annually, faster than the population's, down to 0.1 per cent, far below the population's, during 1985–90. During the last decades of the Soviet period the population reached the rates of growth of highly developed countries. The same is true of the rates of labour force participation, especially of women; indeed, on this score the Soviet rates surpassed those in some
developed countries. As a result, as time went by the ‘extensive’ model turned more and more into ‘capital-led’. The negative effects on output per capita of the saturation of labour participation rates are clear. The excess decline in the rate of growth of population negatively affects GDPPC through an increased per capita burden of public services such as defence and public administration.

Extensive, or ‘capital-led’ growth, Soviet-style, is therefore first of all a dead end. Second, any given level of GDPPC is achieved with more labour (including during off-work hours) and capital, which leaves the population a smaller share for consumption as compensation, than in market economies at similar levels of development.

**Soviet growth strategy: catching up and haste**

As mentioned above, the strategy of maximum growth was also motivated by the desire and drive to catch up with the West and surpass it. The rationale was provided by Stalin in 1931: ‘We are fifty or a hundred years behind the advanced countries. We must make good the distance in ten years. Either we do it or they crush us’ (cited by Berliner, 1976, p. 161). This goal was repeated time and again by other Soviet leaders. The growth strategy described above was designed to accomplish just that; but the sense of urgency added one more element to it, namely, ‘virtuous haste’ as termed by Gregory Grossman (1983). Haste is defined here as actions taken in order to bring about higher rates of growth in the near future at the expense of future growth. The economic merits of such an action, or strategy, depend on the rate of time preference of the decision-maker. The more impatient he is, the greater is the room for more worthwhile haste. In what follows we list actions taken by the Soviet leadership that seem to testify to a very high rate of time preference. Alternatively, such actions can result from miscalculations regarding the real costs of their actions in terms of future growth. It seems that both played a role and that miscalculation was also important. Haste can also be looked at as an act of borrowing higher growth rates than available in the present. Since the Soviet Union could hardly borrow abroad, it had to mortgage its own resources and future growth. One can therefore learn about the degree of miscalculation by comparing the rate of interest that the system was ready to pay (its rate of time preference) with the rate it actually paid. This is equivalent to comparing the integral below an intended curve depicting growth rates over the period with the curve of actual growth.

A high rate of time preference seems to contradict the essence of the growth strategy, described above, of high rates of investment and readiness to postpone consumption into the future, which signify low rates of time preference. One way to reconcile this apparent contradiction is to note that patience was imposed on the people rather than on the leadership. The people would probably have preferred a ‘normal’ maximization of utility over time. The objective function of the leadership reflects high time preference, the maximization of present growth even at the expense of future growth. Therefore, compared with an objective function that maximizes the welfare of the people, the policy of haste will be depicted as a steeper down-sloping trend of growth rates, cutting the ‘optimal’ curve from above.

Soviet growth was notorious for over-depleting natural resources and in causing costly damage to the environment. When the rates of oil extraction started to decelerate during the 1970s, pressures to keep oil flowing resulted in over-pumping and the flooding of wells. Overuse of fertilizers and land in order to grow more cotton depleted large areas of arable land and of water sources in Uzbekistan. Lake Baikal and other water and land resources were contaminated by overuse and by industrial and nuclear waste;
air pollution and other environmental issues were disregarded. Relevant here are also the acceleration of the demographic transition and the early mobilization of labour at the cost of labour shortages later. The high and increasing volume of investment, combined with pressures to complete projects fast, was responsible for lower quality, for a thinner technological content, and for mistaken decisions when taken in a hurry, all with negative effects on future efficiency and growth. Investment is treated by growth theory as a major vehicle for the introduction of new technologies and of processes of ‘endogenous growth’. Haste prevented this from taking place in the Soviet Union despite high investment rates. The haste to construct many new projects simultaneously was also responsible for the permanently large and increasing stock of incomplete projects, further reducing the levels of capital productivity.

Rapid industrialization required vast investments in infrastructure, in urbanization, utilities, and in transport and communication networks. Haste demanded that these should be limited to the minimum level necessary or below, saving investment resources for ‘productive’ projects with shorter payback periods. This was also true of infrastructure services inside enterprises, where the peripheral activities serving production lagged behind. Over time, and especially towards the end of the regime, the level of maintenance of infrastructure services deteriorated. Over the second half of the period the quality of education and health services also deteriorated, a result of conservatism and inertia and little contact with the outside world, as well as mounting resource constraints.

In sum, haste contributed to the trend of declining rates of growth, over and above the factors mentioned earlier. The deficit in growth during the later period can be thought of as payments of interest and payments against the still growing stock of debt. The accumulated debt was endowed to the new regime in the forms of obsolete production capacities, over-depleted natural resources, a large environmental deficit, run-down physical and service infrastructure, a debt that would have to be repaid as a precondition of and barrier to the resumption of growth. It definitely contributed to the initial decline in output and other difficulties during the transition.

More generally, ‘haste’ is part and parcel of the selected growth strategy, and of the economic system and political regime. One justification for such a choice, discussed in the economics literature, but also advanced by the Soviet Communist leaders, is that it provided the (only?) method, or at least an efficient and quick one, of economic take-off, the break away from the vicious circle of the low-development trap. We now know that the selection of the Soviet model of growth had to take into account a future model shift. While it is clear that the choice made by the Soviet leaders was motivated, at least partly, by internal and external power considerations, it is worthwhile examining the merit of such a choice from a purely economic point of view. As mentioned above, the choice of an economic growth strategy was hotly debated in the Soviet Union during the 1920s (Erlich, 1960).

Two-stage development strategies and the cost of switching

In 1991 Russia joined, *ex post* and with no initial intention, a group of countries with two-stage development strategies: a first stage for the purpose of take-off, an initial modernization and industrialization drive, and a second stage, starting with the transition, for joining the ‘normal’ route to ‘modern economic growth’, consisting of a more balanced growth via market mechanisms and private property, moderate government intervention, and a democratic and open society (Rodrik, 2005). The argument justifying a special initial strategy, is that a successful take-off requires more drastic policy steps, more forceful institutions and more determined and intensive government intervention.
economic payoff of such a strategy differs across countries. However, usually little attention is paid to the costs of switching to the second stage of normal growth. These costs are higher the wider the differences are between the economic, social and political tools used for the take-off effort and those required for ‘modern economic growth’. Therefore, even if the first stage is considered successful, the overall evaluation and the calculation of net benefits have to take into account these costs too. The costs of switching are made up of three elements: the costs of delaying the shift beyond its appropriate timing, caused by vested interests of the regime in power and fear of the unknown future; the actual costs of switching and transition when they come; and the size of the accumulated debt from ‘haste’, which is an intrinsic part of any take-off. The delay and the transition periods are longer, and all three cost elements higher, the wider the difference is between the economic and institutional set-up of the take-off and the post-switching system. One clear advantage of a uniform strategy of ‘balanced growth’ from the start is that economic modernization and growth go hand in hand with the evolutionary development of the appropriate institutions, so that virtually no radical switching is required.

The case of the Soviet Union is one where the above described gap between the two stages is near the maximum thinkable; so accordingly also are the expected costs. The central political and economic control and the suppression of freedoms of all kinds made it easier to take strategic decisions and to impose a heavier burden on the population. But these came at the costs of destroying and blocking the development of social and political institutions needed eventually for the second stage.

As mentioned above, to this day there are some disagreements as to the merit of the Soviet take-off strategy, standing alone. Most observers see some benefits in, even an economic justification for, the big push forward and the early Soviet industrialization drive. To be sure, nobody condones Stalin’s atrocities, and few if any are ready to accept the human costs associated with that period, whatever the achievements. But, assuming that similar, even better results could have been achieved with a milder variant of the same model, one can appreciate some of the economic outcomes – relatively fast growth and radical structural change. Even if one takes into account the destruction caused by the Second World War and the exaggerated concentration on the Cold War and on military build-up, the Soviet economy did succeed by 1970 in accomplishing a degree of catching up and, even more than that, in putting the Soviet Union on the road towards economic modernization. Robert Allen (2003), writing after the collapse of the Soviet regime, goes beyond the above and argues that the take-off strategy saved the Soviet Union from the dismal fate of many developing countries, and that no alternative strategy could have accomplished such a feat. At the same time, the only serious attempt at a counterfactual calculation produced a feasible and better alternative, along a route to more balanced growth, and, what is significant, a strategy that would have reduced considerably the costs of switching (Hunter and Szyrmer, 1992).

The figures presented in the first part of this article suggest a degree of support for the Soviet growth and modernization record during the regime’s first three decades or so, but only when no account is taken of the oceans of human suffering inflicted on the population by Stalin and, somewhat less so, by the other leaders. At the same time, the calculation so far, including the cost of shifting, demonstrates without any doubt that, even on the basis of pure economic considerations alone, the Soviet growth project was probably not worthwhile.

The Soviet system was established as a long-term and sustained alternative economic and social system, with no intention whatsoever to switch later. Yet, during the 1950s and early 1960s, the Soviet leaders became worried about the low efficiency of the economy and lagging technology, and the prospect of
declining growth rates. For a time there were quite open discussions over the proper future course,
including various proposals to move to a more decentralized system, in the direction of what was termed
‘market socialism’. The discussions and proposals were limited to the economic mechanisms and did not
include any ideas regarding changing the political regime. Yet, in retrospect, this seems to have been the
appropriate time for switching to a new system altogether. Per contra, the discussions culminated in
1964 in a package of the so-called Kosygin reforms. It was a watered down variant of previous
proposals. Only mild attempts were made at implementation, and within a few years the Soviet Union
had sunk into the ‘stagnation era’ under Brezhnev and his followers. The actual delay in the shift is fully
understandable, given the strong regime and economic system and strategy introduced in 1928. The
totalitarian Communist regime, backed by a strong ideological paradigm and an even stronger military
backing, could not have been expected to replace itself only on the basis of rational and valid arguments.
Would President Gorbachev have acted as he did had he known the final consequences?
The change came 15–20 years later. During 1970–90, the period of delay, the average rate of growth of
GDPPC stood at just above one per cent per year or at near zero if 1991 is added in, as compared with
3.4 per cent during 1928–70. It was followed, starting in 1990 or 1991, by the transitional output decline
of nearly 40 per cent, which was halted and reversed only from 1999. This decline is partly a
manifestation of the difficulties in making the extreme shift of institutions, formal and informal. Over
the entire period of delay plus early transition – that is, from 1970 to 1998 – GDPPC declined at an
average annual rate of 1.3 per cent.
The entire period related to the take-off lasted, therefore, 70 years, from 1928 to 1998, rather than about
30, its segment of rapid growth. The rate of growth associated with this entire period stands at a mere
1.5 per cent per year, less than half the rate during the period of fast growth. This is not a great
achievement by comparison with other countries at similar levels of development, or even developed
countries. It is even more dismal when the higher sacrifices in terms of labour inputs and lower
consumption levels are factored in.
One can think of other dates than 1998 to signal the end of the transition period: one is when Russia
resumes its pre-fall GDPPC level of 1990 or 1991, possibly around 2008; yet another date could be
when Russia regained the highest level of GDPPC of 37.5 per cent of the US level, reached back in
1970. An optimistic date, based on much guessing, could come between five and ten years after 2008. If
true, then the delay plus transition periods will last much longer than the period of rapid growth itself,
reducing the hypothetical growth rates still further.

Concluding note

The Soviet Union initiated and implemented a heroic social experiment that included a rapid and fairly
successful, albeit rather distorted, process of modernization and growth. It culminated more then 70
years later in a dead end that required a difficult ‘transition’ in order to join the main road to modern
economic growth. Ex ante it was not intended to be an experiment, nor a temporary phenomenon. There
are many lessons to draw: one is that, even on the basis of economic accounting alone, and when the
costs of transition are included, it is highly doubtful whether the experiment, judged as a take-off
strategy, paid off. It clearly failed as a sustained alternative. Yet the counterfactual analysis, based on the
experience of other countries that did better, is always conditioned on the issue of feasibility: could an
alternative strategy, as indeed was advocated for the Soviet Union during the 1920s, have pulled the

Soviet Union, economics in

Vincent Barnett

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Soviet economics reflected the contradictory attitude of Marxist theory to Western economics, and the different stages of the development of the Soviet economy itself. The most original work occurred in the 1920s, with many contributions by Soviet-based economists to fields like business-cycle analysis and agricultural economics still enduring today. After 1929 the repression of leading intellectuals affected economists in a particularly damaging way, and Soviet economics never recovered its cutting-edge position thereafter. After 1953 a partial thaw led to reform-minded economists gaining confidence, and their efforts provided inspiration for the early stages of market reform after 1985.

Keywords

Economics in the Soviet Union progressed through a number of distinct stages of development that were linked to the evolution of the Soviet system itself. It was also replete with multi-level contradictions. Actively building upon the foundations laid down by the British classical economists, Karl Marx's prognosis of capitalist collapse had envisaged a new role for economic ideas as the blueprint for the creation of a socialist utopia; even so, official Soviet doctrine came to view Western ‘bourgeois’ economics with unreserved hostility. After 1929 much of Soviet economics declined dramatically to become a subservient puppet of its Communist Party masters, yet before 1929 the Russian contribution to mainstream economic theory had bloomed to a new level of international respectability. Even under Joseph Stalin's gaze the works of some Western economists were translated into Russian – J.M. Keynes's *General Theory* was published in the USSR in 1948 – but other Western authors who were critical of the Soviet system were banned. And just as the USSR collapsed at the end of the 1980s and central planning was finally laid to rest, a number of Western economists were actively planning exactly how to transform Soviet-type economies into their market-based opposites. To summarize the results of the Soviet experiment for economics widely interpreted, it was an essential failure coupled with an episodic success.

1917–1929

The first problem encountered after 1917 was whether ‘economics’ as a discipline would be required at all, given that planning was supposed to be a science of collectively organized production. Did economic laws as natural regulators apply only to commodity production, or would new economic laws be developed in socialism? N.I. Bukharin's *Economics of the Transition Period* (1920) exemplified the liquidationist call for an end to all monetary accounting, anticipating that the naturalization of economic thinking would occur. This approach was however soon discarded when the New Economic Policy (NEP) was introduced in 1921. Bolshevik leaders then enthusiastically embraced the principles of ‘sound money’ and market exchange. For example V.I. Lenin declared that what was needed was ‘less politics and more economics’ and advised that communists should ‘learn to trade’. But against Bukharin's proposal for an industrial democracy, Lenin still declared that politics should take precedence over economics and that the proletarian dictatorship must prevail. This contradictory attitude remained an undercurrent in all official Soviet proclamations on economics until 1991. Despite such inconsistencies there is no doubt that the 1920s were the decade in which Russian and Ukrainian economists contributed the most to international developments in economic theory. Immediately recognizable names like N.D. Kondratiev, E.E. Slutsky and A.V. Chayanov were only the tip of an iceberg in terms of the contributions made by Soviet-based economists to fields like business-cycle analysis, agricultural economics, monetary theory and the economics of planning. Kondratiev and Slutsky were actively involved in cross-country collaborations through personal connections with Western economists like Wesley Mitchell and through their membership of international bodies such as the Econometric Society. Moreover, if the influence of Russian-born émigré economists is also considered, then the international impact of economics originating in the Soviet Union before Stalin's rise to dominance is difficult to deny.
To take the relevant fields of economics in turn: with respect to business-cycle analysis, Kondratiev and his colleagues in the Moscow Conjuncture Institute built upon the pre-revolutionary contributions of M. I. Tugan-Baranovsky, and added various extra dimensions of analysis including Mitchell-style empiricism, greater statistical sophistication (such as Fourier analysis) and a more direct interest in contemporary policy concerns (the effects of peasant taxation). Kondratiev (1922) began the decade with a detailed study of the Russian grain market, using differing levels of farm marketability to explain its collapse during the war and revolution, before embarking upon a more general analysis of the world economy (1925) using a three-cycle schema of long, medium and short cycles that was later employed by Joseph Schumpeter. The notion of 50-year-long cycles generated by the periodic creation of basic capital goods quickly achieved some international notoriety. Other members of the Conjuncture Institute focused on topics such as scientific discovery as causation (T.I. Rainov), the methodology of cycle analysis (N.S. Chetverikov), seasonal fluctuations (Ya.P. Gerchuk) and the theory of economic prognosis (A.L. Vainshtein). Outside the Conjuncture Institute, S.A. Pervushin (1928) analysed cyclical movements as being composed of various shifts in price relations, and suggested that in Russia from 1890 to 1913 domestic factors such as the harvest were increasing in importance as causative influences. Even before 1917, agriculture had been a key focus for Russian economists; after 1917, this interest blossomed into a multitude of different approaches. As director of the Institute for Agricultural Economics, Chayanov (1925) focused on the structure and optimal size of farms, and the motivating drive of peasants. He argued that peasants should not be modelled as *homo economicus*, but rather a labour-consumption balance was more appropriate to them, in which both the monetary and the non-monetary needs of the family were evaluated against the drudgery of labour performed. L.N. Litoshenko, by contrast, viewed peasant proprietors as driven solely by acquisitive motives, and supported rural class differentiation as a means of improving agricultural techniques. E.A. Preobrazhensky (1926) identified the agrarian sector of the economy as a source of funds for state-induced industrialization that should be ‘pumped over’ into the industrial sector by price policy, as part of a process called ‘primitive socialist accumulation’. Against this idea Bukharin encouraged peasants to ‘enrich themselves’ as a means of fostering growth in both agriculture and industry. And Kondratiev provided detailed forecasts of international grain markets using the latest insights of cycle theory in order to facilitate Russian agricultural exports as a means of financing industrial development (Barnett, 1998).

Monetary theory experienced an unexpected boost in the early Soviet context through the need to establish a stable currency in civil war conditions. Debates over the role of money in a socialist economy occurred from 1917 onwards, with contributors from the left and the right clashing over fundamentals. Tugan-Baranovsky advocated a system of paper money in which metallic reserves would not circulate, while Marxists like S.G. Strumilin proposed various non-monetary accounting schemes such as labour time vouchers and energy units. Preobrazhensky celebrated the profligate issue of paper currency as a method of political confrontation, but L.N. Yurovsky's idea (1925) for a parallel gold-backed currency to counter the resultant hyperinflation eventually won out after 1921. Keynes's design for a currency board for north Russia in 1918 was quickly overtaken by events. These issues were part of a larger debate over the significance of war communism (1918–1920), a system that A.A. Bogdanov characterized as being driven by acute shortages, rather than being the result of the rational application of socialist economics. Most obviously of all, the economics of planning attracted a huge amount of effort from many Soviet
Soviet Union, economics in: The New Palgrave Dictionary of Economics

economists, especially in relation to industrialization strategy. In 1917 Tugan-Baranovsky outlined a method of planning using marginalist techniques, but this soon became doctrinal heresy. The first detailed Soviet effort was the GOELRO electrification plan of 1920 that employed an engineering approach, but as NEP progressed a more sophisticated planning methodology developed. Debate centred on questions such as the weight of extrapolation from current trends (genetic planning) against desired ultimate goals (teleological planning), the nature of the interrelation between state industry and private agriculture, and the role of Quesnay-type balances in the planning process (Barnett, 2005).

For example, building on the agricultural census developed by pre-revolutionary zemstvo (local government) statisticians, P.I. Popov pioneered the preparation of an economy-wide balance for 1923/24 from within the Central Statistical Administration. As part of the genetic approach to planning developed inside the State Planning Agency, V.G. Groman and V.A. Bazarov (1925) uncovered various empirical regularities that operated in the NEP economy, such as the law of market saturation, using models adapted from the natural sciences. From within the Conjuncture Institute, N.N. Shaposhnikov applied the net present value principle to the planning of capital investment projects, and Kondratiev prepared a detailed plan for agriculture and forestry for 1924–8 that was based on an indicative ‘perspectives’ approach. By the end of the 1920s, both yearly ‘control figures’ and five-year imperative plans had been developed, the latter containing hundreds of pages of figures that plotted the progress of all branches of Soviet industry as centralized directives.

Slutsky's economics-related work in the 1920s was in a theoretical league of its own. His first important contribution was to the mathematical modelling of currency emission, where he compared various complex formulae with the reality of Soviet monetary policy after 1917, in order to calculate the income that the state received from emission. He then turned his attention to the praxeological foundations of economics and provided a set of axioms for describing the parameters of an economic system. And in the same year as he published the groundbreaking paper suggesting that cyclical processes in the economy might be modelled as the summation of independent chance causes (1927), he also wrote a critique of Bohm-Bawerk's conception of value. An important feature of Slutsky's random cycles was periodic disarrangement and consequently regime change, which served to distinguish them from approximately regular business cycles. The 1927 article was the result of many years of work on the theory of stochastic processes that eventually produced a new conception of the stochastic limit. After the closure of the Conjuncture Institute in 1930 Slutsky was not arrested, and he continued to pursue related topics such as the use of the extrapolation method in relation to random processes. Slutsky's mathematical work was also employed in the set theoretic approach to probability theory developed by A.N. Kolmogorov.

In various unconnected fields, in 1924 A.A. Konyus drew upon the contributions of Irving Fisher to develop a sophisticated cost of living index that lay between the Paasche and Laspeyres indices, and in 1926 he suggested the idea that consumer preferences could be represented in terms of both prices and income. In 1925 Strumilin assessed the economic benefits of education by evaluating the length of study undertaken against the increased skills obtained, suggesting that education should be taken to the point where marginal cost equalled marginal revenue. And in 1928 G.A. Fel'dman developed a two-sector model of economic growth in which the ratio of the capital stock of the producer and consumer goods sectors was related to projected growth rates, predicting that (for a stable growth path) investment must be divided between the two sectors in identical proportion to the stock of capital. This model had direct implications for Soviet planners.
Finally, the emigration of economists like Jacob Marschak, Simon Kuznets, Evgeny Domar and W.W. Leontief after 1917 transferred some of the existing themes of Russian economics to the USA. Leontief’s input-output approach (1941), Marschak’s Walrasian market socialism, Domar’s growth theory and Kuznets’ work on secular trend all owed an important debt to their Russian origins, although such work was transformed by the American context. But the 1920s were unquestionably successful in terms of producing many influential developments of relevance outside of the immediate Soviet context.

1929–1953

After 1929 the storm clouds of Stalinism poured down upon Soviet economists with uncompromising force. Key figures like Bukharin and Kondratiev were sentenced to long periods in jail, and important centres like the Conjuncture Institute were closed: in response Kondratiev wrote an account of the methodology of economic statics and dynamics. Lesser members of the various economics groupings like Vainshtein and Konyus were dispersed. What took the place of the pioneering Soviet economics of the 1920s was a polarization to ideological and technical extremes.

Vacuous general statements about the current direction of Soviet policy, such as Stalin’s ‘law of the harmonious development of the national economy’, sat alongside the minute detail of the planning of every branch of Soviet industry. This polarization facilitated the Orwellian discrepancy between officially declared aims (economic equality for all) and actual government policies (a system of slave labour camps). The central question of deciding overall plan targets was resolved politically in the Politburo (with assistance from Gosplan and the Commissariats), and the advisory function of economists evaporated. Soviet economic discourse consequently became an instrument of its political masters. However, there remained limited scope for dissent in tangential fields such as mathematics. For example, L.V. Kantorovich initiated his conception of optimal planning in 1939, in response to the problem of distributing the manufacture of parts to available machine tools so as to produce the maximum number of sets of components, or a method of machine loading to obtain the highest productivity. To generalize this idea, an optimal plan was one in which the proposed product assortment was optimally distributed amongst firms at the lowest possible cost of production. Shadow prices or ‘objectively determined valuations’ were to be used in this process. Kantorovich won the Nobel Prize (jointly with Tjalling Koopmans) in 1975 for this work on linear programming.

Further afield, émigré economists like Boris Brutzkus and S.N. Prokopovich contributed to the debates over the nature of the Soviet system in the 1930s. Brutzkus (1935) took an Austrian-type approach that focused on the centralizing and information-gathering issues, while Prokopovich (1924) criticized the reliability of official Soviet statistics and the state control of property. The socialist calculation debate that viewed the problem either as a computational issue relating to solving sets of equations (Oscar Lange) or as erroneously assuming perfect knowledge (F.A. Hayek) failed to fully engage with the reality of Soviet planning, where bureaucratic and interest group factors were dominant. The Institutionalist response was quite different, with Thorstein Veblen (1921) analysing the Soviet success in Russia in terms of long-prevalent national traditions of economic organization, and John Commons viewing the USSR as the outcome of collective action. Keynes (1925) characterized Bolshevism as business in subordination to religion.

In terms of contextual influences, it is difficult to exaggerate the effect that the Second World War had
on Soviet society. The Soviet economy had been placed on a war footing since the mid-1930s, and centralized accounting of material production was seen as crucial to military success. Hence the Soviet system was the direct result of the needs of a war economy, including features such as consumer rationing and strict hierarchical control of industrial production. When the war was finally over, planners found it difficult to adapt to a consumer-led approach. Consequently a semi-underground second economy developed in the USSR that was built upon informal connections, yet was tolerated because of its role in facilitating plan fulfilment. This was theorized by Aron Katsenelinboigen (1977) as a network of coloured markets with differing degrees of non-legality, black being the most extreme. This aspect of the Soviet economy encouraged criminality and had serious consequences for the market reforms of the late 1980s.

1953–1985

After Stalin's death in 1953, a thaw began in Soviet intellectual life that had positive consequences for Soviet economics. Previously repressed economists like Vainshtein resurfaced, alongside the coming of age of a new generation of Soviet economists who demonstrated a greater mathematical sophistication than their predecessors. Key members of the mathematical school included N.Ya. Petrakov, V.S. Nemchinov and V.V. Novoshilov, and their organizational base was the Central Economic Mathematical Institute of the Academy of Sciences. Alongside the concern for mathematics went an interest in cybernetics, in Kantorovich-type optimality problems and in economic reforms in general. The outcome of this new infusion was the development of the concept of a system of optimally functioning economy (SOFE), in which the idea of an optimal plan was taken a number of steps further by adding the notions that plans should be calculated using optimal prices and with concern for resource scarcity and incentive rewards. It also included the idea of an economy as a hierarchical structure in which decision-making should occur at various levels appropriate to the specific task being considered, such as the national economy, a given industry or an individual enterprise, rather than always at the apex of the pyramid. Another important centre of this period was the Institute of Economics and Organization of Industrial Production in Siberia, where in 1965 Abel Aganbegyan stirred controversy by presenting a very negative evaluation of the Soviet economy as antiquated and undemocratic. Foreign commentators also highlighted problems endemic to the Soviet system such as gigantomania (large units were easier to plan), investment cycles linked to production bottlenecks, and soft budget constraints (Nove, 1990). The Khrushchev era witnessed the first major attempts at economic reform since Stalin, initiated by E.G. Liberman's campaign (1962) to allow enterprises the capacity to plan their own production programmes. While some reforms were implemented in 1965 that attempted to improve industrial management, the impetus for change diminished after 1968, when Soviet tanks were sent into Czechoslovakia. In the 1970s Soviet economics continued to develop along various mathematical, ideological and empiricist paths, including the suggestion of oxymorons such as ‘planned markets’, while the Soviet economy entered a period of relative decline. Burdened by the need to maintain nuclear parity with the West and by imperial overstretch (Afghanistan), its superpower status was increasingly difficult to sustain. Answers about how to solve these problems were not always forthcoming from within official Soviet economics, and, if they were, they were rarely immediately heeded. For example, it took Aganbegyan's reformist economics nearly 20 years to be taken seriously by Soviet leaders. However, in less contentious areas worthwhile contributions came in the post-Stalin period from...
Vainshtein on measuring national wealth and D. I. Oparin on multi-sector accounting. The standard of empirically focused economic investigation without obvious ideological significance was usually high, and it was often easy to separate out the pseudo-Marxian framework from the valuable detailed content. However, in areas with direct policy significance the quality and reliability of the economics declined dramatically. For example, official statistics on growth rates in the USSR after 1928, perhaps the most contentious subject of all for Soviet economists, certainly suffered from ideological interference, but even Western economists who tackled this topic objectively (such as Kuznets) came to somewhat ambiguous conclusions. In general Soviet economic theory between 1929 and 1985 was thoroughly dominated by political concerns, but this did not necessarily invalidate every aspect of the all of the work done in this period.

1985–1991

With Mikhail Gorbachev's accession to power, the twin tracks of cultural openness (glasnost) and economic restructuring (perestroika) were opened. This was presented as a return to a NEP-style mixed economy, with ‘socialist markets’ and entrepreneurial cooperation being hailed as solutions. This opened the floodgates to the reprinting of material by repressed economists like Bukharin and Litoshenko, and to the open discussion in Soviet economics journals of topics like the neoclassical theory of production and distribution. Soon after this, Western authors like Hayek and von Mises were being translated. In 1989, a government programme was issued acknowledging that ‘the market’ must take precedence over the plan. Some of the key economists of the Gorbachev period were Aganbegyan, Stanislav Shatalin and Leonid Abalkin, who were part of an old guard that had always advocated reform. They were, however, quickly overtaken in the audacity of their transition programmes by a younger generation of economists such as Grigory Yavlinsky and Yegor Gaidar. Various concepts were applied to explain the dilemmas facing the Soviet economy in this period, such as monetary overhang (savings without prospect of being spent), market Stalinism (state decrees pronouncing market activity) and then spontaneous privatization (impromptu transfer of state property).

A key point to recognize is that, in the USSR at the end of the 1980s and after being suppressed for so long, pro-market economics was a ‘revolutionary’ set of ideas that gave Russian advocates a sense of liberation from decades of stale dogma, although some had made the intellectual change much earlier. The main focus of the early proponents of market reform was mass privatization of state-owned property and the liberalization of state-controlled prices, as contained in Yavlinsky's 500-days programme of 1990. Macroeconomic stabilization policies (such as balancing the state budget) took third place. This shock-therapy approach was influenced by Western economists like Jeffrey Sachs, and also by eastern European theorists such as Janos Kornai. Advice on upholding the appropriate sequence of economic reforms, as articulated by Ronald McKinnon (1991) based on previous experience in Latin America and Asia, was not fully heeded in the ‘transition fever’ of the time. Many Western economists were actively involved in propagating market-friendly ideas and policies even in the early Gorbachev period, and they often overwhelmed any lingering loyalty to Marxist economics through the greater sophistication and more rigorous technical framework of their work.

It should also be acknowledged that the particular conception of ‘the market’ espoused by many Russian economists at this time was somewhat one-sided, an amalgam of favourable assessments such as Frank Knight's conception of entrepreneurial capacity, early Austrian capital theory and Milton Friedman-style
monetarism, complemented by Kornai’s account (1980) of the Soviet shortage economy. The Keynesian tradition was difficult to discern. In discarding the socialist heritage, the baby (market critiques) had been thrown out with the bath water (central planning). In hindsight, many market advocates appeared rather naive about the consequences of releasing the genie of unfettered self-interest from the Soviet bottle. The question of whether ‘the market’ as a universal general mechanism (Adam Smith’s ‘invisible hand’) actually existed, as against the idea of many different types of markets as institutions that were influenced by local and national conventions, grew in significance as the reforms progressed. Perhaps one reason for the sidestepping of Keynes’s work was that it had been openly discussed even under Stalin, and hence was seen by some as tainted.

In terms of results, the consequences of the post-Soviet transition are fundamentally contested, with some economists celebrating the creation of a successful market economy in Russia (Anders Aslund) while others protested against oligarch-controlled mafia capitalism (Boris Kagarlitsky). What is unquestionable is that the initial rush to privatization and liberalization has been tempered by more recent concern for the development of stable legal institutions and a mature business culture. If banking panics and financial crashes are a sign of a functioning market system, then in the summer of 1998 Russia experienced a classic example, sparked by the government defaulting on its debts.

Conclusion

With the collapse of the USSR at the end of the 1980s, and China’s conversion to ‘capitalism with a socialist mask’, the West has undoubtedly triumphed in the battle of comparative economic systems. However, it did so at significant ideological cost. Firstly, state intervention in the economy had to be embraced by many Western governments after 1936. Secondly, the goals of full employment, a welfare state and (more recently) fairness in international exchange have become accepted policies in many developed countries, even if they are not often achieved. And thirdly, Western economics was transformed after 1945, with the mainstream integration of ideas such as public goods, monopolistic competition, cooperative games, social cost and even status goods, that would make it unrecognizable to someone like Bukharin versed in the Austrian approach of 1914, and even more so to Marx, who had never even recognized the ‘marginal revolution’ of the 1870s. The refusal of Soviet economists to officially engage with new developments in Western economics was thus understandable, since had they had done so they would have realized the simplistic caricature that had been foisted onto them.

Furthermore, the existence of the USSR altered to some extent the purpose of mainstream economics as it was conducted in the West. Before 1917, economists served the state mainly as academic theorists and as advisers on specific topics, for example on monetary or fiscal policy. After 1945, with the onset of the Cold War, the role of some economists widened to providing more general advice on economic development issues. Moreover, the responsibility of a few Western economists increased even further than this. For example W. W. Rostow, famous for his stages theory of economic growth, was a development economist with a detailed knowledge of British trade cycles. Summoned to serve in the Kennedy administration he became a key advocate of increased US involvement in Vietnam, arguing for more American troops on the ground and heightened bombing of the North, in order to contain the expansion of communism in South-East Asia. That it was a professionally trained economic historian giving advice to US presidents on geopolitics was indicative.

To conclude, the USSR collapsed spectacularly, and its official economic ideology was derisory even
when first issued, yet many Russian/Soviet economists produced work of lasting value that was influential at the time of its first issue, and is still being referred to today. All things considered, the Soviet contribution was (in spite of Stalin's efforts) perhaps the most influential experimental failure in the development of economic ideas thus far.

The development of economic thought in Spain should be understood as occurring in a country which,
due to the delay in the development of its economy and scientific thought, became a recipient of
economic ideas from more advanced centres. Spain went from empire to decadence, and awareness of
this led people to search for strategies which would remedy the situation. The delay in the reception of
foreign theories was determined by strong institutional obstacles, though these did not prevent theories
from becoming known. This process of reception and redevelopment of foreign ideas was not always
linear, nor was it uniform in time. The Spanish case is of interest when explaining and analysing and the
effectiveness of different theories once they cross the borders of the country in which they have been
developed.

The conquest of America and the world of scholasticism

The first traces of economic thought in the Iberian Peninsula are found in the age of the Arab
civilization. A writer and politician of Tunisian origin, between the 14th and 15th centuries, Ibn-Jaldún,
rewite *The Muqaddima*, a treatise on the science of civilization, in which he added an explanation of the
birth and decline of dynasties, and which contains the first global vision of economics. *The Muqaddima*
also contains an analysis of the cyclical nature of economics, as well as an embryonic model of
development.

Later, the conquest of America set a new stage for the prosperous Hispanic monarchy. The transport of
precious metals from the Indies and the increase in commercial exchange sparked off a revolution in
prices which accompanied the commercial revolution. Population increase and the cultivation of new
lands brought about a decline in productivity and, together with a lack of technical innovation, the
problems of pauperism and the monetary and financial problems associated with unprecedented
inflation, which originated in the discovery of the New World, led a group of theologians and members
of the colonial administration to set forth their opinions on the situation of a country which had begun a
long process of decline.

The first diagnoses came from a group of doctors, naturalists, politicians, philosophers and theologians,
scholastic latecomers, members of the so-called School of Salamanca, whose founder was Francisco de
Vitoria (1483–1546). These writers were to be found at the prestigious University of Salamanca, though
they had been educated at the most important European universities. They were witnesses to the
problems which originated during the conquest of America, and though the trade practices of wealthy
Spaniards returning to Spain from Latin America were always ahead of theological doctrine, the scholars
attempted to reconcile economics and morality by using natural law based on probabilism and casuistry.
This led them to apply Thomistic philosophy to resolve practical affairs and to explain economic
problems which had arisen in the world of the Counter-Reformation before the scenario which had
opened with the discovery of America. They used the manuals of confessors and wrote a set of works in
which they tackled economic problems with the utmost insight, amongst which stood out a subjective
theory of value, the quantity theory of money, the theory of exchange, the general doctrine of interest
and the workings of the market, as well as questions of fiscal policy in relation to distributive justice.
The cleric Martín de Azpilcueta early on formulated the quantity theory of money in his *Comentario
resolutorio de cambios* of 1556, and, through considering of the variations in exchange rates, came close
to the purchasing power parity theory. His successor, Tomás de Mercado, author of *Suma de Tratos y
Contratos* of 1571, managed to integrate quantity theory into a theory of prices. The Spanish scholastics
built a bridge between medieval scholasticism and modern philosophy. They were contemporary with

the writers of the first mercantile system, but, unlike them, they were privileged by having had a philosophic-cum-systematic training of Aristotelian–Thomistic origin, which enabled them to focus on economic questions not only from a moral viewpoint but also from a more analytical one. The ideas of the School of Salamanca were disseminated throughout the rest of Europe and the American colonies from the universities of Coimbra, Alcalá, Mexico, Lima, Rome and Paris. Together with Azpilcueta and Mercado, their principal members included clerics such as Domingo de Soto, Luís de Molina and Juan de Lugo. Scholastic doctrines at the end of the 16th century coexisted with those of the first mercantilist writers, in some cases resulting in an authentic symbiosis.

The age of mercantilism

A group of writers, royal advisers, social reformers and Spanish political economists swelled the ranks of the bullionists, among whom the first of the so-called mercantilists were often found. However, Schumpeter discovered among them a few economics writers whose ideas were distinct from primitive bullionism, and whom he considered to be authors of a quasi-systems, such as Luís Ortíz, who wrote a Memoir in 1558, the year following the first bankruptcy of Phillip II of the House of Austria. Aware of Spain's economic decline, Ortíz investigated a set of remedies which constituted a programme of industrial development. Ortíz attributed the problems of the Spanish economy to internal price rises in Castile, to the inability of national industry to meet demand from the American continent, and to social disdain towards the skilled classes. The remedies consisted of prohibiting exports of raw materials from Spain and preventing imports of foreign goods. In addition, he investigated Spain's political and social institutions in relation to the workings of the economic system.

With an optimistic vision based on the potentialities of the Spanish economy, some Spanish mercantilists saw the fundamental problem not in the limitations of nature itself, but in social and institutional factors. This led to their proposing the elimination of idleness, the abolition of laws which considered manual labour contemptible, limitations on of luxuries for the rich, and changes in a taxation system whose burden fell unjustly on farm workers, aggravating depopulation. Some, such as Ortíz, saw market unification as necessary, the nobility and the Church being the main obstacle. The expulsion of the ‘Moriscos’ at the beginning of the 17th century undermined the demographic base, already weakened by epidemics in the previous century; this was combined with a reduction in shipments of precious metals from the Indies. The disastrous policies of the King’s advisors only added to the problems caused by the territorial and political dispersal of the Spanish monarchy. Some writers, such as Sancho de Moncada, in his work Restauración política en España of 1619, summed up the efforts made by the best writers of the time. He was concerned with quantifying the crisis and identifying the variables which brought it about and the links between them.

As a whole, the mercantilists at the beginning of the 17th century concluded that the root of all evil was international trade, since it enabled foreigners to extract from Spain undeveloped raw materials, as well as silver and gold. The remedy consisted in prohibiting manufactured foreign imports, as well as prohibiting the export of raw materials from Spain. This would stimulate the domestic market and internal spending, benefiting the people by increasing the monarchy's revenue. Some mercantilists, such as Martínez de Mata, insisted on increasing production when establishing a relation between cost and the production function.
Not all voices clamoured for prohibition; they explained the crisis in terms of the enrichment of foreigners and the unfair commerce which Spain maintained with them; some, exceptionally, such as Alberto Struzzi, who published a *Diálogo sobre el comercio destos Reinos de Castilla* in 1624, and, later, Diego José Dormer, author of several politico–historical discourses in 1684, defended economic plans which would reactivate commercial relations with foreign countries, with a different strategy based on improving the domestic competitiveness of Spain's economic sectors.

A second mercantilist phase began in Spain with the economic recovery at the end of the 17th century, during the reigns of the last monarch of the House of Austria, Charles II, and the first Bourbon, Philip V. The political economists of the period, amongst whom Jerónimo de Uztáriz and Bernardo de Ulloa were outstanding, were already more seasoned writers. The former, the most important of the Spanish mercantilists, wrote the *Theórica y práctica de Comercio y de Marina* in 1724, a work which aroused the interest of Adam Smith, and which was translated into several European languages. Uztáriz obtained quantitative data on the Spanish economy, on the basis of which he proposed the lowering of production costs in order to lower domestic prices as a solution. He also proposed a free trade zone with America. In general, the ‘mature’ Spanish mercantilists concerned themselves with questions such as political unification, the elimination of internal customs and excessive indirect taxes, which accumulated in a chain effect and raised final sale prices. They equally supported privileged commercial companies and the existence of a strong navy, which could be used not only for military purposes but also for commercial ones. Their fundamental aim was to encourage industry, in terms of which they continued to defend the protection of domestic industry from foreign competition, in this way relegating agriculture, though only in order of preference. Foreign countries were no longer considered enemies, but were now an example to be followed, especially the Netherlands, France and the United Kingdom.

A characteristic of the Spanish mercantilists in this last period was their belief in the need to establish a more complex analysis of underdevelopment, with reference to the disadvantages of international trade (with consequent problems for the balance of trade) as well as the problems stemming from low labour productivity, which had its origin in the socio–political and cultural structure of the period. To break out of this vicious cycle of underdevelopment, they proposed that industry should be the key to development and consumption the driving force of industry.

**The Enlightenment and economic reform**

The long expansive cycle that began at the end of the 17th century had brought about a marked population increase, crop expansion, growth in industrial production and greater development of internal and external trade. Spain, however, was still a feudal society in which the land ownership system had not changed and, despite crop development, agrarian production techniques had not substantially changed.

Although Spanish mercantilism had been characterized as a ‘hardy perennial’, the age of Enlightenment in Spain started under the reign of the House of Bourbon of Charles III (1759–88), in which mercantilist stances in their most extreme version were abandoned, bringing about internal market liberalization and a set of reforms which began to liberate the economy.

For the economic writers of the period, the problem was still the same as in the past: to remove obstacles to economic growth, but with a clear awareness that this should be combined with certain institutional and legal changes, provided that they did not affect the absolute power of the monarch in any way.
Despite the survival of mercantilist ideas, they now had new analytical tools at their disposal, thanks especially to economic ideas received from abroad, such as those of the new British political arithmeticians and of the French Physiocrats and agrarian reformers, together with those of the so-called Gournay group, and later, those of Adam Smith himself, which would circulate uninterruptedly until shortly before the end of the century, when the multiple wars with France and the United Kingdom largely hindered the circulation of ideas.

Some politicians who enjoyed great power and who were close to the monarch, such as the Count of Campomanes, author of The Discurso sobre el fomento de la industria popular (1774), amongst other works, and a genuine inspirer of this first transitional phase between mercantilism and enlightenment, drew up a renewal programme whose central element was economic reform. His modernizing ideas were founded on a gradual transformation consisting of (a) liberalizing colonial commerce, (b) abolishing the price-regulated ‘tax’ on cereals, (c) stimulating their commerce, and (d) putting an end to the increase in the considerable unproductive properties of the Church, and to the excessive interventionism of guilds. All in all, he designed a coherent system of development based on domestic economic freedom, together with protection against foreign trade, which granted a key role to the promotion of agriculture based on the figure of the independent farm worker, the expansion of ‘popular industry’ and occupational increase.

The Enlightenment saw the creation of the Sociedades Económicas de Amigos del País, organizations which encouraged the study of regional economy, of agricultural techniques and of economic science in general. In these societies, after the Italian model, the first professorships in civil economy and commerce were created, giving rise to the beginning of the institutionalization of political economy in Spain at the end of the 18th century. These societies disseminated economic ideas developed in other European countries, such as those of the British political arithmeticians of the 17th century and those of the French thinkers, mercantilists, advocates of agrarian reform, and physiocrats, namely, Cantillon, Melon, Forbonnais, Mirabeau, Montesquieu, Turgot, and, later on, Condillac, Necker and Adam Smith. The Spanish economics writers, of whom the most prominent were Pablo de Olavide, Enrique Ramos, Nicolás de Arriquíbar, Bernardo Danvila and Francesco Roma i Rossell, were acquainted with the ideas of physiocracy and were especially attracted to their advocacy of agrarian reform, even if the theoretical and analytical core on which they were based, as well as ideas of exclusive agricultural productivity and the single tax, were not accepted as a whole. In this sense, many of the first enlightened Spaniards were more in tune with the ideas developed by the so-called Gournay group, which better reconciled the importance of agriculture, industry and commerce, and in which indigenous mercantilism was in its turn very pronounced.

It was also in this period that knowledge of the Wealth of Nations began to spread. However, it was not translated until the 1790s. Not all viewpoints were in favour of liberal agrarianism; others opted for industrial development, the influence of German sources being obvious, especially in the territories of the Crown of Aragon, by which the ideas of the Baron von Bielfeld and von Justi led to more industrialist formulations and justified greater participation by the state and by the nobility in the development of economic activities. Enlightened Spaniards of this first period found themselves at a crossroads between tradition and innovation, and although the influence of mercantilism remained, they created a favourable environment so that in the following years the enlightenment movement would manifest itself with greater strength, giving impetus to the modernization of Spain.

A second stage of enlightenment coincided with the French Revolution. At that time Gaspar Melchor de Jovellanos was commissioned by the Real Sociedad Económica Matritense to write the most important
work on economics in 18th century Spain, the Informe de Ley agraria of 1795, based on the concept of the economy as the main ‘government science’. He designed a programme of pragmatic, gradual and moderate liberal reforms, which included the redistribution of land, freedom from leasing, and imposing limits on property inheritance. He also proposed abolishing the privileges of the powerful stock-breeding organization, the ‘Mesta’, and the liberalization of domestic commerce, which, however, did not include freedom to export or with revision of the taxation system. All of this was contemplated with a programme of public investment and special attention to education, since it conferred decisive importance on human capital. Jovellanos, very well-acquainted with the works of European economists such as Cantillon, Galiani, Mirabeau, Turgot and Necker, among many others, was one of the Spanish economists who read Smith's work with discernment, as a result of which the idea of self-interest as the driving force of economic activity would be consistently present in his work, as it would be for many Spanish economists of the time.

In short, it may be said that in Spain the Enlightenment occurred later than in other countries and had different overtones arising not only from Spain's political and institutional situation but also from other factors such as its comparative economic backwardness. This did not present an obstacle to the enlightened Spaniards when disseminating the main economic ideas synthesized in the United Kingdom, France, Italy and in the Germanic countries; in any case, the canonical plan for the dissemination of economic ideas through the mercantilism–physiocracy–liberal economy chain did not appear to be suitable for Spain, where, along with a more persistent neo-mercantilism, fundamentally of an Italian and French nature, the weak presence of physiocracy in its theoretical aspects could be detected, and also a strong influence from the British and French agrarian reformers, who were widely dispersed throughout the peninsula.

The enlightened Spaniards applied the ideas they received to the solution of the problems of their age. In this sense it may be considered to have been an active reception, stimulated both by the economic societies in which the Economy was studied and which promoted the translation of the principal texts of the economists mentioned above, and by economic publications, which multiplied during the second half of the century. These disseminated ideas, making the last decade of the century an especially fertile one, in which, despite heightened censorship because of the French Revolution, the principal works of the European economists saw the light of day.

Classical economics in the liberal age

The Court of the Spanish Inquisition had already denounced Lorenzo Normante, the first lecturer in political economy, who had begun his classes in the Aragonese Economics Society under the influence of Melon, Genovesi and Condillac, for considering economic ideas which were not in accordance with dictates of the Catholic religion. The same trial dealt with the Wealth of Nations, which was censored by the Inquisition in 1792, being accused of tolerance and naturalism.

Despite this, Smith's influence had already been felt by some Spanish economists, who generally made an adapted interpretation of his work. Government collaboration and the suppression of his identity allowed a compendium of his work to be translated by the Marquis of Condorcet in the same year, and only two years later the first complete edition saw the light of day, with a few adjustments here and there to avoid the rigours of the censor. The Wealth of Nations was translated by one of the Spanish economists on whom the influence of Smith was clear, the diplomat José Alonso Ortíz. Smith's work
quickly became a reference point for the teaching of economics, even though it must be emphasized that its late translation and the prevailing doctrinal influences in Spain simultaneously brought several interpretations of Smith's work into being, especially those of an agrarian nature, which coincided with an avalanche of influences which converged at the beginning of the 19th century.

The introduction of Smith's work was accompanied by the first versions of the mathematical economics of N.-F. Canard, of the neo-physiocratic doctrines of Germain Garnier, or the partially physiocratic ones of Jean Herrenschwand, and those of the other advocates of agrarian reform of a non-physiocratic origin, both British and French. Together with these, the doctrines of the French economist J.B. Say had special relevance. His *Traité d'Économie Politique* was translated early in Spain (1804–7) and used as an official text to teach economics, when Spanish economics took its first step towards institutionalization in universities at the beginning of the 19th century.

Nevertheless, the influence of Smith lasted throughout the first decades of the 19th century; however, by that time the influence of the French economist was decisive. This strong influence (eight editions in Spanish of the *Traité* alone) can be explained by its support for keeping the same groups in power and its more pragmatic nature, which favoured its reception, together with greater accessibility of the French language in Spain, and because it was not subject to the vicissitudes of censorship. The fact is that it inspired all university texts for the first three decades of the 19th century. Smith's ideas were used by his followers to defend non-Malthusian interpretations with respect to population and an industrial development model, modified with a defence of customs prohibition. Some authors, such as Gonzalo de Luna, made an interpretation of the ideas of Say and Smith in a neo-mercantilist vein, which defended industrial development models without altering the political bases of the old regime.

Only those who were in exile for political reasons when the absolute monarch, Fernando VII, returned escaped such influences. They lived in the United Kingdom and became acquainted with the ideas of the classical British authors, especially Ricardo, McCulloch and James Mill. Amongst them stood out José Canga Argüelles, the Chancellor of the Exchequer in the brief liberal period which began in 1820 and author of *Elementos de la Ciencia de la Hacienda* (1825), and the most important Spanish economist of the 19th century, Álvaro Flórez Estrada, the main introducer in Spain of the ideas of Ricardo and James Mill, and in whose works the influence of Sismondi and Richard Jones could also be appreciated. In Flórez Estrada's *Curso de Economía*, published for the first time during his exile in London in 1828, a limited influence of Ricardo's ideas (the *Principles* were not translated until the 20th century) could be seen. Also disseminated with the ideas of Say and Ricardo, though with less intensity, were those of Malthus (almost exclusively his ideas on population), Sismondi (his ideas on the agrarian development model) and Bentham, Condillac and Gaetano Filangieri (though their influence was not solely in the sphere of economics).

Say's influence dwindled from the 1840s, allowing greater doctrinal plurality. The influence of Say's disciples left a clear mark on the main Spanish economists of the time, such as Eusebio María del Valle, Andrés Borrego and Manuel Colmeiro. It was a period characterized by eclecticism, in which distancing from the ideas of the classical school is associated on one hand with criticism of deductive methodology, and on the other with recognizing the negative effects of the development of capitalism on the lowest social classes. This favoured reception of Sismondi's ideas and those of the social Christianity of Alban de Villeneuve-Bargemont, so influential in France. All this included a distancing from free trade and favouring industrial protection.

Richard Cobden's journey to Spain in 1844, in his crusade for the free trade league, united with reception
of the ideas from the French liberal economists, directed most Spanish economists towards free trade, a trend supported by such texts as *Cinco proposiciones sobre los males que causa la Ley de Aranceles a la nación*, published in 1837 by the liberal economist Pablo Pebrer, and the writings of another exile, José Joaquín de Mora, which sparked off the lengthy so-called protectionism–free trade debate, which continued until the beginning of the protectionist era with the Restoration in 1874. The decisive influence of the ideas of Frederic Bastiat and his *Harmonies Économiques* established an age of economic optimism and defence of liberal ideas in their French version, an influence which separated Spanish economists from knowledge of the most relevant developments in the classical British economy, minimizing the influence of economists like John Stuart Mill, an economist of more advanced and complex interpretation, especially after the events of 1848. Perhaps it was the sparseness of the theoretical analysis in Bastiat's work which favoured its dissemination, together with his outspoken opposition to the situation of social confrontation, which by that time was beginning to spread from France, fuelled by criticism of the republican groups and of incipient socialism in its utopian aspects. The debate was situated in the territory of common-sense economic discourse, which brought about pragmatic empiricism and led to the pronounced stagnation of economic science. In the last three decades of the century even marginalist ideas were unknown, perhaps due to a lack of mathematical preparation of the economists, most of them university professors in law schools, or perhaps due to their lack of dedication to investigation. Neither did the historicism of the German Historical School of Schmoller make its mark, and the influence of the Historical School was reduced to methodological relativism which legitimized public intervention, both commercially and socially. Neither did incipient theoretical Marxism make its mark; Bakunin's anarchism was introduced first, and when this happened it was initially separated from the workers' movement, and with a level of popularization in which the ideas of Marx arrived clearly transformed.

Undoubtedly, Spanish economists lost the thread of economic science in the second half of the 19th century; the main criticisms of classical thought came from their own ranks, where the protectionist change of tack that took place in the 1870s later combined with concern for social problems. This led to a defence of liberalism tempered by historicist influence which legitimized protectionism and social reform when not influenced by fundamentalist pseudo-religious postures which would later be taken up in corporatist thought. Likewise, the German Philosopher Krause's ideas, received through the influence of the philosophy of H. Ahrens, contributed to elaborating the first labour legislation of a paternalist nature in defence of the working class, which in these authors, amongst whom stand out G. de Azcárate, A. Álvarez Buylla and J.M. Piernas Hurtado, was compatible with free exchange and economic liberalism. In this breeding ground, tinged with a spirit of regeneration and extra-scientific approaches, the populist ideas of Henry George had a great impact, his *Progress and Poverty* having a tardy but enthusiastic reception in Spain.

**The economic modernization of Spain**

In the last few years of the 19th century and in the first few of the 20th century, the educational reform project carried out by the Institución Libre de Enseñanza allowed Spanish undergraduates to travel to foreign universities and become acquainted with doctrines developed beyond Spanish borders, especially in Germany. This was how the renewal of economic studies began, after its long stagnation in the previous century.
Antonio Flores de Lemus, the principle Spanish economist of the first half of the 20th century, was educated at the turn of the century in the lecture halls of German universities under the tuition of Schmoller and Wagner, and, on returning to Spain, became the great disseminator of a neo-historicist and realist stream in economic science which dominated Spanish science until the outbreak of the civil war in 1936. A university department chair in the service of the Inland Revenue, he did research on official economic statistics. The reformation of the Inland Revenue and monetary problems were some of the questions in which his intervention was decisive, such as the period between 1927 and 1929, when the possible return to the gold standard was being considered. Some of his successors, such as Luís Olariaga, an expert in monetary matters, Francisco Bernis, an Inland Revenue scholar, economist and statistician, Olegario Fernández Baños, or Germán Bernácer, who developed a macroeconomic model with Keynesian connotations, distanced themselves from the neo-historicist stance in order to embrace more recent developments in economic science.

At the same time the influence of corporatist doctrines was equally making itself felt, based on fin de siècle conservative Christian thought, and an outward admiration for the Fascist movement and the corporatist doctrines of the Italians which quickly took root in the most conservative sectors of the Spanish intelligentsia. The Spanish corporatist model inspired economic policy during the dictatorship of Primo de Rivera (1923–30) and Franco’s fledgling dictatorship, where its influence united with economic planning, on which the economic policy in the first years of Franco’s autarky was based. In any case, corporatism in Spain had neither the significance nor the duration which it enjoyed in Portugal, and had no level of analysis, being reduced to plans which were ostensibly superior to capitalism and socialism, but in which the economy was completely subordinated to political ends.

On the other hand, the marginalist revolution was almost unknown in Spain during the 19th century and for a good part of the 20th, with the exception of some teachers in the engineering schools. Later, thanks to the creation of the Faculty of Political and Economic Sciences at the University of Madrid (1943), neoclassical microeconomics began to spread in university lecture halls. Equally influential was the arrival in Spain in 1941 of Heinrich Von Stackelberg, an economist of German origin with a mathematical education. He was mainly responsible for training future university lecturers in economic theory, participating in courses at the Faculty of Economic Sciences, created only three years before his death. The delay in the reception of neoclassical thought is attributable to the economists’ poor mathematical preparation and perhaps to the neo-historicist focus which prevailed in Spain in the first decades of the 20th century.

The reception of Keynesianism in Spain

Knowledge of the work of Keynes was hindered by the fact that the General Theory appeared only months before the outbreak of the Spanish civil war, though previously the worldwide dissemination of The Economic Consequences of the Peace had allowed Keynesian ideas to be known through the press, and Keynes himself had visited Spain in 1930. In the intense debate held on monetary questions in Spain in the period 1927–30, no influence can be detected of the ideas contained in the Tract on Monetary Reform. With the benefit of hindsight, during Keynes’s visit, agreement can be detected between Keynes’s ideas and those of the Spanish economists who had rejected the revaluation of the peseta because of its repercussions on production and employment, especially with the Dictamen sobre la implantación del patron oro drawn up in 1929. In the years leading up to the Spanish civil war,
Keynesian ideas were interpreted in the context of attempts to escape from the depression through economic policy which did not conform with the orthodox line: the promotion of public works at the cost of a budget deficit, the abandonment of the gold standard and the granting of credit facilities, in the framework of moderate protectionism.

The later reception of the *General Theory* was complicated, not only because of the civil war but also because the tradition of a more neo-historicist slant had prevailed in the academic world until then. There was first ‘underground’ dissemination among a depleted group of Spanish economists during the civil war and the first few years of the Second World War. Later, however, in the 1940s, there was a wide dissemination of Keynesian literature within the context of wider discussion of post-war reconstruction policies and the framework necessary for stability. There was a varied reception to Keynesian thought by some economists such as Manuel de Torres, Emilio de Figueroa, or Joan Sardá, who in some cases considered the primary formulations of the neoclassical synthesis, while others combined the ideas of the *General Theory* with some contributions from Austrian and Scandinavian economists.

Another group of experienced economists, very knowledgeable of Keynesian literature, such as Germán Bernácer and Luís Olariaga, harboured reservations about Keynesian ideas, especially on an analytical level.

On the economic and political level, the interpretation is more complex due to the political situation during General Franco's long dictatorship. In this context, Keynesian proposals were used by the regime itself and by some of its principal advisors, such as Higinio Paris Eguilaz, to encourage employment policies and economic stability. This meant misuse on the part of an official authority which used a ‘bastardized’ Keynesianism identified with systematic interventionism, resulting in a confusing clash between Keynesianism and corporatist dirigisme, in which Franco's ‘autarky’ was propped up by an interventionist recipe of price and wage controls, rationing, credit manipulation, and an import substitution policy, rounded off by a system of licences and official authorizations. This model distanced itself completely from Keynesianism since, in reality, its economic strategy relied upon a revision of the assisted capitalist model which had begun in the time of the dictatorship of Primo de Rivera (1923–30), of clearly corporatist influence, and was now being updated in the light of pre-war national socialist experiences.

Together with these, there was a group of expert economists which used Keynesianism for establishing the basis of a more rational economy, and it was precisely from this group that the main criticism came of the autarkic regime, of its disastrous and suffocating interventionism and of its self-destructive effects. Within this new generation of economists educated at the new Facultad de Ciencias Económicas there were also subtle differences, among those who embraced the postures of the Ordo group and the school of Freiburg (liberals linked to research institutes, tolerated, but critical of Franco's regime), as well as some university lecturers who defended mixed viewpoints in which well-received Hayekian liberalism was tempered from viewpoints which appealed to a ‘liberating’ intervention along the lines of Röpke or Eucken.

The 1950s saw a considerable expansion of Keynesianism through debate by several disciples of Professor Manuel de Torres, such as Enrique Fuentes Quintana, Manuel Varela and Emilio de Figueroa on the applicability in Spain of the ideas contained in the *General Theory*; the debate was useful for advancing Keynesian ideas on unemployment towards more relevant problems which ran deep in Spanish economic backwardness, such as the limitations of Spanish industry and the consequences of...
very restricted international trade. It also tested awareness of the need to maintain applicable economic policy measures, with better knowledge of economic macro-magnitude principles, which led to the reactivation of the first studies in national accounting and the first estimations on the national revenue and its provincial distribution. In 1954, studies for the drafting of the first input–output table for the Spanish economy began under the direction of Professors Manuel de Torres and Valentín Andrés Álvarez who, with the assistance of the Italian economist Vera Cao-Pinna and the Instituto per la Cogiuartura di Roma, allowed the first table to be drawn up in 1958, with data referring to the Spanish economy of 1954.

Resistance to this expansion of Keynesianism was less than in other countries; abandonment of the neo-historicist line helped, of a realistic nature which had dominated the teaching of economics up to the Spanish civil war, along with the fact that, unlike in Portugal, economic corporatism did not attain an influence beyond the first moments of Franco's regime.

The clearest influence on Keynesian economic policy was the Stabilization Plan (1959), which helped to bring about a thawing in Franco's autarky, which by then had become untenable. A paradox existed in that, in reality, this late application of the Keynesian programme consisted of a ‘cooling off’ and restriction on the economy, with a view to an opening up of the Spanish economy to foreign markets. Later on, a more mature assimilation of Keynesian ideas came about, the main focus of which was the Bank of Spain's Research Department, where an econometric model was developed for the Spanish economy on a Keynesian base. Later, recognition of the effectiveness of monetary policy to combat inflation and macroeconomic imbalance contributed in an indirect way to the favourable penetration of the ideas of Milton Friedman, which were almost unknown in Spain until the 1980s.

Concluding remarks

Unlike in other countries, the academic institutionalization of economic studies, begun in the 19th century, did not gel into the creation of specific centres for the study of economic science, which until then had been taught in law schools, and later in schools of commerce at non-graduate level. From the beginning of the 20th century there were several attempts to create a specific centre, which were not successful until 1943, with the creation of the School of Political, Economic and Commercial Sciences at the University of Madrid. This was the main factor which led to the consolidation of the academic study of economics in Spain, and to the fact that economic theory, first microeconomics and later macroeconomics, became known in the Spanish academic world. From these same lecture halls later in the 1960s Keynesian ideas spread, in their diverse formulations, initially the neoclassical synthesis, and later on in the 1960s and 1970s Keynesian macroeconomics in its truest interpretation and its later developments, as with the monetarist theories and those of the new macroeconomics.

Assimilation of economic theory and the training of economists constituted an essential step in that the policies of stabilization and the opening up to foreign markets, first within Franco's regime in a phase in which Spain, once the autarky had been exhausted and abandoned, began to be incorporated into the main international economic organizations and later on during the democratic transition. These policies allowed change from a closed economic model to an open economy, from which integration into the international economic panorama became possible.

spatial econometrics

Abstract

Spatial econometrics is concerned with modelling dependent observations indexed by points in a space. Complicated patterns of interdependence can be parsimoniously described in terms of these points’ locations. Covariances between observations, for example, can be modelled as functions of their distances. Index spaces are not limited to the physical space or times inhabited by economic agents and can be as abstract as required by the economics of the application. This entry discusses the use of generalized method of moments and other common estimators with spatial data, as well as simultaneous equation methods specialized to certain types of spatial data.

Article

Spatial econometrics is concerned with models for dependent observations indexed by points in a metric space or nodes in a graph. The key idea is that a set of locations can characterize the joint dependence between their corresponding observations. Locations provide a structure analogous to that provided by the time index in time series models. For example, near observations may be highly correlated but, as distance between observations grows, they approach independence. However, while time series are ordered in a single dimension, spatial processes are almost always indexed in more than one dimension and not ordered. Even small increases in the dimension of the indexing space permit large increases in the allowable patterns of interdependence between observations. The primary benefit of this modelling
strategy is that complicated patterns of interdependence across sets of observations can be parsimoniously described in terms of relatively simple and estimable functions of objects like the distances between them.

The fundamental ingredients in any spatial model are the index space and locations for the observations. In contrast to the typical time series situation where calendar observation times are natural indices and immediately available, the researcher will often need to decide upon an index space and acquire measurements of locations/distances. The role of measured locations/distances is to characterize the interdependence between economic agents’ variables, particularly those that are unobservable – for example, regression error terms. The appropriate index space depends on the economic application, and its choice is inherently a judgement call by the researcher. Fortunately, the economics of the application often provide considerable guidance and the index space/metric(s) can be tailored to promote a good fit between the economic model and the empirical work. For example, when local spillovers or competition are the central economic features, obvious candidate metrics are measures of transaction/travel costs limiting the range of the spillovers or competition. If productivity measurement were the focus, distances between observed firms or sectors could be based upon economic mechanisms that might generate co-movement in productivity – for example, measures of similarity between production technologies. Index spaces are not limited to the physical space or times inhabited by the agents and can be as abstract as required by the economics of the application.

Locations/distances are almost never perfectly measured, and this puts a premium on empirical methods that are robust to their mismeasurement. Even if the ideal metric were physical distance, usually agents’ physical locations are imprecise, known only within an area – for example, census tract or county. At best this will result in imprecise distance information between agents, and if inter-agent distances are approximated with measurements based on these areas, such as distance between centroids, errors result. Moreover, in the great majority of applications the ideal metric is not physical distance and must be either estimated or approximated, inevitably resulting in some amount of measurement error.

There are two main approaches to modelling a spatial data generation process (DGP). The first is to model explicitly a population residing in an underlying metric space and the process of drawing an observed sample from this population. The second is to model the data-set of observed agents’ outcomes as being determined by a system of simultaneous equations. In the remainder of this article, I discuss each of these approaches in turn for the simplest case of cross-sectional data. It is important to note, however, that the methods in the following section – covariance and generalized method of moments (GMM) estimation, spatial correlation robust inference – can be directly applied to panel or repeated cross-section data by simply including time as one of the components in the spatial index (s defined below). Most if not all cluster/group effect models can be considered a special case of spatial models with a binary metric indicating common group/cluster membership. See Wooldridge (2003) for an excellent review of these models. I do not discuss them here because their associated empirical techniques and sampling schemes do not translate well to more general spatial models. I conclude with a brief discussion of areas of econometrics where links to spatial econometrics are perhaps underappreciated.

1 Models for samples from a population

This section discusses spatial econometric models that view the data as being a sample from some
arbitrarily large population (see, for example, Conley, 1999, for a more formal treatment). The popula-
tion of individuals is assumed to reside in some metric space, typically $\mathbb{R}^k$ or an integer lattice, 
with each individual $i$ located at a point $s_i$.

The basic model of dependence characterizes dependence between agents’ random variables via their 
locations. The data are assumed to be weakly dependent (perhaps after de-trending). (Andrews, 2005, is 
an important exception that explicitly considers strong cross sectional dependence arising from common 
shocks.) If two agents’ locations $s_i$ and $s_j$ are close, then their random variables $\varphi_{s_i}$ and $\varphi_{s_j}$ may be 
highly dependent. As the distance between $s_i$ and $s_j$ grows large, $\varphi_{s_i}$ and $\varphi_{s_j}$ become essentially 
independent. Notions of weak dependence can be formalized in essentially the same manner as for time 
series, for example, with mixing coefficients. Under regularity conditions limiting the strength of 
dependence, laws of large numbers and central limit results can be obtained for properly normalized 
averages of $\varphi_s$. See, for example, Takahata (1983) or Bolthausen (1982). These approximations almost 
always use what is called an increasing domain approach to limits, with the corresponding thought 
experiment being that, as the sample size grows, an envelope containing the locations would be growing 
without bound.

When one works within this framework, it is often useful to approach an empirical problem in two steps. 
First, decide upon a (small) set of metrics based on the economics of the application, and then consider 
statistical modelling of dependence as a function of the metrics. It is much easier to conduct statistical 
modelling given a metric than to try to simultaneously vary both the model specification and the metric 
itself.

Statistics that describe spatial correlation patterns are simple to construct. Any statistic relating co-
variation of $\varphi_{s_i}$ and $\varphi_{s_j}$ to some measure of their proximity could be used to characterize patterns in 
dependence. Classic references are Moran (1950) and Geary (1954), and the text by Cliff and Ord 
(1981) contains a good treatment. One useful approach is based on nonparametric estimation of a 
covariance function (see for example Conley and Topa, 2002, or Conley and Ligon, 2002). The $\varphi_s$ 
process is covariance stationary if its expectation is the same at all locations and $\text{cov}(\varphi_s, \varphi_{s+h})$ 
depends only on the relative displacement $h$. For high-dimensional $h$, it is useful to consider a special 
case called isotropy where covariances depend only on the length of $h$; covariance depends upon 
distance but not direction. Take an isotropic covariance stationary $\varphi_s$ with expectation zero for 
simplicity. Its covariance function $f$ can be expressed in a regression equation involving distances $d_{i,j}$:

$$E(\varphi_{s_i} \varphi_{s_j} | s_i, s_j) = f(d_{i,j}).$$  
(1)

The function $f$ in eq. (1) can be estimated parametrically or, as is particularly useful in preliminary data 
analysis, via a nonparametric regression of $\varphi_{s_i} \varphi_{s_j}$ on $d_{i,j}$. Investigation of correlation patterns when
there is more than one candidate metric can be done by simply letting $f$ be a function of more than one distance measure.

In cases where $\phi_s$ is not isotropic or non-stationary, $f$ can still be interpretable as a measure of average co-movement. If the process is covariance stationary but not isotropic, an estimate at a given distance $d_0$, call it $\hat{f}(d_0)$, will converge to a weighted average of $\text{COV}(\phi_s, \phi_s + h)$ for displacements $h$ that have length $d_0$. The relative weights of different directions $h$ will depend on their frequency of sampling. An analogous interpretation of $f$ is available when $\phi_s$ is non-stationary, $\text{COV}(\phi_s, \phi_s + h)$ depends on $s$, but still weakly dependent with averages of $\text{COV}(\phi_s, \phi_s + h)$ across $s$ remaining convergent. In this case, $\hat{f}(d_0)$ will converge to a weighted average of $\text{COV}(\phi_s, \phi_s + h)$ across those $h$ with length $d_0$ and across all $s$. Typically, this is still a valuable measure of co-movement. If non-stationarity is suspected, it is also very useful to construct localized versions of measures of spatial correlation. Localized $f$ estimates for subregions of the locations can easily be constructed by just confining the observations used to estimate (1); see Anselin (1995) for extensive treatment of localized versions of Moran (1950) and Geary (1954) measures of spatial correlation.

Estimates of $f$ can also be viewed directly as test statistics for the null hypothesis of independence. Under the null hypothesis of independence, the sampling distribution of an $f$ estimator can be approximated and compared to the realized value of $f$ estimates to test the hypothesis of independence. Such tests for independence remain valid even with measurement errors in distances (see Conley and Ligon, 2002).

Parameter estimation via moment conditions

In most econometric applications, the parameters of interest can be estimated using GMM. GMM estimation with weakly spatially dependent data is straightforward, and the spatial dependence is relevant for inference and efficiency (see Conley, 1999). Consider instrumental variables (IV) estimation in the linear model with outcome $y_{si}$, regressors $x_{si}$, and instruments $z_{si}$

$$y_{si} = x_{si}\beta + u_{si}$$

and

$$Ez_{si}u_{si} = 0$$

(2)

The IV estimator is identified by the moment condition (2): that the instruments are not correlated with the error term. Since this is a moment condition with respect to the marginal distribution of the data across agents, it is valid with or without spatial dependence. The familiar solution remains:

$$\beta = \left(Ez_{si}x_{si}^{'s}\right)^{-1} Ez_{si}y_{si}.$$
approximate these expectations since a law of large numbers applies to weakly dependent spatial data. Thus, the usual IV estimator, 
$$\hat{\beta}_N = \left(\frac{1}{N} \sum_{i=1}^{N} z_{i}^\prime x_{i}^\prime\right)^{-1} \frac{1}{N} \sum_{i=1}^{N} z_{i}^\prime \psi_{i}$$
remains consistent with weak spatial dependence. It is of course feasible to construct \(\hat{\beta}_N\) without any knowledge of locations/distances, so it is trivially robust to measurement error in them. The impact of such spatial dependence is only upon inference, getting correct standard errors or testing. This logic carries over to any GMM estimator of a parameter \(\theta_0\) that is identified from a moment condition involving a (potentially nonlinear) function \(g\):

$$Eg(\psi; \theta_0) = 0.$$ 

The majority of econometric models with nonlinearity or limited dependent variables can be estimated via some choice for \(g\). Under mild regularity conditions, \(\theta_0\) can be consistently estimated by minimum distance methods using 
$$\frac{1}{N} \sum_{i=1}^{N} g(\psi_{i}; \theta)$$
to approximate \(Eg(\psi_{i}; \theta)\). A GMM estimator is the argument minimizing the criterion function, \(J_N(\theta)\), which takes the same form as with time series or independent data:

$$J_N(\theta) = \left[\frac{1}{N} \sum_{i=1}^{N} g(\psi_{i}; \theta)\right]' \Omega \left[\frac{1}{N} \sum_{i=1}^{N} g(\psi_{i}; \theta)\right],$$

where \(\Omega\) is some positive definite matrix. Just as for the time series case (Hansen, 1982), an efficient GMM estimator can be obtained by taking \(\Omega\) to be a consistent estimator of the limiting variance-covariance matrix of 
$$\frac{1}{\sqrt{N}} \sum_{i=1}^{N} g(\psi_{i}; \theta_0)$$
whose form depends on the spatial covariance structure of the data. One such covariance matrix estimator is described in the following subsection.

**Inference**

The usual approach to inference using large sample approximations can be employed with weakly spatially dependent data. Returning to the IV model, the typical approximation for the distribution for \(\hat{\beta}_N\) is based on the expression:
\[
\sqrt{N}(\hat{\beta}_N - \beta) = \left(\frac{1}{N} \sum_{i=1}^{N} Z_{si} X_{si}' \right)^{-1} \left[ \frac{1}{\sqrt{N}} \sum_{i=1}^{N} Z_{si} u_{si} \right].
\] (3)

Under regularity conditions, the first term in the product converges to the matrix \(Ez_{si} X_{si}'\). The second term in brackets has a limiting normal distribution:

\[
\frac{1}{\sqrt{N}} \sum_{i=1}^{N} Z_{si} u_{si} \Rightarrow N(0, V)
\] (4)

where \(V\) is the limiting variance-covariance matrix of

\[
\frac{1}{\sqrt{N}} \sum_{i=1}^{N} Z_{si} u_{si}
\]

\(V\) contains terms of the form \(Ez_{si} u_{si} z_{si}' u_{si}\) and cross-covariance terms, \(Ez_{si} u_{si} z_{sj}' u_{sj}\), that will be non-zero for at least some \(i, j\) pairs. With weak dependence, the covariance between variables indexed \(i\) and \(j\) will eventually vanish as the distance between \(s_i\) and \(s_j\) grows.

In some cases, \(V\) has a nice form. For example, suppose locations were on an integer lattice, \(Z^k\); samples consist of all integer coordinates in a region (assumed to grow as \(N \rightarrow \infty\)); and variables are covariance stationary. In this case, \(V\) can be expressed as an infinite sum of a covariance function:

\[
V = \sum_{h \in \mathbb{Z}^k} \text{Cov}(z_{s+h}, z_{s+h}).
\] (5)

With integer locations on the line, this expression coincides with its analog for covariance stationary time series.
With a consistent estimate of $V$, call it $\hat{V}_N$, the approximate distribution implied by (3) and (4) can be used for inference:

$$\sqrt{N}(\hat{\beta}_N - \beta) \approx N \left( 0, \left( \frac{1}{N} \sum_{i=1}^{N} z_{s_i}' x_{s_i} \right)^{-1} \hat{V}_N \left( \frac{1}{N} \sum_{i=1}^{N} z_{s_i} x_{s_i}' \right)^{-1} \right).$$

There are of course many ways $V$ could be estimated. If it were assumed to have a parametric form, for example, by parameterizing the covariance function in (5), then consistent estimates could be obtained by GMM. Perhaps the most popular approach has been nonparametric estimation of $V$ following Conley (1996; 1999). This approach is analogous to time series heteroskedasticity and autocovariance (HAC) consistent covariance matrix estimation, and can be viewed as a smoothed periodogram spectral density estimator. (See Priestley, 1981, for a discussion of the vast literature on spectral methods in time series and some extensions to spatial processes. Spectral methods for spatial processes date back to at least the 1950s; for example, Whittle, 1954; Bartlett, 1955; Grenander and Rosenblatt, 1957; Priestley, 1964).

With the use of residuals $\hat{u}_{s_i}$ to approximate $u_{s_i}$, $V$ can be estimated as a weighted sum of cross products $z_{s_i} \hat{u}_{s_i} z_{s_j} \hat{u}_{s_j}$:

$$\hat{V}_N = \frac{1}{N} \sum_{i=1}^{N} \sum_{j=1}^{N} K_N(s_i, s_j) \cdot z_{s_i} \hat{u}_{s_i} z_{s_j} \hat{u}_{s_j}.$$

$K_N(\cdot, \cdot)$ is a kernel used to weight pairs of observations, with close observations receiving a weight near 1 and those far apart receiving weights near zero. $K_N(s_i, s_j)$ is commonly specified to be uniform kernel that is 1 if $s_i$ and $s_j$ are within a cut-off distance and zero otherwise. (This indicator function $K_N$ is not guaranteed to provide positive definite (PD) covariance matrix estimates; however, this is very rarely a problem in practice. PD estimates can be insured by an alternate choice of kernel; see Conley, 1999.) $\hat{V}_N$ will be consistent if as $N \to \infty$, $K_N(s, s + h) \to 1$ for any given displacement $h$, but slowly enough so that the variance of $\hat{V}_N$ collapses to zero.

In practice, this estimator will require a decision about the exact form of $K_N(\cdot, \cdot)$. With a uniform kernel, this is just an operational definition of which observations are near and which are far. A conservative distinction between near and far observations can be made even with multiple candidate metrics by assigning a far classification only when all metrics agree. There is no need for the data to be covariance stationary, nor is the specific sampling framework here necessary. Analogous HAC methods can be applied to weakly dependent but non-stationary data, including that generated by simultaneous
equations DGP's like those discussed in the following section 2 (see Pinkse, Slade and Brett, 2002; Kelejian and Prucha, 2007).

The main reason nonparametric estimators like \( \hat{V}_N \) are often preferred to parametric models for \( V \) is their robustness to measurement errors in locations/distances. Parametric \( V \) estimators are generally inconsistent with such errors, while \( \hat{V}_N \) remains consistent under mild conditions. \( \hat{V}_N \) can be consistent with spatially correlated and even endogenous errors; a sufficient condition is simply that they be bounded (Conley, 1999). With location/distance errors, the weight assigned to pair \( i,j \) can be altered relative to the weight \( K_N(\cdot, \cdot) \) would assign with exact locations. But \( \hat{V}_N \) remains consistent, because the altered weights will still satisfy the necessary conditions for consistency of \( \hat{V}_N \): the weight on observations at any true displacement will still converge to 1, slowly enough. Even when working with parametric models of \( V \), \( \hat{V}_N \) remains of interest since the discrepancy between it and a parametric \( V \) estimator can provide a useful joint test for the absence of location/distance errors and proper parametric specification (Conley and Molinari, 2007).

More important than \( \hat{V}_N \) remaining consistent is its robustness in practice to moderate amounts of location error. Consider the impact of introducing location error for \( \hat{V}_N \) defined with a kernel \( K_N(s_i, s_j) \) equal to 1 if \( s_i \) and \( s_j \) are within \( L_N \) units, and zero otherwise. If the magnitude of measurement error is moderate relative to \( L_N \), then the weights on most pairs of points would be unchanged if erroneously measured locations were used in place of true locations. Changes in weights occur only for those points whose true distance is near enough to the cut-off \( L_N \) that location errors result in measured and true distances being on opposite sides of \( L_N \). With moderate amounts of location error, these pairs of observations with true distance near \( L_N \) will usually not be a large portion of the sample, so \( \hat{V}_N \) will tend to be close to its value with true locations. Similar results obtain for other kernels as weights arising from moderately mismeasured locations remain close to those received with true locations (see Conley and Molinari, 2007).

2 Population simultaneous equation models

The second approach to modeling spatial data is with a simultaneous equations model, most directly interpretable as a model for a population of \( N \) agents. This approach explicitly specifies a joint model for the population, in contrast to typical models in Section 1, where the joint determination of outcomes in the population is not explicitly treated. These simultaneous equation models are directly applicable to situations where the entire population of agents is observed, like all US states or counties or even all firms in an industry. Typical applications include studies of games being played among these agents or of spillovers across agents; see, for example, Case, Hines and Rosen (1993) and Pinkse, Slade and Brett (2002).

The most common type of model is a simultaneous spatial autoregression (SAR). Its simplest formulation for an \( N \times 1 \) outcome vector \( Y_N \) is:
with scalar parameter $\rho$ and IID shocks $\varepsilon \sim N$ (typically Gaussian). The $N \times N$ matrix $W_N$ is commonly referred to as a ‘spatial weights’ matrix and assumed known. $W_N$ has zero main-diagonal elements, and its off-diagonal elements reflect some notion of interaction. Typical $W_N$ contain $(i,j)$ elements that are non-zero only if locations $i$ and $j$ are adjacent on a graph or elements inversely related to distances between locations. $W_N$ is usually row-standardized so that its rows sum to 1. The parameter space is restricted so that $(I - \rho W_N)^{-1}$ exists and the model has reduced form:

$$
\gamma_N = (I - \rho W_N)^{-1} \varepsilon_N.
$$

Thus $Y_N$ is a linear combination of the $\varepsilon \sim N$ IID shocks. Though SAR models are finite (usually) irregular lattice models, their origins date to at least the infinite regular lattice models of Whittle (1954). Textbook treatment of SARs can be found in Anselin (1988).

Typical specifications for $W_N$ imply a great deal of heterogeneity across observations. Variances will typically differ across the elements of $Y_N$ by construction unless $\rho = 0$. Unconditional heteroskedasticity is thus coupled with spatial dependence. Covariances between pairs of agents will differ in patterns that are of course determined by $W_N$ but will depend on the entire structure of this matrix and will not generally follow a simple pattern in terms of some metric. For example, with $W_N$ defined based upon a graph, covariance between agents $i$ and $j$ will not be a function of their graph distance, though it can be characterized in terms of properties of the graph (Martellosio, 2004). A given graph will ‘hard-wire’ patterns in correlations across agents. For example Wall (2004) notes, with model (6) for US states with $W_N$ based on adjacency, that Missouri and Tennessee are constrained to be the least spatially correlated states, while relative correlations between other pairs of states change depending on $\rho$. Even with a more flexible parameterization – for example, specifying the elements of $W_N$ to be flexible functions of distance, as in Pinkse, Slade and Brett (2002) – there is still a tendency for heterogeneity in the implied joint distribution to be difficult to anticipate. While this complicates their use as statistical models, as discussed below, it is in my view likely to be a desirable property in a structural model. For example, if the model’s joint distribution is to be taken seriously as capturing equilibrium outcomes for $N$ asymmetric agents playing a game, then one would expect ‘hard-wired’ heterogeneity depending on the exact structure of the game.

Though the population of agents is observed, large sample approximations taking limits as $N \to \infty$ are still potentially useful. However, the requisite limit theorems technically differ from those referenced in Section 1. Since the DGP is changing as $N$ grows, triangular array limit results are required. Consistency
and distribution results for Gaussian maximum likelihood estimators (MLEs) with spatial dependence have existed at least since Mardia and Marshall (1984). An extensive set of SAR limiting distribution results is obtained by Lee (2004a) for likelihood-based estimators under a variety of conditions upon ‘spatial weights’ matrices like $W_N$. Quite useful limit theorem results can also be found in Kelejian and Prucha (2001). Correct specification of $W_N$ is essential for these results, as SAR estimators will generally be inconsistent when there is measurement error in locations/distances used to specify this matrix (the same holds true for other parametric models of dependence structure).

A great deal of the literature has focused on computational issues involving MLEs. Non-trivial $W_N$ matrices make computation of normalizing constants challenging. Substantial progress has been made in techniques for computing MLEs by exploiting sparseness or specific structure of ‘spatial weights’ matrices and re-parameterization to facilitate computation (see Pace and Barry, 1997; Barry and Pace, 1999; LeSage and Pace, 2007). These numerical techniques allow likelihood-based inference for even very large data-sets in certain applications or specifications. It is also feasible, of course, to estimate SAR parameters without computing MLEs, by using only a subset of the implications of the model to obtain method of moments estimates (see Kelejian and Prucha, 1999, and Lee, 2007, and subsequent work by these authors). This literature has been successful in addressing most computational issues with SAR models.

The key remaining difficulties in using SAR models are in terms of model specification and interpretation. Even for the simplest SAR model (6), it is hard to characterize implications of different $\rho$ without explicitly calculating their implied joint distributions. The parameter $\rho$ is not a simple correlation coefficient; in general it is not comparable across different specifications for $W_N$. In my experience, explicit calculations of descriptive measures of the implied joint distributions for many different $\rho$ are required to understand whether varying this parameter will trace out a useful path through the space of joint distributions.

Unless one has access to virtually complete data on a population, SAR models are very difficult to properly specify as structural models. To take an optimistic case, suppose model (6) with Gaussian $\epsilon$ applied to a population of $N$ agents, but a subset of agents were sampled. The likelihood of such a sample is well-defined, and in principle its form could be found by integrating out all the unobserved variables. But this calculation requires the exact form of $W_N$, which depends on all the unobserved agents, a full structure which will rarely be observed if only a small fraction of the agents are sampled. Proper specification of $W_N$ is perhaps feasible only if the vast majority of the population is sampled – for example, if only a few states or counties are missing.

Even with complete data on a population, SARs are difficult to specify because they are inherently fragile. Changing a single element of $W_N$ will in general influence the entire joint distribution of $Y$ and it is difficult to intuitively understand the impact of a given change in $W_N$. Increasing flexibility by parameterizing $W_N$ by taking its elements to be a series expansion in distance(s), as in Pinkse, Slade and Brett (2002), is of limited help. There remains only an indirect link between the series expansion and the implied joint distribution. It is hard to see how much additional flexibility in, for example, allowed covariance structure is gained by adding another term in the expansion.

I think these difficulties should be considered a consequence of modelling a large-dimensional system of structural simultaneous equations rather than SAR-specific problems. It seems likely to be difficult to
anticipate changes in equilibrium outcomes resulting from changes in individual agents’ decision rules or best-response functions in any modelling framework. In my view, SARs remain a useful first step towards the goal of constructing good large-dimensional structural simultaneous equation models. Of course SAR models need not be intended as structural models; they can be viewed, for instance, as tools to incorporate spatial dependence into forecasting models. A mis-specified but parsimonious model might still forecast well. However, the cumbersome relation between specification of ‘spatial weights’ and the implied joint distribution makes it hard to fashion parsimonious SAR models. This seems ample reason to avoid their use in forecasting. Directly specifying measures of dependence like covariances as a parsimonious function of distance appears far easier, even if the true DGP were an SAR.

3 Links between spatial econometrics and other areas

Work on interactions-based models has much in common with simultaneous equations-style spatial models (see Brock and Durlauf, 2001, for an extensive review). In these models, the behaviour of individuals is influenced by the characteristics and/or behaviour of others. Insofar as the relevant set of ‘others’ can be described in a spatial framework, they can be thought of as spatial econometric models. Much of this work is theory, taking the approach of specifying conditional probability measures to capture individuals’ behaviours and then deriving the implied properties of the compatible joint distribution(s). Empirical work with these models has just begun and will share many of the same challenges described above; some can even be cast directly as SARs (see Lee, 2004b).

Spatial models are potentially very useful in modelling high-dimensional vector time series. Limited degrees of freedom with typical length samples require substantial restrictions upon the DGP to make progress. The potential of spatial models to capture complicated interdependence with a small number of parameters (given auxiliary location/distance information) makes them well suited for use in characterizing a variety of restrictions upon high-dimensional vector DGPs. Good examples of the benefits of spatial approaches to this type of time series modelling are Chen and Conley (2001), Giacomini and Granger (2004), and Bester (2005a; 2005b).

Abstract

This article provides a general overview of spatial economics, which covers location theory, spatial competition, and regional and urban economics. After a brief review of the main theoretical traditions, the fundamental role of non-convexities and imperfect competition is highlighted. The main challenges faced by theoretical and empirical research are also discussed, followed by a broader discussion of the relationship between this field of research and other sub-fields of economics and other disciplines.

Article

What is spatial economics? In a nutshell, spatial economics is concerned with the allocation of (scarce) resources over space and the location of economic activity. Depending on how this definition is read, the realm of spatial economics may be either extremely broad or rather narrow. On the one hand, economic activity has to take place somewhere so that spatial economics may be concerned with anything that economics is concerned about. On the other hand, location analysis focuses mostly on one economic question, namely, location choice. This is only one decision among a large number of economic decisions.

Which boundaries for spatial economics?

In practice, we can distinguish three sets of questions for which the importance of the spatial dimension is very different. Consider first the core questions of spatial economics. For example, why are there
cities? Why do some regions prosper while others do not? Why do we observe residential segregation? Why do firms from the same industry cluster? These are intrinsically ‘spatial’ questions, that is, questions in which the spatial dimension plays a dominant role. For instance, it would be difficult to speak meaningfully about the existence and growth of cities without some explicit consideration of space. Then there is a second group of issues concerned with, inter alia, the analysis of technological spillovers, the determinants of trade flows, or even the functioning of social networks. These issues all have a spatial dimension but its importance remains to be determined. Put differently, these are ‘contested’ issues between spatial economists and other economists. Finally, there is an extremely broad range of economic questions for which the spatial dimension is likely to be less important. For example, what are the drivers of investment? How important are firing costs to explain unemployment? What are the returns to education? To answer these questions, the main role of space is to provide possibly a major source of variation for empirical research. If, for instance, different regions of a country have different education systems with, say, different age limits for compulsory schooling, this variation can be used to produce some meaningful estimates of the returns to education. Even if we take this third set of questions to lie outside spatial economics, it nonetheless remains the case that spatial economics is concerned with a broad and heterogeneous set of questions, which involve very different spatial scales (from the very small to the very big) with imprecise boundaries. It is quite possible that this breadth and heterogeneity has hindered the development of the field. This is also what makes it interesting.

The centrality of spatial frictions

To see what makes spatial economics specific, it is useful to reformulate the question about its definition in the following way. Is spatial economics only about adding a spatial dimension? In the Theory of Value, Debreu (1959) answers affirmatively. A commodity is defined by all its characteristics including its location: the same good traded in different locations must be treated as different commodities. This ‘answer’ runs into serious problems, as pointed most clearly by Starrett (1974). Consider the extreme case of homogenous space where firms face the same convex production set, and consumer preferences are the same (and locally not satiated). Transporting commodities between locations is costly. Then the spatial impossibility theorem states that, with a finite number of locations, consumers, and firms, no equilibrium involves transportation. The intuition behind this result is straightforward: since economic activities are perfectly divisible and agents have no objective reason to distinguish between locations, each location operates in autarchy to save on transport costs. To avoid this very counterfactual result (no trade), one of the assumptions behind the spatial impossibility theorem needs to be relaxed. If one takes transport costs as an unavoidable fact of life, one must assume either some non-homogeneity of space or some non-convexity of production sets.

As shown by a first branch of trade theory, it is possible to develop a framework for spatial economics that builds only on local productivity differences. This approach was pioneered by Ricardo (1821), who developed a theory of land use based on relative fertility. This approach was later generalized to consider exogenous technological differences for all types of goods. A second branch of trade theory builds instead on differences in factor endowments over space. This is the so-called Hecksher–Ohlin theory of trade. The Ricardian and Hecksher–Ohlin approaches have led to sophisticated theories of location and trade that rely on the existence of (exogenous) ‘comparative advantages’ across locations.
As shown by a large body of theoretical work in international trade, these approaches can be readily incorporated in the Arrow–Debreu framework. Although these approaches are central to the sister discipline of international trade, they played a much less important role in the development of spatial economic theory.

The pioneers

Instead, spatial economics has focused on the existence of non-convexities in the presence of transport costs. A key reason for this focus is that, although comparative advantage constitutes an appealing explanation for understanding trade flows at the world level, it provides at best a partial explanation for the location patterns of industries within countries, and it is at pains to explain major concentrations of population in large metropolitan areas. Instead, non-convexities in production or consumption seem to hold more promise for providing convincing answers to the core questions of spatial economics. The easiest way to model these non-convexities is to assume some indivisibility in a partial equilibrium framework. This type of work was pioneered by von Thünen (1826). In his model, a competitive farming sector bids for some homogenous land. The key non-convexity is that the output must be sold at a central market. With costly transport costs, farmers are willing to bid for land up to the point where the rent at a given distance from the market is equal to the gross revenue from the output minus the cost of non-land factors and minus transport costs. With a competitive land market, land goes to the highest bidder and the equilibrium typically involves concentric rings of specific land use around the central market.

To understand land use patterns in cities, Alonso (1964) developed an approach that was based on similar principles. His model again assumes a homogenous space, but replaces von Thünen's market by a central business district to which residents must commute at a cost to find work. This very parsimonious microeconomic model manages to replicate key stylized facts about land use and land prices within cities using rigorous microeconomic modelling. This is a showcase for the power of microeconomic approaches. It has spawned a large literature, which first extended the basic model in a number of directions and then went on to model multi-centric cities (for further details, see Fujita, 1989).

Independently of the ‘Thünen tradition’ that relies on an exogenous focal point for trade or production, another tradition was developed following Weber's (1909) work. Weber deals with the location problem of an indivisible and competitive plant that faces transport costs in order to ship its inputs from their sources and its outputs to their markets. With the use of essentially linear-programming techniques, the optimal location (which minimizes total transport costs) can be derived. Like Alonso's monocentric model, Weber's approach has been extended in many directions to consider, among others, more flexible production functions and the optimal location of public facilities.

Hotelling (1929) also explored the location problem faced by producers but went in a very different direction. His fundamental insight is that, because of indivisibilities, there will not be infinitely many producers at each point so that Weber's price-taking assumption is not tenable. With a small number of producers the location decision will involve more than minimizing transport costs since location also affects the competitive process. To make his point, he assumes evenly distributed consumers over a finite segment, each consuming one unit of a homogenous good. The market is served by two firms that need to choose a location and each customer patronizes the firm that minimizes the sum of the ‘mill’
price and shipping costs. At a first stage, firms choose a location and then compete in price. This
deceptively simple game has received a lot of attention. Firms face a fundamental trade-off between
central locations, which allow them to capture a larger share of the market, and more peripheral
locations, which allow them to mitigate the intensity of competition. The resolution of this trade-off
depends on the fine details of the assumptions being made (and particularly how an increase in the
distance affects the price setting power of producers). Difficulties with existence of equilibrium have
also turned out to be an important issue in this literature.

Modern approaches to spatial economic theory

Non-convexities in production lie at the heart of spatial economics. The literature discussed so far treats
them as exogenous. It was not long before the literature started to worry about what these non-
convexities were about. Nowhere was this worry stronger than in the ‘new urban economics’ literature,
where Alonso's assumption of an exogenously given central business district quickly started to look very
ad hoc. To understand central business districts or, more generally, why economic activity agglomerates,
spatial economics had to provide microeconomic foundations for (local) increasing returns. Being able
to generate increasing returns from plausible assumptions without leading to a degenerate market
structure (for example, a monopoly firm for the entire economy) was a fundamental challenge for spatial
economics. This was also true for many other fields such as industrial organization and international
trade, where increasing returns were also needed to explain key stylized facts. Spatial economists were
fortunate because they could draw on the insights provided by Adam Smith (1776) and Alfred Marshall
(1890). Although Smith's argument about the division of labour being limited by the extent of the
market pre-dates Marshall's Principles by more than a century, Marshall's ‘magic trilogy’ proved much
more influential. Following Marshall, local increasing returns could arise because of knowledge
spillovers, linkages between input suppliers and final producers, and thick local labour market
interactions. What the modern literature on the microfoundations of increasing returns has achieved is a
formalization of these insights (see Duranton and Puga, 2004, for an extensive review of this literature).
Three main mechanisms can be used to generate local increasing returns: sharing, matching, and
learning. Sharing mechanisms show how small non-convexities like small fixed costs paid by
heterogeneous producers can be spread across larger quantities as market size increases and thus yield
aggregate increasing returns. Matching mechanisms explore how larger markets might improve the
probability and quality of matching. Finally, learning mechanisms explore the benefits of local size for
the creation and diffusion of knowledge.

The second major problem faced by spatial economics is that many fundamental issues having to do
with regional and urban development call for general equilibrium modelling. For instance, some cities
can afford to specialize because they can trade with other cities. Hence, looking at one isolated city in
the tradition of Thünen and Alonso may not be enough for some purposes. Similarly, the agglomeration
of economic activity in core regions may occur because firms find larger markets there and because
consumers find cheaper and more diverse supplies. These two forces are mutually reinforcing. This is
the famous circular and cumulative causation mechanisms first emphasized by Myrdal (1957).

To model spatial economies, two main approaches came to dominate the intellectual landscape. The first
follows the work of Henderson (1974) and is know as the ‘urban systems’ approach. In this type of
framework, cities arise endogenously as the result of a trade-off between agglomeration economies and urban crowding. Both types of forces are modelled with the use of various microeconomic foundations. Cities can also trade with one another and the workers decide where to work. This strand of literature has been successful in replicating many stylized facts about urban systems, from the tendency of many cities to specialize while others diversify to their role in the innovation process.

Following the work of Krugman (1991), ‘the new economic geography’ is the second main general equilibrium approach in spatial economics. This approach puts trade costs (rather than commuting costs in urban systems) at the heart of the agglomeration–dispersion trade-off. Agglomeration in the larger market is beneficial for firms because it gives them better access to consumers. Following this, workers also want to be in the larger market in order to be able to buy goods without having to pay inter-regional trade costs. Krugman's model is based on Dixit and Stiglitz's (1977) model of product differentiation and offers a formalization of Myrdal's circular and cumulative causation. It goes beyond that because agglomeration is not always an equilibrium outcome. This is because, under agglomeration, most goods sold in the periphery need to be shipped from the core and thus prices there may be quite high. In turn, this can make it profitable for firms to locate in the periphery. When trade costs are high, the even dispersion of manufacturing is indeed the unique equilibrium in Krugman's model. On the other hand, when trade costs are low, serving the residual demand in the periphery can be achieved at a low cost and agglomeration occurs. This strand of literature has grown exponentially since 1990, culminating with Fujita, Krugman, and Venables's (1999) book.

The difficulties of spatial empirical work

What about the evidence, then? Ultimately, it is observation that should allow us to judge of the relevance of our theories. To discuss very briefly what the issues for empirical work are, it is useful to retain the partial versus general equilibrium distinction made above. A typical ‘partial equilibrium’ question that has attracted much attention over the years is that of location choices of new firms. To look at the determinants of location choice, one would like to somehow explain location choices in terms of a bunch of possible determinants. This is a difficult exercise, for several reasons. The first one has to do with the nature of the problem. Location choices are not continuous. Because they are discrete, firms decide to locate ‘somewhere’ rather than be spread continuously. Put differently, new firms choose between discrete alternatives so that one has to use discrete choice methods, which are more complex to implement than standard regression approaches. Then there is a whole range of possible determinants for location choices. This makes this type of exercise very data-intensive and particularly prone to missing variables biases. It is also likely that location decisions are made not only on the basis of the characteristics of the spatial units where firms locate, but are also influenced by what happens in neighbouring units. More generally, it is likely to be the case that different determinants of location matter at different spatial scales. To take these concerns into account, spatial econometrics has developed a set of tools. Spatial econometrics resembles standard time-series analysis in that it takes the values of the explanatory variables of the neighbouring spatial units (as well as their error term) into account. The fundamental complication is that spatial dependence can ‘go both ways’, unlike time dependence in time series. An alternative would be to ignore spatial units altogether and work directly on continuous space. Although there have been some developments in that direction (see Cressie, 1993,
When one looks at more general equilibrium issues, many of the difficulties of partial equilibrium analysis are still there while other concerns also become prominent. Take the analysis of regional disparities as an example. A first issue is that such general equilibrium problems have several endogenous variables. In our example regional population and income are likely to be simultaneously determined. To analyse this type of question, two polar approaches (and everything in between) may be adopted. A more descriptive approach consists in focusing on one particular variable, say, local income, and trying to explain its spatial variation using a range of potential factors as indicated by theoretical models. Many of these factors such as the local population are then likely to be endogenous. This requires finding appropriate instruments for such endogenous variables (since unfortunately natural experiments are even scarcer in this field than elsewhere in economics). In some cases, good instruments may not be available. In contrast to descriptive analysis, structural approaches require writing down a particular model and deriving a set of equations that can then be estimated. The main problem faced by this type of approach is that many possible models are likely to have some explanatory power. To return to our example, regional disparities in a country are likely to be caused by the factors highlighted by the urban systems approach (local external effects and so forth) and those highlighted by the new economic geography (trade costs and pecuniary externalities), as well as factor endowments, institutions, and so on. The list of plausible determinants for regional disparities is long and it is very problematic to impose strong priors regarding the validity of one specific model. For many issues in spatial economics, model selection is in fact a huge concern (see Sutton, 2000, for more). Despite these difficulties, it is fair to say that much has been learnt about cities and regions since the mid-1970s (see Rosenthal and Strange, 2004, and Head and Mayer, 2004, for recent reviews).

The road ahead (?)

What current challenges does spatial economics face? On the theoretical front, three main problems remain open. The first is to provide a unified general equilibrium approach to spatial economics and end the often uneasy coexistence between urban systems and the new economic geography. Despite some attempts, as of 2005 there is no such unified framework, and providing one will be difficult. The main obstacles are about modelling. General equilibrium models of spatial economics entail making detailed assumptions about the spatial structure, the production structure, and the mobility of people, goods and ideas, all this under increasing returns. In such cases, nonlinearities occur everywhere and analytical solutions are the exception rather than the rule. Despite this, a general but tractable model of cities and regions is probably worth fighting for. A second key challenge regards the microfoundations of trade costs. Trade costs play a fundamental role in many models but their microeconomic foundations have received only scant attention. This will probably involve looking beyond transport costs and open the black box of the multiplicity of transactions costs associated with trade between different parties. A third major challenge regards the development of a ‘theory of proximity’ (for lack of a better name). Such theory would provide some answers as to why direct interactions between economic agents matter and how. Non-market interactions will no doubt loom large in any theory of proximity.

On the empirical front, a first key challenge is to develop new tools for spatial analysis. With very detailed data becoming available, new tools are needed. Ideally, all the data work should be done in continuous space to avoid border biases and arbitrary spatial units. We are still a long way from being...
able to do so. The second main challenge for empirical work is of a very different nature. Applied work has over the years managed to produce a reasonable set of estimates regarding a range of issues such as the intensity of local externalities or the determinants of urban growth, among others. No doubt, further progress is necessary and will occur but the main challenge is now to understand the mechanisms behind the elasticities or the decompositions that have been produced. For instance, the elasticity of local productivity to the density of economic activity is now well circumscribed between two and five per cent. We ignore nearly everything about the relative importance of the possible mechanisms behind such numbers. Finally, being able to distinguish between theories – for instance, between factor endowments, urban systems and new geography to explain regional patterns of economic activity – is also a fundamental task where research has barely begun to make progress.

To conclude, one may want to raise the issue of the position of this field within economics and its relationship with other areas of investigation. It is fair to say that, with the advent of Alonso’s modern urban economics and that of strategic models of location, spatial economics traded its breadth of knowledge against some depth on much smaller subset of questions. Since the mid-1970s, spatial economics has managed to broaden again its focus by remaining open to outside influences. For instance, the new economic geography finds its roots in international trade theory, while much modern empirical work is heavily influenced by modern applied labour economics and industrial organization. For spatial economics, there is scope for further expansion. Over the years, housing and real estate economics have become fairly detached from the rest of spatial economics and the time may be ripe for new encounters and new cross-fertilizations. A similar statement also holds for local public economics. Finally, outside economics, the part of geography that deals with economic issues, ‘economic geography’, has a focus that considerably overlaps with spatial economics. The relationship between the two disciplines has been fraught with difficulties. On the one hand many geographers react very negatively to the renewed interest by economists in spatial issues. On the other hand, economists tend to ignore the work done by economic geographers. Despite these difficulties, geographers may learn something from the economists’ more rigorous approach while the greater breadth of geographers may offer a great source of inspiration for economists.

spatial market integration

Article

Markets aggregate demand and supply across actors distributed in space. At the international level, monetary policy, exchange rate adjustment and the distribution of the gains from trade depend fundamentally on how well prices equilibrate across countries, as vast literatures on the law of one price and purchasing power parity emphasize (Froot and Rogoff, 1995; Anderson and van Wincoop, 2004). At the national level, well-functioning markets ensure that macro-level economic policies (for example, with respect to exchange rates, trade, and fiscal or monetary policy) change the incentives and constraints faced by micro-level decision-makers. Macroeconomic policy commonly becomes ineffective without strong market transmission across space of the signals sent by central governments. Similarly, well-functioning markets underpin growth stimuli originating in micro-level phenomena. For example, without good access to distant markets that can absorb excess local supply, firms’ adoption of improved production technologies will tend to cause producer prices to drop, erasing the gains from technological change and thereby dampening incentives for firms to adopt new technologies that can stimulate economic growth. Poorly integrated markets thereby choke off the prospective gains from technological change. Markets also play a fundamental role in managing risk associated with demand and supply shocks in that well-integrated markets facilitate adjustment in net export flows across space, thereby reducing price variability faced by consumers and producers. Finally, the spatial extent of markets has profound implications for antitrust policy (Stigler and Sherwin, 1985).

The micro-level realities of markets in much of the world, however, involve poor communications and transport infrastructure, limited rule of law, and restricted access to commercial finance, all of which can sharply limit the degree to which markets function as effectively as textbook models typically assume. A long-standing empirical literature documents considerable commodity price variability across space, especially in developing countries, with various empirical tests of market integration suggesting
significant and puzzling forgone arbitrage opportunities (Fackler and Goodwin, 2001). The international
trade literature similarly finds substantial and sometimes persistent deviations from the law of one price
and from purchasing power parity, even among advanced market economies (Froot and Rogoff, 1995;
Anderson and van Wincoop, 2004). These results raise important questions about the nature of spatial
market integration in actual economies.

The concept of spatial market integration

Although contemporary economics rests fundamentally upon the concept of markets, the discipline
struggles with the important and practical challenges of clearly defining a market empirically and of
establishing whether markets are efficient in allocating scarce goods and services (Barrett, 2001). Much
of the problem revolves around the concept of ‘market integration’ one employs and the empirical
evidence thereby needed to demonstrate that condition. In macroeconomics and international economics,
a common conceptualization of market integration focuses on ‘tradability’, the notion that a good is
traded between two economies or that market intermediaries are indifferent between exporting from one
nation to another and not doing so. Tradability signals the transfer of excess demand from one market to
another, as captured in actual or potential physical flows. Positive trade flows are sufficient to
demonstrate spatial market integration under the tradability standard. But prices need not be equilibrated
across markets. Spatial market integration conceptualized as tradability is therefore consistent with
Pareto-inefficient distributions.

For this reason, the primary approach one finds in the spatial market integration literature focuses
instead on the notion of competitive equilibrium and Pareto efficiency manifest in zero marginal profits
to arbitrage. At the heart of most analyses of market integration lies the Enke–Samuleson–Takayama–
Judge (ESTJ) spatial equilibrium model (Enke, 1951; Samuelson, 1952; Takayama and Judge, 1971), in
which the dispersion of prices in two locations for an otherwise identical good is bounded from above by
the cost of arbitrage between the markets when trade volumes are unrestricted and bounded from below
when trade volumes reach some ceiling value (for example, associated with a trade quota). More
precisely, in ESTJ spatial equilibrium

\[ p^0 = p^1 + \tau^{10} \text{ if } q^{10} \in (0, q^{10*}) \leq p^1 + \tau^{10} \text{ if } q^{10} = 0 \geq p^1 + \tau^{10} \text{ if } q^{10} = q^{10*} \]

where \( p^0 \) and \( p^1 \) are the prices in two spatially distinct markets, 0 and 1, respectively, \( \tau^{10} \) is the cost of
moving the good from market 1 to market 0, \( q^{10} \) is the physical volume of trade between the two
markets and \( q^{10*} \) is a maximal permitted trade volume between the two markets (for example, due to a
trade quota). These equilibrium conditions imply both firm-level profit maximization and long-run
competitive equilibrium at market level. The strict equality reflects the form of competitive equilibrium
assumed under the law of one price. If trade occurs and is unrestricted, the marginal trader earns zero
profits and prices in the two markets co-move perfectly. The theory, however, implies multiple
competitive equilibria. The first weak inequality reflects a segmented equilibrium in which no trade
Spatial market integration occurs. Prices can be uncorrelated within the price band created by the costs of inter-market arbitrage. The latter weak inequality reflects binding trade quotas that may yield positive marginal quasi-rents to arbitrage.

Note that trade is neither necessary nor sufficient for the attainment of ESTJ competitive equilibria. Hence the difference between tradability-based and efficiency-based conceptualizations of market integration. In the prevailing view, spatial market integration occurs when the ESTJ equilibrium condition holds, irrespective of whether trade occurs.

Empirical estimation methods

The empirical challenge of measuring spatial market integration arises because the ESTJ equilibrium condition involves four variables – prices, transactions costs, trade volumes and trade volume quotas – yet few studies employ more than price data. Spatial price analysis studies typically test for co-movement in time series of prices measured simultaneously at different places. But even with proper controls for autocorrelation or non-stationarity, such studies inevitably impose great structure on the nature of market relationships: for example, linear pricing, continuous unidirectional tradability, and stationary transactions costs series. Tests of the hypothesis of market efficiency thereby become indistinguishable from tests of the veracity of the assumptions that underpin model specification. Simple linear time series tests of market integration-cum-equilibrium using co-integration, error correction or Granger causality models have therefore drawn considerable criticism (Barrett, 1996; Baulch, 1997; Fackler and Goodwin, 2001).

More recent innovations use mixture distribution estimation methods in an attempt to integrate price data with transactions costs, trade volume data, or both, while relaxing some of the strong assumptions that underpin conventional time series methods of testing for market integration. Baulch’s (1997) parity bounds model (PBM) that integrates price and transactions costs series is perhaps the best known of these methods. Barrett and Li (2002) extended the PBM to incorporate trade data. These methods have their shortcomings too, however. They rely on inherently arbitrary distributional assumptions in estimation and typically ignore the time series properties of the data, not permitting analysis of the dynamics of inter-temporal adjustment to short-run deviations from long-run equilibrium and potentially important distinctions between short-run and long-run integration (Ravallion, 1986).

A fragile empirical foundation for guiding policy

Even satisfaction of the ESTJ spatial equilibrium condition does not imply welfare maximization unless the costs of commerce and the quasi-rents associated with binding trade quotas are minimized. In order for markets to fulfil the promise they offer for risk management, efficient distribution of production according to comparative advantage, clear transmission of policy signals, and maintenance of micro-level incentives to innovate, there should be neither segmented competitive equilibria nor effective trade quotas. When the costs of commerce are high or trade restrictions bind, it can be difficult to draw out clear implications for policy even from empirical analyses that take seriously the implications of ESTJ spatial equilibrium. Given limited data, in particular a paucity of data on transactions costs and trade volumes, and the intrinsic limitations of existing empirical methods, economists still have only a fragile
empirical foundation for reaching clear, strong judgements about spatial market integration as a guide for corporate or government policy.

spatial mismatch hypothesis

Yves Zenou
Edited by Steven N. Durlauf and Lawrence E. Blume

Keywords
efficiency wage model; housing market; human capital; labour market; labour productivity; minimum wage model; racial segregation; spatial mismatch hypothesis; unemployment; urban segregation

Article

First formulated by Kain (1968), the spatial mismatch hypothesis states that, residing in urban segregated areas distant from and poorly connected to major centres of employment growth, black workers face strong geographic barriers to finding and keeping well-paid jobs. In the US context, where jobs have been decentralized and blacks have stayed in the central parts of cities, the main conclusion of the spatial mismatch hypothesis is that distance to jobs is the main cause of high unemployment rates and low earnings among blacks. The spatial mismatch literature has focused on race under the presumption that (inner-city) blacks are not residing close to (suburban) jobs, either because they are discriminated against in the (suburban) housing market or because they want to live near members of their own race. Most of this literature has focused on black workers, and it is only recently that the analysis has been extended to other minority workers, especially Hispanics.

Since Kain's study, hundreds of others have been conducted trying to test the spatial mismatch hypothesis (see, in particular, the literature survey by Ihlanfeldt and Sjoquist, 1998). The usual approach is to relate a measure of labour-market outcomes, typically employment or earnings, to another measure of job access, typically some index that captures the distance between residences and centres of employment. Some control variables (typically human capital variables) are also included.

The main econometric problem with this test is that residential location is endogenous, since families are not randomly assigned residential locations but instead choose them (Ihlanfeldt, 2005). Thus, self-selection rather than distance to jobs may explain why black workers have adverse labour market outcomes. This problem has been dealt with mainly by exploiting inter-city variations in black residential centralization to estimate the effect of job access on black employment (Weinberg, 2000). Another way is to focus the analysis on youth who still reside with their parents, since residential
Spatial mismatch hypothesis: The New Palgrave Dictionary of Economics

Location is decided by parents for their children (Raphael, 1998). Given the limits of these approaches, the general conclusions for youth workers are: (a) poor job access indeed worsens labour-market outcomes, (b) black and Hispanic workers have worse access to jobs than white workers, and (c) racial differences in job access can explain between one-third and one-half of racial differences in employment. The theoretical foundations of these empirical results, however, remain unclear. If researchers do agree on the causes (housing discrimination and/or social interactions) and on the consequences of the spatial mismatch hypothesis (higher unemployment rates and lower wages for black workers), the economic mechanisms and thus the policy implications are difficult to identify.

A first theoretical view (Brueckner and Zenou, 2003) is to argue that suburban housing discrimination skews black workers towards the central business district (CBD) and thus keeps black residences remote from the suburbs. Since black workers who work in the suburban business district (SBD) have more costly commutes, few of them will accept SBD jobs, which makes the black CBD labour pool larger than the SBD pool. Under either a minimum wage or an efficiency wage model, this enlargement of the CBD pool leads to a high unemployment rate among CBD workers.

Another theory (Zenou, 2002) has proposed that distance has a negative impact on workers’ productivity. Indeed, because of the lack of good public transportation in large US metropolitan areas, especially from the central city to the suburbs, blacks have relatively low productivity at suburban jobs because they arrive late to work due to the unreliability of the mass transit system, which causes them to frequently miss transfers. If this is true, then firms may draw a red line beyond which they will not hire workers. So, if housing discrimination against blacks forces them to live far away from jobs, then firms will be reluctant to hire black workers because they have relatively lower productivity than whites.

specie-flow mechanism

Article

The ‘specie-flow mechanism’ is an analytic version of automatic, or market, adjustment of the balance of international payments. In competitive markets with specie-standard institutions, behaviour will lead to national price levels and income flows consistent with equilibrium in the international accounts, commonly interpreted in this context to mean zero trade balances.

The classic exposition of the mechanism, for the better part of two centuries all but universally accepted, at least as a first approximation, was provided by David Hume in a 1752 essay, ‘Of the Balance of Trade’. While it is appropriate to associate the essence of the model with Hume, all the ingredients of Hume's argument had long been available. There were even notable prior attempts to fit the analytic pieces into a self-contained model. Further, even if we give to Hume all the considerable credit due to his systematic, compact statement, his version is not the whole of the specie-flow mechanism; and the specie-flow mechanism is not the whole analysis of balance of payments adjustment.

Hume's presentation is a simple application of the quantity theory of money in a setting of international trade and its financing. With a pure 100 per cent reserve gold standard, and beginning with balance in the international accounts, a decrease in the money stock of country A results in a directly proportionate fall in its price level, which is also a decrease relative to the initially unaffected price levels of other countries; as country A's price level falls, consumer response, in Hume's account, will reduce A's imports and increase its exports; when the exchange rate is bid to the gold point, the export trade balance will be financed by gold inflow, which will raise prices in A and lower prices abroad until the international price differentials and net trade flows are eliminated. The line of causation runs from changes in money to changes in prices to changes in net trade flows to international movements of gold that eliminate the earlier price differentials and thereby correct the trade imbalance and stop the

shipment of gold. In equilibrium, the distribution of gold among countries (and regions within countries) yields national (and regional) price levels consistent with zero trade balances. This theory of trade equilibration links with the Ricardian theory of production specialization. In a comparative advantage model of two countries, two commodities, and labour input, country A has absolute advantages of different degrees in both goods. To have two-way trade, the wage rate of country A must be greater than that abroad, within the wage-ratio range specified by the proportions of A's productive superiority in the two goods. Gold will flow until the international wage ratio yields domestic prices that equate total import and export values.

The conclusion that trade imbalances, and thus gold flows, cannot long obtain was in fundamental contrast to the mercantilistic emphasis on persistent promotion of an export balance and indefinite accumulation of gold. Still, the mercantilists decidedly associated gold inflows with export surpluses of goods and services; a good many writers had posited a direct relation between the money stock and the price level; similarly, it had been indicated that relative national price level changes would affect trade flows. However, while we should bow to such predecessors of Hume as Isaac Gervaise (1720) and Richard Cantillon (1734) and perhaps nod to Gerard de Malynes (1601) for attempts to construct adjustment models, Hume put the elements together with unmatched elegance and awareness of implication – and influence.

Hume's version was specifically a price-specie-flow mechanism, with the prices being national price levels (and exchange rates). Even as a price mechanism, the model has problems. While it is reasonable to presume that price levels will move in the same directions (even if not in the same proportions) as the huge changes in the money stock envisioned by Hume, there remain questions of the impact on import and export expenditures. Vertical demand schedules in country A for imports and in other countries for A's exports would leave the physical amounts of imports and exports unresponsive to price changes. If, following Hume, we upset the initial equilibrium by a large decrease in money and thus in prices in country A, foreign expenditure on A's goods will fall proportionately with the fall in A's prices. The import balance of A will be financed with gold outflow, resulting in a further fall in A's prices and export value and an increase in prices abroad and in A's import expenditure. The gold flow, rather than correcting the trade flow, will increase the import trade balance of A when demand elasticities are zero (or sufficiently small). The import and export demand (and supply) elasticity conditions required for price (including exchange rate) changes to be equilibrating – conditions which are empirically realistic – came much later to be summarized in the ‘Marshall–Lerner condition’. Under the most unfavourable circumstances of infinite supply elasticities and initially balanced trade, all that is required for stability is that the arithmetic sum of the elasticities of foreign demand for A's exports and of A's demand for imports be greater than unity.

Aside from the nicety of specifying elasticity conditions for stability, is it appropriate to couch the model in terms of diverging national price levels or of changes in a country's import prices compared to its export prices? Suppose country A has a commodity export balance, resulting perhaps from a shift in international demands reflecting changed preferences in favour of A's goods or imposition of a tariff by A or a foreign crop failure. As gold flows in, A's expenditures expand and prices are expected to rise. Prices of A's domestic goods (which do not enter foreign trade) do rise; but prices of internationally traded goods are affected little, if at all, for the increase in A's demand for such goods is countered by decrease in demand for them in gold-losing countries. Consumers in A, facing the domestic–international price divergence, shift to now relatively cheapened international goods (imports and A-
exportables) from more expensive domestic goods, thus increasing import volume and value and also absorption of exportables. Producers in A shift out of international goods into domestic, thus reducing exports and expanding imports. Corresponding, but opposite, substitutions and shifts are diffused among the other countries. These respective domestic adjustments in consumption and production would continue until the gold flow ceases and the trade imbalance is corrected.

Substantial modern empirical research, however, is more supportive of Hume's changes in the terms of trade or of transitory divergences in relative prices of traded and non-traded goods than of the assumed invariant applicability of the equilibrium 'law of one price' commonly adopted in the modern 'monetary approach' to the balance of payments.

When gold flows into country A, portfolio equilibria of individuals and firms are upset, with cash balances now in excess. People try to spend away redundant balances. Expenditure rises and money income becomes larger. With greater income, demands for goods – including foreign goods – increase: at any given commodity price, quantity demanded has become larger. Import quantities and values rise. Changes in money give rise abroad to opposite portfolio adjustments and changes of income, thereby decreasing A's exports. In all this, there are some changes (upward in A and downward abroad) in prices of domestic goods and production factors, but the adjustment process entails income changes as well as price changes.

Some such role of changes in money income and demand schedules was noted – in different contexts and with different degrees of clarity and emphasis – by many writers in the 19th and early 20th centuries. But single-minded emphasis on income, with little or no explicit role for the money stock and prices, came only with application to balance of payments adjustment of the national income theory of J. M. Keynes. However, such application – with its regalia of marginal propensities and secondary, supplemental repercussions of multipliers – is not contingent on, or uniquely associated with, an international gold standard. Further, neglect of money in the foreign-trade multiplier analysis is a grievous omission. Equilibrium in the income model is characterized by equating of the flows of income leakages (saving, tax payments, imports) and income injections (investment, government expenditure, exports). But such equality of total leakages and injections permits a continuing trade imbalance. And a trade imbalance financed by a gold flow – or accompanied by money change generally – leads to further change in income; that is, income had not reached a genuine equilibrium.

The actual world, even with the classical gold standard in the generation prior to the Second World War, has not conformed well in institutions and processes with the construct of Hume. A world generally of irredeemable paper money and universally of demand deposits along with fractional-reserve banking and discretionary money policy – a world including the International Monetary Fund arrangement of indefinitely pegged exchange rates – has relied on selected adjustment procedures more than on automatic adjustment mechanisms. So Hume's model in its own terms is inadequate and in important empirical respects is even inappropriate. But it provided analytical coherency and expositional emphasis in an early stage of a discussion which continues to evolve.

specification problems in econometrics

Edward E. Leamer

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The theory of econometrics presumes a ‘specification’ that selects a sharp borderline between (a) assumptions that are maintained and (b) questions that the data are allowed to address. For example, one might treat the list of variables in a regression model as known with certainty but the ‘coefficients’ of these variables as uncertain. In practice, a wide and fuzzy border between the maintained assumptions and the uncertain assumptions causes great ambiguity in the inferences economists draw from their non-experimental data.

Specification problems in econometrics arise because economic theory often identifies a generally agreed upon framework (such as market determination of price and volume) but leaves up to the individual analyst the translation of the framework into a fully defined empirical model. With virtually no guidance from theory, a data analyst is expected to choose a list of relevant variables, the functional form, the separation of variables into endogenous and exogenous, the dynamics, and the error distributions. Substantial doubt about these assumptions is a characteristic of the analysis of non-experimental data and much experimental data as well. If this uncertainty is left unattended, it can cause serious doubt about the corresponding inferences.

To emphasize the distinction between the general framework and an instance of the framework on which the data analysis rests, the specific set of assumptions used to draw inferences from a data set is called a ‘specification’. The treatment of doubt about the specification is called ‘specification analysis’. The
research strategy of trying many different specifications is called a ‘specification search’.

Estimation, sensitivity analysis and simplification searches: three treatments of specification ambiguity

When an inference is suspected to depend crucially on a doubtful assumption, two kinds of actions can be taken to alleviate the consequent doubt about the inferences. Both require a list of alternative assumptions. The first approach is statistical estimation, which uses the data to select from the list of alternative assumptions and then makes suitable adjustments to the inferences to allow for doubt about the assumptions. (I am including under the heading ‘estimation’ the kind of two-valued estimation problem that economists usually call hypothesis testing.) The second approach is a sensitivity analysis that uses the alternative assumptions one at a time, thereby demonstrating either that all the alternatives lead to essentially the same inferences or that minor changes in the assumptions make major changes in the inferences. For example, a doubtful variable can simply be included in the equation (estimation), or two different equations can be estimated, one with and one without the doubtful variable (sensitivity analysis).

The borderline between the techniques of estimation and sensitivity analysis is not always clear since a specification search can be either a method of estimation of a general model or a method of studying the sensitivity of an inference to choice of model. Stepwise regression, for example, which involves the sequential deletion of ‘insignificant’ variables and insertion of ‘significant’ variables is best thought to be a method of estimation of a general model rather than a study of the sensitivity of estimates to choice of variables, since no attempt is generally made to communicate how the results change as different subsets of variables are included.

A fundamental distinction between estimation and sensitivity analysis is whether the logic is two-valued or three-valued. The logic of traditional econometric estimation is two-valued: either one takes the action or one does not. A sensitivity analysis offers a third possible conclusion: the data cannot be relied upon to make the decision.

If the data are very informative, estimation is the preferred approach. But parameter spaces can always be enlarged beyond the point where data can be helpful in distinguishing alternatives. When abbreviated parameter spaces appear to be used, there usually lurks behind the scene a much larger space of assumptions that ought to be explored. If this larger space has been explored through a pre-testing procedure and if the data are sufficiently informative in indicating that estimation is the preferred approach, then adjustments to the inferences are in order to account for the pre-testing bias and model uncertainty. If the data are not adequately informative about the parameters of the larger space, we need to have answers to the sensitivity question whether ambiguity about the best method of estimation implies consequential ambiguity about the inferences. A data analysis should therefore combine estimation with sensitivity analysis, and only those inferences that are clearly favoured by the data or are sturdy enough to withstand minor changes in the assumptions should be retained.

Estimation and sensitivity analyses are two phases of a data analysis. Simplification is a third. The intent of simplification is to find a simple model that works well for a class of decisions. A specification search can be used for simplification, as well as for estimation and sensitivity analysis. Confusion among these three kinds of searches ought to be eliminated since the rules for a search and measures of success properly depend on the intent.
These first three kinds of specification searches fall within the reach of traditional econometric theory, both frequentist and Bayesian. But neither theory of inference can deal with another reason for exploring more than one model: a data anomaly that forces the analyst to alter the model and thus to carry out an action that was wholly unanticipated and unplanned. This is not allowed within traditional theories of inference, which presume that responses to data are fully planned and completely committed before the data are observed. From a frequentist standpoint, a fully committed plan is needed to determine sampling properties. From a Bayesian perspective, subjective probabilities fully determine the responses to the data, and, if elicitation of probabilities is allowed to be determined after the data are explored, then we double count the data evidence – once to form the ‘priors’ and again to update the priors. In settings in which the theory and the method of measurement are clear, responses can be conveniently planned in advance. In practice, however, most data analysts have very low levels of commitment to whatever plans they may have formulated before reviewing the data. Even when planning is extensive, most analysts reserve the right to alter the plans if the data are judged ‘unusual’. A review of the planned responses to the data after the data are actually observed can be called criticism, the function of which is either to detect deficiencies in the original family of models that ought to be remedied by enhancements of the parameter space or to detect inaccuracies in the original approximation of prior information. When either the model or the prior information is revised, the planned responses are discarded in favour of what at the time seem to be better responses. The form that criticism should take is not clear cut. Much of what appears to be criticism is in fact a step in a process of estimation, since the enhancement of the model is completely predictable. An example of an estimation method masquerading as criticism is a t-test to determine if a specific variable should be added to the regression. In this case the response to the data is planned in advance and undergoes no revision once the data are observed. Criticism and the prospect of the revision of planned responses create a crippling dilemma for both classical and Bayesian inference. According to classical inference, the choice of procedure for analysing the data should be based entirely on sampling properties, but these are impossible to compute unless the response to every conceivable data set is planned and fully committed. A Bayesian has problems whether or not a criticism is successful. When a criticism is successful, that is to say when the family of models is enhanced or the prior distribution is altered in response to anomalies in the data, there is a severe double counting problem if estimation then proceeds as if the model and prior distribution were not data-instigated. Even if criticism is not successful, the prospect of successful criticism makes the inferences from the data weaker than conventionally reported because the commitment to the model and the prior is weaker than is admitted.

Estimation: choice of variables for linear regression

Specification problems are not limited to, but are often discussed within, the context of the linear regression model, probably because the most common problem facing analysers of economic data is doubt about the exact list of explanatory variables. The first results in this literature addressed the effect of excluding variables that belong in the equation, and including variables that do not. Let $y$ represent the dependent variable, $x$ an included explanatory variable, and $z$ a doubtful explanatory variable. If we...
assume that:

\[ E(y|x, z) = \alpha + x\beta + z\theta. \]
\[ \text{Var}(y|x) = \sigma^2, \]
\[ E(z|x) = \tau + x\gamma \]
\[ \text{Var}(z|x) = s^2 \]

where \( \alpha, \beta, \theta, \tau, \sigma^2, \) and \( s^2 \) are unknown parameters, and \( y, x, \) and \( z \) are observable vectors, then \( \beta \) can be estimated with \( z \) included in the equation:

\[ b_{.z} = \left(x'Mz\right)^{-1}\left(x'MzY\right), \]

or with \( z \) excluded:

\[ b = \left(x'x\right)^{-1}x'y, \]

where

\[ M_z = I - z\left(z'z\right)^{-1}z'. \]

The first two moments of these estimators are straightforwardly computed:

\[ E(b_{.z}) = \beta, \quad E(b) = \beta + r\theta \text{Bias}(b_{.z}) = 0 \text{Bias}(b) = r\theta \text{Var}(b_{.z}) = \sigma^2 \left(x'Mz\right)^{-1} \text{Var}(b) = \sigma^2 \left(x'x\right)^{-1}. \]
A quick algebraic calculation reveals that $\text{Var}(b_z) \geq \text{Var}(b)$. These moments form two basic results in 'specification analysis' made popular by Theil (1957): (a) if a relevant variable is excluded ($\theta \neq 0$), the estimator is biased by an amount that is the product of the coefficient of the excluded variable times the regression coefficient from the regression of the included on the excluded variable; (b) if an irrelevant variable is included ($\theta = 0$), the estimator remains unbiased, but has an inflated variance.

This bias result can be useful when the variable $z$ is unobservable and information is available on the probable values of $\theta$ and $r$, since then the bias in $b$ can be corrected. But if both $x$ and $z$ are observable, these results are not useful by themselves because they do not unambiguously select between the estimators, one doing well in terms of bias but the other doing well in terms of variance. The choice will obviously depend on information about the value of $r\theta$ since a small value of $r\theta$ implies a small value for the bias of $b$. The choice will also depend on the loss function that determines the trade-off between bias and variance.

For mathematical convenience, the loss function is usually assumed to be quadratic:

$$\ell(\theta^*, \beta) = (\beta^* - \beta)^2,$$

where $\beta^*$ is an estimator of $\beta$. The expected value of this loss function is known as the mean squared error of the estimator, which can be written as the variance plus the square of the bias:

$$\text{MSE}(b, z, \beta) - \text{MSE}(b, \beta) = r\left(\text{Var}(\theta^*_x) - \theta \theta'\right)r'.$$

where $\theta^*_x$ is the least squares estimator of $\theta$ controlling for $x$, and where the notation allows $x$ and $z$ to represent collections of variables as well as singlets. Through inspection of this formula we can derive the fundamental result in this literature. The estimator based on the restricted model is better in the mean squared error sense than the unrestricted estimator if and only if $\theta$ is small enough that $\theta^2 / \text{Var}(\theta^*_x) < 1$.
This result is also of limited use since its answer to the question ‘Which estimator is better?’ is another question, ‘How big is \( \theta \)?’ A clever suggestion is to let the data provide the answer, and to omit \( z \) if its estimated \( t \) value is less than one. Unfortunately, because the estimated \( t \) is not exactly equal to the true \( t \), this two-step procedure does not yield an estimator that guarantees a lower mean squared error than unconstrained least squares. Thus the question remains: how big is \( \theta \)? For more discussion consult Judge and Bock (1983).

Since the choice of estimator depends on what we already know about the parameter, we need to find a way to include in the analysis some explicit dependence on the prior state of knowledge. A Bayesian analysis allows the construction of estimators that make explicit use of prior information about \( \theta \). It is convenient to assume that the information about \( \theta \) takes the form of a preliminary data set in which the estimate of \( \theta \) is zero (or some other number, if you prefer). Then the Bayes estimate of \( \beta \) is a weighted average of the constrained and unconstrained estimators:

\[
\hat{\beta} = \left( v^{-1} + v'^{-1} \right)^{-1} \left( v^{-1} \beta_z + v'^{-1} \beta \right)
\]

where \( v' \) is the prior variance for \( h \), and \( v \) is the sampling variance for \( \theta \). Instinct might suggest that this compromise between the two estimators would depend on the sampling variances of \( \beta_z \) and \( \beta \), but the correct weights are inversely proportional to prior variance and the sample variance for \( \theta \).

A card-carrying Bayesian regards this to be the solution to the problem. Others will have a different reaction. What the Bayesian has done is only to enlarge the family of estimators. The two extremes are still possible since we may have \( v' = 0 \) or \( v' \to \infty \) but in addition there are the intermediate values \( v' > 0 \). Thus the Bayesian answer to the question is another question: ‘What is the value of \( v' \)?’

**Sensitivity analysis**

At this point we have to switch from the estimation mode to the sensitivity mode, since precise values of \( v' \) will be hard to come by on a purely a priori basis and since the data usually will be of little help in selecting \( v' \) with great accuracy. A sensitivity analysis can be done from a classical point of view simply by contrasting the two extreme estimates, \( \beta_z \) and \( \beta \), corresponding to the extreme values of \( v' \). A Bayesian approach allows a much richer set of sensitivity studies. A mathematically convenient analysis begins with a hypothetical value for \( v' \), say \( \nu_0 \), which is selected to represent as accurately as possible the prior information that may be available. A neighbourhood around this point is selected to reflect the accuracy with which \( \nu_0 \) can be chosen. For example, \( v' \) might be restricted to lie in the interval

\[
\nu_0/(1 + \epsilon) < v' < \nu_0(1 + \epsilon),
\]
where $c$ measures the accuracy of $V_0$. The corresponding interval of Bayes's estimates $b_b$ is

$$1 / \left( \frac{1}{V_0 (1 + c)} + v \right) < (b - b_z) / v(b - b_z) < (1 + c) / \left( \frac{1}{V_0} + v(1 + c) \right),$$

where it is assumed that $(b - b_z) > 0$. If this interval is large for small values of $c$, then the estimate is very sensitive to the definition of the prior information. For example, suppose that interest focuses on the sign of $\beta$. Issues of standard errors aside, if $b_z$ and $b$ are the same sign, then the inference can be said to be sturdy since no value of $c$ can change the sign of the estimate $b_b$. But if $b > 0 > b_z$, then the values of $c$ in excess of the following will cause the interval of estimates to overlap the origin:

$$c^* = \max \left[ u - 1, u^{-1} - 1 \right],$$

where $u = - \left( \frac{v}{V_0} \right) (b / b_z)$. Thus if $u$ is close to one, the inference is fragile. This occurs if differences in the absolute size of the two estimates are offset by differences in the variances applicable to the coefficient of the doubtful variable. Measures like these can be found in Leamer (1978; 1982; 1983b).

**Robustness**

When a set of acceptable assumptions does not map into a specific decision, the inference is said to be fragile. A decision can then sensibly be based on a minimax criterion that selects a ‘robust’ procedure that works well regardless of the assumption. The literature on ‘robustness’ such as that reviewed by Krasker, Kuh and Welsch (1983) has concentrated on issues relating to the choice of sampling distribution, but could be extended to choice of prior distribution.

**Simplification, proxy selection and data selection**

A specification search involving the estimation of many different models can be a method of estimation or a method of sensitivity analysis. Simplification searches are also common, the goal of which is to find a simple quantitative facsimile that can be used as a decision-making tool. For example, a model with a high $R^2$ can be expected to provide accurate forecasts in a stable environment, whether or not the
coefficients can be given a causal interpretation. In particular, if two explanatory variables are highly correlated, then one can be excluded from the equation without greatly reducing the overall fit since the included variable will take over the role of the excluded variable. No causal significance necessarily attaches to the coefficient of the retained variable.

A specification search can also be used to select the best from a set of alternative proxy variables, or to select a data subset. These problems can be dealt with by enlarging the parameter space to allow for multiple proxy variables or unusual data points. Once the space is properly enlarged, the problems that remain are exactly the same as the problems encountered when the parameters are coefficients in a linear regression, namely estimation and sensitivity analysis.

### Data-instigated models

The subjects of estimation, sensitivity analysis and simplification deal with concerns that arise during the planning phase of a statistical analysis when alternative responses to hypothetical data-sets are under consideration. A distinctly different kind of specification search occurs when anomalies in the actual data suggest a revision in a planned response, for example, the inclusion of a variable that was not originally identified. This is implicitly disallowed by formal statistical theories that presuppose the existence of a response to the data that is planned and fully committed. I like to refer to a search for anomalies as ‘Sherlock Holmes inference’, since, when asked who might have committed the crime, Holmes replied, ‘No data yet … It is a capital mistake to theorize before you have all the evidence. It biases the judgements.’ This contrasts with the typical advice of theoretical econometricians: ‘No theory yet. It is a capital mistake to look at the data before you have identified all the theories.’ Holmes is properly concerned that an excessive degree of theorizing will make it psychologically difficult to see anomalies in the data that might, if recognized, point sharply to a theory that was not originally identified. On the other hand, the econometrician is worried that data evidence may be double counted, once in the Holmesian mode to instigate models that seem favoured by the data and again in the estimation mode to select the instigated models over original models. Holmes is properly unconcerned about the double counting problem, since he has the ultimate extra bit of data: the confession. We do not have the luxury of running additional experiments and the closest that we can come to the Holmesian procedure is to set aside a part of the data set in hopes of squeezing a confession after we have finished identifying a set of models with a Holmesian analysis of the first part of the data. Unfortunately, our data-sets never do confess, and the ambiguity of the inferences that is clearly present after the Holmesian phase lingers on with very little attenuation after the estimation phase. Thus we are forced to find a solution to the Holmesian conundrum of how properly to characterize the data evidence when models are instigated by the data, that is to say, how to avoid the double counting problem. Clearly, what is required is some kind of penalty that discourages but does not preclude Holmesian discoveries. Leamer (1978) proposes one penalty that rests on the assumption that Holmesian analysis mimics the solution to a formal pre-simplification problem in which models are explicitly simplified before the data are observed in order to avoid observation and processing costs that are associated with the larger model. Anomalies in the data-set can then suggest a revision of this decision. Of course, real Holmesian analysis cannot actually solve this sequential decision problem since in order to solve it one has to identify the complete structure that is simplified before observation. But we can nonetheless act as if we were solving this problem, since by doing so we can compute a very sensible kind of penalty for
Holmesian discoveries (Leamer, 1978).

Criticism

Criticism refers to a search for data anomalies that might force a revision of the model. Criticism and data-instigated models are not as frequent as they may appear. As remarked before, much of what is said to be criticism is only a step in a method of estimation, and many models that seem to be data-instigated are in fact explicitly identified in advance of the data analysis. For example, forward stepwise regression, which adds statistically significant variables to a regression equation, cannot be said to be producing data-instigated models because the set of alternative models is explicitly identified before the data analysis commences and the response to the data is fully planned in advance. Stepwise regression is thus only a method of estimation of a general model. Likewise, various diagnostic tests that lead necessarily to a particular enhancement of the model, such as a Durbin–Watson test for first-order autocorrelation and Ramsey's (1969) so-called specification error test for a special kind of nonlinearity, select but do not instigate a model.

‘Goodness of fit’ tests that do not have explicit alternatives are sometimes used to criticize a model. However, the Holmesian question is not whether the data appear to be anomalous with respect to a given model but rather whether there is a plausible alternative that makes the data appear less anomalous and, most importantly, more understandable. Goodness of fit tests have nothing to do with understanding. They measure statistical properties that may or may not be meaningful in the context in which the data are being studied. In large samples, all models have large goodness of fit statistics, and the size of the statistic is no guarantee, or even a strong suggestion, that there exists a plausible alternative model that is substantially better than the one being used.

Unexpected parameter estimates are probably the most effective criticisms of a model. A Durbin–Watson statistic that indicates a substantial amount of autocorrelation can be used legitimately to signal the existence of left-out variables in settings in which there is strong prior information that the residuals are white noise. Apart from unexpected estimates, graphical displays and the study of influential data points may stimulate thinking about the inadequacies in a model.

spectral analysis

Abstract

Spectral analysis is a statistical approach for analysing stationary time series data in which the series is decomposed into cyclical or periodic components indexed by the frequency of repetition. Spectral analysis falls within the frequency domain approach to time series analysis. The spectral density function plays the central role and it summarizes the contributions of cyclical components to the variation of a stationary time series. The spectral density at frequency zero is particularly important because of its direct link to the variance of a time series sample average, that is, the long-run variance.

Article

Spectral analysis is a statistical approach for analysing stationary time series data in which the series is decomposed into cyclical or periodic components indexed by the frequency of repetition. Spectral analysis falls within the frequency domain approach to time series analysis. This is in contrast with the time domain approach in which a time series is characterized by its correlation structure over time. While spectral analysis provides a different interpretation of a time series from time domain approaches, the two approaches are directly linked to each other.
Statistical spectral analysis tools were first developed in the middle of the 20th century in the
mathematical statistics and engineering literatures, and many of the important early contributions are discussed in the classic textbook treatment by Priestley (1981). The label ‘spectral’ has been adopted because of the close link to the physics of light. While the analogy with the physics of light is fairly useless in economics, economists recognized by the 1960s that spectral analysis is a useful empirical tool for understanding the cyclical nature of many time series, and it provides a powerful theoretical framework for developing econometric methodology: for example, the theoretical underpinnings of Granger causality (Granger, 1969) are based in spectral analysis. Since the 1960s, spectral analysis tools have become standard parts of the time series econometrics toolkit, and have influenced a broad range of areas within econometrics. A comprehensive list of references would be long but some notable examples are: band spectral regression (Engle, 1974), generalized method of moments (GMM) (Hansen, 1982), heteroskedasticity autocorrelation (HAC) covariance matrix estimation and inference (Newey and West, 1987; Andrews, 1991; Kiefer and Vogelsang, 2005), unit root testing (Phillips and Perron, 1988), cointegration (Stock and Watson, 1988; Phillips and Hansen, 1990), semiparametric methods (Robinson, 1991), structural identification of empirical macroeconomics models (Blanchard and Quah, 1989; King et al., 1991), testing for serial correlation (Hong, 1996), measures of persistence (Cochrane, 1988), measures of fit for calibrated macro models (Watson, 1993), estimation of long memory models (Geweke and Porter-Hudak, 1983).

Let $y_t$, $t=1,2, \ldots$ denote a second-order stationary time series with mean $\mu = E(y_t)$ and autocovariance function $\gamma_j = \text{cov}(y_t, y_{t-j})$. Most empirical economists find it natural to characterize relationships between random variables in terms of correlation structure, and $\gamma_j$ conveniently summarizes the statistical structure of $y_t$. Autocovariances are fundamental population moments of a time series not directly connected to any specific modelling choice. In contrast, the idea of decomposing $y_t$ into cyclical components may appear to impose restrictions on $y_t$; but an important result, the spectral representation theorem, indicates that nearly any stationary time series can be represented in terms of cyclical components. By using notation from Hamilton (1994), nearly any stationary (discrete-time) time series can be represented as

$$y_t = \mu + \int_0^\pi [\alpha(\omega) \cos(\omega t) + \delta(\omega) \sin(\omega t)] \, d\omega,$$

(1)

where $\omega$ denotes frequency and $\alpha(\omega)$ and $\delta(\omega)$ are mean zero random processes such that for any frequencies $0 < \omega_1 < \omega_2 < \omega_3 < \omega_4 < \pi$,

$$\text{cov}\left(\int_{\omega_1}^{\omega_2} \alpha(\omega) \, d\omega, \int_{\omega_3}^{\omega_4} \alpha(\omega) \, d\omega\right) = 0, \quad \text{cov}\left(\int_{\omega_1}^{\omega_2} \delta(\omega) \, d\omega, \int_{\omega_3}^{\omega_4} \delta(\omega) \, d\omega\right) = 0,$$
and for any frequencies $0 < \omega_1 < \omega_2 < \pi$ and $0 < \omega_3 < \omega_4 < \pi$,

$$\text{cov}\left(\int_{\omega_1}^{\omega_2} \alpha(\omega) \, d\omega, \int_{\omega_3}^{\omega_4} \delta(\omega) \, d\omega\right) = 0.$$ 

It is fundamental that a stationary time series can be decomposed into (random) cyclical (cosine and sine) components.

A useful way of interpreting (1) is to measure how the cyclical components contribute to the variation in $y_t$. Similar to the way in which the area under a density of a random variable determines the probability of a range of values, the area under the spectral density of $y_t$ measures the contribution to the variance of $y_t$ from the cyclical components for a range of frequencies.

Let $f(\omega)$ denote the spectral density of $y_t$ where $\omega \in [-\pi, \pi]$. It can be shown that $f(\omega) \geq 0$ and that $f(-\omega) = f(\omega)$. A fundamental property of $f(\omega)$ is that $\nu \text{var}(y_t) = \gamma_0 = \int_{-\pi}^{\pi} f(\omega) \, d\omega$ and the contribution to the variance of $y_t$ from components with frequencies $\omega \in (\omega_1, \omega_2)$ where $-\pi < \omega_1 < \omega_2 < \pi$ is given by $\int_{\omega_1}^{\omega_2} f(\omega) \, d\omega$. Therefore, loosely speaking, frequencies for which $f(\omega)$ takes on large values correspond to cyclical components that make relatively large contributions to the variation in $y_t$. For those more comfortable thinking in terms of the time domain cycle length, it is easy to convert frequency to cycle length. Suppose $f(\omega_1)$ corresponds to a peak (global or local) of $f(\omega)$; then components with frequencies close to $\omega_1$ make important contributions to the variation in $y_t$. Consider $\cos(\omega_1 t)$ and $\sin(\omega_1 t)$ and rewrite them as $\cos\left(2\pi \frac{\omega_1 t}{2\pi}\right)$ and $\sin\left(2\pi \frac{\omega_1 t}{2\pi}\right)$. Recall that the cosine and sine functions are periodic with period $2\pi$ in their argument. Therefore, $\cos\left(2\pi \frac{\omega_1 t}{2\pi}\right)$ and $\sin\left(2\pi \frac{\omega_1 t}{2\pi}\right)$ repeat whenever $\frac{\omega_1 t}{2\pi}$ is an integer. Setting $\frac{\omega_1 t}{2\pi} = 1$ indicates that the functions repeat every $t = \frac{2\pi}{\omega_1}$ time periods. The quantity $\omega_1$ is called the period corresponding to frequency $\omega_1$.

For a concrete example consider a monthly time series where $f(\omega)$ has a peak at $\omega = \frac{\pi}{6}$. Thus cycles with period $2\pi / (\pi / 6) = 12$ months (annual cycles) are important for variation of $y_t$. Suppose quarterly cycles (period is three months) are also important, then $f(\omega)$ will have a peak at $\omega = \frac{2\pi}{3}$. The highest frequency for which we can learn about $y_t$ is $\omega = \pi$ or two-period cycles because cycles that last fewer than two periods do not have data observed within the cycle. This practical limitation on the frequency is called the ‘alias effect’. The length of the sample size, $T$, also limits what can be learned about long cycles. For cycles that last $T$ time periods, that is, frequency $\omega = \frac{2\pi}{T}$, we observe data for exactly one
Spectral Analysis: The New Palgrave Dictionary of Economics

Cycle. For cycles longer than $T$ time periods, the data does contain information about those cycles, but the information is incomplete because only part of the cycle is observed. It is difficult to learn about very low-frequency components from the data, and in particular, it is difficult to learn about $f(0)$.

What does $f(\omega)$ look like? The spectral representation theorem implicitly defines the integral of $f(\omega)$ but not $f(\omega)$ itself. Because the variance of $y_t$ is the area under $f(\omega)$, there is a direct link between $f(\omega)$ and $\gamma_j$. Suppose $\sum_{j=-\infty}^{\infty} |\gamma_j| < \infty$, then the spectral density can be expressed as

$$f(\omega) = \frac{1}{2\pi} \sum_{j=-\infty}^{\infty} \cos(\omega j) \gamma_j = \frac{1}{2\pi} \left[ \gamma_0 + 2 \sum_{j=1}^{\infty} \cos(\omega j) \gamma_j \right]$$

(2)

where the last expression uses $\cos(0)=1$, $\cos(-\omega j)=\cos(\omega j)$ and $\gamma_{-j} = \gamma_j$. It straightforward to show that a converse relationship holds

$$\gamma_j = \int_{-\pi}^{\pi} f(\omega) \cos(\omega j) \, d\omega.$$

This dual relationship between $f(\omega)$ and $\gamma_j$ makes spectral analysis a powerful analytical tool beyond the direct interpretation of the spectral density in assessing importance of cyclical components.

For the class of stationary autoregressive moving average (ARMA) models $f(\omega)$ takes on a simple form. Let $L$ denote the lag operator, $Ly_t = y_{t-1}$, and define lag polynomials

$$\varphi(L) = 1 - \varphi_1 L - \varphi_2 L^2 - \ldots - \varphi_p L^p$$
and $$\theta(L) = 1 + \theta_1 L + \theta_2 L^2 + \ldots + \theta_q L^q$$. Suppose $y_t$ is a stationary ARMA($p$, $q$) process given by $\varphi(L)(\gamma_t - \mu) = \theta(L)\epsilon_t$ where $\epsilon_t$ is a mean zero uncorrelated time series (white noise process) with $\text{var}(\epsilon_t) = \sigma_\epsilon^2$. Then

$$f(\omega) = \frac{\sigma_\epsilon^2 \theta(e^{i\omega}) \theta(e^{-i\omega})}{2\pi \varphi(e^{i\omega}) \varphi(e^{-i\omega})}$$

(3)
where $i = \sqrt{-1}$. If the lag polynomials can be factored as $\varphi(L) = (1 - \lambda_1 L)(1 - \lambda_2 L)\cdots(1 - \lambda_p L)$ and $\theta(L) = (1 - \delta_1 L)(1 - \delta_2 L)\cdots(1 - \delta_q L)$, then $f(\omega)$ can be written as

$$f(\omega) = \frac{\sigma^2 \prod_{j=1}^q (1 + \delta_j^2 - 2\delta_j \cos(\omega))}{2\pi \prod_{j=1}^p (1 + \lambda_j^2 - 2\lambda_j \cos(\omega))}.$$

In the AR(1) case $f(\omega) = \frac{\sigma^2}{2\pi} \left(1 + \varphi_1^2 - 2\varphi_1 \cos(\omega)\right)^{-1}$. If $\varphi_1 > 0$ (typical for many macroeconomic and finance time series), $f(\omega)$ has a single peak at $\omega = 0$. As $\omega$ increases, $f(\omega)$ steadily declines. As $\varphi_1$ approaches one, the peak at $\omega = 0$ increases and sharpens. Thus, variation of autoregressive time series with strong persistence is driven primarily by short frequency/long cycle components. At the other extreme, when the time series is uncorrelated ($\varphi_1 = 0$), the spectral density is constant/flat for all $\omega$, so cyclical components contribute equally at all frequencies to the variation in $y_t$. An uncorrelated series is called a white noise process because of the analogue to white light which is comprised equally of all visible frequencies of light (all colours).

The special case of $f(0)$ is important for inference in time series models because the asymptotic variance of many time series estimators depends on $f(0)$. For example, consider $\bar{y} = \tau^{-1} \sum_{t=1}^{\tau} y_t$, the natural estimator of $\mu$. A simple calculation gives

$$\text{var}(\bar{y}) = \tau^{-1} \left(y_0 + 2 \sum_{j=1}^{\tau-1} \left(1 - \frac{j}{\tau}\right) y_j\right).$$

If $\sum_{j=-\infty}^{\infty} |y_j| < \infty$, then $\lim_{\tau \to \infty} \tau \text{var}(\bar{y}) = y_0 + 2 \sum_{j=1}^{\infty} y_j = 2\pi f(0)$. Therefore, the asymptotic variance of a sample average, often called the long-run variance, is proportional to the spectral density at frequency zero. Inference about the population mean would require a standard error, that is, an estimate of $f(0)$. The link between asymptotic variances and zero frequency spectral densities extends to estimation of linear regression parameters and nonlinear estimation obtained using GMM. The estimation of asymptotic variance matrices that are proportional to a zero frequency spectral density is commonly known as HAC covariance matrix estimation.

Estimates of the spectral density can be obtained either parametrically or nonparametrically. For the case of ARMA models, parametric estimators are straightforward in principle and involve replacing the lag polynomial coefficients in (3) with estimators. Although estimation methods for ARMA models are well established, there are numerical and identification issues that can complicate matters when an MA
component is included, especially in the case of vector time series. In contrast, pure AR models are easy to estimate (including the vector case) and, in principle, AR models can well approximate a stationary time series with suitable choice of the lag order. For these reasons, autoregressive spectral density estimators are the most widely used parametric estimators (see, for example, Berk, 1974; Perron and Ng, 1998; den Haan and Levin, 1997). One important practical challenge of implementing autoregressive spectral density estimators is the choice of autoregressive lag order. Advice in the literature on choice of lag order often depends on the intended use of the spectral density estimator.

Nonparametric estimators of the spectral density are appealing at the conceptual level because they do not depend on specific parameterization of the model. In principle nonparametric estimators are flexible enough to provide good estimators for a very wide range of stationary time series. In practice, though, implementation of nonparametric estimators can be a delicate matter, and large sample sizes are required for accuracy. Notwithstanding the practical challenges, nonparametric spectral density estimators are widely used in econometrics primarily because of the central role they play in HAC covariance matrix literature due to the influential contributions by Newey and West (1987) and Andrews (1991). These so-called Newey–West or Newey–West–Andrews standard errors are routinely used in practice; yet many empirical researchers are unaware of the direct link to nonparametric spectral density estimation. Nonparametric estimators are obtained by estimation of (2) using sample autocovariances

$$\hat{Y}_j = T^{-1} \sum_{t=j+1}^{T} (y_t - \bar{y})(y_{t-j} - \bar{y}).$$

The challenge is that $f(\omega)$ depends on an infinite number of autocovariances of which only a finite number can be estimated. The highest-order autocovariance that be estimated is $Y_{T-1}$, but it is estimated badly because there is only one observation, $(y_T - \bar{y})(y_1 - \bar{y})$. Plugging the $\hat{Y}_j$ into (2) gives the estimator

$$l_T(\omega) = \frac{1}{2\pi} \left[ \hat{Y}_0 + 2 \sum_{j=1}^{T-1} \cos(\omega j) \hat{Y}_j \right],$$

which is the periodogram. Like $f(\omega)$ the periodogram is non-negative. For $\omega \neq 0$ the periodogram is asymptotically unbiased but its variance does not shrink as the sample size grows, so it is not a consistent estimator. At frequency zero, the situation is even more problematic because simple algebra can used to show that $l_T(0) = 0$. This result holds as long as $\hat{Y}_j$ is computed using a quantity that sums to zero (like $y_T - \bar{y}$). Therefore, $l_T(0)$ is useless for estimating $f(0)$. Fortunately, the periodogram can be
spectral analysis: The New Palgrave Dictionary of Economics

modified to obtain better estimates of \( \hat{f}(\omega) \). Consider

\[
\hat{f}(\omega) = \frac{1}{2\pi} \left[ \hat{y}_0 + 2 \sum_{j=1}^{T-1} k\left(\frac{j}{M}\right) \cos(\omega j) \hat{y}_j \right]
\]

where \( k(x) \) is a weighting function or kernel such that \( k(0)=1, k(-x)=k(x), \int_{-\infty}^{\infty} k(x)^2 dx < \infty \) and \( |k(x)| \leq 1 \). The number \( M \) is called the bandwidth or, for some \( k(x) \) functions, the truncation lag. The kernel downweights the higher order \( \hat{y}_j \), and the bandwidth controls the speed at which downweighting occurs. A recent paper by Phillips, Sun and Jin (2006) achieves downweighting by exponentiating the kernel, for example by using \( k(j/T)^{\rho} \), where \( \rho \) controls the degree of downweighting.

While a large number of kernel functions have been proposed and analysed since the 1940s, two have become widely used in econometrics: the Bartlett kernel and the quadratic spectral (QS) or Bartlett–Priestley kernel. These kernels are in the class of kernels that guarantee \( \hat{f}(\omega) \approx 0 \). The Bartlett kernel is

\[
k(x) = \begin{cases} 
1 - |x| & \text{for } |x| \leq 1 \\
0 & \text{for } |x| > 1 
\end{cases}
\]

and it puts linearly declining weights on \( \hat{y}_j \) up to lag \( M-1 \) and weight zero on higher lags so that \( M \) plays the role of a truncation lag. Consistency of zero frequency Bartlett kernel estimators was established by Newey and West (1987) in a very general setting. The QS kernel is

\[
k(x) = \frac{25}{12 \pi^2 x^2} \left( \frac{\sin(6\pi x/5)}{6\pi x/5} - \cos(6\pi x/5) \right),
\]

and it does not truncate; weight is placed on all \( \hat{y}_j \). The weights decline in magnitude as \( j \) increases but some weights can be negative. Andrews (1991) showed in a general setting that the QS kernel minimizes the approximate mean square error of \( \hat{f}(0) \) for a particular class of kernels.

The idea of downweighting \( \hat{y}_j \) is natural and is not merely a technical trick. For any stationary time series, \( \lim_{j \to \infty} \hat{y}_j = 0 \), therefore downweighting \( \hat{y}_j \), or replacing it with zero when \( j \) is large, is similar
to replacing an unbiased, high variance estimator with a biased, small variance estimator. If \( \gamma_j \) shrinks quickly as \( j \) increases, the bias induced by downweighting is small. For \( \hat{f}(\omega) \) to be a consistent estimator \( M \to \infty \) and \( M/T \to 0 \) as \( T \to \infty \). These conditions suggest that while downweighting is required it cannot be too severe. Unfortunately, these conditions do not restrict the value of \( M \) that can be used for a given sample because, given \( T \), any value of \( M \) can be embedded in a rule that satisfies these conditions. For example, suppose \( T=100 \). Then the bandwidth rules \( M = 10\sqrt{T} \) and \( M = 0.2\sqrt{T} \) satisfy the conditions for consistency but yield very different bandwidths of \( M=100 \) and \( M=2 \).

The finite sample properties of \( \hat{f}(\omega) \) are complicated and depend on \( M \) and \( k(x) \). Formulas for the exact bias and variance of \( \hat{f}(\omega) \) have been worked out by Neave (1971) when \( \omega \neq 0 \), and by Ng and Perron (1996) for \( \omega = 0 \). Because the exact formulas are complicated, approximations are often used. The variance can be approximated by

\[
\frac{T}{M} \text{var}(\hat{f}(\omega)) \approx \begin{cases} 
V & \text{for } 0 < \omega < \pi \\
2V & \text{for } \omega = 0, \pi 
\end{cases}
\]

(4)

where \( V = f(\omega)^2 \int_{-\infty}^{\infty} k(x)^2 \, dx \). An approximation for the bias was derived by Parzen (1957) and it depends on the behaviour of \( k(x) \) around \( x=0 \). For the Bartlett and QS kernels the approximate bias formulas are

\[
-\frac{1}{M} \sum_{j=1}^{\infty} j \gamma_j \]

and

\[
-\frac{18}{125} \pi^2 \frac{1}{M^2} \sum_{j=1}^{\infty} j^2 \gamma_j
\]

respectively. Under suitable regularity conditions, an asymptotic normality result holds:

\[
\sqrt{\frac{T}{M}} \left( \hat{f}(\omega) - E(\hat{f}(\omega)) \right) \to^d N(0, V).
\]

According to these approximations, the variance is proportional to \( f(\omega)^2 \) and increases as \( M \) increases whereas the bias depends on additional nuisance parameters but decreases as \( M \) increases. These well known results are discussed at length in Priestley (1981) and are the source of commonly held intuition that says that, as \( M \) increases, bias decreases but variance increases. This intuition is usually valid but only holds for \( \hat{f}(0) \) when \( M \) is small. As \( M \) increases the relationship between bias/variance and \( M \) is more complicated, as discussed by Ng and Perron (1996). Recall that if no downweighting of \( \gamma_j \) is used, then \( \hat{f}(0) \) becomes \( l_T(0) = 0 \). Obviously, this estimator has a large bias and zero variance. As \( M \) increases, less downweighting is used and, once \( M \) is large enough, the bias/variance relationship flips
with bias increasing and variance decreasing in \( M \).

An asymptotic approximation that can capture this more complex bias/variance bandwidth relationship for \( \hat{f}(0) \) can be obtained using fixed-\( b \) asymptotics. Suppose \( \hat{f}(0) \) is embedded into a sequence of random variables under the assumption that \( b=M/T \) is a fixed constant with \( b \in (0,1) \). Neave (1970) first used this approach to derive an alternate asymptotic variance formula for \( \hat{f}(0) \). Let \( B(r) \) denote a standard Brownian bridge, that is, \( B(r)=W(r)-rW(1) \) where \( W(r) \) is a standard Wiener process, and let \( \Rightarrow \) denote weak convergence. Under suitable regularity conditions Kiefer and Vogelsang (2005) show that

\[
\hat{f}(0) \Rightarrow f(0) Q(b),
\]

for the Bartlett kernel and

\[
Q(b) = \frac{2}{b} \left( \int_0^1 B(r)^2 \, dr - \int_0^{1-b} B(r+b)B(r) \, dr \right)
\]

for the QS kernel with analogous results for \( \omega \neq 0 \) obtained by Hashimzade and Vogelsang (2007). Phillips, Sun and Jin (2006) obtain similar results for exponentiated kernels. The fixed-\( b \) asymptotic result approximates \( \hat{f}(0) \) by the random variable \( Q(b) \) which is similar to a chi-square random variable. When \( \hat{f}(0) \) is used to construct standard errors of an estimator like \( \bar{Y} \), fixed-\( b \) asymptotics provides an approximation for \( t = (\bar{Y} - \mu) \sqrt{2 \pi \hat{f}(0)} / T \) of the form \( t \Rightarrow W(1) / \sqrt{Q(b)} \). This limiting random variable is invariant to \( \hat{f}(0) \) but depends on the random variable \( Q(b) \). Because \( Q(b) \) depends on \( M \) (through \( b=M/T \)) and \( k(x) \), the fixed-\( b \) approximation captures much (but not all) of the randomness in \( \hat{f}(0) \). In contrast, the standard approach appeals to a consistency result for \( \hat{f}(0) \) to justify approximating \( \hat{f}(0) \) by \( f(0) \) and \( t \) is approximated by a \( N(0,1) \) random variable that does not depend on \( M \) or \( k(x) \). Theoretical work by Jansson (2004) and Phillips, Sun and Jin (2005) has established that the fixed-\( b \) approximation for \( t \) in the case of Gaussian data is more accurate than the standard normal approximation. Some results for the non-Gaussian case have been obtained by Goncalves and Vogelsang (2006).

The fixed-\( b \) approximation provides approximations of the bias and variance of \( \hat{f}(0) \) that are polynomials in \( b \). For the Bartlett kernel Hashimzade, Kiefer and Vogelsang (2005) show that
Spectral analysis: The New Palgrave Dictionary of Economics

\[ E(\hat{f}(0) - f(0)) \approx f(0)(-b + \frac{1}{3}b^2) \]
and

\[ \nu \varphi(\hat{f}(0)) \approx \nu \varphi(f(0)Q(b)) = f(0)2 \left( \frac{4}{3}b - \frac{7}{3}b^2 + \frac{14}{15}b^3 + \frac{2}{9}b^4 - \frac{1}{15}b^2(2b - 1)^51(b > \frac{1}{2}) \right). \]

(5)

where \(1(b > \frac{1}{2}) = 1 \) if \( b > \frac{1}{2} \) and 0 otherwise. Because \( b = \frac{M}{T} \), the bias and variance of \( \hat{f}(0) \) are approximated by high order polynomials in \( M/T \). The leading term in the variance exactly matches the standard variance formula (4). Because of the higher order terms, the fixed-\( b \) variance is more closely related to the exact variance. A plot of the variance polynomial would show that as \( M \) increases, variance is initially increasing but once \( M \) becomes large enough, variance decreases in \( M \). The fixed-\( b \) bias can be combined with the Parzen bias to give

\[ E(\hat{f}(0) - f(0)) \approx -\frac{1}{M} \sum_{j=-\infty}^{\infty} |j|Y_j + f(0) \left( -\frac{M}{T} + \frac{1}{3}\left(\frac{M}{T}\right)^2 \right). \]

(6)

This combined formula better approximates the behaviour of the exact bias. As \( M \) increases, the first term shrinks, but the second and third terms increase in magnitude. Depending on the relative magnitudes of \( \sum_{j=-\infty}^{\infty} |j|Y_j \) and \( f(0) \), bias will be decreasing in \( M \) when \( M \) is small, but as \( M \) increases further bias becomes increasing in \( M \). It is interesting to note that \( 1/M \) and \( M/T \) terms in (6) match the terms in the type of bias approximations used by Velasco and Robinson (2001) in third order Edgeworth calculations.

Bandwidth choices that minimize approximate mean square error (MSE) of \( \hat{f}(0) \) were used by Andrews (1991) and Newey and West (1994) where the bias and variance were approximated using only the leading terms in (5) and (6). A simple, closed form, solution is obtained for \( M \) that depends on \( \sum_{j=-\infty}^{\infty} |j|Y_j \) and \( f(0) \). Andrews (1991) recommends plugging in parametric estimators of these unknown quantities, whereas Newey and West (1994) recommend using nonparametric estimators. Including the higher order terms provided by (5) and (6) would allow a higher order approximation to the MSE. Given the polynomial structure of (5) and (6) with respect to \( M \), the first order condition to this optimization problem is a high order polynomial in \( M \) with coefficients that depend \( \sum_{j=-\infty}^{\infty} |j|Y_j \) and \( f(0) \). Given plug-in estimates, obtaining the value of \( M \) that minimizes the approximate MSE would
amount to numerically finding the root of a polynomial, which is not difficult. Such an analysis does not appear to exist in the econometrics literature.

While the focus of this article has been on the spectral analysis of a univariate time series, extending the concepts, notation, and estimation methods to the case of a vector of time series is straightforward. A vector of time series can be characterized by what is called the spectral density matrix. The diagonal elements of this matrix are the individual spectral densities. The off-diagonal elements are called the cross-spectral densities. The cross-spectral densities in general can be complex valued functions even when the data is real valued. The cross-spectral densities capture correlation between series and co-movements of series can be characterized in terms of cross-amplitude, phase and coherency, which are real valued functions. Many of the ideas and concepts in the original Granger (1969) causality paper were expressed in terms of cross-spectral densities.

speculative bubbles

Miguel A. Iraola and Manuel S. Santos

Abstract

We review some work on speculative bubbles on asset prices. Some empirical evidence suggests that asset prices fluctuate more than their fundamental values, and so asset pricing bubbles do occur. Empirical tests on bubbles are inconclusive. Also, most commonly used models in macroeconomics and finance can generate bubbles only under rather specialized assumptions.

Article

We maintain that a speculative bubble exists if the market price of an asset differs from its fundamental value – the expected present value of the stream of future dividends attached to the asset. In an economy with a finite sequence of trading dates, the fundamental theorem of asset pricing (see Dybvig and Ross, 1987) guarantees that the equilibrium market price of any asset equals its fundamental value. But in some economies with an infinite sequence of trading dates, this result does not hold, and speculative bubbles may arise. An investor might buy an asset at a price higher than its fundamental value if she expects to sell it later on at a higher price – Harrison and Kreps (1978) call this process ‘speculative behaviour’. In general equilibrium models, however, agents take prices as given and trade assets to transfer income across time and states. These models do not contemplate ‘speculative behaviour’ as it is usually understood. Therefore, the term ‘speculative bubble’ may seem inappropriate in some theoretical frameworks. Santos and Woodford (1997) talk broadly about ‘asset pricing bubbles’.
Speculative bubbles: The New Palgrave Dictionary of Economics

There have been famous historical examples of sudden asset price increases followed by an abrupt fall as the Dutch ‘tulipmania’ (1634–7), the ‘Mississippi bubble’ (1719–20) and the ‘South Sea bubble’ (1720). Kindleberger (1978) argues that these are examples of bubbles, whereas Garber (2000) provides market-fundamental explanations for these episodes. More recently, we have seen sharp changes in stock and housing markets. The Japanese stock and land prices experienced a sharp rise in the late 1980s and a dramatic fall in the early 1990s. During the ‘technology bubble’, the Nasdaq Composite Index rose by more than 300 per cent between August 1996 and March 2000, and then fell sharply, reaching the August 1996 level in October 2002. This pattern has been especially intense for the Internet-related sector (Ofek and Richardson, 2003).

There is a vast literature following the variance-bound tests proposed by LeRoy and Porter (1981) and Shiller (1981) that finds significant excess volatility of stock prices (see Gilles and LeRoy, 1991, for a survey). The violation of these variance bounds suggests that asset prices are not determined by fundamental values (see Flood and Hodrick, 1990, and Cochrane, 1992 for a discussion). Various tests have been proposed to detect the presence of rational bubbles in asset prices (see Camerer, 1989, and Cuthbertson, 1996, for a survey). But these tests have important shortcomings. Estimating the fundamental values of an asset is usually a complex task. Hence, rejections of the null hypothesis could be due to an incorrect specification of the fundamental value and not necessarily to the existence of a bubble (Flood and Hodrick, 1990). Even in the most famous apparent bubble episodes, some authors have provided a fundamentalist explanation (see, for example, Donaldson and Kamstra, 1996; Pástor and Veronesi, 2006). To avoid the uncertainty associated with the specification of the fundamental value, Diba and Grossman (1988a) develop a test to detect bubbles based on the investigation of the stationary properties of asset prices and dividends. The main drawback of this test, as Evans (1991) shows, is its limited power to detect periodically collapsing bubbles. Given the severe problems in establishing empirically the existence of bubbles, it is of great importance to understand the theoretical conditions under which bubbles may exist.

If all traders are rational, a backward induction argument precludes the existence of bubbles for assets traded at a finite sequence of dates. More specifically, assume that the economy ends at time $T$, and there is an asset that provides a dividend of $d_T$ at time $T$. Then the price of the asset at $T-1$ must be equal to the present value of $d_T$. By backward induction a bubble cannot exist at any point in time $t$ less that $T$. Hence, a rational bubble begins on the first date of trading. Moreover, in present value terms the size of the bubble must be constant. (This is usually called the martingale property of bubbles.) Diba and Grossman (1988b) argue that negative rational bubbles cannot exist because it would imply that investors expect that the price of the asset will become negative at a finite future date. Tirole (1982) concludes that, in an economy with a finite number of infinitely lived traders, any asset must be valued according to its market fundamental. However, Tirole (1985) shows that under certain circumstances a deterministic overlapping generations economy allows for the existence of bubbles. In infinite-horizon optimization economies, bubbles are not compatible with the transversality condition: the present value of optimal asset holdings must converge to zero. But by definition the discounted price of the asset will converge to the size of the bubble. Hence, either the asset is in zero net supply or the size of the bubble is equal to zero.

Santos and Woodford (1997) explore the existence of asset pricing bubbles in an infinite-horizon
speculative bubbles: The New Palgrave Dictionary of Economics

competitive framework, allowing for potentially incomplete markets, arbitrary borrowing limits and incomplete participation of agents (this framework considers jointly economies with a finite number of infinitely lived households and overlapping generations economies). They show that the price of any asset in positive net supply must be equal to its fundamental value, provided that the present value of aggregate wealth is finite. This latter condition is satisfied empirically (see Abel et al., 1989) since in industrialized economies the aggregate share of income that goes to capital is greater than the investment rate. Loewenstein and Willard (2000) extend these results to a finite horizon economy where assets are negotiated continuously. Some key conditions underlying the negative results of Santos and Woodford (1997) are rational expectations, symmetric information and competitive behaviour.

This analysis has important implications for monetary theory because it precludes the existence of valued fiat money as a store of wealth in a broad class of economies. Santos (2006) extends these results to an economy with liquidity constraints and proves that these constraints must be binding infinitely often for all agents in the economy. Hence, in his simple model the aggregate value of the money supply must be equal to the value of aggregate output infinitely often. This is in the spirit of the quantity theory of money. On a related matter, the absence of rational bubbles guarantees that the initial real value of public debt is equal to the present value of future net public revenues. This is a necessary condition to establish the validity of the ‘fiscal theory of the price level’ (Sims, 1994; Woodford, 1995).

The presence of bubbles has also been explored in theoretical frameworks with asymmetric information or boundedly rational agents. Allen, Morris and Postlewaite (1993) find necessary conditions for the existence of bubbles in a model with asymmetric information and a finite sequence of trading dates, and provide examples satisfying these conditions. The existence of a bubble is possible because there is private information which is not common knowledge (all agents know that all agents know, and so on, ad infinitum) that the stock price will fall. Everybody realizes that the stock is overpriced but each agent expects to sell at a higher price before the true value becomes publicly known.

Bubbles may appear in the presence of agency problems associated with short-run optimization behaviour. Allen and Gorton (1993) show that for some compensation schemes a manager may purchase a stock with some prospect of capital gains although with certainty the price will fall below its current level at some point in the future. Allen and Gale (2000) develop a model in which intermediation by the banking sector leads to an agency problem that results in asset bubbles. Investors borrow from banks to buy a risky asset, and they can default in the case of low payoffs. Hence risky assets are more attractive, and therefore investors bid up asset prices.

The behavioural finance literature (see Barberis and Thaler, 2003; Shleifer, 2000 for a survey) often assumes that some agents – called noise traders – are not fully rational. In models in which noise traders and rational agents coexist, the price of an asset can deviate from its fundamental value if rational agents are limited in their capacity to eliminate the mispricing. Shleifer (2000) describes bubbles as the interaction between a significant number of positive feedback investors (who buy securities when prices rise and sell when prices fall), and rational arbitrageurs who anticipate the bursting of bubbles. In this framework, rational arbitrageurs buy initially after a good-news event to increase the price of the asset and to stimulate the demand of the positive feedback traders; later, they undo their position before the bubble explodes. Abreu and Brunnermeier (2003) develop a model in which noise traders coexist with rational arbitrageurs who become aware of the existence of a bubble sequentially. These rational arbitrageurs would like to exit the market just before the bubble bursts, because before bursting the asset
speculative bubbles: The New Palgrave Dictionary of Economics

displays high capital gains. The bubble can explode for exogenous reasons, or endogenously when a sufficient number of arbitrageurs decide to abandon the market. In this setting some news could facilitate synchronization and, as a consequence, the bursting of the bubble. Scheinkman and Xiong (2003) develop a model in which overconfidence generates disagreements among agents regarding asset fundamentals. They show that the price of an asset can be above its fundamental value.

In summary, asset prices seem rather volatile – more than their fundamental values. By definition this implies the existence of speculative bubbles. Most empirical exercises to detect the presence of bubbles seem inconclusive. The conditions under which general equilibrium models generate bubbles seem rather fragile, since optimizing agents are unwilling to accumulate arbitrary amounts of wealth. Most recent work has explored the existence of bubbles in economies with limited rationality, asymmetric information and strategic behaviour. The main challenge for these approaches is to explain the mechanisms that lead agents to hold overpriced assets. Specifically, if agents accumulate those assets for arbitrary reasons, then these exercises will not be very enlightening.

Abstract

Michael Spence is a pioneer in the economics of information. His most famous work is on signalling. Spence's fundamental insight is that individuals can take actions that provide information to others, even though the actions themselves have no effect on productivity or on that which is desired by the buyer. This work has proven fundamental to understanding phenomena ranging from education to advertising.

Article

Andrew Michael Spence was awarded the Nobel Prize in 2001 for his work on information economics. His pioneering doctoral dissertation on signalling formed the basis of an enormous subsequent literature in the economics of information. Spence's insight is that individuals can take actions that provide information to others, even though the actions themselves have no effect on productivity or on that which is desired by the buyer. In Akerlof's classic 1970 paper on lemons ‘The Market for “Lemons”: Quality Uncertainty and the Market Mechanism’, a market characterized by adverse selection is described where goods that are put on the used market are not a random selection of all goods. Spence asked whether there were actions that could be taken that might identify one type of seller from another in a market for lemons. For example, sellers who knew that their goods were particularly high-quality might offer warranties, whereas those who were concerned about the quality of their products would refrain from doing so.

This simple insight stimulated Spence to create an entire new way of thinking about information in markets. His dissertation, which, published in 1974, became one of the most influential of the second half of the 20th century, is a work that is well ahead of its time, incorporating complexity of equilibrium concepts, game-theoretic strategies and notions of multiplicity that were not to be fleshed out until a number of years later.

Education as signalling

Spence's classic paper ‘Job Market Signaling’ (1973a) considers whether education might be used merely as a signal of worker quality rather than as a tool to enhance productivity. There are two assumptions behind it. First, information is asymmetric. Workers know their own productivity, but firms do not. Second, there is a negative correlation between the cost of acquiring education and worker productivity. That is, the individuals who are most productive in the labour market are also those who find it cheapest to acquire education. The easiest way to think of this is that the most able people can pass an exam with fewer hours of study than the least able people.

Spence shows that an equilibrium exists where high-ability types acquire more schooling than low-ability types, even though schooling has no inherent effect on productivity. The simplest analysis is shown in Figure 1.
Suppose that there are two groups, the high-ability group with costs shown by $C_I$ and a low ability group shown $C_I$. Suppose further that the employers make the assumption that individuals who have $y^*$ or more education are high-ability, whereas those with $<y^*$ education are of low ability. The low-ability group has a cost of schooling equal to $y$, whereas the high-ability group has a cost of schooling equal to $y/2$. The productivity of high-quality workers is 2, whereas the productivity of low-quality workers is 1. Spence shows that the employers’ expectations will be validated in equilibrium.

First, consider a high-ability group. If workers are deemed to be high-ability, then their output and wage is 2. If workers are deemed to be low-ability, then their output and wage is 1. Low-productivity individuals, whose cost is given by $C_I$, find it best to accept the low wage and to invest in zero units of schooling, as shown by the point at the origin in the diagram labelled group I. But because high-ability individuals have sufficiently low costs, it is profitable for them to acquire $y^*$ of schooling because $2(-y^*/2) > 1$.

The assumptions behind this model lead immediately to predictions on which signals may survive in the market. In order for a signal to be effective, it must be correlated with productivity, and also have different costs across high-ability and low-ability groups. So, for example, skill in origami is rarely suggested as a signal in labour markets because origami prowess is unlikely to be highly correlated with productivity in most jobs.

The basic insight that comes out of the signalling structure can be extended. In the job market signalling paper itself, Spence lays out an early version of the statistical discrimination argument, where male and female workers may end up with different levels of education, but the signal that a given level of education conveys in the male population may be quite different from that conveyed by the same level of education in the female population. This results from multiple equilibria in the basic signalling model, a point that Spence makes clear even in his very early analysis.

When Spence presented his Nobel lecture in 2001 (Spence, 2002), he revisited the signalling analysis and discovered that differential costs were unnecessary. Indeed, it is possible to

Spence considers how willingness to spend time acts as a signal. When a political leader attends an event at which he has no role, he signals that he values the organization that has sponsored the event. Indeed, the fact that he has no role makes the signal stronger. Another example involves pricing sporting events at less than the market-clearing level, while using time spent in a queue as an allocative mechanism. Although the wasted time creates deadweight loss, it may be that time is a better signal of interest in the sporting event than is the money that an individual is willing to spend on the tickets. To the extent that the quality of the event depends on the active participation of the fans, it may be optimal to use time in addition to money to allocate tickets to potential buyers.

In an extension ‘Time and Communication in Economic and Social Interaction’ (1973b) Spence considers how willingness to spend time acts as a signal. When a political leader attends an event at which he has no role, he signals that he values the organization that has sponsored the event. Indeed, the fact that he has no role makes the signal stronger. Another example involves pricing sporting events at less than the market-clearing level, while using time spent in a queue as an allocative mechanism. Although the wasted time creates deadweight loss, it may be that time is a better signal of interest in the sporting event than is the money that an individual is willing to spend on the tickets. To the extent that the quality of the event depends on the active participation of the fans, it may be optimal to use time in addition to money to allocate tickets to potential buyers.

Time operates differently from other costs in the traditional signalling model that applied in the job market. The high cost of time actually may preclude using education as a signal. If

the most able individuals have the most valuable use of time in other (unobservable) activities, then the correlation between cost of schooling and productivity may be reversed. The

highly productive individuals in the labour market would also be the ones with the high cost of schooling because the time that they allocate to schooling is so valuable. In this case schooling would not be an effective signal. Spence works out situations where the schooling may be an adverse signal of productivity in his 2001 Nobel address.

Spence notes in his early signalling paper that signalling creates a divergence between social and private value. While individuals may have an incentive to signal and firms may have an incentive to pay for that signal, the signal in the purest case reflects wasted resources. In the simplest version, where information has no sorting or allocative role, individuals who acquire education receive higher earnings, and those who do not receive lower earnings. The market equilibrium has higher inequality of income than one without signalling, but no higher output in the labour market. Because signalling is in itself unproductive, resources devoted to schooling are wasteful. A law that said ‘firms are precluded from paying on the

basis of education’ would be welfare enhancing.

Spence's interest in the economics of information has motivated him to consider issues that arise in product markets. Specifically, he questions whether the information that is present

in a market provides appropriate signals to producers and consumers, or whether those signals would lead to inefficient outcomes under certain circumstances. Information, he

reasons, is an important component of markets that provides incentives and alters behaviour. One of the first questions that Spence considers is whether the information that is

transmitted by the market induces firms to produce the correct quality of a good. Spence (1975) shows that, as a general matter, the market produces the wrong quality, although not

necessarily a quality that is too high or too low. Price is determined by the marginal consumer, but the rents associated with the particular quality of a good depend on the area under

the demand curve up to the quantity produced, and not just the value that the marginal consumer places on it. If the marginal consumer's valuation of higher quality is lower than the average consumer's, then the market underproduces quality. If the marginal consumer's valuation is higher than the average consumer's, then the market overproduces quality. (A related idea is explored in Spence and Owen, 1977.)

Spence's forays into quality and product choice have led him to consider more general questions relating to the interaction between information and industry structure. In ‘Cost

Reduction, Competition, and Industry Performance’ (1981a), Spence examines the trade-off between a duplication of R&D expenditures and having the competitive industry that

makes the market statically efficient. If there is only one firm, then that firm will charge a monopoly price. However, if there is a multiplicity of firms, then each firm must do its own

R&D when R&D is appropriate. The output is closer to the competitive equilibrium with more firms than with fewer. The optimal degree of competition trades off replication of

R&D expenditures against competitive outcomes. R&D in this world creates natural monopoly-like characteristics for the industry. Just as it is inefficient to duplicate electrical lines

that go from power plants to individual houses, it is also inefficient to force every firm to do its own R&D. One solution discussed is to have an R&D consortium with appropriate

subsidies. The firms in the consortium can share the information generated, and the subsidies may provide enough incentives to undertake efficient R&D activity.

A related idea is explored in the ‘The Learning Curve and Competition’ (1981b). The learning curve makes costs a function of past output. The more firms there are in an industry, the

less output that any single firm produces. Each firm learns more slowly and costs are higher when there is a large number of firms than when there is a small number of firms. But

the advantage of a large number of firms is that output is closer to the competitive level. Unfortunately, the competitive level is at a higher cost than if output were produced by one

firm alone. This trade-off is analysed and a market structure is suggested.

an American by birth, was raised in Winnipeg. The Spence family moved to Toronto from rural Canada when Mike was nine years old. Mike lived in Toronto until he went to Princeton in 1962. Having grown up in Canada, Mike acquired important skills, in particular the ability to play hockey. An excellent athlete, Spence played hockey for four years while at Princeton. He graduated summa cum laude and went on to be a Rhodes Scholar, attending Oxford University, where he studied mathematics. After getting his training at Oxford, he enrolled for a Ph.D. at Harvard. His most important mentors were Kenneth Arrow, Thomas Schelling and Richard Zeckhauser. In 1972 he completed his landmark thesis on signalling and was awarded a Ph.D. Mike taught at the Harvard's J. F. Kennedy School of Government for a couple of years. In 1973 he moved to Stanford University's economics department, but was lured back to Harvard in 1976. After a few more years doing research, Mike became the Dean of the Faculty of Arts and Sciences in 1984, and stayed in that position until he moved back to Stanford in 1990, when he took over as Dean of the Graduate School of Business. He retired from that position in 1999.

Mike's output in family life has been as high-quality as his output in research. He has three children. Graham, born in 1979, graduated from Princeton; Catherine, born in 1982, graduated from Columbia; and Marya, born in 1985, enrolled at Harvard in 2003. Michael Spence, a great friend and exceptional individual, excels at everything that he attempts. Mike's hobbies include windsurfing and motorcycle riding.

Article

Though largely ignored today, Herbert Spencer was one of the most influential scientists and philosophers of the late 19th century. He was born at Derby to a family of Dissenters, and educated at home. As a young man he worked on the London & Birmingham Railway, acquiring considerable practical knowledge of civil engineering and, through his observation of railway cuts, expertise in geology. He had no university training, but read extremely widely in an array of fields. He was an early and enthusiastic partisan of Darwin and of evolutionist ideas. In 1860 he published a prospectus for a ‘system of synthetic philosophy’, a general compendium of knowledge, which was to occupy him for much of the rest of his life. He set out to survey, from the ‘evolutionary point of view’, the fields of biology, psychology, sociology and ethics, publishing in turn First Principles (1862); Principles of Biology (2 vols, 1864–7); Principles of Sociology (3 vols, 1876–96) and Principles of Ethics (2 vols, 1879–93).
His most important work bearing on social policy was the polemical The Man Versus the State (1884). Spencer was a highly vocal champion of social Darwinism, applying the principle he termed ‘survival of the fittest’ to a broad variety of struggles, including economic competition. He conceived society by analogy to an organism, arguing that it developed according to immanent processes of growth, and hence that the positive actions and interventions of politicians were likely to be harmful or superfluous.

Spiethoff was born on 13 May 1873 in Düsseldorf and died on 4 April 1957 in Tübingen. He was a student of Adolph Wagner and research assistant to Gustav Schmoller. In 1908 he was appointed professor at Prague University and from 1918 held a chair of political economy at Bonn University until his retirement in 1939. He was the long-time editor of Schmollers Jahrbuch and (with Edgar Salin) of Hand- und Lehrbücher aus dem Gebiet der Sozialwissenschaften.

Spiethoff is best known for his path-breaking research into business cycles, as well as for his studies on methodology, culminating in his concept of ‘economic style’ (Wirtschaftsstil). In his methodological studies Spiethoff, strongly influenced by the German Historical School, sought for a solution to the antinomy of history and theory: the quest for generalizing statements about an ever-changing reality. He stressed the distinction between two methods of inquiry: pure economic theory (brought to perfection by Quesnay, Ricardo, Thünen, Menger, Jevons and Pareto) and ‘observational’ (anschauliche) or ‘economic Gestalt theory’ (in the tradition of the mercantilists, List, Sombart and Schmoller). Pure economic theory, whether or not it exclusively deals with timeless phenomena, such as those common to all forms of economic life, abstracts and isolates arbitrarily, depending on the particular purpose in view. ‘Observational theory’, on the other hand, takes its time-conditioned data from the real world and abstracts only from their historical uniqueness to isolate the regular and essential features. It thus yields an ‘explanatory description’ – that is, an effigy, or replica, of reality – ‘purged of historical accidents’ (Spiethoff, 1953b, p. 76). With its findings derived from time-conditioned data, ‘economic Gestalt theory’ is a ‘historical’ theory, the validity and applicability of its generalizations dependent on the existence and dominance of a certain ‘economic style’, representing uniformities of economic life in a certain historical epoch (for example, the ‘economic styles’ of medieval town economy, of free market capitalism or of interventionism). Spiethoff’s ultimate aim was an all-embracing general economic
theory that would include as many different ‘historical’ theories as there are ‘economic styles’, together
with the pure theory of timeless phenomena.

The foremost field of application of Spiethoff's methodological approach has always been his research
on business cycles. In his writings (see Schweitzer, 1941, for a comprehensive bibliography), starting
from the work of Clément Juglar, he emphasized three points: first, the necessity not to focus
exclusively on crisis or overproduction, but instead to visualize the phenomenon of cyclical fluctuations
as an entity; second, the strategic role to be ascribed to capital investment in the explanation of business
cycles; and third, the fact that booms and depressions should not be considered as merely an accidental
and insignificant concomitant of economic activity but must be understood as the essential form of
capitalist life itself. This basic perception made him one of the founding fathers of modern business
cycle research.

In keeping with this notion of ‘time-conditioned’ theory, Spiethoff considered his findings to be valid
only for a certain ‘economic style’, representing an age marked by the prevalence of a highly developed
capitalist economy and a free-market system. This era lasted from 1820 to 1913, with the capitalist
economy not yet fully developed in earlier periods, while increasingly becoming subject to
manipulation, planning and management in later times. Spiethoff's striving for ‘historical’ generalization
took the form of distilling a ‘typical cycle’ to give account of the recurrent and essential features of all
historically known business cycles. This ‘typical cycle’, now generally accepted, consists of three
‘cyclical stages’ (upswing, crisis and downswing), two of which may be subdivided into five ‘cyclical
phases’: the downswing comprises the recession phase with investment declining and a ‘first revival’
during which the decline in investment is halted, while the upswing includes the ‘second revival’ with
rapidly increasing investment, the boom phase characterized by rising interest rates and, finally, ‘capital
scarcity’ with declining investment paving the way for the next downturn.

With his observation of ‘cyclical periods’, during which years of either boom or depression
preponderate, Spiethoff in fact anticipated what later would become known as the Kondratieff cycle or
‘long wave’.

spline functions

Dale J. Poirier

Abstract

Spline functions are smooth piecewise functions that are popular tools in approximation theory and which arise naturally in economics.

Keywords

least squares; linear regression models; maximum likelihood estimation; New Jersey Income-Maintenance Experiment; nonparametric regression; spline functions; structural change

Article

In the everyday use of the word, a ‘spline’ is a flexible strip of material used by draftsmen in the same manner as French curves to draw a smooth curve between specified points. The mathematical spline function is similar to the draftsman's spline. It has roots in the aircraft, automobile and shipbuilding industries. Formally, a spline function is a piecewise continuous function with a specified degree of continuity imposed on its derivatives. Usually the pieces are polynomials. The abscissa values, which define the segments, are referred to as ‘knots’, and the set of knots is referred to as the ‘mesh’.

The terminology and impetus for most contemporary work on spline functions can be traced to the seminal work of I.J. Schoenberg (1946), although the basic idea can be found in the writings of E.T. Whittaker (1923) and, in Schoenberg's (1946, p. 68) own modest opinion, in the earlier work of Laplace. Today the literature on spline functions comprises an integral part of modern approximation theory. Useful monographs covering splines are De Boor (2001), Eubank (1988), Green and Silverman (1994), Poirier (1976), Schumaker (1981), and Wahba (1990). The many important contributions of Grace Wahba in the 1970s and 1980s (for example, Kimeldorf and Wahba, 1970; Wahba, 1978; 1983) united the approximation theory and the emerging statistics literatures involving spline functions.

Given a degree $d$ and a knot vector $t = [t_1, t_2, ..., t_K]^T$, where $t_1 < t_2 < ... < t_K$, the collection of polynomial splines having $s$ continuous derivatives forms a linear space. For example, the collection of
spline functions: The New Palgrave Dictionary of Economics

...linear splines with knot sequence $t$ is spanned by the functions

$$1, x, (x-t_1)^+, ..., (x-t_K)^+.$$ 

where $( \cdot )^+ = \max( \cdot , 0)$. This set is called the truncated power basis of the space. In general, the basis for a spline space of degree $d$ and smoothness $s$ is made up of monomials up to degree $d$ together with terms of the form $(x-t_k)^{s+j}$, where $1 \leq j \leq d - s$. For example, cubic splines have $d = 3$ and $s = 2$ so that the basis has elements

$$1, x, x^2, x^3, (x-t_1)^3^+, ..., (x-t_K)^3^+.$$ 

Unfortunately, these truncated power functions have poor numerical properties. For example, in linear regression problems the condition of the design matrix deteriorates rapidly as the number of knots increases. A popular alternative representation is the so-called B-spline basis (see De Boor, 2001). These functions are constructed to have support only on a few neighbouring intervals defined by the knots. The importance of spline functions in approximation theory is explained by the following best approximation property. Consider the data points $(x_i, y_i) (i = 1, 2, ..., n)$ and suppose without loss of generality that $0 < x_1 < x_2 < x_3 < ... < x_n < 1$. Given $\lambda > 0$, consider the optimization problem

$$\min_{f(\cdot)} \sum_{i=1}^{n} [y_i - f(x_i)]^2 + \lambda \int_{0}^{1} [D^m f(x)]^2 dx,$$

(1)

where $D^m$ denotes the differentiation operator of degree $m$, $f(\cdot)$ is a function defined on $[0, 1]$ such that $D^j f, j \leq m - 1$, is absolutely continuous, and $D^m f$ is in the set of measurable square integrable functions on $[0, 1]$. The first term in (1) comprises the familiar least squares measure of fit and the second term comprises a measure of the smoothness in $f(\cdot)$. The parameter $\lambda$ measures the trade-off between fit and smoothness. The solution to (1) is a polynomial smoothing spline of degree $2m - 1$ with knots at all the abscissa data points. As $\lambda \to 0$, the solution is referred to as an interpolating spline and it fits the data exactly. The choice of $\lambda$ is crucial and the method of cross-validation is a popular method for choosing $\lambda$ (see for example Craven and Wahba, 1979, or Green and Silverman, 1994, pp. 30–8). The most popular choice for $m$ is $m = 2$ yielding a natural cubic spline as the solution to (1). The
adjunctive 'natural' implies that the second derivative equals zero at the endpoints. To interpret the first term in (1) as the log-likelihood of normal linear regression model, smoothing splines can be viewed as the outcome of penalized (reflected in the second term in (1)) maximum likelihood estimation. A Bayesian interpretation of smoothing splines, provided by Kimeldorf and Wahba (1970) and expanded by Silverman (1985) and Wahba (1978; 1983), views (1) as a log-posterior density with

$$\exp \left[ -\frac{1}{2} \lambda \int [D^m f(x)]^2 \, dx \right]$$

serving as a prior density over the space of all smooth functions.

In econometrics spline functions are most often employed to parametrize a regression function. For example, splines were the functional form chosen to parametrize the treatment in the first major social experiment in economics: the New Jersey Income-Maintenance Experiment. Such *regression splines* usually include only a few knots and not necessarily at the design points. This usage may simply reflect the flexibility and good approximation properties of splines, or the attempt to capture structural change. For example, a researcher may believe the relationship between two variables $y$ and $x$ is locally a polynomial, but that at precise points in terms of $x$ the relationship ‘changes’, not in a discontinuous fashion in level but rather continuously in derivative of order $2m - 1$. Common choices for such $x$ variables are time, age, education or income, to name a few, with a nearly unlimited number of choices of candidates for $y$ variables.

In statistics spline functions are used in isotonic regression, histogram smoothing, density estimation, interpolation of distribution functions for which there is no closed-form analytic representation, and nonparametric regression. In the latter case spline smoothing corresponds approximately to smoothing by a kernel method with bandwidth depending on the local density of design points. While spline functions have proved to be valuable approximation tools, they also arise naturally in their own right in economics. Income tax functions with increasing marginal tax rates constitute a *linear spline*, as do familiar ‘kinked’ demand curves and ‘kinked’ budget sets. *Quadratic splines* serve as useful ways of generating asymmetric loss functions for use in decision theory. In distributed lag analysis, spline functions have been used as natural generalizations of Almon polynomial lags. *Periodic cubic splines* have proved useful in seasonal adjustment and in analysis of electricity load curves. Spline functions in these applications are attractive partly because, given the knots, the spline can be expressed as linear functions of unknown parameters, hence facilitating statistical estimation.

Knots play different roles in the approximation theory and structural change literatures. In the former they are largely nuisance parameters, and, apart from parsimony considerations, the number and location of the knots are of no particular importance other than that they serve to define a smooth best-fitting curve. When viewed as *change points*, however, the knots become parameters of interest. In applications involving structural change, the number of potential knots is small, and their location reflects subject-matter considerations. For example, when fitting a time trend with a regression spline, the knots may reflect the effect on the dependent variable of a specific event of interest – for example, a war. A prior distribution can then be specified over the interval bounded by the start and end of the war. Estimation of the number and location of the knots is hindered by numerical and statistic complications. The knots enter spline functions nonlinearly, and there are typically numerous local minima in the residual sum-of-squares surface. Many of these local minima correspond to knot vectors with *replicate knots*, that is, knots which pile up on top of each other, signalling that further discontinuities in the derivatives of the function are required. When knot locations are set free, knots move to areas where the
spline functions: The New Palgrave Dictionary of Economics

function is less smooth. If, in addition, the number of knots is unknown, the difficulties multiply. For example, under the null hypothesis that adjacent intervals are identical, the location of the unnecessary knot is unidentified.

Different solutions have emerged to the problem of unknown location and number of knots. Some introduce a large number of potential knots from which a subset is to be selected (for example, Halpern, 1973; Friedman and Silverman, 1989; Smith and Kohn, 1996). The problem then becomes one of variable selection where each knot corresponds to a column of a design matrix from which a ‘significant’ subset is to be determined. In some Bayesian nonparametric regression studies (for example, DiMatteo, Genovese and Kass, 2001; Smith, Wong and Kohn, 1998; Denison, Mallick and Smith, 1998), knot locations are treated as parameters and given prior distributions. Additional constraints are usually imposed to keep knots some minimum distance apart. The definitive treatment of the problem of unknown location and number of knots has not yet emerged.

Early applications of splines to multivariate problems (see Green and Silverman, 1994, ch. 7) involved tensor product spaces that of necessity depended on the choice of coordinate system. An example is the two-dimensional thin plate spline of Wahba (1990) which simulates how a thin metal plate would behave if forced through some control points. This is similar to the one-dimensional draftsman's spline. The tensor product structure of these spaces implicitly defines the domain of an unknown function to be a hyperrectangle, and this can restrict the ability to capture important features in the data that are not oriented along one of the major axes. There is a considerable literature on constructing and representing smooth, piecewise polynomial surfaces over meshes in many variables. In particular, much has been written about the case in which the underlying partition consists of triangles or high-dimensional simplicies. Because of their invariance to affine transformations, barycentric coordinates (that is, coordinates expressed as weighted combinations of the vertices of the triangle) are used to construct spline spaces over such meshes. The triogram methodology of Hansen, Kooperberg and Sardy (1998) employs continuous, piecewise linear (planar) bivariate splines defined over adaptively selected triangulations in the plane. Analogous to stepwise knot addition and deletion in a univariate spline space, the underlying triangulation is constructed adaptively by adding and deleting vertices.

spontaneous order

Peter Boettke and Jennifer Dirmeyer
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

A spontaneous order is a pattern that is recognizable with human reason but is not created by design. The market process is a spontaneous order that is created by the process of entrepreneurship and competition. A spontaneous order is self-correcting. Prices are formed through the actions of self-interested individuals in the market, buying and abstaining from buying. They make possible an extended order so complex that it is able to communicate information worldwide to producers and consumers alike so that production plans may be coordinated to consumer demands despite any change in resources, tastes or income.

Article

I am convinced that if it were the result of deliberate human design… this mechanism would have been acclaimed as one of the greatest triumphs of the human mind.
—F.A. Hayek (1945, p. 87)

A spontaneous order is a recognizable pattern that is produced by a process that is neither directed by deliberate design nor created for a specific purpose, though it may produce useful results. The economy is a spontaneous order of dizzying magnitude, with billions of individuals coordinating their plans in order to satisfy their individual desires, with no overarching direction. One of most important characteristics of a spontaneous order is that it consists of patterns that are recognizable with human reason despite the fact that they are not the result of human design. In the market, the distribution and allocation of resources according to some principle or predictable relationship, such as the fact that...
prices correspond to opportunity costs or that the price of a good equals the firm's marginal cost, is an example of such a pattern. These systematic and predictable patterns, while obviously recognizable with human reason, are not the result of any person or group actively trying to achieve this result.

The origin of money or a medium of exchange can be explained purely by self-interested actions on the part of individuals who had no intention of creating it. ‘As each economizing individual becomes increasingly more aware of his economic interest, he is led, by this interest, without any agreement, without legislative compulsion, and even without regard to the public interest, to give his commodities in exchange for other, more saleable, commodities even if he does not need them for an immediate consumption purpose’ (Menger, 1871, p. 260). As more people begin realizing the gain to be had from collecting goods that others want, a medium of exchange spontaneously arises even though no person was intending this result, only their own gain. In this example, it is easy to see that emergence of a medium of exchange was ‘of human action but not of human design’ (Hayek, 1967).

Hayek (1948, p. 78) defines the economic problem as ‘how to secure the best use of resources known to any member of society, for ends whose relative importance only these individuals know’. In the market, the spontaneous order that serves this function is the systematic elimination of ‘mutual ignorance on the part of potential market participants’ (Kirzner, 1992, p. 44). The mechanism that produces this result is the price system. The price system permits the spread and use of dispersed knowledge of time and place so the actions of individuals are coordinated. The self-interested actions of entrepreneurs searching for profit opportunities and competing for potential trading partners is what insures that prices embody the relevant information that people need in order to adjust their plans to the constantly changing circumstances of the market. Wealth creation throughout the market system is driven by the continuous discovery of new opportunities to trade, and the ceaseless desire to innovate in a manner that will either lower the costs associated with previous trades or open the opportunity for new trades to be made.

This result, while spectacular, is not an end to be actively sought. That the spontaneous order of the market process is means-driven implies that the information that is generated through this process is not available by any other means. We cannot know the utility function of even one other individual (perhaps not even our own), much less that of every individual in society. The only way to generate the allocation of resources that best provides for the varying ends of individuals is to allow the market process to function. That is why we stress that the process that generates a spontaneous order is ends-independent. Although it performs an extremely useful function in the coordination of knowledge and action, this coordination is not the result of action aimed at coordination, but the result of action aimed at gaining profit.

The fact that the generation of a spontaneous order relies not on purpose but on the elements following particular rules of behaviour is significant in that such behavioural rules need to be self-enforcing. In the market process, the behaviour that produces the order is profit-seeking, and as such is self-enforcing as long as people prefer more to less. However, there is an additional criterion that must be met for the order to emerge: ‘…people must also observe some conventional rules, that is, rules which do not simply follow from their desires and their insight into relations of cause and effect, but which are normative and tell them what they ought or ought not to do’ (Hayek 1973, p. 45). There must be an accepted and well-defined sphere over which the individual has control. The importance of clearly defined and enforced property rights cannot be overstated in terms of its impact on the emergence and maintenance of a spontaneous market order.
Features of a spontaneous order

The unique characteristics of a spontaneous order imply certain features that are in contrast to planned or designed orders. Since the order is a result of a process that depends only on the individual elements following certain rules, the complexity and scale of a spontaneous order can be much greater than that of a planned order. The limitations of planned orders are readily apparent when we first consider the necessity of channelling everything through one mind. What is amazing is the possible complexity of the spontaneous order. Leonard Reed's ‘I, Pencil’ (1958) is among the best expositions of the degree of complexity that the market process achieves, and, since he wrote of the amazingly complicated task of producing pencils, it is safe to say that the process has become even more complex when one considers such products as automobiles, airplanes and computers. (See Adam Smith, 1776, pp. 15–16, for a similar examination of the common woollen coat worn by a day labourer and the multitude of exchanges that must be coordinated to produce even this homely product. See also Milton and Rose Friedman, 1980, pp. 1–29, for a classic discussion of the implications of the ‘I, Pencil’ story for our understanding of the market order.) This ability to maintain orders of such complexity is the source of the continued productive and technological growth that has characterized modern history. The importance of this feature of the spontaneous order lies in the astounding ability not just to develop such a complex order but, more importantly, to maintain it though circumstances are changing at almost every instant.

A related feature that spontaneous orders have in common is their abstract nature. Because the order is not the result of deliberate action, the individuals within it do not need to understand or even be aware of the process at work. This feature allows for a level of abstraction that is beyond the understanding of the human mind. The evidence for this in nature is abundant. Although the frontier of scientific knowledge is constantly being pushed out, it seems that there is no limit to what we still have to learn about the workings of the universe. This is true also in the realm of social sciences, but to an even greater extent. Since there is no one mind that must understand the implications of every action, there is almost no limit to experimentation in the market. The profit incentive provides for the generation of endless variation in attempts to better satisfy consumer desires. The abstract quality of the market process is that the goal, satisfying consumers, is never clearly defined. It is the market test, the ‘systematic plan changes generated by the flow of market information released by market participation’ that directs activity toward this end, not a comprehensive plan (Kirzner, 1973, p. 10).

Finally, spontaneous orders are dependent on the structure within which the elements are acting. (An excellent discussion of this point can be found in Vernon Smith's 2002 Nobel Prize address, where he contrasts ‘ecological rationality’ with ‘constructivist rationality’; see V. Smith, 2003.) A purposeful design is dependent on the conception of the designer and his control over the elements. The specific state of a spontaneous order is determined not only by the characteristics of the elements but also by the structure that determines motivation. In the market the entrepreneurial profit incentive is a characteristic of the process. However, this characteristic produces coordination only if the easiest way to get a profit is to provide buyers and sellers with opportunities to better their trading positions. If, instead, the best way to profit is to manipulate the political process in order to confiscate others’ wealth, then the order that emerges will not be recognizable as the coordination of knowledge and action.

Conclusion
Social norms, language, money and the price system are all examples of spontaneously emerging institutions in the social realm which, while certainly products of purposive human action, are nevertheless not of direct human design. The role of the political process is to define the structure within which the filter processes and the equilibrium processes of the ‘invisible hand’ operate. Understanding this concept means admitting a limit to the social states that are achievable. It means realizing that ‘most of these social states that are romantically imagined to be possible are inconsistent with the motivational postulate of economics, with human nature as it exhibits its uniformities’ (Buchanan, 1997, p. 37). Instead the political process must be confined to creating ‘conditions in which an orderly arrangement can establish and ever renew itself’ (Hayek, 1960, p. 161). That the market process is a spontaneous order means that our span of control is limited, yes, but there is no need to despair! For recognizing the spontaneous order of the market economy as an ongoing entrepreneurial process of discoveries for mutual benefit and wealth creation also means that we can achieve states of civilization that could not be imagined were it necessary that we designed them.

Abstract

The economic analysis of professional sport proceeds from the uncertainty of outcome and competitive balance. Members of sports leagues seek to restrain economic competition and claim that they need to do so in order to make contests more attractive. In 1956 Rottenberg analysed this ‘competitive balance defence’, arguing that the reserve clause would not have an effect on the distribution of playing talent in a league, since players would migrate to teams where their economic return was highest, regardless of whether the club or the player owned the right to the revenue stream.

Article

Why study the economics of sport? In purely financial terms it is not a very important part of the economy. In 1998, out of the $8 trillion US economy, the commercial sports industry generated only $17.7 billion of revenue – a sizeable sum to be sure, but only 0.2 per cent of US GDP and one-quarter the size of the automotive repair industry ($69.6 billion) in that year (U.S. Bureau of the Census, 1999, Table 6.1). We have no field of study on the economics of car repair. We advance five reasons for special interest in sport.

First, the cultural significance of sport is huge. Either by choice or because of economic constraints, organizers have extracted only a portion of the consumer surplus generated by sporting events;

Second, professional sports as business activities are unique in that the service is (sporting) competition itself, and one supplier cannot create the product without the cooperation of his or her (sporting) rival.

Third, investing public money in building facilities to host sports teams and sporting events such as the Olympics is widely advocated by politicians and boosters, and using cost–benefit methods to evaluate
Fourth, the sports industry is also a marvellous laboratory for testing and applying economic theory: it is Frederick Winslow Taylor's fantasy, where practically every aspect of worker (player) performance is observed and most are measured.

Fifth, when properly handled, sport can be one of the most effective ways of introducing students to fundamental economic concepts.

Sport and culture

Games and sports are a universal cultural phenomenon. Many animal species engage in what humans call play, and perhaps it is the lengthy adolescence characteristic of humans which has facilitated such an astonishing range of game playing. All ancient civilizations had their sports, and athletic contests are characteristic of even the least developed societies. In most civilizations sport has been connected with religion, as was true, for example, of the ancient Olympic Games. Modern sports, however, are characterized by secular rules. They also tend to be more formalized than traditional games, encouraging the gathering of statistical records for the purposes of evaluation and comparison. Almost all of the popular modern sports were formalized somewhere between 1840 and 1900: for example, baseball (1846), soccer (1848), Australian football (1859), boxing (1865), cycling (1867), rugby union (1871), tennis (1874), American football (1874), ice hockey (1875), basketball (1891), rugby league (1895), motor sport (1895) and the modern Olympic Games (1896). Many historians have noted the coincidence between the creation of the rigid, scientific sports, and the advent of rigid industrialized societies in the United Kingdom and United States during the 19th century. The only major modern sports whose organization pre-dates this era are golf, cricket and horse racing, all of which had established rules and clubs from the mid-18th century.

The fact that almost all the sports which today dominate the world originated either in the United Kingdom or the United States also reflects Anglo-Saxon economic dominance. Soccer was spread at the end of the 19th century, when British expatriates or foreign students studying in Britain taught local elites the virtues of British culture and British games. American economic hegemony has given further impetus either to sports that were invented in Britain and taken up by Americans (such as golf and tennis) or to indigenous inventions such as basketball.

The cultural significance of sport has made most countries reluctant to see it exploited for business purposes. Even in the United States, the National Collegiate Athletic Association (NCAA) insists in retaining the myth of amateurism within the confines of the billion-dollar college sports industry. The myth of amateurism prevailed until recent years in a wide variety of international sports. Increasing commercialization is still opposed today in world soccer, and even in baseball the fans object to the idea of corporate sponsorship emblazoned on the sacred team shirt or on the bases.

This reluctance to mix business with sport explains in part how sport can attain such cultural centrality without achieving an equivalent economic status. Another reason is the difficulty involved in capturing rents. Each match in a championship is a mini-soap opera, involving high drama and the unexpected, and much of the pleasure derives from discussion among fans both before and after the event, but the protagonists have few opportunities to secure property rights over these external effects. Even the news media that pore ceaselessly over the latest sporting gossip pays little for the privilege. Another explanation may be the elastic supply of sporting contests (even if demand is frequently inelastic).
Sporting competition is generally cheap to supply. Thus, even if the fans complain bitterly about the prices they pay, only a small fraction of personal disposable income is devoted to sport. Nonetheless, sports consumption is also a luxury good, and total expenditure rises rapidly as national income increases.

The business of professional sport

The starting point for the economic analysis of professional sport is the uncertainty of outcome and competitive balance. Almost from their inception, professional sports leagues have sought to restrain economic competition in the name of creating a more attractive contest. Thus, baseball's National League, the world's first professional sports league, was created in the United States in 1876 and introduced the reserve clause, a mechanism for tying each player in perpetuity to his club in 1879. From the 1880s, the clubs in the league argued that this restraint was necessary to ensure that all the best players did not end up playing for the biggest teams. Were this to happen, they reasoned, the championship would become predictable, fans would lose interest and the competition would collapse. In economic terms, they were arguing that a non-cooperative equilibrium would lead to a less balanced distribution of results than would be selected by a planner interested in maximizing interest in the sport. Given the frequent use of this argument by sports leagues to defend antitrust challenges levelled against economic restraints in the sporting labour and product markets, it might reasonably be termed the ‘competitive balance defence’.

Economic analysis of the competitive balance defence began with Simon Rottenberg's 1956 article in the *Journal of Political Economy*. Rottenberg argued that the reserve clause would have no effect on the distribution of playing talent in a league, since players would always migrate to teams where their economic return (or marginal revenue product) was highest, regardless of whether the club or the player owned the right to the revenue stream. This is clearly an articulation of the Coase theorem, despite being published four years before Coase's ‘On the problem of social cost’. Moreover, references to empirical tests of the Coase theorem commonly present sports leagues as an outstanding example. Much of the sports literature is an elaboration of these issues. El-Hodiri and Quirk (1971) developed the first theoretical model of revenue sharing, and used this to advance the proposition that revenue sharing would not affect the distribution of talent in a league, also for Coasean reasons. Much of the early literature involved examining a sport league's objective function, which in North America typically has been considered to be characterized by profit maximization (see, for example, Jones, 1969), while Sloane (1971) drew attention to the not-for-profit structure and culture that obtained in British sports, notably football, and in the rest of the world (for a detailed comparison of the American and European sports business models see Szymanski and Zimbalist, 2005). Since the 1990s there has been renewed interest in the theoretical modelling of league structures, focusing on the North American model (see, for example, Fort and Quirk, 1995; Vrooman 1995) and the European model (Késenne, 2000; Hoehn and Szymanski, 1999). Szymanski (2003) advances a synthesis based on the contest or tournament framework, and there is a good deal of current research in this vein. Much of this analysis has been applied in the context of antitrust either in the United States or in the European Union. The courts, in line with most economists, consider leagues as cartels that impose restraints on economic competition in labour and product markets. In North America, the competitive
The balance defense has been applied in cases such as *NCAA v. Board of Regents of the University of Oklahoma*, 468 U.S. 85 (1984), which argued that collective selling of broadcast rights was necessary to maintain competitive balance. In this case, as in several others, the defense failed, not because the courts did not accept that leagues were special cases where ancillary restraints could be justified, but because the restraints were excessive given their stated aims (see, for example, Flynn and Gilbert, 2001). As a result, most labor market restraints in sports have been built into collective bargaining agreements that are exempt from antitrust, while broadcasting rights generally enjoy the exemption granted by Congress in the 1962 Sports Broadcasting Act. In Europe, where equivalent exemptions do not exist, labor market restraints akin to the reserve clause have been ruled illegal (by the European Court of Justice in the 1995 *Bosman* case), while collective selling of broadcast rights has been treated differently in EU member states, some outlawing collective selling (Italy and Spain) and others permitting it (Germany and the UK).

**Economic impact of sports teams and facilities**

Top-level professional sports teams have an immense cultural impact on their communities but very little, if any, positive economic impact. All independent empirical research concurs on this point (see, for example, Siegfried and Zimbalist, 2000). There are three principal reasons why no positive economic development effect should be expected from a new team or facility. First, most of the money spent at a facility is replacement for spending at other entertainment activities elsewhere in the metropolitan area. Second, leakages of spending at a ballpark or arena out of the local economy tend to be much greater than at other locally owned entertainment venues, thereby depressing sports expenditure multipliers. Third, public subsidies for facility construction and maintenance create a negative budgetary impact, engendering either higher taxes or lower services, thereby dragging down economic expansion. Nonetheless, the existence of externalities, public good benefits and consumer surplus (consumer demand for sporting contests is generally assumed to be inelastic) may justify some level of public support for facility construction.

**Sport as laboratory**

Sports involve forms of competitive behaviour that are readily observed and measured. Often we know the precise output and productivity of agents, and their compensation packages are frequently a matter of public record. Hence, it is not surprising that labor economists have looked to the sports field for natural experiments of theories such as incentive design, teamwork, and discrimination. Gerald Scully (1974) pioneered attempts to empirically estimate a player's marginal revenue product (MRP) in baseball, and much of the subsequent research on labor market performance has followed his innovation. He also applied his method, which involved estimating individual contributions to winning through measures of batting performance, and then the value of winning for team revenues, to compare the relationship between wages and MRPs for players from different races, thus providing a test of discrimination. Disputes over Scully's MRP methodology has kept a lively debate going in the literature (see, for example, Zimbalist, 1992). Another example of the use of sports data to test labor market theories is Ehrenberg and Bognanno
Sports, economics of: The New Palgrave Dictionary of Economics (1990), who used scores of professional golfers in different tournaments to test the incentive effects of different prize structures. Other important studies include the use of trading in baseball cards to test for discrimination on the part of fans (Nardinelli and Simon, 1990) and the effect of strikes on demand in baseball (Schmidt and Berri, 2004).

Sports in the classroom

Sports economics has become extremely popular in the classroom, often because many students find it easiest to appreciate economic reasoning in the context of an activity with which they have a certain degree of familiarity. As the discussion of the competitive balance defence suggests, using sport to teach economics can be risky given that sports are often a special case. However, using sport to study concepts such as demand or labour market incentives can be illuminating. For example, the case of spectator demand can be used to develop a number of key economic concepts. Since the marginal cost to an owner of an additional fan attending any given game is approximately zero, profit and revenue maximization at the ballpark are congruent. This implies that a profit-maximizing strategy for an owner is to set ticket prices so that the price elasticity of demand equals 1. Much of the early empirical literature, however, yielded estimates of inelastic demand at existing prices. This literature suffered from various deficiencies: the use of weighted average, rather than individual, ticket prices; the absence of important control variables; and the failure to specify the model properly. Possibly significant control variables include the probability of home team victory, the uncertainty of outcome, the quality of the visiting team and importance of the contest in league competition, the weather, the age of the stadium, the number of star players on the teams, the distribution and level of local income, and whether the game is televised. Modelling should be affected by the existence of a stadium capacity constraint, the positive dynamic (demonstration) effect of having a full or nearly full stadium on future attendance, and the simultaneity effect whereby higher attendance increases the home field advantage, which improves home team performance and increases attendance. Finally, the profit-maximizing owner will seek to maximize not just gate revenues but all stadium revenues (ticket sales, net concessions, catering, signage, memorabilia, and parking). Many of these considerations will cause ticket prices to appear to be set below the point of unitary elasticity when, in fact, they are set at revenue-maximizing levels.

Conclusion

The economics of sport is a relatively new and rapidly growing field. While the literature is gaining sophistication and relevance, there is still much ground to be covered. Nonetheless, there are some important areas of research that have not been covered properly here, such as research in college athletics in the United States or studies of team production in sports. In our view the most pressing area for economic research remains the competitive balance defence, both in terms of theoretical foundations and in terms of empirical evidence.

spurious regressions

Clive W.J. Granger
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Simulations have shown that if two independent time series, each being highly autocorrelated, are put into a standard regression framework, then the usual measures of goodness of fit, such as $t$ and $R$-squared statistics, will be badly biased and the series will appear to be ‘related’. This possibility of a ‘spurious relationship’ between variables in economics, particularly in macroeconomics and finance, restrains the form of model that can be used. An error-correction model will provide a solution in some cases.

Article

For the first three-quarters of the 20th century the main workhorse of applied econometrics was the basic regression

$$Y_t = a + bX_t + \varepsilon_t.$$  \hspace{1cm} (1)

Here the variables are indicated as being measured over time, but could be over a cross-section; and the equation was estimated by ordinary least squares (OLS). In practice more than one explanatory variable $x$ would be likely to be used, but the form (1) is sufficient for this discussion. Various statistics can be used to describe the quality of the regression, including $R^2$, $t$-statistics for $\beta$, and Durbin–Watson
statistic $d$ which relates to any autocorrelation in the residuals. A good fitting model should have $|\bar{t}|$ near 2, $R^2$ quite near one, and $d$ near 2.

In standard situations the regression using OLS works well, and researchers used it with confidence. But there were several indications that in special cases the method could produce misleading results. In particular, when the individual series have strong autocorrelations, it had been realized by the early 1970s by time series analysis that the situation may not be so simple; that apparent relationships may often be observed by using standard interpretations of such regressions. Because a relationship appears to be found between independent series, they have been called ‘spurious’. Note that, if $b = 0$, then $e_t$ must have the same time series properties as $Y_t$, that is, it will be strongly autocorrelated, and so the assumptions of the classical OLS regression will not be obeyed. The possibility of getting incorrect results from regressions was originally pointed out by Yule (1926) in a much cited paper that discussed ‘nonsense correlations’. Kendall (1954) also pointed out that a pair of independent autoregressive series of order one could have a high apparent correlation between them; and so if they were put into a regression a spurious relationship could be obtained.

The magnitude of the problem was found from a number of simulations. The first simulation on the topic was by Granger and Newbold (1974), who generated pairs of independent random walks, from (1) with $a = b = 1$. Each series had 50 terms and 100 repetitions were used. If the regression is run, using series that are temporarily uncorrelated, one would expect that roughly 95 per cent of values of $|\bar{t}|$ on $b$ would be less than 2. This original simulation using random walks found $|\bar{t}| \leq 2$ on only 23 occasions; out of the 100, $|\bar{t}|$ was between 2 and 4 on 24 occasions, between 4 and 7 on 34 occasions, and over 7 on the other 19 occasions.

The reaction to these results was to reassess many of the previously obtained empirical results in applied time series econometrics, which undoubtedly involved highly autocorrelated series but had not previously been concerned by this fact. Just having a high $R^2$ value and an apparently significant value of $b$ was no longer sufficient for a regression to be satisfactory or its interpretations relevant. The immediate questions were how one could easily detect a spurious regression and then correct for it. Granger and Newbold (1974) concentrated on the value of the Durbin–Watson statistic: if the value is too low, it suggests that the regressions results cannot be trusted. Remedial methods such as using a Cochrane–Orcutt technique to correct autocorrelations in the residuals, or differencing the series used in a regression, were inclined to introduce further difficulties and could not be recommended. The problem arises because the equation is mis-specified; the proper reaction to having a possible spurious relationship is to add lagged dependent and independent variables until the errors appear to be white noise, according to the Durbin–Watson statistic. A random walk is an example of a I(1) process, that is, a process that needs to be differenced to become stationary. Such processes seem to be common in parts of econometrics, especially in macroeconomics and finance. One approach that is widely recommended is to test whether $X_t$, $Y_t$ are I(1) and, if so, to difference before one performs the regression. There are many tests available; a popular one is due to Dickey and Fuller (1979).

A theoretical investigation of the basic unit root, ordinary least squares, spurious regression case was undertaken by Phillips (1986). He considered the asymptotic properties of the coefficients and statistics of eq. (1), $\hat{\beta}$, $\hat{b}$, the $t$-statistic for $b$, $R^2$ and the Durbin–Watson statistic $\hat{D}$. To do this he introduced the link between normed sums of functions of unit root processes and integrals of Weiner processes.
spurious regressions: The New Palgrave Dictionary of Economics

For example, if a sample $X_t$ of size $T$ is generated from a driftless random walk, then

$$T^{-2} \sum_{1}^{T} X_t^2 \rightarrow \sigma^2 \int_0^1 W^2(t) \, dt,$$

where $\sigma^2$ is the variance of the shock, and $W(t)$ is a Weiner process. As a Weiner process is a continuous time random process on the real line $[0,1]$, the various sums involved are converging and can thus be replaced by integrals of a stochastic process. This transformation makes the mathematics of the investigation much easier, once one becomes familiar with the new tools. Phillips is able to show that

- the distributions of the $t$-statistics for $\hat{a}$ and $\hat{b}$ from (1) diverge as $t$ becomes large, so there is no asymptotically correct critical values for these conventional tests;
- $\hat{b}$ converges to some random variable whose value changes from sample to sample;
- Durbin–Watson statistics tend to zero; and
- $R^2$ does not tend to zero but to some random variable.

What is particularly interesting is not only that do these theoretical results completely explain the simulations but also that the theory deals with asymptotics, $T \rightarrow \infty$, whereas the original simulations had only $T = 50$. It seems that spurious regression occurs at all sample sizes. Haldrup (1994) has extended Phillips's result to the case for two independent I(2) variables and obtained similar results. (An I(2) variable is one that needs differencing twice to get to stationarity, or, here, difference once to get to random walks.) Marmol (1998) has further extended these results to fractionally integrated I(d) processes. Durlauf and Phillips (1988) regress I(1) process on deterministic polynomials in time, thus polynomial trends, and found spurious relationships.

Although spurious regressions in econometrics are usually associated with I(1) processes, which were explored in Phillips's well-known theory and in the best known simulations, what is less appreciated is that the problem can also occur, although less clearly, with stationary processes. Table 1 shows simulation results from independent series generated by two first order autoregressive models with coefficients $a_1$ and $a_2$ where $\square a_1 = a_2 \square 1$ and with inputs $\xi_{xt}$, $\eta_{yt}$ both Gaussian white noise series, using regression 1 estimated using OLS with sample sizes varying between 100 and 10,000.

spurious regressions: The New Palgrave Dictionary of Economics

\[ a_1 = a_2 = \text{a percentage of } |\tau| > 2 \]

It is seen that sample size has little impact on the percentage of spurious regressions found (apparent significance of the \( b \) coefficient in (1)). Fluctuations down columns do not change significantly with the number of iterations used. Thus, the spurious regression problem is not a small sample property. It is also seen to be a serious problem with pairs of autoregressive series which are not unit root processes. If \( \alpha = 0.75 \), for example, then 30 per cent of regressions will give spurious implications. Further results are available in the original paper but will not be reported in detail. The Gaussian error assumption can be replaced by other distributions with little or no change in the simulation results, except for an exceptional distribution such as the Cauchy. Spurious regressions also occur if \( \alpha_1 \neq \alpha_2 \), although less frequently, and particularly if the smaller of the two \( \alpha \) values is at least 0.5 in magnitude.

The obvious implications of these results is that applied econometricians should not worry about spurious regressions only when dealing with I(1), unit root, processes. Thus, a strategy of first testing whether a series contains a unit root before entering into a regression is not relevant. The results suggest that many more simple regressions need to be interpreted with care when the series involved are strongly serially correlated. Again, the correct response is to move to a better specification, using lags of all variables.

Concerns about spurious regressions produced interest in tests for unit roots, of which there are now many; and empirical works with time series will usually test between I(1) or I(0), or may sometimes consider more complicated alternatives. If series are found to be I(1), simple regressions have been replaced with considerations of cointegration and construction of error-correction models. A recent survey of studies of spurious relationships is Pilatowska (2004).

In the history of economics, Piero Sraffa is an enigma. His reputation as a major economic theorist rests on but three works: the Economic Journal article of 1926, the Introduction to his edition of Ricardo's Principles (the first of the 11 volumes of the complete Works and Correspondence of David Ricardo, which established Sraffa as the finest scholar to have edited a major work in the literature of economics), and the 99 pages of Production of Commodities by Means of Commodities, a sparse, terse collection of logical propositions, the significance of which is a matter of often heated debate. A reclusive figure, of great personal warmth and puckish humour, Sraffa spent most of his life in Cambridge. Yet his influence extended far beyond academic economics. Throughout the 1930s he spent every Thursday afternoon and evening, during term, with Ludwig Wittgenstein. It was Sraffa who forced Wittgenstein to accept that the theory of language advanced in the Tractatus Logico-Philosophicus was logically inadequate, paving the way for the recognition of the social content of signs and language presented in Philosophical Investigations. In the preface of the latter, Wittgenstein acknowledged the importance of Sraffa's criticism of his arguments over many years,

and added ‘I am indebted to this stimulus for the most consequential ideas of this book’. He later commented that after discussion with Sraffa he felt ‘like a tree stripped of all its branches’, but that a consequence of this drastic pruning was healthier growth.

Of perhaps wider significance was Sraffa's close friendship with Antonio Gramsci. After Gramsci's imprisonment, Sraffa led the effort to ameliorate the harsh conditions in which he was held, and to secure his release. The essential contents of Gramsci's letters from prison, written to his sister-in-law Tatiana, were channelled through Sraffa in Cambridge to the exiled Italian Communist Party. And it was Sraffa who ensured, by establishing an account with unlimited credit at a Milanese bookshop, that Gramsci was supplied with the materials he needed to work on his Prison Notebooks.

The philosophical debates with Wittgenstein, and his political and intellectual commitment to socialism, point to important elements in Sraffa's intellectual make-up. His economics, always rigorous, became in the 1930s increasingly formal, to the extent that the search for logically precise and unambiguous expression inhibited his writing. His socialism demanded an economics that was concrete; that, however abstract, was appropriate to the interpretation of real economic institutions and phenomena.

The compelling empiricism of Marxian socialist thought, and the rejection of the use of subjective concepts, are themes running throughout Sraffa's economics. Economics should be constructed from variables and relationships which are, at least in principle, observable and measurable. The classical analysis of value and distribution is constructed on just such ‘empirical’ foundations, whilst neoclassical theory, based as it is on unverifiable hypotheses concerning individual choice, evidently is not. But although Sraffa's contribution to economic theory may have been motivated by these methodological concerns, its substance involves the logic of theoretical argument, in particular the demonstration of the logical consistency of the classical analysis of value and distribution, and, as a corollary, the logical deficiencies of neoclassical theory.

Life and works

Piero Sraffa was born in Turin on 5 August 1898. His father was Angelo Sraffa, a professor of commercial law who later became Chancellor of the Bocconi University in Milan. The Piazza Sraffa in Milan is named for Angelo, not Piero. Piero's mother was Irma Tivoli.

Sraffa was educated at the Liceo d'Azeglio in Turin, where he was greatly influenced by Umberto Cosmo, who introduced him to socialist ideas and, in 1919, to Antonio Gramsci. Sraffa's studies at the University of Turin, from 1916 to 1920, were interrupted by military service, which he spent as both a ski instructor and an engineer, blowing up bridges to stem the Austrian advance. He attended relatively few lectures. Nonetheless his honours thesis, ‘Monetary Inflation in Italy During and After the War’, was considered by his supervisor, Luigi Einaudi, to be quite brilliant. It was published in 1920.

After graduation, Sraffa worked for a few weeks in a bank to learn some banking ‘from the inside’. He then went to the London School of Economics (1921–2) where he attended lectures by Cannan, Foxwell and Gregory.

During his stay in London, Sraffa visited Cambridge, bearing a letter of introduction to Keynes from Mary Berenson, a friend of Sraffa's family who, ten years earlier, had entertained Keynes and other young Cambridge graduates in her villa near Florence. Keynes was at the time engaged in the debate on the reconstruction of the international monetary system, and had agreed to be editor of a weekly supplement to the Manchester Guardian, dealing with the monetary and financial problems of Europe.
Keynes asked Sraffa to contribute an article on the Italian banking system, which was at the time experiencing a severe crisis. The article proved to be too long for the newspaper, and was published in the *Economic Journal* instead, a shorter version appearing in the *Manchester Guardian*. These two articles were also published in Italian, and caused the Fascist regime considerable irritation.

Now back in Italy, Sraffa was accused by Mussolini of ‘banking defeatism’ and ‘sabotage of Italian finance’. Keynes invited Sraffa to return to England until things had calmed down. However, on 23 January 1923 Sraffa was detained at Dover, and after being questioned for three hours was informed that he had been refused permission to land by order of the Home Secretary. The reason for the denial of entry is still not clear. Keynes secured the removal of Sraffa's name from the list of ‘undesirables’ in 1924.

Fortunately the situation in Italy was less severe than had been expected, though Sraffa resigned the job he had obtained as Director of the Bureau of Labour Statistics of the Province of Milan. The Bureau had been established by the socialist provincial administration in 1922, and was experiencing difficulties with the Fascist government. A few months later he was appointed to a lectureship in Political Economy and Public Finance at the University of Perugia.

The preparation of his lectures at Perugia stimulated him to write ‘Sulle relazioni fra costo e quantità prodotta’ (1925). As a result of this article Sraffa was appointed to a professorship in Political Economy at the University of Cagliari, a post he held *in absentia* to the end of his life, donating his salary to the support of the library. Edgeworth's high opinion of the article led to an invitation to submit a version to the *Economic Journal* (1926). This, in turn, led to Sraffa's being offered the lectureship in Cambridge, which he took up in October 1927.

Before leaving Italy, Sraffa had pursued his interest in monetary problems by translating Keynes's *Tract on Monetary Reform* into Italian, and writing several short reviews of books on money and banking for the *Giornale degli Economisti* (1925b; 1926b; 1926c; 1927b).

In 1919, Sraffa had joined the Socialist Students’ Group at the University of Turin and had participated actively in the political life developing around *Ordine Nuovo*, the magazine founded in 1919 by Gramsci, Tasca, Terracini and Togliatti, the group who were to play the crucial role in the split from the Socialist Party at the Congress of Livorno in 1921 and the foundation of the Italian Communist Party. Whilst in London Sraffa wrote three articles for *Ordine Nuovo* on the condition of the working class in England and the role of trade unions. In 1924 he published an open letter to Gramsci in *Ordine Nuovo* criticizing the Communist Party for its dogmatic refusal to contemplate an alliance with other democratic groups against Fascism. A few years later Gramsci, now imprisoned, accepted Sraffa's argument.

Sraffa also opposed the orthodox Party line in two letters to *Stato Operaio* in 1927. In a discussion of the devaluation of the Italian lira, he criticized the prevalent view that policy decisions are always mechanically and ‘directly’ dictated by the immediate interests of the banks and the big industrialists’ (1927a, p. 180). He advanced instead the view that political bodies such as the Fascist Party have their own interests which can enter into the dynamics of the decision process.

In October 1927 Sraffa began his lectures in Cambridge, presenting courses on the theory of value and on the relationship between banks and industry in continental Europe. He was to lecture for only three years, finding the very process increasingly difficult. Joan Robinson, who attended the lectures on her return from India, recalled them vividly, not least because Sraffa liked to develop a dialogue with his class – a procedure unknown in Cambridge. In 1930 Sraffa was appointed Marshall Librarian, and also
placed in charge of graduate studies. He gave up lecturing for good.

Shortly after arriving in Cambridge, Sraffa had shown Keynes the set of propositions (derived from Marx's reproduction schemes) which were to grow into *Production of Commodities*. But this work was somewhat overwhelmed both by the intense debate in Cambridge surrounding Keynes's *Treatise on Money* and, later, *The General Theory* (it was Sraffa who organized the famous 'circus' which discussed the *Treatise* in 1931), and by Sraffa assuming in 1930 the editorship of the Royal Economic Society edition of *The Works and Correspondence of David Ricardo*. Sraffa's work on the theory of value, and his interest in monetary theory, coalesced in a critical review of Hayek's *Prices and Production* (Sraffa, 1932a; 1932b).

Sraffa's participation in political debate was necessarily limited after his arrival in Cambridge. He maintained contact with the leadership of the Italian Communist Party in Paris, and in 1927 wrote to the *Manchester Guardian* denouncing the ill treatment of the imprisoned Gramsci. He visited Gramsci and attempted, to no avail, to use the influence of his uncle, an eminent judge, to secure Gramsci's release. Following Gramsci's death in 1937, it was Sraffa who conveyed to Togliatti Gramsci's wishes concerning the editing of the *Quaderni dal Carcere*.

In another service to a friend, Sraffa travelled to Austria following the Anschluss to inform Wittgenstein's family that Ludwig had renounced his Austrian citizenship.

In 1939 Sraffa was elected to a Fellowship of Trinity College (he had previously held dining rights at King's), a post he took up shortly after the outbreak of war. When Italy entered the war in June 1940, Sraffa was interned as an enemy alien on the Isle of Man. Keynes managed to extricate him by the end of the summer. Sraffa never gave up his Italian citizenship.

By the late 1940s, the publication of the edition of Ricardo had been long delayed. This was partly due to the reorganization required when in 1943, after six volumes were already in the press, Ricardo's letters to Mill and, amongst other writings, the papers on Absolute and Exchangeable Value were discovered. But delay was also caused by the difficulty Sraffa was having in writing the introductions to the volumes, particularly the introduction to the *Principles*. The second problem was solved after 1948 with the assistance of Maurice Dobb. Dobb and Sraffa would discuss each paragraph in detail. Dobb would write it up. Sraffa would revise what Dobb had written. Dobb would rewrite. And so on, until the job was done. The first four volumes of the *Works and Correspondence of David Ricardo* were published in 1951, the next five volumes in 1952, a bibliographical miscellany formed the tenth volume published in 1955, and, after a number of false starts by others, a general index, compiled by Sraffa himself, was published as the eleventh volume of the set in 1971.

The edition is widely acknowledged to be a scholarly masterpiece. George Stigler (1953) commented,
The Ricardo completed, Sraffa could return to the work he had done on the theory of value and distribution in the 1930s and early 1940s. Old notes were reassembled, including a proof of the Perron–Frobenius theorem on non-negative square matrices, which the Trinity mathematician Besicovitch (an analyst with no prior knowledge of the theorem) had provided on a postcard delivered on Christmas Day 1944. The result of assembling these old notes was *Production of Commodities by Means of Commodities* (1960).

This book was greeted with almost universal puzzlement. It seemed to present, in odd, formal terms, propositions which had become familiar with the development of linear models in the 1940s and 1950s. Had Sraffa's brilliant insights of 30 years before been overtaken by events in mainstream theory? Of the earlier reviewers only Dobb (1961), Meek (1961) and Newman (1962) grasped the fact that this was a work of profound significance, with implications for the logical foundations of both classical and neoclassical theories of value and distribution.

Sraffa spent the rest of his life in Cambridge though up to 1973 he visited Italy in every vacation, staying in his apartment in Rapallo, and going to Rome to attend meetings of the economic section of the Academia dei Lincei. Other than economics and politics, Sraffa's great interest was the collection of books. He assembled a magnificent collection of economics books and pamphlets, including a first edition of *Kapital* inscribed by Marx himself (which he later presented to the Istituto Gramsci) and a copy of the *Wealth of Nations* containing Adam Smith's bookplate. He shared this enthusiasm with Keynes. Together they discovered, identified, and wrote an introduction to an edition of David Hume's *An Abstract of a Treatise on Human Nature* (1938). When he died, on 3 September 1983, Sraffa left his collection to Trinity College.

**Contributions to economic theory**

**The early years**

Sraffa's dissertation (1920) dealt with central practical issues occupying writers on monetary matters at the end of the First World War – the causes and consequences of inflation, the stabilization of internal prices and exchange rates within an unstable international monetary system, the argument for restoring the gold standard and revaluing the currency to the pre-war gold parity.

Sraffa argued that since the abandonment of the gold standard at the beginning of the war had been followed by halving of the purchasing power of gold, then a return to the gold standard would require a rise in the value of the metal, forcing countries which fixed parity either to devalue or to bear the consequences of deflation. Since, in these circumstances, the monetary authorities could not achieve stability of both prices and the rate of exchange, it was better to opt for the former. There is no law which forced the authorities to stabilize the currency at the pre-war level. The normal value of the currency is completely ‘conventional’, that is, it can be at any level that common opinion expects it to be (Sraffa, 1920, p. 42). Sraffa, in opposition to Einaudi, and in common with the position which Cassel, Hawtrey and Keynes were to urge on the Genoa Economic Conference in April 1922, favoured a ‘managed currency’.

Sraffa's ‘practical’ case embodied an implicit theoretical argument. He stressed the role of the state,
moulded by the pressure of the major economic classes, in determining the distribution of income. Monetary policy was thus considered in terms of its impact on the real wage. Sraffa, like Keynes in *A Tract on Monetary Reform*, accepted a version of the quantity theory. But whereas Keynes's views on the determination of the distribution of income were essentially neoclassical, Sraffa's position was more akin to that of the classical economists and Marx. Keynes argued that social forces and monetary factors have only temporary effects on the distribution of income, influencing only the disequilibrium real wage rate. Unless, that is, they were able to effect the real factors which determined the equilibrium distribution (Keynes, 1923, p. 27). Sraffa, however, argued that monetary policies, and hence inflation and deflation, are aspects of the social conflicts that directly regulate the equilibrium or normal real wage rate (Sraffa, 1920, pp. 25, 40–2).

A similar view of the role of economic institutions in social conflict was spelt out in the *Economic Journal* and *Manchester Guardian* articles. The articles focused on the financial needs of newly developing Italian industry, and on the evolution of the links between industry and the banks. His study of the formation of large groups or ‘concentrations’ of financial and industrial power is similar to that in Hilferding's *Finance Capital*. He stressed the enormous economic and political power which such groups can acquire and outlined the way in which conflicts within the groups might affect economic policy. He also revealed the accounting tricks which had been used by two major banks to disguise their financial difficulties, and showed how the authorities had evaded legal restrictions in order to favour some major financial groups (Sraffa, 1922b, p. 676). No wonder Mussolini was so upset.

### Laws of returns

Sraffa's early writings, although imbued with a certain critical radicalism, provided no hint of the theoretical tour de force that was to come. It is true that he had emphasized the role of social classes and institutions in the normal (as opposed to disequilibrium) operation of the economy, but in Sraffa's examination of the neoclassical (predominantly Marshallian) theory of cost (1925; 1926) these concerns with the ‘objective’ characteristics of economic activity were transformed into a penetrating critique of the logical foundations of the theory of the equilibrium of the competitive firm and of the supply curve. Sraffa's starting point in the *Annali di Economia* was a distinction between an analysis in which the relationship between cost and quantity produced was determined by ‘objective’ factors, such as the ordering of different qualities of land, and a relationship which was based on ‘subjective’ factors, namely the marginal disutility which accompanies the offer of increased quantities of factor services. The former relation is, as Wicksteed had argued (1914), essentially descriptive; it is the latter which is, in neoclassical theory, analytic. The supply curve is simply the demand curve ‘reversed’ (Wicksteed, 1914).

In the *Economic Journal* Sraffa made the same point in a rather different way. In classical economics, he argued, the ‘laws of returns’ did not derive from a unified analysis of cost. Quite the contrary. The discussion of increasing returns was associated with the analysis of accumulation, most notably Adam Smith's examination of the relationship between the extent of the market and the division of labour. Diminishing returns, on the other hand, were the distinctive component of the theory of rent. The suggested symmetry of increasing and diminishing returns is a quite different construction, characteristic of the neoclassical supply curve.
But if cost is subjective disutility, how does a phenomenon which is defined by personal psyche manifest its influence in the determination of the equilibrium of the competitive firm, and in the determination of the supply curve of the industry? The apparent similarity between the determination of equilibrium in individual choices, and the equilibrium of the firm, is quite spurious. For whereas all the determinants of individual choice – preferences and endowments – are peculiar to the individual, the determinants of the equilibrium in production in a competitive economy – the technical conditions of production and the supply of factor services – are external to the firm.

Sraffa then demonstrated that neither increasing nor diminishing returns are compatible with the assumption of perfect competition in the determination of the supply curve of an industry, except in the peculiar case in which economies or diseconomies of scale are external to the firm but internal to the industry.

Diminishing returns are incompatible with perfect competition, since the presumption of price taking precludes any impact of the output of individual firms, or, in Marshall's *ceteris paribus* world, the output of individual industries, on prices, unless it is assumed that endowments are fixed in individual firms, or are peculiar to individual industries.

Increasing returns are also incompatible with assumption of perfect competition – other than those which are external to the firm, but internal to the industry.

Only the assumption of constant returns to scale is compatible with the assumption of perfect competition:

> In normal cases the cost of production of commodities produced competitively … must be regarded as constant in respect of small variations in the quantity produced. And so, as a simple way of approaching the problem of competitive value, the old and now obsolete theory which makes it dependent on the cost of production alone appears to hold its ground as the best available. (Sraffa, 1926a, pp. 540–1)

There were two ways out of the conundrum, either to adopt the general equilibrium reasoning which Sraffa had deployed so effectively against the notion of the supply curve, or to abandon the assumption of perfect competition. Marshall's theory must be abandoned (Sraffa, 1930a; 1930b).

The first course was ruled out on the grounds that examination of ‘the conditions of simultaneous equilibrium in numerous industries’, though a well-known approach, is far too complex; ‘the present state of our knowledge … does not permit of even much simpler schemata being applied to the study of real conditions’ (1926a).

The second course recognizes both the ‘everyday experience … that a very large number of undertakings – and the majority of those which produce manufactured consumers’ goods – work under conditions of individual diminishing costs’, and that

> the chief obstacle against which they have to contend when they want gradually to increase their production does not lie in the cost of production … but in the difficulty of selling the larger quantity of goods without reducing the price, or without having to face increased marketing expenses. This … is only an aspect of the usual descending demand curve, with the difference that instead of concerning the whole of a commodity, whatever its origin, it relates only to the goods produced by a particular firm … (1926a).
Sraffa's second option launched the Cambridge analysis of imperfect competition, first in Richard Kahn's fellowship dissertation (1931) at King's, then in Joan Robinson's *Economics of Imperfect Competition*. Apart from his contribution in the *Economic Journal* symposium on increasing returns, Sraffa did not participate further in the debate on the Marshallian theory of cost. The reasons are not hard to seek. First, imperfect competition theory, instead of providing a new, more concrete approach to the analysis of value and distribution, was simply absorbed into neoclassical theory. The fact that imperfectly competitive models do not provide a foundation for a theory of value, seemed to enhance the status of partial equilibrium analysis, rather than hasten its rejection; with the competitive theory of value still holding sway at the level of general equilibrium (a neat rationale is provided by Hicks, 1946, pp. 83–4). The survival of the ‘U’ shaped cost curve as an analytical tool, constructed from the presumption of increasing, then diminishing returns, is in no small part attributable to the longevity provided by models of the imperfectly competitive firm. Nonetheless, the appearance of the ‘U’ shaped curve in models of the competitive firm, more than 60 years after Sraffa clearly demonstrated the illegitimacy of the construction, is an indication of just how intellectually disreputable theoretical economics can be. Second, Sraffa's implicit identification of classical and Marxian theory with the notion that competitive value is ‘dependent on the cost of production’ is clearly wrong, as examination of neoclassical models which take account of ‘simultaneous equilibrium in numerous industries’ readily demonstrates. Sraffa had deployed general equilibrium reasoning to demolish the theory of the competitive firm and the industry supply curve. Further criticism of neoclassical theory would require consideration of general equilibrium models of value and distribution. And a constructive rehabilitation of classical theory would require a general analysis too. It would require, that is, an analysis of ‘the process of diffusion of profits throughout the various stages of production and of the process of forming a normal level of profits throughout all the industries of a country’ – the problem Sraffa acknowledged was ‘beyond the scope of this article’ (1926a, p. 550).

**Monetary theory**

There was no sign of Sraffa's emerging critique of neoclassical theory in his review of Hayek's *Prices and Production* (1932a; 1932b). Instead, the review displays some similarities between Sraffa's position and that held by Keynes soon after the publication of the *Treatise*. Sraffa argued that Hayek had failed to identify the essential properties of money by neglecting the fact that money is not only a medium of exchange, but also a store of value and the standard in terms of which debts, and other legal obligations, habits, opinions, conventions, in short all kinds of relations between men, are more or less rigidly fixed. (Sraffa, 1932a, p. 43)

The absence of any conception of wage agreements and debts fixed in money terms prevented Hayek from analysing correctly the effects on the distribution of income of a general fall or rise in prices. Since money had been thoroughly ‘neutralized’ it could not effect the distribution of income or the rate of

accumulation. Hence Hayek could characterize ‘forced saving’ as a disequilibrium phenomenon, with no permanent effects.

Sraffa argued that this conclusion was contrary to a ‘common sense’ view of the economy. During a period of inflation

one class has, for a time, robbed another class of a part of their incomes; and has saved the plunder. When the robbery comes to an end, it is clear that their victims cannot possibly consume the capital which is now well out of their reach. (Sraffa, 1932a, p. 48; see also 1932b, p. 249)

Sraffa's view that class conflict determines the normal real wage, and that monetary policy may be part of that conflict, is an echo of Sraffa's earlier position, yet nothing is said on the theory of distribution as such.

The most enduring construction in the article is Sraffa's invention of the concept of the own rate of return. Sraffa utilized the idea to elucidate the concept of equilibrium underpinning much of Hayek's discussion. In particular he demonstrates that whilst in disequilibrium there may be as many ‘natural’ rates of interest (that is, own rates of return) as there are commodities, competition will tend to equalize these natural rates just as competition eliminates any divergence between market prices and normal prices – indeed these are two aspects of the same process.

Yet Sraffa does not consider how the equilibrium rate of interest is determined. Nor does he criticize Hayek's association of the rate of interest with the length of the production process.

Ricardo

Sraffa's edition of The Works and Correspondence of David Ricardo proved to be more than a great scholarly achievement. For in his introduction to The Principles of Political Economy and Taxation Sraffa presented an entirely new interpretation of Ricardo's theory of value and distribution. Sraffa's interpretation established a new, theoretically consistent version of the surplus approach to the analysis of distribution in the Essay on Profits. Further, he demonstrated that this approach was sustained in the Principles by Ricardo's use of the labour theory of value, and that, contrary to the accepted view of Ricardo's analysis presented by Jacob Hollander (1904), Ricardo did not retreat from his use of the labour theory of value in successive versions of the Principles.

In the Essay on Profits Ricardo stated that it is the rate of profit in agriculture which determines the rate of profit in the economy as a whole. Sraffa argued that

The rational foundation of the principle of the determining role of the profits of agriculture, which is never explicitly stated by Ricardo, is that in agriculture the same commodity, namely corn, forms both the capital (conceived as composed of the subsistence necessary for workers) and the product; so that the determination of profit by the difference between total product and capital advanced, and also the determination of the ratio of this profit to the capital, is done directly between quantities of corn without any question of valuation. (Sraffa, 1951, p. xxxi)
The beautiful simplicity of this interpretation – the rate of profit being determined in the agricultural sector as a ratio of quantities of corn, and in the other sectors as a ratio of values, with the price ratio between corn and other commodities adjusting so as to equalize the rate of profit (corn, being the wage good, is part of the capital in all sectors) – suggested itself in the preparation of *Production of Commodities by Means of Commodities*. If there is but one ‘basic’ commodity in the economy (that is, but one commodity which enters directly or indirectly the production of all others), then not only must all the inputs to that commodity consist of itself, but the general rate of profit must be determined by the ratio of surplus of the commodity produced to its means of production.

This powerful result, in which the rate of profit is clearly determined as the ratio of surplus to means of production was sustained in the *Principles*, where it was generalized to incorporate the fact that surplus and means of production will consist of heterogeneous ‘bundles’ of commodities. The homogeneity necessary to find the ratio of surplus to means of production was achieved by evaluating the two bundles in terms of the labour embodied directly and indirectly in their production.

As is well known, this generalization foundered on the fact that commodities do not exchange at their labour values, and hence that the ratio, evaluated in terms of labour values, does not measure the rate of profit. As Sraffa pointed out, Ricardo's persistent struggle with this difficulty was expressed as the fact that prices might change due to a change in distribution when labour values (dependent upon conditions of production) were unchanged. Hence he sought an ‘invariable standard of value’ which would tie movements in price to movements in labour values alone:

Ricardo was not interested for its own sake in the problem of why two commodities produced by the same quantities of labour are not of the same exchangeable value. He was concerned with it only in so far as thereby relative values are affected by changes in wages. The two points of view of difference and of change are closely linked together; yet the search for an invariable measure of value, which is so much at the centre of Ricardo's system, arises exclusively from the second and would have no counterpart in an investigation of the first. (Sraffa, 1951, p. xlix)

Sraffa was able to demonstrate that Ricardo had continued the search for an invariable standard to the end of his life, sustaining thereby the exposition of his theory of distribution in terms of the labour theory of value. The conclusive proof of Sraffa's argument was found in Ricardo's papers on *Absolute and Exchangeable Value* discovered together with other papers and letters in 1943, their existence having been previously unknown.

Sraffa's interpretation of Ricardo had a considerable impact at the time of its publication, not least because there was great interest in the analysis of growth at the time. The analysis of distribution plays a central role in the classical theory of growth (accumulation by the capitalists is determined by their share of the product). The problems in the theory of the rate of profit posed by the neoclassical analysis of growth, and in some versions of Keynesian growth theory, excited interest in Ricardo's approach. However, the real importance of Sraffa's new interpretation was for the understanding of Marx's analysis of value and distribution, which is based on Ricardo's theory, and for the general rehabilitation of the surplus approach to value and distribution, which had, for so long, been regarded as logically deficient.
The subtitle of Sraffa's book (1960) is *Prelude to a Critique of Economic Theory*, and in the Preface he suggested that ‘If the foundation holds, the critique may be attempted later, either by the writer or by someone younger and better equipped for the task’ (Sraffa, 1960, p. vi), echoing Ricardo's comment in the Preface to his *Principles* (1817, p. 6).

*Production of Commodities* is a peculiarly sparse book. The argument has been pared to the absolute minimum to sustain the propositions which Sraffa wishes to advance. Yet the precision and logical elegance of the argument are ‘the work of an artist working in the medium of economic theory’ (Newman, 1962).

The theoretical essence of the book may be distilled from the argument of Part I in which Sraffa deals with single-product industries and circulating capital. There Sraffa demonstrates that the approach to the analysis of value and distribution adopted by Ricardo and by Marx is logically consistent. Taking as data the size and composition of output, the conditions of reproduction, and the real wage it may be shown that (1) in an economy which is capable only of reproducing itself, relative prices are determined by the conditions of production; and (2) that, in an economy which is capable of producing a physical surplus over and above the needs of reproduction, relative prices are determined by the conditions of production of basic commodities, and the manner in which the surplus is distributed. If, in the latter case, the surplus is distributed as a rate of profit, then the data determine relative prices and that rate of profit. The economically meaningful solution – that with non-negative prices – is unique. (The prices of non-basics depend upon their own conditions of production and the prices of basics, but the prices of basics are not affected by the prices of non-basics.) These propositions had already been advanced by Dmitriev (1898), though they were not well known.

Sraffa then drops the assumption that the real wage is given. The degree of freedom thus introduced into the analysis is expressed in the locus of the rates of profit associated with any particular values of the wage (in terms of the *numéraire*). For any given value of the wage there is a unique rate of profit (and associated prices), and vice versa. There is a maximum wage, when the rate of profit is equal to zero; and a maximum rate of profit when the wage is equal to zero. Closure of the model requires either that the real wage be given (that is, determined outside the determination of the rate of profit and normal prices) as in classical theory; or that the rate of profit be given.

Sraffa's suggestion that the rate of profit is ‘susceptible of being determined from outside the system of production, in particular by the level of the money rates of interest’ (1960, p. 33), is essentially symmetrical with the classical approach in which the real wage is ‘given’. For the classical economist the real wage is determined by social and historical forces, circumstances which may be analysed quite separately from the determination of relative prices and the rate of profit. Likewise, it may be argued that the money rate of interest, to which, in a competitive economy, the rate of profit must conform, is determined by the normal operations of monetary institutions, especially the state. This position is reminiscent of Sraffa's earlier work in monetary theory, and of Keynes's remark that ‘the rate of interest is a highly conventional, rather than a highly psychological, phenomenon’ (Keynes, 1936, p. 203).

While the ‘data’ of Sraffa's analysis of value and distribution are identical with the data of the analyses advanced by Ricardo and by Marx (other than in his not taking the real wage as given), and hence his results are a validation of their arguments, his method of solution is different. Whereas Ricardo and Marx sought to determine the rate of profit as a ratio of aggregates, Sraffa solves for the rate of profit.
and prices simultaneously. Indeed, his argument demonstrates the necessity of doing so. Yet in his construction of the standard commodity, Sraffa seeks to recreate the clarity of the classical derivation of the rate of profit from the ratio between surplus and means of production.

Sraffa first constructs from the given conditions of production a ‘standard system’, an hypothetical economy in which the composition of means of production and net product (wages and profits) are the same. If the wage is expressed as a proportion of standard net product, $w$, then the proportion of net product accruing to profits is $(1 - w)$. If the ratio of total net product to surplus is $R$ – a ratio which may be evaluated because the composition of inputs and net output is the same – then the rate of profit will be equal to $R(1 - w)$.

The standard system is therefore a direct descendant of the agricultural sector in the Essay on Profits, the rate of profit is expressed as a ratio between two physical quantities.

Sraffa then demonstrates that if the standard net product is adopted as numéraire, and hence as the measure in terms of which the wage is expressed, then the rate of profit will be equal to $R(1 - w)$, exactly as in the standard system in which the relationship between the wage and the rate of profit is expressed in purely physical terms.

The purpose of this construction is, Sraffa tells us, to ‘give transparency to a system and render visible what was hidden’ (1960, p. 23). The rate of profit is seen to be determined by the magnitude of surplus. Yet the use of the standard commodity must be distinguished from Ricardo's use of the ‘corn sector’, or the use of the labour theory of value by Ricardo and Marx. In Sraffa's case, the rate of profit is determined by the solution of the simultaneous equations, the standard commodity is a purely auxiliary construction. In the case of Ricardo and Marx, the rate of profit is determined (albeit imperfectly) by calculating ratio of surplus to means of production by means of the labour theory of value.

It cannot be said that the standard commodity is entirely successful as a means of rendering visible what might otherwise be hid. It is, perhaps, too complex, lacking the simple force of the labour theory. It has the virtue, however, of being analytically correct.

Considerable puzzlement was engendered by Sraffa's statement in the Preface of his book that ‘The investigation is concerned exclusively with such properties of an economic system as do not depend on changes in the scale of production …‘ (1960, p. v). The absence of any reference to demand led unsuspecting readers to equate his results with the non-substitution theorem, and hence with the assumption of constant returns to scale. However, a careful reading of Sraffa's analysis reveals that no knowledge of any relationship between changes in outputs and changes in inputs, or between price and quantity is necessary for the solution of the equations, and hence for the determination of the rate of profit and prices (given the wage). This contrasts with neoclassical theory, in which the determination of prices is dependent upon knowledge of functional relationships between supply and demand. If, in Sraffa's analysis, quantities should change, then any consequential change in conditions of production will result in changes in prices.

In Part II of his book, Sraffa extends his analysis to multi-product industries and fixed capital, and to the analysis of economies with more than one non-reproducible input. As might be expected, the analysis is considerably more complex, and in some cases the results less clear-cut (the solution of the system may not, for example, be unique, and the definition of basics and non-basics is more abstract than is the case with single-product industries). Yet the basic structure of classical analysis is preserved – the prices, the rate of profit, and other distributive variables (say, land rents), are determined by the conditions of production, given the wage.
Sraffa's analysis is a triumphant restatement of the classical analysis of value and distribution. It is therefore somewhat misleading to refer to a ‘Sraffa-based critique of Marx’, a phrase which implies, perhaps unintentionally, that Sraffa has developed a method of analysis which is conceptually different from that advanced by his predecessors in the theory of surplus value. This is not the case.

The label ‘neo-Ricardian’ which is often attached to Sraffa's work (a term which he himself vehemently rejected) is also unfortunate, implying as it does that the argument of Production of Commodities is in some way a solution to problems posed by Ricardo, but not encountered by Marx or by other surplus theorists. The confusion may have derived from simplistically identifying Sraffa with Ricardo, given his edition of Ricardo's works, or from a confusion of the standard commodity with Ricardo's invariable standard of value (even though the latter cannot exist). It may also derive from a fear that any weakening of ‘commitment’ to the labour theory of value implies a rejection of surplus theory. This is to confuse a tool which is used to solve an analytical problem, with the data of the problem. The labour theory of value is not a datum in surplus theory (if it were, Quesnay would not be a surplus theorist), it is a means of demonstrating that the rate of profit is determined by the magnitude of surplus (less rent).

Almost as a by-product of his examination of the fundamentals of classical theory, Sraffa produced a decisive critique of the neoclassical theory of the rate of profit (and hence of the neoclassical theory of long-run normal prices). An examination of the relationship between the changes in the distribution of income and the consequent changes in relative prices leads to the conclusion that such changes ‘cannot be reconciled with any notion of capital as a measurable quantity independent of distribution and prices’ (1960, p. 38). In Part III of Production of Commodities Sraffa extended his examination of changes in distribution and prices to the case in which changes in distribution lead to changes in the technique of production. He demonstrates that as distribution is varied switches between methods of production, according to which is cheapest, do not follow any particular pattern. Indeed, a technique which is cheapest when the rate of profit is low, may be superseded by another technique at a higher rate of profit, and at a yet higher rate of profit the first technique may again prove to be cheapest and so supersede the second technique. In other words, competitive choice of technique does not result in any particular ordering of techniques. Most notably, the capital intensity of production is not an inverse function of the rate of profit, as is implied by the concept of the marginal productivity of capital.

The discussion of ‘reswitching’ (see Symposium, 1966; Garegnani, 1970) following Levhari's failed attempt (1965) to demonstrate that Sraffa's result was confined to decomposable systems, blossomed into a general critique of the logical foundations of the neoclassical theory of the rate of profit. The conclusion of the debate may be stated as:

it is not possible, using the data of neoclassical theory – the preferences of individuals, the technology, and the size and distribution of the endowment – to determine the normal long-run rate of profit and the associated prices.

Neoclassical models of competitive value which are consistent in their own terms (say, the model presented in Debreu's Theory of Value, 1959) do not determine a long-run equilibrium, in which stocks of produced means of production are adjusted to the demand for them and, in consequence, there is a uniform rate of profit. The definition of equilibrium used in such models is different from the traditional long-run equilibrium (Garegnani, 1976; Milgate, 1979). If the model in Debreu (1959) were constrained...
to yield a uniform rate of profit, it would be over-determined to degree \( k-1 \), where \( k \) is the number of reproducible means of production. Paradoxically, this latter result is derivable from Hahn's (1982) attempt to refute the above conclusion.

**Conclusion**

Piero Sraffa's consistently critical approach to the neoclassical theory of value and distribution was motivated by a distaste for 'subjective' models, but was conducted in purely logical terms, at least in his later works. His admiration for the 'objective' structure of classical theory, and for the 'openness' of that structure which permits the incorporation of concrete institutional factors into the formal analysis, led him to attempt to establish that theory on logically more rigorous grounds than had hitherto been available. The critical debate set off by *Production of Commodities* has been somewhat blunted by the change in the notion of equilibrium used in general equilibrium theory (the implications of this change for the operational content of economic theory, that is, for the relationship between the theory and the competitive market economy it purports to analyse, have not as yet been satisfactorily analysed). The well-known propensity of economists to ignore uncomfortable results has also led to the critique being viewed as an esoteric debate in capital theory, with little general significance. This view is clearly wrong. Any critique of the neoclassical theory of value and distribution is a critique of the entire corpus of neoclassical analysis, for the theory of price formation is central to all neoclassical results. (See, for example, Eatwell and Milgate, 1984, on the relevance of these results for the theory of output and employment.)

But it was the revival of the classical (and Marxian) approach to value and distribution, with all the consequences that has for the study of employment, accumulation, technical change, and so on, which was Sraffa's central concern. *Production of Commodities* was designed to lay the groundwork for that revival.

Abstract

The Sraffian claim that the forces of competition can fail to determine the distribution of income stands opposed to the neoclassical conclusion that competitive equilibria are determinate. We show that when Sraffa is embedded in a general equilibrium model the indeterminacy claim can sometimes be valid. Sraffians go on to argue that economies use just the right number of production activities to generate exactly one dimension of indeterminacy. If, however, the devices Sraffians use to block extra dimensions of indeterminacy are applied systematically, then all indeterminacy can disappear. Sraffians also argue that capital-theory paradoxes lead to instability of equilibrium, but this position is hard to reconcile with the fact that if consumer demand satisfies the weak axiom then production economies are tâtonnement stable, even in the presence of linear activities and capital-theory paradoxes.

1 Introduction

In an earlier era, Sraffians took aim at the neoclassical assertion that the demand for and supply of labour and other resources determine factor incomes. In stalking the big game, a smaller question served as bait: is there a homogenous substance, aggregate capital, whose marginal product determines the return to capital? After a brief episode of disagreement in the 1960s, the neoclassical side conceded that in models with even a minimal disaggregation of capital goods the answer to the smaller question was ‘no’. Despite this bloodletting, the chase petered out. When the hunter and hunted ran out of formal modeling disagreements, a settlement was drawn up. The agreement stipulated that there are two neoclassical theories. The first is an aggregative model that tells the familiar parables of Solow growth theory: increases in savings raise the ratio of the value of capital to labour employed, the rate of interest falls as production becomes more capital intensive, and so on. But once a multiplicity of capital goods is introduced these parables no longer hold true. General equilibrium theory, on the other hand, places no limit on the number of capital or consumption goods and still gives a coherent, determinate account of markets and price determination and hence of the distribution of factor incomes. While both parties could agree to this decree, they took different views as to who walked away with the more valuable share of the community property. By the time of the split in the early 1970s, general equilibrium had already been singled out as the jewel of microeconomic theory. The results that had to be jettisoned were confined to the steady-state effects of capital accumulation, leaving the prize results of general equilibrium theory – the existence of equilibrium and its welfare properties – untouched. Moreover, a multiplicity of consumption goods will by itself (without multiple capital goods) imply that the distribution of income cannot be determined by the marginal products of capital and labour.
The resilience of general equilibrium theory to the Sraffian assault had the curious effect that aggregative empirical work could proceed unaffected by the Sraffa episode. Even a literature such as growth accounting for which the Sraffa critique was pertinent showed no influence – it took off just as the Sraffa attack reached its height. Since general equilibrium theory viewed all forms of aggregation as suspect, overlooking Sraffian concerns about capital aggregation seemed to be one of the ordinary compromises that applied work demands. The Sraffian reaction was more complicated. Some held that modern general equilibrium theory, although internally consistent, fails because it does not explain how relative prices converge through time to long-run values, in this view the proper goal of economic science (Garegnani, 1976; Eatwell, 1982; Kurz and Salvadori, 1995). Another strand simply promoted Sraffian and classical economics more generally as a distinct type of economic theory (for example, Harcourt, 1974; Marglin, 1984). Sraffians take as their starting place a wage or wage-share of output that is determined by non-economic forces, for example by political power or by social consensus. The general equilibrium model in contrast explains factor prices as the outcome of the endogenous play of supply and demand. Different assumptions, different theories: let the evidence decide.

An agreement to disagree should leave all parties dissatisfied. If Sraffian economics and general equilibrium theory are merely two contenders, each with its own starting place about the causal forces that move factor prices, to be adjudicated by empirical test, then all the wrangling in the 1960s was for nought. For if wages are determined by political power, say, rather than supply and demand, then political power could remain the prime determinant even if capital always aggregated perfectly or in models where prices do not converge to long-run values. What makes the Sraffa–neoclassical debate significant is its critical dimension, the Sraffian arguments that the forces of competition cannot pin down the distribution of income, that any supply-and-demand theory is riddled with internal flaws. The neoclassical side of the debate has contributed its share of confusion: the mere existence of competitive equilibria does not speak to the adequacy of a supply-and-demand account of factor incomes. When translated into the language of general equilibrium, the Sraffian complaints presumably concern the determinacy and stability of equilibrium, not existence or optimality. Yet Hahn (1982), for example, treats determinacy only casually and leaves stability unaddressed. Fortunately, some decades of delay after the noisy 1960s and 1970s, the literature on Sraffa has turned to these points. The Sraffian complaints about supply-and-demand theories of price determination can be spelled out in two ways. The first appears in Sraffa's *Production of Commodities by Means of Commodities* (1960): the laws of competitive markets do not fully determine factor prices or the distribution of income. Competition requires that the same rate of return is earned in every sector; when laid out as a system of equations, this requirement leaves one more variable than equation, thus revealing a single dimension of indeterminacy, or, as Hahn (1982) put it, a ‘missing equation’. Hahn and other neoclassical economists responded that the missing equation would be found as soon as supply-equals-demand equalities are incorporated into Sraffa's model. Sraffians vacillate on market clearing for factors of production: the land market has to clear, but the labour market does not. This asymmetry drives the single dimension of indeterminacy. As we will see, if the same market-clearing conditions that Sraffians impose on land markets to push extra dimensions of indeterminacy are applied to the labour market then even the standard single dimension of indeterminacy can disappear. This conclusion would seem to undercut Sraffa's book: if indeterminacy stems solely from failing to require the labour market to clear then Sraffians hardly need an elaborate model to press their point. In essentially any setting, the deletion of labour-market clearing will turn the wage into a free variable and hence leave the distribution of income indeterminate. On this score at least, there would be no need to object to the aggregate neoclassical production function.

But the story is not so simple: the neoclassical presumption that the full gamut of market-clearing conditions necessarily brings determinacy is not correct. Although the ingredients have to be recombined, the Sraffian tradition takes just the right modeling steps that lead factor prices in general equilibrium models to be indeterminate. Sraffians have long insisted that linear activities provide a more faithful representation of technology than the differentiable production functions that dominate practical work in neoclassical economics. Although linear activities by themselves do not generate indeterminacy, they can when endowments of capital goods are governed by rational savings decisions rather than by chance. The Sraffian view of the economy as an ongoing cycle of reproduction thus paves the way for factor-price indeterminacy. On the other hand, the particular way Sraffa and his followers have spelled out their long-run view of the economy, by requiring that relative prices be constant through time, undermines their ‘missing equation’ criticism: linear activities models with constant relative prices have determinate factor prices. And the aggregation of capital has no bearing on the matter: the determinacy of a supply-and-demand theory of factor incomes depends on how many activities operate compared with the number of scarce factors, not on the number of capital goods.

The second completion of the Sraffa critique focuses on the potential for the value of capital per worker to behave badly, for example to increase in response to a rise in the interest rate. Although it might seem that this possibility could by itself lead to instability, this turns out not to be the case. Instability can arise in general equilibrium but it stems from the demand side of the model, not the failure of capital goods to aggregate. Little of the Sraffian–neoclassical settlement therefore withstands scrutiny. While a couple of assertions in Solow growth theory about steady states hinge on whether the economy has a single sector and whether capital aggregates, the operation of competitive markets does not. The neoclassical confidence that the general equilibrium model answers all Sraffian challenges is equally misplaced: the Sraffian indeterminacy thesis can be reclaimed. As for neoclassical growth theory, its main message that the return to saving diminishes as savings increase can be re-expressed to avoid the limitations of single-sector models. But here too the Sraffian tradition points the way to important corrections. The characteristic neoclassical equality between an economy's interest rate and its marginal rate of transformation is an artifact of differentiable technologies. With linear activities this equality need not obtain, although for the failure of the neoclassical maxim to be robust, we must follow the neoclassical program, rejected by some Sraffians, of letting utility functions determine consumption.

Sraffian economics (new developments) : The New Palgrave Dictionary of Economics

This article's focus on determinacy and stability aims to complement Paul Samuelson's Sraffian economics, which draws the lessons to be learned from Sraffa regarding aggregative parables.

2 The single dimension of Sraffian indeterminacy

We set a benchmark model of linear activities. Let there be $N$ goods, one type of labour, $L$ types of land, and finitely many activities. Each activity $i$ when operated at the unit level requires an investment one period in advance of $a_i = (a_{i1}, \ldots, a_{iN}) \geq 0$ units of the $N$ material inputs and then a contemporaneous application of $\ell_i \geq 0$ units of labour and $\lambda_i = (\lambda_{i1}, \ldots, \lambda_{iL}) \geq 0$ units of the $L$ land types to produce the outputs $b_i = (b_{i1}, \ldots, b_{iN}) \geq 0$. The level at which activity $i$ is operated is given by $y_i$. We assume to begin that the prices $p = (p_1, \ldots, p_N) \geq 0$ of the material goods purchased as inputs equal the prices of the same material goods when sold as outputs one period later. Profit maximization requires that no activity makes positive economic profits and that any activity $i$ in use ($y_i > 0$) makes zero economic profits. Let $r$ be the intertemporal interest rate, $w > 0$ be the wage, and $\rho = (\rho_1, \ldots, \rho_L) \geq 0$ be the rental rates on land. So profit maximization dictates, for each activity $i$,

$$p_1b_1 + \ldots + p_Nb_N \leq (1 + r)(p_1a_1 + \ldots + p_Na_N) + w\ell_i + \rho_1\lambda_1 + \ldots + \rho_L\lambda_L$$

(2.1)

and that equality holds for any $i$ such that $y_i > 0$.

The Sraffa literature equivocates on market clearing for resources. While land types are required to have a 0 rental rate when in excess supply, the situation for labour is often left unspecified. Let $e_{A_k}$ denote the supply of type $k$ land and $e_\ell$ denote the supply of labour. We then have the market-clearing conditions

$$\sum_i \lambda_i y_i \leq e_{A_k}$$
$$\sum_i \lambda_i y_i < e_{A_k} \Rightarrow \rho_k = 0,$$

(2.2)

for land type $k = 1, \ldots, L$. The analogous conditions for labour are

$$\sum_i e_{j\ell y_i} \leq e_g,$$
$$\sum_i e_{j\ell y_i} < e_g \Rightarrow w = 0.$$

Letting $y$ denote a vector activity levels, an equilibrium is a $(p, w, 1 + r, y)$ that satisfies (2.1) and (2.2). When we impose labour-market clearing, we say so explicitly. In the background lurk additional market-clearing conditions for produced goods, which we introduce in Section 3.

Since we are interested only in relative prices, we can normalize prices by choosing one of the goods or a bundle of goods as numéraire. We set

$$p_1 + \ldots + p_N = 1.$$
In the basic Sraffa model, the focus of the first generation of literature, each activity produces only one good and uses no land, and only one activity is available to produce each good \( j \) and is therefore given the index \( j \). So in this case we can rescale each \((b_i, a_i, \cdot)\) so that \(b_{ij}\) (the sole non-zero coordinate of \(b_i\)) equals 1. Assuming that each activity is in use, then (2.1) gives us the classical Sraffa equalities:

\[
\rho_j = (1 + r)(\rho_1 a_{1j} + \ldots + \rho_N a_{Nj}) + w e_j, \quad i = 1, \ldots, N.
\]

The simplest version of Sraffa's missing equation or single dimension of indeterminacy thesis amounts to the observation that (2.4) and the normalization (2.3) comprise \( N + 1 \) equations but contain \( N + 2 \) price variables \((\rho, w, 1 + r)\). A complete argument that any \((\rho, w, 1 + r) \gg 0\) that satisfies (2.3) and (2.4) is locally contained in a one-dimensional set of points that solve the same equalities might seem to require a rank condition, but the linearity and homogeneity of the model make this unnecessary (see the Note on the dimension of indeterminacy of the basic Sraffa model at the end of the text). Since typically we can parameterize the solutions to (2.3) and (2.4) by \( w \) or \( r \), the distribution of income is indeed indeterminate. Competition, Sraffians suggest, does not pin down a division of social wealth between capital and labour.

The indeterminacy of the above model has little significance from the neoclassical point of view: the only alarming possibility would be if market-clearing equalities for some reason could not close the model. The Sraffian literature does not engage this argument, however, and instead takes either \( w \) or \( r \) to be exogenous, set by political factors or by a macroeconomic determination of the interest rate. The rationale for this practice is perpetually unclear: is it that market-clearing equalities cannot fill the indeterminacy gap or does some principle trump the laws of supply and demand?

We now document the efforts of Sraffa and his followers to maintain precisely a single dimension of indeterminacy. ‘Single dimension of indeterminacy’ is not standard terminology; a more conventional but equivalent description would be that Sraffians aim to show that (2.1) and (2.3) locally determine prices once \( w \) or \( r \) has been set, and hence that, given \( w \) or \( r \) and given an equilibrium, a small exogenous change in demand will leave prices unaffected. Indeed, the view that prices in the long-run are affected only by technology and the distribution of income, not the composition of demand, has long been a top item of the Sraffian theoretical agenda.

Single-dimensional indeterminacy faces three threats – rent, joint production, and the choice of technique – the same topics that dominate the second half of Sraffa's book and the second generation of the Sraffian literature. Although we will see that the arguments available against extra dimensions of indeterminacy can sometimes be turned against the presence of any indeterminacy at all, our position is that zero, one, and more than one are all plausible equilibrium possibilities for the dimension of indeterminacy. It may seem in some of our exhibits that demand and market-clearing should eradicate any indeterminacy, but Section 3 will show that they are compatible.

**Exhibit A. land and rent**

If we add an additional non-produced factor with a positive price to a Sraffa model the number of endogenous price variables will increase. If no further activities are drawn into production, the dimension of indeterminacy will normally go up.

For an elementary example, let there be one produced good \((N = 1)\), one type of land \((L = 1)\) with endowment \(\theta_{11} > 0\), and multiple activities. Let the rental rate of the single land type be \(\rho\) and again normalize activities so that when activity \( i \) is operated at the unit level one unit of output is produced. Suppose activity \( i \) with \((a_{11}, e_{1j}, \cdot) \gg 0\) is in use and \(Y_m = 0\) for \(m \neq i\). Then (2.1) reduces to

\[
1 = (1 + r) a_{11} + w e_j + \rho e_j,
\]

(2.5)
where we have substituted in our normalization \( p_1 = 1 \). To ensure that (2.2) does not constrain \( p \) to equal 0, the land must be fully employed: \( \Lambda^j V_j = \varepsilon^j \). With \( p \) as an additional free variable, if \( (w, 1 + \frac{1}{r}, \rho) \gg 0 \) satisfies (2.5) and (2.6) and each inequality in (2.6) is strict, an additional dimension of indeterminacy obtains: if we independently vary \( w \) and \( 1 + r \) a small amount then \( \rho \) can be adjusted so that (2.5) and (2.6) remain satisfied.

Another type of equilibrium occurs when two or more activities are in use. If two activities \( i \) and \( j \) are in use, then (2.5) is replaced by two equalities,

\[
1 = (1 + r) a_{1j} + w e_{1j} + \rho \Lambda_j, 1 = (1 + r) a_{1j} + w e_{1j} + \rho \Lambda_j.
\]

(2.7)

Condition (2.6) now holds for \( m \neq i, j \), and full employment for land is given by \( \Lambda^i V_i + \Lambda^j V_j = \varepsilon^i \). Evidently the argument for an additional dimension of indeterminacy now fails; we cannot independently vary \( w \) and \( 1 + r \) and expect to satisfy both equalities in (2.7) using the single free variable \( \rho \).

The Sraffa literature largely focuses on the second type of equilibrium with a single dimension of indeterminacy. Is this the more likely type? To make the best case, notice that in the first type of equilibrium the produced input must be accumulated in an amount that leads the stock of land to be fully utilized using only activity \( i \) – otherwise (2.2) would require \( \rho = 0 \). If \( e_c \) is the stock of the produced input accumulated each period, then to fully employ both \( e_c \) and the entire land supply \( e \Lambda \) using only activity \( i \) there must be an activity level \( V_i \geq 0 \) such that \( a_{1i} V_i = e_c \) and \( \Lambda^i V_i = \varepsilon^i \). Since \( e_c \) must therefore equal \( \varepsilon^i \Lambda^i / \Lambda^i \), perhaps one could conclude that the accumulation of this exact amount is unlikely to occur. But consider how the shape of the production possibilities set changes as \( e_c \) changes. If we fix \( w \) arbitrarily (and suppose implicitly there is no constraint on labour supply), then, outside of exceptional values for \( w \) and barring flukes in the input usage coefficients, at most two activities can have the least cost per unit of output and be employed by profit-maximizing firms. If exactly two activities are in use, then the economy can raise its usage of the produced input and increase output by switching the mix of the two activities towards whichever activity economizes on the use of land and uses the produced input intensively – the activity \( j \) with the higher \( a_{1j} / \Lambda_j \) ratio. This remixing delivers a linear increase in current output as \( e_c \) rises. Since increases in \( e_c \) must come from the previous period, the production possibilities frontier (PPF) for the current and previous period's consumption is also linear at points where two activities are in use. Once remixing has been exhausted (a 'switch point'), a new activity with a higher \( a_{1j} / \Lambda_j \) must be adopted if more capital is to be used to produce more current output. At the switch point, the first type of equilibrium occurs where one activity is in use and the PPF exhibits a kink (non-differentiability). But optimizing agents may well choose to save a quantity of the produced input so as to end up at a kink in the PPF. See Figure 1, which pictures the tangency between a kink in a PPF and a smooth indifference curve, where consumption at other periods is fixed at optimal levels. (In a multi-agent model, one may interpret the indifference curve as the boundary of the set of consumptions that can Pareto improve on the optimum.) Such one-activity-in-use optima are robust to perturbations of the model. Hence, contrary to Sraffian practice, the first type of equilibrium with the extra dimension of indeterminacy should not be excluded.

Figure 1
Production possibility frontier and indifference curve
We will see in Exhibit C that if nevertheless we dismissed the first type of equilibrium as unlikely then we would be compelled also to dismiss equilibria with the traditional Sraffian single dimension of indeterminacy. The view that a single dimension of indeterminacy obtains across modeling environments therefore cannot be upheld.

The Sraffian theory of rent often considers cases where a given type of land is used in only one sector out of many. A different rationale is then available for concluding that a single...
dimension of indeterminacy will be the norm. Let \( N = 1 \) and suppose some good \( j \) is produced by single output activities that use various types of land in addition to labour and material inputs. We consider the simplest scenario, extensive rent, where each type of land is used by only one activity (Sraffa, 1960, ch. 11; Quadrio-Curzio, 1980; for more general models, see Salvadori, 1986, and Bidard, 2004, ch. 17). We assign each land type the same index as the activity that uses it. Renormalizing again so that activities produce one unit of output when run at the unit level, the profit-maximization conditions for the production of \( j \) appear as

\[
p_j \leq (1 + r)(p_1 \xi_1 + \ldots + p_N \xi_N) + w \eta_j + \rho l_b
\]

(2.8)

for each activity \( i \) that produces \( j \) and where equality holds if \( V_i > 0 \). The market-clearing requirements (2.2) for land types are assumed to hold. Let the remainder of the economy’s sectors satisfy the assumptions of the basic Sraffa model: for each good \( k \neq j \), one single-output activity that uses no land is available and in operation. To avoid the distraction of feedback from changes in \( p_j \) into \( j \)'s cost of production, we assume that \( j \) does not directly or indirectly enter into the production of any other good. We pick some good besides \( j \) as numéraire and fix \( w \). Finally, letting \( c_i \) denote the non-land cost of production \( (1 + r)(p_1 \xi_1 + \ldots + p_N \xi_N) + w \eta_j \) for an activity \( i \) that produces \( j \), we assume that \( w \) and technology coefficients are such that no ties occur among the \( c_i \); if \( i \) and \( m \) are distinct activities that produce \( j \) then \( c_i \neq c_m \).

As in the previous \( N = 1 \) example, the presence of an extra dimension of indeterminacy will depend on the extent of production. But since \( N > 1 \) we may view the extent of the production of \( j \) as a consequence of the demand for \( j \) rather than of different levels of accumulation. As increases in demand progressively raise \( p_j \) the economy will first use the type \( i \) land for which \( c_i \) is lowest. When this land type is exhausted \( p_j \) must rise further, until the type \( i \) for which \( c_i \) is second lowest earns the rate of return \( r \), at which point production can expand further. And so on. The supply ‘function’ thus consists of steps where the ‘horizontals’ indicate that some type \( i \) is partly but not fully utilized and the ‘verticals’ that a set of land types is fully utilized but that \( p_j \) is not yet high enough for the lowest cost of the remaining types to be drawn into production.

On the horizontals the standard one dimension of indeterminacy obtains. If \( l \) types of land are used to produce \( j \), the single zero-profit equality in (2.4) for \( p_j \) is replaced by \( l \) equalities from (2.8). But the additional \( l - 1 \) equalities are matched by \( l - 1 \) additional endogenous rental rates – the one land type that is partly utilized is constrained to have a 0 rental rate. Hence, since (2.4) and (2.3) generate a single dimension of indeterminacy, so do the horizontal equilibria. On the verticals an additional dimension of indeterminacy appears: with \( l \) types of land in use, \( l - 1 \) additional zero-profit equalities are again present, but now, since the last type of land to be brought into production is no longer constrained to have a 0 rental rate, there are \( l \) additional endogenous factor prices.

The Sraffa literature concentrates on the horizontals rather than the verticals, in line with the Sraffian tradition of taking demand to be exogenous. If the demand for \( j \) were completely inelastic – unresponsive to price – then it would be an unlikely accident if this inelastic demand happened to coincide with one of the verticals of the supply function. The horizontal have added the advantage for Sraffians that any small shift in demand will leave the equilibrium at the same step and hence have no effect on any price. From the neoclassical point of view, completely inelastic demand seems far-fetched and does not obtain even when agents have Leontiev utilities. An inelastic demand argument for the horizontal equilibria also sometimes has no bite. When \( N = 1 \) there is no division of demand into separate outputs; only an inelastic accumulation of the produced input can then allow escape from an extra dimension of indeterminacy.

But in the \( N > 1 \) case and if we grant an elastic demand function for \( j \), the additional indeterminacy of the vertical equilibria is hardly a reason for worry. More land is brought into cultivation because of demand-led increases in \( p_j \); at a vertical equilibrium the demand for \( j \) therefore pin down \( p_j \) and determine each rental rate. While the vertical equilibria dash the Sraffian hope to show that demand is locally irrelevant for price determination, they have no broader significance. The ease with which demand disposes of additional dimensions of indeterminacy underscores the pressing need for demand functions in the Sraffa model; without explicit demands, we will never be able to check whether any apparent case of indeterminacy is the genuine article.

Outside of our attention to extra dimensions of indeterminacy, the above account of rent stays close to Sraffa (1960). Sraffa pays heed to the supply-and-demand restrictions on rental rates: he complies with the rule that factors in excess supply must have a zero price and argues that when the scale of production expands the price of a scarce factor used in production should increase. While Sraffa applies these principles only to land, they pertain to labour as well, as we will see in Exhibit C.

Exhibit B. Joint production

The simplest case of joint production occurs when \( N = 2 \) and there is no land. Profit maximization then requires
for each activity \( i \) and with equality if \( y_i > 0 \). We again consider two types of equilibria. In the first type, one activity \( i \) is in use and each of the unused activities satisfies (2.9) with strict inequality. Then just one equality constrains the four prices \((p_1, p_2, w, 1 + r)\), and so, given the normalization (2.3), there are two dimensions of indeterminacy. In the second type of equilibrium, two activities are in use, in which case just the standard single dimension of Sraffian indeterminacy obtains.

Dual to the dimensions of indeterminacy in the two types of equilibria are the dimensions of possible net productions of goods. In first type, the net production in a steady state must lie in the one-dimensional cone

\[
\{ (y_1, y_2, y_i - a_1, y_j - a_2, y_1, y_2, y_i - a_1, y_j - a_2, y_1, y_2) : y_i \geq 0 \}
\]

while in the second type, with activities \( i \) and \( j \) active, net production lies in the two-dimensional cone

\[
\{ (y_1, y_2, y_i - a_1, y_j - a_2, y_1, y_2, y_i - a_1, y_j - a_2, y_1, y_2) : (y_i, y_j) \geq 0 \}
\]

The first type of equilibrium might therefore seem implausible: if labour is inelastically supplied, then this supply determines \( y_i \) and hence pins down exactly one vector of net outputs in the one-dimensional cone. But this restriction does not undermine the one-activity equilibria; there is ample room for the relative price \( p_1/p_2 \) to equilibrate demand to the fixed supply. While the one-activity equilibria therefore cannot be dismissed as pathological, it would seem, as in the extensive rent example in Exhibit A, that the additional indeterminacy will vanish once we introduce explicit market-clearing conditions. See the ‘sheep’ example in Sraffian economics for an illustration of how an economy can move from one type of equilibrium to the other as demand shifts. Many Sraffians contend that the two-activity equilibria – called ‘square’ since the number of activities in use equals the number of goods – are more likely (Steedman, 1976; Schefold, 1978a; 1978b; 1988; Lippi, 1979). One interesting rationale for this view, Schefold (1990), argues that, if agents always consume goods in fixed proportions, as with Leontiev utilities, then price adjustment will not be able to bring demand in line with supply in the one-dimensional cone. But if the fixed proportions of consumption vary from person to person, then a change in \( p_1/p_2 \) will have a differential effect on the scale of consumption of dissimilar agents. The ratio of demands for the two outputs will then vary with \( p_1/p_2 \) and equilibration can occur (Salvadori, 1982; 1990; Bidard, 1997; and see also the Samuelson–Schefold interchange in Bharadwaj and Schefold, 1990, and for an overview of the extensive literature Salvadori and Steedman, 1988).

Exhibit C. choice of activities

So far, we have considered how an extra dimension of indeterminacy can arise. When a choice of activities is available to produce one or more goods even the standard single dimension of Sraffian indeterminacy can disappear. Let each activity produce just one good. We suppose there is no land and consider equilibria – \((p, w, 1 + r)\) that satisfy (2.1) and (2.3) – where each good is produced. If we ignore whether the labour market clears, the standard single dimension of Sraffian indeterminacy will obtain and we may index equilibrium prices \((p, w, 1 + r)\) by \( w \). For most values of \( w \), and if we bar fluctuations of the production coefficients, the resulting equilibrium \((p, w, 1 + r)\) will permit exactly \( N \) activities to satisfy their 0-economic profit conditions, that is, earn exactly the rate of return \( r \). If an additional \( N + 1 \) activity were required to satisfy its 0-profit condition, then the prices \((p, w, 1 + r)\) that satisfy (2.1) and (2.3) will be pinned down. Hence, with a menu of only finitely many activities available, there are only finitely many \( w \) at which \( N + 1 \) zero-profit equalities could be satisfied at an equilibrium obeying (2.1) and (2.3) – these are the ‘switch points’ at which the economy moves from one set of \( N \) cost-minimizing activities to another. Since there are only finitely many switch points, the required values for \( w \) might seem like flukes. But once we impose market clearing for labour, equilibrium can demand a
For an example, let \( N = 1 \) and thus by normalization \( \rho_1 = 1 \). Suppose two activities are available with input coefficients \( (a_{11}, \epsilon_1) \) and \( (a_{12}, \epsilon_2) \). If both activities are in use, then the profit-maximization condition (2.1) and the normalization (2.3) reduce to the two equalities

\[
1 = (1 + r) a_{11} + w e_1, \quad 1 = (1 + r) a_{12} + w e_2. \tag{2.10}
\]

Flukes in coefficients aside, (2.10) will determine a unique \((w, 1 + r)\). In contrast, if only one activity is in use and the idle activity makes strictly negative profits (its inequality in (2.1) is strict), then the standard single dimension of Sraffian indeterminacy obtains. But now consider market clearing, which we impose on both labour and the material input. If labour is inelastically supplied in the quantity \( \epsilon_c \), and if \( \epsilon_i \) is the amount of the material input accumulated each period, then full employment of the input and labour requires

\[
a_{11} \epsilon_1 + a_{12} \epsilon_2 = \epsilon_c \quad 1 = \epsilon_1 \epsilon_1 + \epsilon_2 \epsilon_2 = \epsilon_c. \tag{2.11}
\]

where if \( \gamma_i > 0 \) then activity \( i \) satisfies its zero-profit condition with equality. Evidently equilibria with both activities in use can be robust (they are not accidents of the parameters). For typical values of the model’s parameters – \( \epsilon_c, \epsilon_1, \epsilon_2 \), and the \( a_{ij} \) coefficients – (2.10) and (2.11) will have a unique solution \((\bar{w}, 1 + \bar{r}, \bar{y})\) and any small variation in the parameters will through a small adjustment of \((w, 1 + r, y)\) lead to a new unique solution. So if we begin with a model that has a two-activity equilibrium \((\bar{w}, 1 + \bar{r}, \bar{y})\) that is strictly positive in each coordinate then as the model is perturbed a two-activity equilibrium will continue to be present. Marginal products for \( \epsilon_i \) and \( \epsilon_1 \) are also well-defined at these equilibria and equal \((w, 1 + r)\). We have taken the savings/accumulation level \( \epsilon_c \) to be exogenous, but we could let \( \epsilon_c \) be a function of the prices \((w, 1 + r)\) without affecting the robustness of the two-activity equilibria. Indeed, a two-activity equilibrium could well be the unique equilibrium – as when, for example, the accumulation level \( \epsilon_i \) is increasing in \( r \). (That is, if \( (1 + r, w) \) and \((1 + r', w')\) both satisfy (2.10) and \( r > r' \) then \( \epsilon_i \) is strictly larger with \((1 + r, w)\) than with \((1 + r', w')\).) The robustness argument in no way hinges on there being a single material good. With two goods and three activities, the analogues to (2.10) to (2.11) would each consist of three variables and equations, and again indeterminacy would disappear.

The Sraffian dismissal of cases where \( N + 1 \) activities are in use rarely receives explicit defence. The rationale presumably is that the labour market is not required to clear, in which case there is no reason to suppose that \( w \) should equal one of the unusual values where \( N + 1 \) activities all earn the same rate of return.

The indeterminacy-reducing effect of factor-market clearing has already appeared. In the \( N = 1 \) example in Exhibit A we saw the dimension of indeterminacy drop from 2 to 1 when two activities are in use rather than one. Indeed, that example and the present example are essentially the same: \( \epsilon_c \) and the wage are the endogenous price variables in Exhibit A whereas \( r \) and the wage are the endogenous price variables here (\( \epsilon_c \) also appears in Exhibit A but we treated \( w \) as a parameter and ignored labour-market clearing). And just as in Exhibit A, the one-activity-in-use equilibrium requires a special configuration for \((\epsilon_c, \epsilon_1, \epsilon_2)\): when one activity \( i \) is in use and \((w, 1 + r) \gg 0\) we must have \( \epsilon_c = \epsilon_i \epsilon_{1i}/\epsilon_i \). Similar conclusions hold when \( N > 1 \) (see Section 3).

Sraffians cannot have it both ways: if the case against an extra dimension of indeterminacy in the presence of land – that the special resource configurations are unlikely – is compelling, then consistency would seem to demand rejection of the single dimension of indeterminacy in the classical Sraffa setting. Of course, one may argue instead that labour unlike land is traded in a market that does not clear. But then the indeterminacy of the wage becomes an assumption rather than a conclusion: in any model where the labour market does not clear, the wage can be treated as a free parameter. We will expand on this point in the next section.

Gathering our exhibits together, we can summarize concisely what determines the extent of indeterminacy. Counting labour as an input, the dimension of indeterminacy equals the difference between the number of positively priced (hence fully utilized) inputs and the number of activities in use (see factor prices in general equilibrium). In basic Sraffian indeterminacy, \( N + 1 \) inputs are used by \( N \) activities: hence 1 dimension of indeterminacy. In the \( N = 1 \) extensive-rent example with 1 activity in use, 3 inputs are used by 1 activity: 2 dimensions of indeterminacy. In the extensive-rent example where \( l \) types of land are in use and all \( l \) are fully utilized, \( N + 1 + l \) inputs have a positive price and are used by \( N + l + 1 \) activities: again 2 dimensions of indeterminacy. In the joint production example with 2 goods, 3 inputs have a positive price: 2 dimensions of indeterminacy occur when 1
activity is in use and 1 dimension of indeterminacy occurs when 2 activities are in use. Finally, in our choice-of-activities example indeterminacy disappears when 2 positively priced inputs are used by 2 activities.

As we will now see, a general equilibrium account of factor-price indeterminacy also reports a dimension of indeterminacy equal to the difference between the number of scarce inputs and the numbers of activities in use.

3 Sraffian indeterminacy with explicit market clearing

The forces of supply and demand have been nipping at the heels of Sraffian indeterminacy: the labour market clearing requirement in Exhibit C sometimes eliminates indeterminacy, and our informal appeals to output demand functions appeared to eclipse the extra indeterminacy that arose in Exhibits A and B. So perhaps a careful inclusion of market clearing for all goods will suff all the indeterminacy out. This turns out not to be the case.

We include labour among the markets that are required to clear. The only formal feature of labour in Sraffian models that distinguishes it from land is that homogenous labour is used in every sector whereas a specific type of land need not be. (In reality, different varieties of labour are used in different industries and some type of land is used in every industry.) So we treat labour (and stocks of other inputs) as we have previously modelled land: for a positive price to rule, demand must equal supply. Labour markets are distinctive of course – labour can require an efficiency wage to induce effort, wage contracts can serve as decades-long insurance contracts, workers can be in unions, and so forth – and perhaps these special traits lead labour markets not to clear. But if we simply exempt labour from market clearing by fiat, one purpose of the Sraffa model is undermined. Wage indeterminacy will obtain whenever the labour market does not have to clear – whether or not capital aggregates, relative prices are constant through time, or linear activities describe technology. Models that allow the labour market not to clear in effect assume that markets do not pin down the distribution of income; they do not demonstrate that principle.

We now distinguish explicitly between material goods when they are inputs at an earlier point in time and outputs at a later point. Two periods will be enough; material inputs and labour will be supplied inelastically at time 1, and labour supplied and output sold at period 2. Relative prices will no longer be restricted to remain proportional through time.

Relative prices that vary from period to period run counter to Sraffian tradition but are indispensable: if indeterminacy is to survive in the presence of market clearing, additional free price variables are imperative.

The prices of the N material inputs supplied at time 1 will be denoted \( p^1 = (p_1^1, \ldots, p_N^1) \) while the prices of the goods sold at time 2 will be \( p^2 = (p_1^2, \ldots, p_N^2) \). As in the basic Sraffa model, suppose just N activities are available, one for each produced good, and let \( y \) denote the activity levels. Output demand is given by the demand function

\[
x(p^1, p^2, w, 1 + r) = (x_1(p^1, p^2, w, 1 + r), \ldots, x_N(p^1, p^2, w, 1 + r)),
\]

and the exogenous supply of labour and material inputs is given by \( e \), and the N-vector \( e \). Together these ingredients must obey Walras' law:

\[
\frac{1}{1 + r} \cdot x(p^1, p^2, w, 1 + r) = \frac{1}{1 + r} \cdot w + p^1 \cdot e.
\]

An equilibrium at which \( (p^1, p^2, w, 1 + r, y) \neq 0 \) satisfies

\[
p_i^2 = (1 + r)(p_i^1 a_{i1} + \ldots + p_N^1 a_{iN}) + w e_i, \quad i = 1, \ldots, N,
\]

(3.1)
There are two normalizations, (3.5) and (3.6), since the model uses an interest rate \( r \) rather than present value prices. The explicit inclusion of demand ensures that the model takes into account the indeterminacy-reducing effect of demand that we saw in Exhibits A and B.

The equilibria described by the above equalities typically will exhibit indeterminacy. If we fix \( y \) at an equilibrium value, then the market-clearing equalities for the material inputs and labour, (3.3) and (3.4), will remain satisfied as \( \rho_1, \rho_2, w, 1 + r \) varies. Of the remaining \( 2N + 2 \) equalities, one of the remaining market-clearing or zero-profit equalities is redundant due to Walras' law. But since the remaining \( 2N + 1 \) equalities have the \( 2N + 2 \) endogenous variables \( \rho_1, \rho_2, w, 1 + r \), one dimension of indeterminacy will typically obtain. The qualification 'typically' is necessary because a rank condition must hold in order to prove indeterminacy via the implicit function theorem (Mandler, 1999).

Several points give the above reasoning a Sraffian flavour. First, just as in Sraffa's book, aggregate quantities remain fixed and hence the indeterminacy operates on prices alone (though as the prices consistent with the fixed aggregate quantities change, individual incomes and individual consumption vary). Of course, unlike Sraffa, we know that markets
clear at the fixed aggregate quantities. Second, linear activities are essential: With a differentiable technology a given vector of aggregate quantities would be incompatible with multiple equilibrium price vectors (Mandler, 1997). Third, it is no accident that the present supply-and-demand model and the basic Sraffian model both display a single dimension of indeterminacy. The degree of indeterminacy is the same because first, with inelastic input supply the market-clearing conditions for inputs do not restrict prices, and second, the $N - 1$ independent market-clearing equalities for output are exactly counterbalanced by the $N - 1$ new second-period prices (we lose one price due to the added normalization (3.6)). This match between added equilibrium conditions and added prices variables means that if we open the door to the variations considered in the previous section – inelastically supplied land, joint production, choice of activities – the dimensions of indeterminacy of the two approaches will still coincide. In both models, the dimension will equal the difference between the number of inelastically supplied first-period factors that have a positive price and the number of activities in use.

Indeterminacy therefore need not always obtain when the Sraff price equations are embedded in a supply-and-demand model. If more than one activity per produced good is available, then equilibria may have $N + 1$ rather than $N$ activities in use. This possibility should come as no surprise since the $N = 1$ no-indeterminacy example in Exhibit C had two activities in use. Indeed if $N = 1$ and we introduced choice among activities, the present supply-and-demand model would be exactly the model in Exhibit C (the market-clearing equality omitted in Exhibit C is superfluous by Walras’ law and (3.5)-(3.6) imply $p^1 = p^2$). Despite their neglect in the Sraffian literature, equilibria where the number of activities in use exceeds the number of produced goods are perfectly plausible if all factor markets are required to clear.

To complete the case for the compatibility of Sraffian indeterminacy and market clearing, we must deal with a famous counterargument that with overwhelming probability any equilibrium will have at least as many activities in use as positively priced factors (Mas-Colell, 1975; Kehoe, 1980) – we faced a similar argument in Exhibit A. Conditions (3.3) and (3.4) consist of $N + 1$ equalities in the $N$ unknowns $y$; hence for almost every endowment $(e, e_*)$ there will exist no $y$ that obeys these equalities. Consequently for these generic endowments there will be no equilibrium satisfying (3.1)-(3.6). If only these $N$ activities are available, then at the generic endowments one of the material inputs or labour will be in excess supply and have a 0 price. Hence for generic endowments the number of positively priced factors will not exceed the number of activities in use. But the seemingly unusual endowments $(e, e_*)$ at which (3.3) and (3.4) do have a solution can arise systematically (see factor prices in general equilibrium and Mandler, 1995). The material endowments $e$ are the outcome of past savings–investment decisions; agents will not knowingly accumulate so much of a material input that it ends up in excess supply. Even when resources can be used productively no matter how great their supply, the endowments where $N + 1$ resources are used by $N$ activities can still arise – those endowments appear at kinks on the production possibilities frontier (for example, see Figure 1 where the material input is accumulated just to the point where the available land is fully utilized using only one activity).

This view of capital as a set of accumulated goods rather than a random endowment of nature fits well with Sraffa’s view of production as circular. More heretical from the Sraffian point of view, we have had to let relative prices vary across time periods. Time-varying prices allow output prices to clear the output markets without constraining input prices. The $N = 1$ case obscures this feature of the indeterminacy since then there are no relative output prices. But when $N > 1$ relative prices will be constant through time in a market-clearing model only if the economy is in a steady state, and steady states typically are determinate. For example, an overlapping generations model, even with a linear activity analysis technology, has locally unique steady states (Mandler, 1999). Indeed steady states will be determinate in virtually any model where markets clear and saving responds to the rate of return (including Marxian models where investment is increasing in the profit rate). There are two reasons. First, in any given period of a steady state, the prices of that period’s given stocks of producible factors are constrained to equal the prices of the same factors being produced for the next period; the indeterminacy arguments we gave earlier therefore cannot be applied. Second, for factors that are not produced, endowment levels then should be seen as random parameters, and it would therefore be a fluke if some set of $k$ factors were used by fewer than $k$ activities without one of them being in excess supply.

4. Sraffian instability

One may also read the Sraffian critique of neoclassical economics as arguing that the failure of capital to aggregate can lead the savings–investment market to be unstable. The case for instability relies on ‘reverse capital deepening’, where the ratio of the value of an economy’s capital goods relative to the number of workers employed increases as a function of the interest rate. Consider a constant-relative-price Sraffa model with one or more activities available to produce each good, no joint production and hence no fixed capital, and where the economy is in a steady state. Set some consumption good to be the numéraire. Then, if we fix the economy’s vector of outputs per worker, the ratio of the value of capital to labour is well-defined at any given $r$. An increase in $r$ can affect the value-of-capital to labour ratio in two ways. First, for any produced good $j$, a ‘real effect’ can change which activity produces $j$ at lowest cost, which in turn will alter the vector of capital goods per worker used in the production of $j$. Second, even if the activities in use remain the same (and with the composition of output still fixed), a change in $r$ will affect the relative prices of capital goods. This ‘price effect’ will typically change the value of the capital goods each worker uses. So although the real effect of an increased interest rate might lead to a decrease in the quantity of each capital good used per worker, the price effect can cause the value of capital per worker to rise; hence reverse capital deepening can occur. This possibility can appear in an economy with one consumption good and just one capital good. An increase in the interest
rate will then lower the physical-capital-to-labour-ratio, but the price of the capital-good can increase by enough that the ratio of the value of capital to labour-rises (Bloise and Reichlin, 2009). Since this chain of events can happen with a single capital good, it is, strictly speaking, misleading to identify reverse capital deepening with the failure of capital goods to aggregate.

Here is the instability scenario. To ensure that Sraffian ‘long-run’ prices rule, we must assume that before and after a shock the economy is in a steady state, where relative prices are constant. If for simplicity there is no fixed capital, the steady state assumption implies that the value of capital per worker equals investment per worker. Consequently, with reverse capital deepening, investment per worker can exceed savings per worker when the interest rate is above its equilibrium value, thus pushing the interest rate higher, further away from equilibrium. Similarly, investment per worker can fall short of savings per worker when the interest rate is below equilibrium, pushing the interest rate lower.

The difficulty with this reasoning is that there is no market where long-run or steady-state savings and investment meet. When a shock to savings or investment occurs, the only instability that could undermine the economy must appear in markets at some specific set of dates – presumably the markets concurrent with the shock. Those markets, however, can equilibrate only at the out-of-long-run-equilibrium prices that obtain when the economy with the pre-shock endowments of resources begins its transition to a new post-shock long run. Long-run prices are therefore of dubious pertinence to the stability issue.

Garegnani (2000) and Schefold (2005) have argued that Sraffian instability surfaces in market-clearing general equilibrium models as a failure of tâtonnements to converge to equilibrium prices. This innovation in the Sraffian agenda has cleared away the cobwebs from the well-rehearsed interchange where Sraffians grouse that capital goods do not aggregate and Walrasians reply that equilibria in the Arrow–Debreu model exist.

The traditional model of a tâtonnement does not apply to an economy with linear activities: whenever positive economic profits can be earned, firms will want to expand without bound, and hence excess demands and tâtonnement price adjustments will be ill-defined. The most detailed and specific proposal to embed Sraffian instability in a general equilibrium model, Schefold (2005), steps around this problem by assuming that output prices are always set so that no activity makes positive profits, and letting the tâtonnement operate only on factor prices, which are the primary object of interest. Given a vector of factor prices, one may calculate the prices for outputs that minimize costs and then the consumer demand for outputs that result from these factor and output prices. The profit-maximizing decisions of firms, assuming they produce these output levels, then determine factor demands, and the difference between factor demand and factor supply leads to a tâtonnement price adjustment. Even in this setting, factor demand can be multi-valued since there can be many cost-minimizing factor combinations that produce any given output vector. To tackle this problem, one may define the tâtonnement with a differential inclusion rather than a differential equation (Mandler, 2005, and for differential inclusions generally see Aubin and Cellina, 1984).

Goods are distinguished by the date at which they appear and are of two types, factors which are not produced and outputs which can be produced. Factors can include the initial period's stock of capital goods as well as various types and dates of labour, land, and raw materials. Technology is given by a matrix of linear activities $A$ where each activity (a column of $A$) produces only one output but may use any of the non-produced factors and produced goods as inputs. We follow the standard sign convention where positive entries in the output rows of $A$ denote outputs and negative entries indicate inputs, index goods so that outputs come first and factors second, and assume that positive quantities of all outputs can be produced simultaneously. To permit intermediate goods, an output can have negative as well as positive entries in the set of factors $A_f$ which are not produced and productions $A_g$ are distinguished by the date at which they appear and are of two types, outputs which can be produced.

For an arbitrary vector of factor prices $p_f$, we may find the competitive output prices $P_o(P_f)$ by solving the cost minimization problem $\min y - P_f A_f x_f$ subject to $A_o y \geq (1, \ldots, 1)$, $y \geq 0$, and setting $P_o(P_f)$ equal to the Lagrange multipliers at a solution to this problem. With output prices set in this way, consumers’ output and factor excess demands become functions of $p_f$ alone. Let $x_o(P_f)$ and $x_f(P_f)$ denote these functions, which we assume obey Walras’ law. The demand for factors by firms is a $x_f$ in the set

\[
X_f(P_f) = \{x_f : x_f \text{ maximizes } (P_o(P_f), P_f) \cdot (x_o(P_f), x_f) \text{ subject to } (x_o(P_f), x_f) = A y, y \geq 0\}.
\]

As we mentioned, $X_f(p_f)$ may have multiple elements.

An equilibrium is a $p_f$ such that $x_f(P_f) \in X_f(P_f)$. A factor tâtonnement is then a function $p_f(t)$, differentiable almost everywhere, such that when differentiable there is a $x_f \in X_f(P_f(t))$ with

\[
p_f(t) = x_f(P_f(t)) - x_f.
\]
Due to the sign convention governing $A$ and since $x_f(p_f)$ is an excess demand, $x_f(p_f)$ and $x_f$ will both usually be negative.

Since the factors can appear at any date, the model can cover a classical Sraffa economy with just labour and produced goods as inputs, so long as the economy is finite-lived: the factors subject to the tâtonnement would consist of the initial period's stocks of capital goods and labour at all dates, while all capital goods that appear after the initial period would be classified as outputs.

While our initial story of reverse-capital-deepening instability was driven by responses of the value of capital to the interest rate, comparable stories are possible that refer just to the non-produced factors that appear in the above factor tâtonnement. Suppose in the classical Sraffa setting that some bundle of activities is cost-minimizing at both low and high $r$'s and some other set of activities is cost-minimizing at intermediate $r$'s (this is called 'reswitching'). And suppose further that a steady state with a small labour supply will use one of these sets of activities and a steady state with a large labour supply will use the other set. Then, if the economy initially is in a steady state at either a high or intermediate $r$ and has the small labour supply, an exogenous shift to the large labour supply would lower $r$ in a new steady state and hence raise $w$, hardly the intuitive price response to a supply increase. This tale compares steady states and tracks the movement of the wage through time, whereas all prices in a factor tâtonnement respond simultaneously to disequilibrium. Scheffold (2005) nevertheless suggests that reswitching can lead a factor tâtonnement to be unstable.

Evaluation of this claim faces an immediate difficulty: no matter how well-behaved firms’ factor demands are, consumer behaviour, which here appears as the factor supply function $x_f$, never suggests that reswitching can lead a factor tâtonnement to be unstable.

5 Back to growth theory

Sraffa saw the economy as embedded in time, with endowments of produced inputs determined by the accumulation of capital, and he modelled technology using the plausible primitive of linear activities, not production functions packaged with suspicious differentiability assumptions designed to make factor returns determinate. These points add up to an effective criticism of a supply-and-demand theory of factor pricing, but the details of the argument need to be rearranged. The impossibility of capital aggregation plays no role. But does the Sraffian stress on capital aggregation at least serve as an effective criticism of growth theory and the parables of the Solow model? On the surface, the fact that in a comparison of steady states the value of capital per worker or consumption per worker can increase with the interest rate may appear to undermine boilerplate neoclassical maxims on the impact on consumption at a specific future date with all other consumption levels held constant. And when capital goods and consumption goods are separate commodities, changes in the relative prices of capital goods can break the linkage between increases in savings – sacrifices of present consumption – and increases in the value of capital; thus an increase in savings that lowers $r$ and the value of capital per worker is not remarkable.

Following Solow (1963), define an economy's rate of return between the present and some future date $t$ as the return in consumption at $t$ as present-day consumption is sacrificed. If there is one consumption good per period, the gross rate of return between the present and $t$ is the ratio of the gain in consumption at $t$ relative to the quantity of today's consumption forgone, holding consumption at all other dates fixed. No reference to the value of capital is involved. With this definition, the familiar neoclassical maxims reappear: with linear activities and free disposal production possibilities set, a sacrifice of consumption today must lead to a weak increase in consumption at $t$ (holding all other consumption levels fixed) and the rate of return between today and $t$ must weakly diminish in the quantity of consumption sacrificed. Comparisons of steady states can also be cleansed of references to the value of capital, but here a less than impressive set of claims is available. If again there is one consumption good per period and we avoid settings with infinitely many agents, such as the overlapping generations model, then any increase insteady-state consumption per worker entails an increase of the amount of at least one of the capital goods used per worker,
and the move to a steady state with higher consumption per worker requires a sacrifice of consumption at some set of dates prior to arrival at the new steady-state. The no-free-lunch moral of neoclassical growth theory rears its head.

But beneath these broad conclusions lies a vein of caveats, so far unmined by the Sraffian movement. When technology is described by linear activities, the rate of return can differ depending on whether it is defined by decreases or increases in present consumption. The reason is that the production possibilities sets are convex and the production coefficients must lie between the lower bound given by the rate of return for small increases in present consumption and the upper bound given by the rate of return for small decreases. In the planning case, the mismatch is between agents’ intertemporal rates of substitution and the technological rate of return. Neoclassical growth theory has largely ignored these discrepancies, perhaps because of the blinders of its long reliance on differentiable production functions. But as in static factor pricing, linear activities in a growth setting open up a conceptual gap between prices and material rates of return: r no longer has to align with the physical return to sacrifices in consumption.

The presence of a kink in a production possibilities set will hinge on the number of activities in use, just as with factor-price indeterminacy. An irony crops up here: it is only in an optimal growth exercise that maximizes agents’ utilities that an allocation at which the production possibilities set is kinked normally would be selected. Consider a planner with access to linear activities and stocks of resources at dates from the present (period 1) to the distance future (period T) that can be used to produce a sequence of consumption levels (again one consumption good per period). Resources are inelastically supplied and an arbitrary number of intermediate capital goods is permitted. Any consumption sequence \( \bar{x} = (x_1, \ldots, x_T) \) that is on the economy’s PPF must satisfy the property that, for any \( t = 1, \ldots, T \), \( x_t \) solves the problem of maximizing \( x_t \) subject to \((x_t, (\bar{x})): (\bar{x}) \) being in the production possibilities set. Pick one such problem with \( t > 1 \) where, if we view \( \bar{x}_1 \) as a parameter, the solution \( x_t(\bar{x}_1) \) is non-constant. Consider those activities in use at some initial solution whose usage levels change as \( \bar{x}_1 \) changes. If no subset of \( k \) of these activities utilizes or produces more than \( k \) goods at the initial optimum, then (barring flukes of the production coefficients) the function \( x_t(\bar{x}_1) \) will be differentiable at the initial \( \bar{x}_1 \): the PPF is smooth. (The good \( x_t \) should not be included in the count of the number of goods utilized or produced.) In the remaining cases, the initial \( \bar{x}_1 \) is a point where \( x_t(\bar{x}_1) \) is non-differentiable and the PPF is kinked; here inputs are accumulated just to the point where some set of \( k \) activities uses or produces more than \( k \) goods. Since almost every \( \bar{x} \) on the PPF does not sit at a kink, a planner who selects a consumption stream arbitrarily could safely ignore the nondifferentiable points and declare that given the selection \( \bar{x} \) the forces of technology alone determine the marginal rate of intertemporal transformation between any two time periods. If, furthermore, this planner decentralized the economy’s investment decisions to private entrepreneurs the planner would have to choose this rate as the market rate of interest. Curiously, the Sraffian hostility to utility maximization and substitution in consumption (see Exhibits A and B) also leads to the conclusion that a \( \bar{x} \) at a PPF kink is an unusual event; hence the Sraffian view comes to the aid of the neoclassical identification of interest rates with rates of technological transformation. On the other hand a planner who maximizes a sum of agent utilities could well choose a consumption stream at a kink (see Exhibit A and Figure 1).

While the Sraffian emphasis on linear activities serves as a welcome corrective to the neoclassical habit of assuming that any function or surface is differentiable, in the end it is utility functions that prevent a linear activities growth model from providing a purely technological determination of the interest rate.

As we have seen, this lesson goes beyond growth theory. Market economies also gravitate to kinks on PPFs. Consequently, even when an economy has a single consumption good per period, which allows consumption output to be modelled with an aggregate production function, that production function may well not be differentiable when evaluated at the factor endowments that arise in equilibrium. Empirical work that relies on a differentiability assumption – for example, the classical growth-accounting estimates of total factor productivity (Solow, 1957; Kendrick, 1961; Denison, 1962) – is therefore subject to coherent Sraffian criticism.

6 Conclusion

The Sraffian insistence on linear activities casts critical light on the instinctive neoclassical habit of assuming that interest rates and marginal rates of transformation must be equal and that production functions must be differentiable. Another more abstract Sraffian principle proves just as illuminating: economic activity is ongoing, not a one-time exchange among agents with disparate endowments and preferences. As we have seen, it is when the endowments of capital goods are determined by rational accumulation rather than by chance that factor-price indeterminacy can appear.

The Sraffian view of equilibrium, which revives earlier classical ideas, fits well with subsequent mainstream developments. Modern macroeconomics, both new Keynesian and new classical, has rejected models where the government’s actions, such as an aggregate demand stimulus, systematically surprise agents; instead government actions are governed by a distribution that agents know. The new understanding of expectations is not driven by a belief that agents are never surprised or never hold an incorrect model of the economy but in order to pinpoint results that are immune to invalidation as agents learn and adapt to their environment, a precept close to the Sraffian view of equilibria as ongoing. The Sraffian perspective has wide application. For example, while the production of capital endowments by past equilibrium activity can lead to factor-price indeterminacy, a similar dependence of the present on past equilibrium decisions can eliminate some disturbing features of other brands of indeterminacy (Mandler, 2002). In overlapping-generations indeterminacy, market clearing is compatible with agents at the beginning of economic time unanimously anticipating any future price path that lies in a multidimensional set. But if one sees an equilibrium as ongoing, rather than commencing anew each period, the indeterminacy problem disappears after an equilibrium gets under way. The agents in an economy that has
already followed an anticipated price path for a number of periods and that experiences no shock will continue to hold their previously formed expectations, and given those expectations equilibrium prices at each period will be locally unique.

Note on the dimension of indeterminacy of the basic Sraffa model

We may rewrite (2.4) as \( \rho \left( I - \left( 1 + r \right) A \right) = w \overline{\epsilon} \), where \( A \) is the matrix whose \( i \)th column is \( a_i \) and \( \overline{\epsilon} = (\epsilon_1, \ldots, \epsilon_N) \). Due to the homogeneity of (2.4) in \((p, w)\), we can replace (2.3) with \( w=1 \) without changing the relative prices \( \frac{1}{|\rho|} \overline{\rho} \) in any solution \((\rho, w, 1 + r)\) to (2.3) and (2.4) or changing the dimension of the set of solutions. If at a solution \((\overline{\rho}, w, 1 + \overline{r}) \gg 0\) to \( \rho \left( I - \left( 1 + r \right) A \right) = \overline{\epsilon} \), \( I - (1 + \overline{r}) A \) has rank \( N \), then, for \( r \) near \( \overline{r} \), \( \rho = \overline{\rho} \left( I - (1 + r) A \right)^{-1} \) solves \( \rho \left( I - (1 + r) A \right) = \overline{\epsilon} \). Hence locally there is a one-dimensional set of solutions. If \( I - (1 + \overline{r}) A \) has rank \( \leq 60/N \), then \( \rho' \rho \left( I - (1 + \overline{r}) A \right) = \overline{\epsilon} \) has dimension \( \geq 1 \), and so locally the solution set contains a set of dimension \( \geq 1 \).

Abstract

Sraffa's 1960 book *The Production of Commodities by Means of Commodities* has spawned an extensive literature but still needs to relate itself to the vast post-1945 finite mathematics literature of von Neumann, Dantzig, Kuhn-Tucker-Gail and Bellman. The Sraffa-Leontief circulating capital model provides by itself a prism with which to diffract the paradigms of Marx, Ricardo, and various brands of neoclassicism. It can serve to help judge Ricardo's editor and to illuminate the unity in Sraffa's scientific vision, from before 1926 until death in 1983.

Article

Piero Sraffa, born in 1898 at Turin as the son of a well-off professor of law, lived from the twenties to his death in 1983 the quiet bachelor life of a don at King's and Trinity Colleges, Cambridge. Though his published and unpublished works are few, Sraffa has four claims to fame in the science of economics and the history of ideas.
(i) His 1926 article, ‘The Laws of Returns Under Competitive Conditions’, was a seminal progenitor of the monopolistic competition revolution. It alone could have justified a lifetime appointment.
(ii) An intimate of Keynes and Wittgenstein, Sraffa is said to have speeded Wittgenstein on his second philosophical road to Damascus by a rail station query, ‘What then is the meaning of this [Sicilian] gesture?’ The young Sraffa provided books and pin money to the marxist Antonio Gramsci jailed by Mussolini, and he...
remained quietly interested in leftist matters. Sraffa was an organizer of the famous 1931–5 Cambridge ‘Circus’ which included Joan and Austin Robinson, Roy Harrod, James Meade and many others. Using Richard Kahn as messenger Gabriel, Maynard Keynes derived much benefit for his nascent *General Theory* from their brilliant group. Except for the chapter 17 discussion of own rates of interest, where Keynes must have benefited from Sraffa's 1932 polemic with Friedrich Hayek, there are few signs of a Sraffian interest in the macro-economics of effective demand. Sharing with Keynes an antiquarian's preoccupation with rare books, Sraffa and Keynes jointly discovered, identified, and edited the valuable *Abstract of A Treatise on Human Nature* that David Hume had published anonymously as a puff for his great initial work on philosophy.

(iii) Sraffa's editing of *The Works and Correspondence of David Ricardo*, a lone-wolf effort over a quarter of a century (aided much toward the end by Maurice Dobb) is one of the great scholarly achievements of all time, ranking in its perfections with the team efforts of the editors of Horace Walpole and James Boswell.

(iv) Finally, in the seventh decade of his life, Piero Sraffa published a classic in capital theory, *The Production of Commodities by Means of Commodities* (1960). As with Mozart if not Mendelssohn, Sraffa's death leaves posterity wistful that his full potential never came into print: what would we not give the good fairies, if somewhere in the attic of a country house there should be discovered a manuscript presenting Sraffa's planned critique of marginalism?

A fresh survey of Sraffa requires the reverse of a chronological order. First comes his 1960 book, which has spawned an extensive literature but still needs – if the technology is to be adequately handled – to have Sraffa's special equalities embedded in the general inequalities–equalities of the 1937 von Neumann model. The essentially completed Sraffa–Leontief circulating capital model provides by itself a prism with which to diffract the paradigms of Marx, Ricardo, and various brands of neoclassicism; and, self-reflexively, it can serve to help judge Ricardo's editor. The unity in Sraffa's scientific vision, from before 1926 until death at age 85, then becomes visible.

**Truly general time phasing**

The polemics of Böhm-Bawerk, Knight, and other capital theorists are illuminated, and seen through, by the 1937 von Neumann general model once that is made explicitly *time-phased* and open-ended, to allow (a) for primary factors (labour, land, …) not necessarily producible within the system, and (b) for net consumptions of outputs not necessarily ploughed back into the system for self-propelled growth.

We can summarize the $n$ outputs produced by $J$ activities, where each $j$th activity uses as inputs a vector of $M$ primary factors and a vector of commodity-inputs, while producing a vector of joint products:

$$ q_{i}^{t+1} = \sum_{j=1}^{J} b_{ij} \min \left[ Q_{1j}^{t} / a_{1j}, ..., Q_{nj}^{t} / a_{nj}, l_{1j}^{t} / l_{1j}, ..., l_{Mj}^{t} / l_{Mj} \right] $$

(1)
The \( a \)'s are input/output coefficients; \( l \)'s are Walrasian factor coefficients; \( b \)'s are joint-product proportions (as with 1 bu. wool and 2 pounds mutton per sheep). We use standard notation: for a matrix or vector \( z \), \( z > 0 \) means all its elements are positive; \( z = 0 \) means all elements zero; \( z \geq 0 \) means no element negative, with all possibly zero; \( z \preceq 0 \) means no element negative, but at least one being strictly positive; \( z' \) is the transpose of \( z \): thus, \([1\ldots1]'\) is a column vector of ones. \( I \) is the identity matrix, with 1's in the main diagonal and zero elsewhere:

\[
\begin{align*}
a &= [a_{ij}] = [a_{11} \ldots a_{1j} \\
&\quad \vdots \quad \vdots \\
&\quad a_{n1} \ldots a_{nj}] \preceq 0; \quad b = [b_{ij}] = [b_{11} \ldots b_{1j} \\
&\quad \vdots \quad \vdots \\
&\quad b_{n1} \ldots b_{nj}] \succeq 0; \quad l = [l_{ij}] = [l_{11} \ldots l_{1j}] \\
&\quad \vdots \quad \vdots \\
&\quad l_{M1} \ldots l_{Mj}] \preceq 0; \quad j \preceq M \preceq n
\end{align*}
\]  

For systems in a stationary state, regardless of the variable we have \( z^{t+1} = z^t = z \). An important case is where supplies of primary factors are specified to be positive constants:

\[
\sum_{j} l_{mj} \geq l_m, \quad m = 1, \ldots, M.
\]

Remark: the circulating capital models occupying most pages in Sraffa (1960) are a special case of (3) where each column of \((b_{ij})\) can be written to contain a single ‘one’ with the remaining elements zero. In general, any or all \( a_{ij} \)'s could be assumed by a mathematician to be zero; but, to be interesting, every \( b \) must have at least one positive element in each of its rows and its columns, so that every good is produced somewhere and every activity produces at least one good. An activity might not require any direct primary input; but, if we...
are not to be in the Land of Cockaigne, where lollipops grow freely on trees and don’t even require picking, indirectly or directly every good must require some primary factor(s).

**General Hawkins–Simon conditions**

For a circulating-capital system to be ‘productive’, in the sense of providing positive net consumptions, \( a \) must satisfy simple Hawkins–Simon conditions, such as that powers of \( a, a^k \) go to zero as \( k \to \infty \). When \( b \) involves joint products, matters are more complex and the literature needs the equivalent of the following two constructive tests:

**Axiom 1** (No Land of Cockaigne). The following standard linear programming problem must have a solution of zero:
Subject to

\[
\begin{align*}
\lambda & \leq 0, \quad x \geq 0 \left[ b - a \right] x \neq 0, \max_x \left[ 1 - 1 \right] \left[ b - a \right] x = Z^* = 0
\end{align*}
\]

**Axiom 2** (Generalized Hawkins–Simon). The following standard LP problem will have a positive solution if, and only if, the system is ‘productive’.
Subject to

\[
\begin{align*}
\lambda & \leq \left[ L_1 \ldots L_M \right] > 0, \quad x \geq 0 \left[ b - a \right] x \geq C \geq 0 \quad C \geq \left( c - c^* \right) \geq C_{\text{max}} c = c^* > 0 \\
x, C
\end{align*}
\]

**Example**: Suppose, as in the joint-production passages of Sraffa (1960), that \( b - a \) is \( n \times n \), with \( l = n \). It will then be sufficient that \( b - a \) have row sums positive for the productiveness axiom to be satisfied. (Contrary to what seems to be suggested by the mathematician C. F. Manara (1979), these row-sum conditions are not necessary—as \( b - a \) with diagonal elements near to 1's and off-diagonals of \(-10\) and \(-0.01\) demonstrates.)

**Competitive pricing relations**

In the absence of any uncertainty, or restrictions on entry and knowledge, perfect competition will be led in (1) by Darwinian arbitrage to equality of the profit rate in all processes positively operated. In matrix terms, with \( P \) a non-negative row vector of \( n \) goods prices, \( W \) a non-negative row vector of \( M \) primary-factor prices, and \( r \) the common profit or interest rate, we have the general dynamic equalities–inequalities:

\[
p^{t+1}b \leq \left( p^t r + W^t \right) \left( 1 + r^t \right), \quad \left( p^t, p^{t+1}, W^t, r^t \right) \geq 0
\]
where $x^{t+1}$ is the column-vector of the $J$ ‘intensities’ at which the respective activities are carried on:

$$0 \leq x^{t+1}_j \leq \frac{L_{mj}^j}{l_{mj}^j}, \quad m = 1, \ldots, M; \quad j = 1, \ldots, J \leq Q_{ij} / a_{ij}, \quad i = 1, \ldots, n \leq q_{i}^{t+1} / b_{ij}$$

The convention is understood in (4) and (1) that when a denominator vanishes, the term in which it appears is ignorable. In (4) $P$'s and $W$'s are measured in any numeraire and equality of $r$'s in all processes used does not imply equality of different goods’ own rates of interest when $P^{t+1}$ is not proportional to $P^t$.

Wherever a strong inequality holds in (4), that activity must cease to operate, in accordance with the perfect-competition duality conditions:

$$0 = x^{t+1}_j \left[ \sum_{i=1}^n P^{t+1}_i b_{ij} - \sum_{i=1}^n P^{t}_i a_{ij}(1 + r^t) - \sum_{m=1}^M W^t_m / m_{ij}^j \right] \quad j = 1, \ldots, J$$

In stationary equilibrium, $(P^t, W^t, r^t) = (P, W, r)$ and all time scripts can be omitted. All own rates of interest are then the same. Then (4) becomes

$$Pb \leq (Pa + Wb)(1 + r)$$
These equality-of-profit-rate conditions are not merely competitive arbitrage conditions. Taken together with the steady-state version of (1)–(2), namely with

\[ Pbx = (Pax + Wnx)(1 + r) \]

\[ (5b) \]

(5a)–(5b) are the necessary and sufficient conditions for *inter-temporal* production efficiency (or inter-temporal Pareto efficiency on the allocation side). Unless there exists, at the observed steady state, an existent \((P, W, \text{uniform } r)\), the society must be planning wastefully. So aside from Marx's 1867 innovation being a backward step in positivistic realism, it was a bad (avoidable) blunder from the standpoint of social planning and efficiency – a point never glimpsed by Marx or his admiring editor Engels. Because Sraffa's brief text never grapples with the *inter-temporal* relations implied by *his* steady states, his readers are left unaware of this technocratic property of dualistic competitive pricing.

Sraffa (1960) considers for the most part very special cases of (5), and of (1)–(2), cases for which \( n \) happens to equal \( J \) with a square and of rank \( n \) and with all equalities holding in (4). Save for the brief chapter on land, he mostly works with labour as the only primary factor and seems to presuppose that \((b - a)x \geq C \geq 0\), \( \Delta x \leq \omega > 0 \)

\[ (5c) \]

(Remark: in many technologies, even when \( J \) greatly exceeds \( n \), the number of activities operated at a positive level will be equal to \( n \); this endogenous fact should not obscure the more general truth, that changes in demand will generically alter the choice of \( n \) viable activities – so that, as will be seen, von Neumann's rectangular matrices cannot be sidestepped.)

**Properties of competitive equilibrium**

The following twenty properties of Sraffian steady-state systems are straightforwardly verifiable:

1. When goods require more than one primary input, as for example labour and land, a shift in demand away from a land-intensive good and toward a labour-intensive good, will at each ruling profit rate raise the price ratio of the latter relative to the former; and it will tend to raise labour's distributive share at the expense of land's. The *labour theory of value*, even in the absence of the complication of time-phasing and interest, *thus generally fails and the theory of distribution cannot be separated from the complications of value theory* (of supply–demand pricing theory).

2. Even when labour is the only primary factor, time-phasing means that Smith's bipartite formula of wage-plus-interest is indeed a necessary statement of price and of national income. Save in singular cases where all goods happen to have exactly the same percentage of direct-wage cost to total cost – what Marx called the
case of ‘equal organic compositions of capital’ – a change in the interest rate must alter relative commodity prices – again vitiating the simple labour theory of value.

3. Suppose there are no joint products, all raw materials being used up in a single employment. It follows from the last paragraph that competitive prices in time-phased systems must generally at positive interest rates differ from the ‘marked-up values’ of Marx’s *Capital* (1967, Volume I, ch. IX) which replace a uniform industry-by-industry rate of profit by a uniform rate of surplus value: the 1867 marked up values mark up the direct wage costs only, with allegedly no mark up earned on raw-materials outlays for produced goods (for ‘constant’ capitals). Ratios of these peculiar ‘marked-up values’ agree with ratios of zero-profit-rate prices, and do so no matter how great the capitalists’ surplus! So, in consequence of paragraph numbered 2 above, the 1867 Marxian constructs do systematically depart from realistic competitive prices and need to be ‘transformed’ into correct Sraffian competitive prices by abandoning them – as L. von Bortkiewicz had demonstrated in 1907.

4. Staying with the assumption of no joint products, we can deduce the existence of a *factor-price trade-off frontier*: at any specified Sraffian interest rate, there is defined a convex trade-off frontier between the maximal real wage rate of labour and real rent rate of land (where any good is the numeraire for measuring such real factor prices); a rise in the interest rate must shift inward the convex contour relating real factor prices (but equal upward increments of $r$ can induce inward shifts in the frontier that both accelerate and decelerate). Though Sraffa does not use this name for the frontier, for the case where labour is the sole primary factor, he recognizes the properties of this basic frontier.

5. The amount of net consumptions produced in the stationary state will be maximal when the competitive system chooses those golden-rule techniques that are supported by a zero rate of interest. (If all primary factors grow at a Harrod natural rate of $[1+g]t$, the maximal per capita net consumptions will be realized only when competition mandates use of the golden-rule techniques supportable by an interest rate of $g$: $1 + r = 1 + g$.) This paragraph states something different from the earlier remarks around equations (5) concerning inter-temporal Pareto efficiency.

6. At any interest rate $r$, prevailing in Sraffa’s time-phased system, the competitively viable techniques observed can be verified from (5) to achieve inter-temporal Pareto optimality. By contrast, consider the 1867 Marxian techniques that maximize the rate of surplus value for a specified vector of relative primary-factor prices. Not only are these techniques unrealistic describers of the positive facts about the laws of motion of capitalism. In addition they would achieve a Planner’s nightmare, in general producing permanently in the steady state less of goods than the system is capable of and involving more of society’s scarce primary factors than is technologically needed. When Sraffa’s readers begin to worry about consumption preferences over different time periods, they will additionally have to revert back from 1867 Marxian values to (5)’s dualistic competitive pricing to restore *inter-temporal* Pareto efficiency of consumption.

**How demand-tastes affect pricing and distribution**

The above half-dozen rules of a Sraffian system are valid either for *his* von Neumann technologies or for *all* versions of neoclassical technologies (involving convexity and first-degree homogeneity). Although Sraffa reserved judgement for half a century on whether he wanted to assume constant returns to scale, experiments with returns laws that depart from that property will be found to rob his algebra of *any* interesting economic applications, as the paucity of results on this point in the literature of the last quarter of a century attests. (Thus, specify for the coal and iron example of the opening page of Sraffa (1960) that in the iron industry doubling inputs quadruples output, while in the wheat industry tripling inputs doubles output. Then none of
Sraffian economics: The New Palgrave Dictionary of Economics

The pricing relations have other than empty defal content!) The Perron input/output matrices don't define existent prices of production.

Further properties of steady-state competitive systems are the following.

7. Prior to Sraffa (1960), the Leontief literature had established and generalized the 1949 Non-Substitution Theorem. When labour is the only primary factor and there are no joint products, at any observed profit rate the competitive prices at which all goods are positively produced must be independent of the composition of steady-state demand: even when alternative techniques could be reasonably substituted, changes in demand can never mandate their new use. Also, with labour the only primary factor, a shift in demand toward goods that involve a high relative fraction of direct-wage cost must be at the observed profit rate raise the wage-profit share. As already indicated, when labour must cooperate with land, shifts in demand toward or away from goods that are relatively labour-rather-than-land-intensive must at the observed competitive profit rate raise or lower their relative prices and presumptively alter the distribution of income between workers and landlords. The Ricardian dream of ridding distribution theory from the complications of (consumer-demand) value theory is seen to be, in general, a pipe dream – as Ricardo realized in his occasional lapses into good sense (as for example, when recognizing that Napoleonic-war shift of demand toward labour-intensive soldiering would raise the wage share prior to a repopulating of the countryside). At a given interest rate, in the absence of technical innovation and non-labour primary factors, a rise in the money wage rate cannot force a permanent substitution of machines for labour since machines’ steady-state costs then rise proportionally with the wage rate.

Some joint-product phenomena

The following properties of joint-product systems are also common to Sraffian technologies of the von Neumann type and to all versions of neoclassical technologies.

8. When joint products are admitted – surely the realistic case – the classical economists’ hope to deduce steady-state price ratios from technology and supply alone is generally frustrated. When one species of sheep produces wool and mutton in joint proportions – or when one round trip of a ship supplies east and west transportation jointly – each alteration in tastes and demands for the joint products alters their steady-state price ratio and does so even under perfect Arrow–Debreu certainty.

Sraffa’s favourite case of joint products would involve as many independent activities used as there are goods: \( l = n \). For a simple example, consider 2 sheep species, each producing 2 products: say, species 1 produces 2 of wool and 1 of mutton, while species 2 produces 1 of wool and 2 of mutton; for simplicity let both sheep require the same inputs and cost, which might as well be labour only.

So long as consumer’s demand involves relative expenditures on the two goods not too unequal – no good ever attracting more than two-thirds of consumers’ dollars – Sraffa is correct in expecting cost-technology alone to determine competitive pricing of \( P_{\text{mutton}} / P_{\text{wool}} = 1.0 \). But, as soon as people want to spend more than two-thirds of their incomes on mutton, Sraffa loses his equality of number of goods and number of positively used activities: only the meat-intensive species is competitively viable; consumer demand functions are then price determining.

Let us add a third sheep species, producible like the others but yielding 1.75 of wool and 1.75 of mutton.

Now \( l = 3 > 2 = n \). When people singularly spend exactly half their incomes on wool and mutton, only the species 3 is viable and \( P_m / P_w = 1.0 \) as set by demand. When people spend a bit more on mutton than wool, less than \( l = 3 \) activities are positively viable, namely, \( 2 = n < l = 3 \), as species 3 and species 2 alone survive. For a range of demands, \( P_m / P_w = 1 / 3 \), a numerical value that can be calculated from Sraffa’s 2 cost-prices of production relations. However, as the demand for mutton relative to that of wool runs the...
gamut of possible ratios, we reach the limit of each Sraffian horizontal step and must traverse the staircase's vertical risers with market price being consumer-demand determined. In realistic cases, \( J \) is large relative to \( n \); and there are many different \( n \)-by-\( n \) square sub-matrices that consumer-demand functions will endogenously select out of the rectangular \( n \)-by-\( J \) matrix of technology.

In sum, globally demand generally helps determine relative prices of Sraffa's joint products between zero and infinity, doing so along a staircase's vertical risers and (locally horizontal) step segments. This general rule of global dependence on demand of joint-products' price ratios does admit of an exceptional case where an aspect of a Non-Substitution theorem does obtain. Let us, so to speak, introduce so weak a degree of jointness of production that we are still in a close neighbourhood of indecomposable non-joint-production. This will occur when a positive \( net \) amount of each good is available only from a single process, and where each process does produce one such positive amount net. Under this stipulation the square matrix \((b_{ij} - a_{ij})\), after feasible renumbering of the goods and of the processes, will be specified to have positive elements in its diagonal and negative off-diagonal elements. Its general Hawkins–Simon conditions will also require that the inverse \([b - a]^{-1}\) exists and is positive. Under these strong stipulations, as is well known, the same Non-Substitution theorem that holds for circulating-capital and exponential-depreciation models will hold for joint production.

Otherwise, however, demand conditions can in general have an essential effect on relative prices; and can do so even when we grant Sraffa special indulgences (such as equality of \( J \) and \( n \), non-singularity of \( b - a \), and labour the only primary factor). Thus, often, even when \((I_1)J\) is positive, some elements of \((b - a)^{-1}\) will be negative – with the result that for some ratios of consumptions, \((b - a)^{-1}c\) will not define positive feasible gross outputs, and price ratios will have to be influenceable by demand-tastes.

**Sraffian artifacts: standard commodity baskets**

The following properties are special and hold only for singular subsets of von Neumann technologies or for singular subsets of neoclassical technologies.

9. Postulate no joint products, no primary factors other than labour, no alternative techniques for producing goods, and that all goods considered are basics in the sense that \( a \) is indecomposable so that every good requires for its production something directly or indirectly of every good as input. Then, Sraffa (1960) deduces the existence of a market basket of goods or _standard commodity_, with unique positive weights \((Q^*_1, \ldots, Q^*_n)\), such that the _real wage expressed in terms of the standard commodity_ and paid to the workers _postfactum_ (at the end of the period when they work at the beginning of the period) is a declining _linear_ relation:

\[
w = 1 - \left( \frac{r}{r^*} \right)
\]

where \( r^* \) is the maximum positive profit rate the system can pay, with the column vector \((Q^*_i)\) uniquely
Sraffian economics: The New Palgrave Dictionary of Economics

definable by the eigenvector relation:

\[ a(1 + r^*) \left[ Q_i^* \right] = \left[ Q_i^* \right] > 0 [l_{11} ... l_{1n}] [l - a]^{-1} Q^* = 1 \]

(6b)

Some real prices rise faster with the profit rate than the standard commodity's price does; some rise less fast. When the real standard-basket wage rate is half its zero-profit-rate level, the post-factum wage share of the basket's cost is also one half; and similarly for any other fraction.

Sraffa, for reasons not easy to understand, thought that (6)’s truth somehow provided Ricardo with a defence for his labour theory of value. Even in the restricted case where (6) does validly obtain, one perceives no successful resurrection of Ricardo's desired labour theory of value or absolute standard of value that is provided by Sraffa's demonstration of the existence of this standard commodity: price ratios are still not equal to zero-profit-rate price ratios as the crude labour theory of value wants them to be.

10. It is by now understood that a Sraffian Standard Commodity often fails to exist, for a variety of reasons:
   (i) In circulating-capital and exponentially depreciating models, as soon as competition mandates a switch in technology when interest rates or relative primary factor prices change, there will then generally not be any market-basket weights that entail a linear tradeoff frontier between the real wage and the profit rate.
   (ii) In these same models, realistic decomposabilities can negate the existence of positive weights that yield linearity.
   (iii) In still other cases, as shown by Takahiro Miyao in 1977, for various vectors of direct-labour coefficients, there can be an infinity of positive weights that produce the same normalized linearity as the Sraffian standard.
   (iv) In joint-product cases, as C. F. Manara (1979) instanced. \((b - a[1+r])\) may have only complex eigenvalues and eigenvectors. Again, no Sraffian standard validity obtains. (For such Manara cases, at some feasible interest rates certain processes cease to be competitively viable; so Ricardo can never find his middling composite, which is neither too time-consuming nor too time-economizing, to provide him with the chimera of an absolute standard of value for making comparisons across time and space.)
   (v) There exist many joint-product cases in which Sraffa’s eigenvector of \((b - a[1+r])\) is real, but involves some negative elements. Playing the game of defining market baskets with negative weights cannot, by some analogy with foreign-trade exports and imports or debtor-creditor ownings and owings, make economic sense useful to a Ricardian critical of Adam Smith or of J. B. Clark.
   (vi) There are many joint-product cases in which Sraffa's eigenvector for \((b - a[1+r])\) is all positive. But still there may be no standard market basket that yields a linear factor-price frontier validity applicable over the whole interval of feasible profit rates. (On one side of some critical \(r\), all of Sraffa's \(J(=n)\) processes are competitively viable. On the other side of that \(r\), less than \(n\) processes can earn the competitive profit rate. The true market cost of Sraffa's nominated market basket there ceases to obey the linear law that allegedly Ricardo's value theory could benefit from.)
   (vii) Instead of abandoning the hunt for a chimera, some Sraffians sought comfort in the belief that the important joint-product cases are not those of the wool-mutton type but rather are those of the new-machine-old-machine type or are of the permanently-durable-land type; and nursed a hope that for these important cases, the ‘pathologies’ of non-existent standard commodities might be absent.
If anyone ever believed this, it was an illusion. Under (i) above, we saw land–labour models in which induced changes in $a_{ij}$ coefficients take place, which induce violation of the Sraffian desired linearity. A locus linear piecewise is not linear.

Also, a model where the only jointness is of the durable-good type may well not admit of a standard commodity defined over the whole interval of feasible profit rates. The following counterex settles the issue of possible non-existence:

$$b = \begin{bmatrix} 1 \\ 7/8 \\ 1 \end{bmatrix}, \quad a = \begin{bmatrix} 7/8 & 0 \\ 0 & 1/2 \end{bmatrix}, \quad \left[ l^{11l12} \right] = [1 \ 9]$$

Here is its story. Good 1 can be consumed directly or be used as a new machine to produce, in cooperation with labour, Good 1 itself along with the joint product of an old machine. The used machine, called Good 2, can be used with labour to produce Good 1 and worthless scrap. (Later, we'll recognize that Good 2 might be an object of final utility for its own sake, distinct from Good 1's marginal and total utility.)

This ex's numbers involve the need in Process 2 for (relatively) much labour and little of the old machine to produce 1 of Good 1. Process 1, by contrast, produces 1 of Good 1 with relatively little labour and a fair amount of new machines: for Process 1, labour with 7/8 of a new machine, produces 1 of a new machine and 7/8 of an old machine; for Process 2, 9 of direct labour, with 1/2 of an old machine, produces 1 of a new machine and scrap.

Calculation shows that competition must then work out as follows:

At very low profit rates, the used machine is so consuming of high-wage direct labour that it (and Process 2) cannot be used in production under viable competition. The price ratio $P_2/P_1$ will then be set completely by utility tastes for Goods 1 and 2: with enough yen for Good 2, $P_2/P_1$ can be anything from zero to infinity at low profit rates.

Between the critical profit rates of 1.59%, and 109.67% both processes could be used competitively. If both are useable throughout that interval, then over that interval (and only it) Sraffa will get his desired linear standard commodity; but it must fail him at the lower interval of profit rates. Worse still, even in the higher interval where algebra does yield him a linear function, economics can veto the relevance of Sraffa's standard function: as soon as people have strong enough marginal utility for Good 2, all of it is bid away from production uses! Process 2 becomes competitively unviable and Sraffian cost-prices lose relevance; demand becomes decisive, frustrating the primitive classicist's yearning to determine prices from supply considerations alone. The 1960 purported defence of Ricardo's absolute standard has collapsed.

**Moral**

The Walrasian paradigms are in general unavoidable in the most unrestricted von Neumann paradigm. What began as a classicist-inspired critique of 'marginalism' ends up as a demonstration that the classical-economics paradigm does need to be broadened into the post-1870 mainstream economics – even when smooth Clarkian marginal products are scrupulously avoided! Where a critique succeeds, and is needed, is in exposing how special are the one-sector, homogeneous-scalar-capital paradigms of Clark.

The genuine Fisher, von Neumann, Arrow–Debreu structure of time-phased general equilibrium stands confirmed by the Sraffa–Leontief probings.

1960 light on Clarkian oversimplifications

Heroic works clarifying faults of neoclassical parables have been done by Joan Robinson, Luigi Pasinetti, Pierangelo Garegnani, Bertram Schefold, J. S. Metcalfe and I. Steedman, C. F. Manara, V. K. Dimitriev, and many others. 11. Before she knew of Sraffa's 1960 model, Joan Robinson had usefully debunked the notion that some aggregate Platonic Kapital, $K = \sum P_jk_j$, enters into real-world production functions and defines (aggregate) marginal net product of Kapital, $\frac{\partial [K(t+1) - K(t)]}{\partial K(t)}$, to give the real-world interest or profit rate. Sraffa's model showed once and for all the falsity of the following neoclassical apologetics:

Roundabout ['mechanized'] methods are productive and the interest rate measures the incremental social product obtainable by extending the degree of roundaboutness through the effective action of saving (by the exercise of painful 'waiting' and 'abstinence').

Sraffa showed this: as soon as there are more capital goods than 1, it is impossible to say of every pair of techniques which one is the more roundabout, time-intensive, or mechanized. Increases in the interest rate above zero can first raise various $P_2/P_1$ ratios and then later lower them. So above a critical high interest rate, competition may revert back to a technique that had been viable only at very low interest rates.

Sraffian reswitching thus implies: lowering the interest rate may result in lower steady-state consumption levels, prior to its ultimately raising them to the maximal golden-rule level.

Oskar Lange once wrote, sardonically but seriously, that Ludwig von Mises, the enemy of socialism, deserved a statue in the socialist Hall of Fame for compelling Abba Lerner and Lange (to say nothing of earlier Pareto, Barone and Fred Taylor) to work out how socialists might devise efficient decentralizing-pricing planning algorithms. One can insist, seriously, that a neoclassical Hall of Fame deserves Sraffa's statue.

1. 12. Actually all of Sraffa's findings about the impossibility of defining 'more roundaboutness' and 'less roundaboutness' apply precisely to smoothly differentiable vector-capital Clarkian models. Neoclassicists should reproach themselves, and thank Robinson and Sraffa, for belated recognition that the locus of (stationary-state consumption, interest rate) need not be a one-way trade-off. This recognition is achievable quite apart from the dramatic case of double-switching.

Example. Let $[L, K_1, K_2, C_1, C_2, \dot{K}_1 = dK_1/dt, \dot{K}_2]$ depict, for a 2-sector neoclassical economy in which marginal products are not illusory, its labour, its 2 heterogeneous capital good's stocks, its 2 consumptions, and its net investments. Its production function and steady-state profit-rate are given by

$$L = F[K_1, K_2, C_1 + \dot{K}_1, C_2 + \dot{K}_2]$$
where $F$ is a first-degree-homogeneous, smooth, convex function. Set $L$ by convention at a plateau of unity, and for simplicity specify $C_2/C_1$ always to be unity; and, as a condition of stationarity, make all $\dot{K}_i$ vanish.

Then the above pair of relations permit us to determine the level of consumption as a function of the profit rate: $C_1 = f(r)$. What neoclassicals insufficiently realized before 1960, away from there is no necessity for $C_1$ to fall as $r$ rises. This valid Sraffa–Robinson point does not score against ‘marginalism’. Their razor cuts as deeply against the discrete-activity technology!

‘Marginalism’ per se is not what deserves the razor of Sraffa’s critique. As already said, whatever Clarkian marginalism can display for good or ill is already capable of being displayed by a von Neumann discrete-activities technology.

Space permits only a few further mentions of paradoxical neoclassical phenomena that can result from positive profit rates in time-phased models. A critique to reveal them, as shown by several valuable works of Metcalfe and Steedman, cuts as much within von Neumann-activities models as within smooth marginalist models of the marginal-product type.

13. The Non-Substitution Theorem, which makes relative costs and prices, at each interest rate, independent of the composition of final demands when only one primary factor is present, is common to discrete and marginalist models. When more than one primary factor is present, the Non-Substitution Theorem becomes a Substitution Theorem – again, generally both for discrete and marginalist models.

14. Both for discrete and marginalist no-joint-product models, for each interest rate there is a convex trade-off between various real factor returns (expressed in terms of any good as numeraire). For both models, it is not necessarily true that the trade-off relation between the interest rate itself and real factor returns is convex. (Point 14 has a considerable overlap with Point 4.)

15. For both models, the substitutions of technique that win out under competition are Pareto efficient. For both models, any technique observed to be viable under competition is a golden-rule technique for that Harrod-growth rate which is equal to the observed interest rate!

16. For both models, when the real wage rises relative to the real land-rent (independently of the good used as numeraire), any mandated technical substitution must (if anything) involve a shift to lower embodied-dated-labour contents of each good and to higher embodied-dated-land contents. This is as true for a positive interest rate as for a zero one, since we deal exclusively with golden-rule technologies. (The difference, when $r$ is zero, is that there is then no need for dating of the direct-and-indirect labour and land contents.)

17. As shown by Metcalfe and Steedman, Pasinetti, Samuelson, and others, in both models one must guard against a tempting fallacy.

In both models, when $r$ is zero, the change in technique induced by a rise in the Wage/Rent ratio must economize on the actual Labour/Land ratios observed to be used in the various industries in the stationary
state. Something like this remains true for very low interest rates. (For economy of space, explanatory qualifications are omitted.) However, for large enough \( r \), what are called embodied-dated-labour contents and embodied-dated-land contents can be substantially different from synchronized-stationary-state labour and land actually observed to be used. So beware of believing that observed \((\Delta W)_m (\Delta L)_m\) must be negative when \( r \) is positive. This has implications for the correct Heckscher–Ohlin and Stolper–Samuelson trade theorems under time-phasing.

18. Related to the above is the following observation. At \( r=0 \), the competitive system is out on its true stationary-state production-possibility-frontier. At positive \( r \), although the system moves to a new steady-state (not stationary-state!) golden-rule set of techniques, what it can produce and does produce in the stationary state is generally not out on the stationary-state production-possibility frontier – but rather is inside that frontier. As demand changes, what we observe inside that frontier need not trace out well-behaved concave loci.

Some Marxians, bemused by notions of ‘unequal exchange’, think that the above phenomena are Pareto inefficient: the system and the world get less product than is producible in the zero-interest-rate golden-rule state. Yes, of course. But that is unavoidable in any scenario where the economic system could only obtain the produced inputs needed for Schumpeter's golden-rule zero-interest rate utopia by doing current ‘waiting’ and sacrificing of current consumptions. The curse of the poor societies is their poverty – even when intertemporal Pareto efficiency is always obtaining. Again, all this is as true of discrete as of marginalist technologies.

Sraffian refutation of Marxism

On the basis of this elaborate description of findings about Sraffian time-phased systems, one can apply the results to appraise and correct (1) neoclassical economics, (2) Marxian economics, (3) Ricardian and classical economics. Its thrust on neoclassical economics was sampled in the previous section.

20. Sraffian economics, as earlier passages make clear, devastatingly repudiates that central part of Marx's economics, Capital, Volume I (1867) which proposed a new paradigm involving an equal 'rate of surplus value' by industries or departments. Sraffa and Darwinian arbitrage require an equal 'rate of profit' by industries or departments. Under exploitative capitalism, Marx misidentifies what is out there to be observed in the competitive market, for the reason that Marx has the capitalists garnering too little in the industries using much capital goods and garnering too much in those using relatively little capital goods. It is a gratuitous error, and a sterile one, since Marx's paradigm does not help predict the laws of motion of competitive capitalism, or help understand the average magnitude of the profit level around which Marx's errors spread. Equal profit rates are not a capitalist shibboleth; dual to the primal variables of the von Neumann technology is an equalized profit rate.

Ian Steedman, a scholar sympathetic to the Weltanschauung of Marx and of economic reform, has documented the Sraffian rejection of 1867 Marxian rate of surplus value in his book, Marx After Sraffa (1981). So here it need only be said: in the end, from the posthumous publication of Capital, volume III (1894), one can recognize that the 'transformation' from Marx's 1867 [marked-up] 'values' to bourgeois 'prices' involves abandoning the 1867 relations and returning to the pre-Marx and post-Marx cost-profit relations of the Sraffian model.

One cannot quite leave it at that. Karl Marx does deserve a statue in the Sraffian Hall of Fame. Not, of course, for his sterile detour into the rate of surplus value. As documented by Samuelson in the 1974 Lloyd Metzler Festschrift, Marx was the first scholar after Quesnay to grapple explicitly with input/output capital models. Implicitly, Marx was the first to use \((a_{ij})\) coefficients. Moreover, in his Tableaus of Steady Reproduction and

of Expanded Reproduction, *Capital*, volume II (1885), Karl Marx was the first to present coherent row-and-column arrays of steady-state equilibrium. This is Marx's imperishable contribution to analytical economics, and it is impervious to the deflating of hyperbole concerning Marx as allegedly a great *Mathematical* economist.

1926 reconsidered from 1960

There were two main parts to Sraffa's celebrated 1926 paper. The first part, which today we realize was by far the more important one, dealt with the phenomena of *increasing returns to scale*. So long as demand is insufficiently large to take a firm beyond such an initial phase of increasing returns or decreasing costs, the firm cannot find a maximum-profit equilibrium while still remaining a perfect competitor. Cournot knew this in 1838, and it was not new doctrine even then. The turn of the century literature on trusts and industrial organization, in America and Germany, was never in doubt on this. By 1926 the whole issue would have been old hat save for Alfred Marshall's tergiversations on the compatibility of *increasing* (internal, statical and reversible) *returns* and perfection of competition. Marshall, at the time of his death in 1924, was at the height of his prestige, with the greatest capacity for good and for potential confusion. Therefore, it was important for Piero Sraffa to restate elegantly that real-life firms, with localized and segmented markets, were in imperfect-competition equilibrium with falling marginal production costs that were offset by selling and transport costs and by price declines inducible by expansion of their own outputs and sales. Independently, E.H. Chamberlin and J.M. Clark were saying much the same thing at the time in America. But the ruling establishment of Cambridge, understandably, could learn something best from one of its own publishing in the *Economic Journal*. The 1960 book has no relation to this part of Sraffa's early work.

Within the mid-1920s, Sraffa's other thesis generated a disproportionate amount of interest. Not only was the familiar downward-sloping Marshallian supply curve to be ruled out as incompatible with perfection of competition; the young Sraffa was newly arguing that upward-sloping supply curves were also of vacuous importance for Marshallian partial equilibrium. All that Sraffa left his reader, then, was a horizontal, *constant-cost* competitive supply curve.

This is plain wrong. Sraffa's 1960 book demonstrates that, when primary factors other than a single homogeneous labour exist, rightward shifting Marshallian and Walrasian demand curves will generally trace *rising* price intersections on the relevant supply curves. Joan Robinson's famous 1941 *Economic Journal* article on rising supply price was the first East Anglian recognition of the formal comparative statics of general equilibrium. I doubt that she or Piero ever noticed the incompatibility with 1926 Sraffa; or the incompatibility of Heckscher–Ohlin and Stolper–Samuelson in the foreign-trade literature with Sraffa's thesis of *constant* costs and implied *linear* production-possibility frontiers. The pre- and post-Ricardian classical literature is full of examples of wine grown on special vineyard lands: for generations students have followed Viner's 1931 example of calling this 'the pure Ricardian case' – while the modern teachers of the young know this as the Jones–Samuelson–Haberler specific-factors model.

Students of rhetoric should be interested to analyse the elements of style that enable the erudite author of a faulty thesis to persuade himself and several generations of thinkers of its truth and importance. Because Sraffa wrote so little, and wrote so rarely on the mainstream topics of contemporary scholarship, his skills as a writer have perhaps been insufficiently noticed.

Knowing what we now know – that it is a mistake to believe that constant-cost cases exhaust the categories of admissible competitive price – we are in a position to study the young Sraffa's extra-scientific motivations. Why does a sophisticated intelligence make *this* mistake? Just as inside a fat man is a thin man trying to get out, so outside the Sraffa of the post-World War I heyday of Walras–Marshall neoclassicism, there was
already in 1925 an atavistic classical economist trying to get back in. This is why one can say that, from before 1925 to after 1960, there is a discernible consistency in Piero Sraffa's thought and ideology. An objective reader will want to be alert to this tendency.

1960 verdicts on 1817 Ricardianism

Sraffa's models, we have by now seen, tellingly reject the following Ricardian stereotypes:

1. (a) Prices are determinable by the labour theory of value.
2. (b) Land and rent can be ignored by concentrating on external-marginal land with zero rent (or on internal margins in every positive-rent acre).
3. (c) The complication for pricing of time and the interest rate can somehow be avoided or ameliorated by defining an intermediate standard commodity or workbasket, which is less time consuming and interest-rate-inflated than the most time consuming goods (old wine and tall trees) and is more time consuming and interest-rate inflated than the most directly produced goods (shrimp picked up by labour on the seashore).
4. (d) One can correctly understand the distribution of income among workers, landowners, and capitalists independently of the complications of demand theory (consumers’ demand functions, marginal utility, revealed preferences, etc.).
5. (e) It is superficial to base goods’ and factors’ pricings on mere supply and demand.
6. (f) Adam Smith committed some grave errors in decomposing price and national income eclectically into wage-plus-rent-plus-profit components, and in enunciating his notion of ‘labour command’.

Enough has been given of current misunderstandings related to Ricardo for the present exegesis. What does a close rereading of Smith and Ricardo reveal under the light of the post-1960 analysis? Most of both scholars’ actual inferences about the real world are compatible with the post-1960 findings. Smith's scorecard is certainly not inferior to Ricardo’s, even after we make allowances for the latter's tendency to proclaim as being universal what is only likely.

Ricardo began to write on microeconomics because he thought he discerned basic logical flaws in Smith's system. Just as Steedman showed, in the Ronald Meek *Festschrift*, that Marx's criticisms of Ricardo could not stand up to modern examination, Robert L. Bishop (1985) has shown that Ricardo's criticisms of Smith similarly cannot stand up.

Both Smith and Ricardo tried to compare, by one scalar parameter, the diverse price vector of two times and places: \([P_i/P_1, P_j/W_1, W_m/W_1; r]\) for China and Scotland, or for the Englands of 1780 and 1688. We know that just cannot be done: then, now, or ever. Smith's ‘labour command’ notions merely proceeded from the prosaic observation that people always have about two-thirds of a 24-hour day available to them: \(\sum P_j C_j / W\), is the hours people have to work for what they consume; because per capita \(C\)s tend to rise only with longterm productivity, the above ratio tends to decline only slowly as people enjoy more leisure.

Ricardo never supplanted this imperfect measure by a better one, for all his palaver about absolute standards of value. Worse: gratuitously he attributed to Adam Smith *unwarranted* deviations from the labour theory of value by virtue of Smith's labour command passages. Actually, there is no valid connection. Smith only introduces deviations between what \([P_i/P_j, P_j/W]\) are and what they would be under a labour theory of value when these deviations are warranted by (1) scarcities of needed lands and natural resources, and (2) timephasing of production that involves produced goods as inputs and which takes place when the
competitive market displays positive interest and profit rates.

For all of Ricardo's scolding of Smith as a recanter from the labour theory of value, Ricardo up to his dying month admitted the cogency of the point (2) – that goods of the same content but involving manifestly different time involvements and relative profits would have prices that systematically fail to be proportional to their embodied labour contents. And on point (1), as we have already seen, Smith was right; and Ricardo was wrong in his belief that he could get rid of the complication of rent by use of external (or internal) margins. George Stigler's Pickwickian 1958 defence of 'Ricardo's 93% labour theory of value' on the positivistic grounds that his labour theory of value allegedly averages out in practice to errors of only about 7 per cent makes one wonder what scientists would think of a defence of Lamarck as being 49.99% right; or of the stone-fire-air-and water paradigm as offering a theory of matter that is at least 0.001% as accurate as Mendelev's 93-element periodic table. For some comparisons a 7% error becomes a 70% or a 700% error. Ricardo does seem to make two major advances on Smith. Paradoxically for Sraffa's hero, Ricardo made a giant step beyond Smith toward marginalism. His ubiquitous numerical examples presuppose almost a continuum of alternative doses of labour-and-produced-goods applied to the same acre(s) of land. Inside Ricardo there is a von Thünen and a J.B. Clark striving to be born!

A second Ricardian advance is not so important or clear-cut. You must read Smith closely to perceive his understanding that the rent of inelastically supplied land is price determined rather than price-determining. In Ricardo the point is made crystal clear; in the chapter on land in Sraffa (1960), you must read with sophistication to perceive the point.

Also, Ricardo stresses, indeed overstresses, the point that the profit rate would not have to decline – as saving brings into existence new capital stocks and enlarged populations – if new lands were ever available in unlimited and redundant supply. A good point, even if readers of his expositions might be forgiven for misunderstanding him to imply that the only reason for a drop in interest and profit rates is a rise in rent: actually, as Smith knew, a persistent excess in the growth rate of capitals relative to population must in many realistic technologies raise the real wage and lower profit rates even in the presence of superabundant lands. The post-1960 Sraffian analysts who grade Ricardo's blue books must often mark down his submissions. It is time therefore to study how Ricardo's 1951 editor dealt with these issues.

1960 light on the 1951 editor of Ricardo

The history of humane letters involves only history. Samuel Johnson's mistakes may be more interesting than his correct observations. To the antiquarian, antiquarianism is all there is to the history of the humanities. The history of scientific thought is a two-fold matter. We are interested in Newton's alchemy and biblical prophecy because we are interested in Newton the man and scientist. At the same time his stepsister's theology is likely to elicit a yawn from even the most besotted antiquarian. How Newton discerned that a homogeneous sphere of non-zero radius attracts as if all its mass were at its center point, that is part of the history of cumulative science. Say that this attitude involves an element of Whig history if you will, but remember that working scientists have some contempt for those historians and philosophers of science who regard efforts in the past that failed as being on a par with those that succeeded, success being measurable by latest-day scientific juries who want to utilize hindsight and example post knowledge.

Economics is in between belles lettres and cold science. Serious economists below the age of 60 will judge Sraffa's edition of Ricardo both for its antiquarian and its scientific interests and insights. How then will they judge it?

From an antiquarian view the work is a jewel of perfection. Reviewers' enthusiasm has been unbounded. By luck and Sraffa's energetic skills, virtually every scrap written by David Ricardo has been made available to
the interested reader. This is a boon to scholars who lack the slightest interest in the history of thought for its own sake: Baconian scientific observation of Ricardo's economics has now been made possible by Sraffa's labours.

Editorial emendations have also been done in the new edition with skill and brevity. You might almost say that the editor has for the most part stayed chastely out of the act, letting David and his friends speak their pieces without an accompaniment of Greek Chorus expressions of approval or disapproval.

From the scientific viewpoint, and now a minority viewpoint is being expressed here, there is something anticlimactic about the great Sraffa edition of Ricardo. It is not just that we see, as if imprisoned in amber, the backward and forward gropings of a scholar who from his 1814 entrance into microeconomics until his death in 1823 makes almost no progress in resolving his self-created ambiguities and problematics. Somehow one had hoped that the whole picture would be a prettier scientific picture, so that the editor's Herculean framings would be for a more worthwhile object.

There is, however, no point in lamenting that Ricardo was only what he was. It is the ‘road not taken’ by the editor that occasions a twinge of regret. From the scientist's rather than the antiquarians’ viewpoint, we appreciate from an editor and commentator what Jacob Viner gave economists in his magnificent 1937 Studies in the Theory of International Trade and what Eli Heckscher supplied in his Mercantilism. It is what Clifford Truesdell's lengthy introductions to the collected works of Euler provide, and what Abraham Pais succeeds in bringing off in his 1984 survey of the scientific physics of Albert Einstein. Admittedly old Edwin Cannan carried to excess his patronizing reviews of past economic giants, not only faulting them for their sins in failing to believe what Cannan believed in 1928 but also managing to convict them of the crime of not being so smart as himself. Surely, there is a golden mean somewhere between Cannan's dominating the act and Sraffa's avoiding getting into it?

Fortunately, in his Introduction to Ricardo's Principles (written late in the day, with the help of Maurice Dobb), Piero Sraffa does let himself go a little bit. Thus, he conjectures that Ricardo, in a lost 1814 manuscript or letter or conversation, may have worked out a model in which the profit rate is determined within agriculture, as a ratio of (so to speak) corn to corn; and, Sraffa all but says, in such a model distribution theory is successfully emancipated from value theory. Unlike Viner and Cannan, who can be very hard indeed on the guinea pigs they are judging, one reads Sraffa in his Introduction as being quite indulgent of Ricardo. When he quotes Ricardo as purporting to get rid of the complication of rent by concentrating on the external margin, Sraffa never seems tempted to add that this is a non sequitur. When Ricardo tries to overdifferentiate his product from Smith's, Sraffa never writes: ‘Of course, when Smith made the emergence of positive interest cause a divergence of price from labour contents, he was doing what Ricardo often admits must be done – namely, formulating a two-factor rather than a one-factor model of pricing.’ The critique of mainstream twentieth century that Sraffa never lived to articulate was evidently festering inside the editor of Ricardo during the 1930–1951 period and serving to soften his critical judgments.

Salutations

Did any scholar have so great an impact on economic science as Piero Sraffa did in so few writings? One doubts it. And there cannot be many scholars in any field whose greatest works were published exclusively in their second half century of life.

Piero Sraffa was much respected and much loved. With each passing year, economists perceive new grounds for admiring his genius.

**Abstract**

The s-S model is the canonical model of infrequent and discrete action. It has been used to explain inertia in durable goods, investment, money demand, and cash management, and to provide microfoundations for price stickiness and the real effects of money. In the model, fixed costs make small adjustment impractical. Agents allow their state to drift in response to shocks until it reaches an adjustment trigger before setting it to a target value. This article reviews the microeconomic comparative statics of the optimal s-S policy, as well as the implications of discrete individual adjustment aggregate dynamics.

**Article**

The s-S model is the canonical model of action arising from costs of adjustment. Individuals do not always react to changes in their environment. Consumers rarely buy a new house or car after every fluctuation in their permanent income. Firms often leave prices fixed for months even though information is arriving at a much greater frequency. Fixed costs of adjustment provide a natural explanation of this inertial behaviour. If an agent faces a fixed cost to taking some action and if the loss to non-adjustment is small in the neighbourhood of the optimal choice, then it will pay to leave things be until the benefits of adjustment exceed the costs. Bar-Ilan and Blinder (1996) call this the ‘optimality of usually doing nothing’.

The term s-S derives from inventory theory. In Arrow, Harris and Marschak's (1951) seminal paper, a firm allows its inventory holdings to decline below a level \( s \) before placing an order that replenishes inventories to a level \( S \). Subsequently, the term s-S has come to denote an entire class of models of discrete and infrequent adjustment in which the optimal strategy is characterized by a set of triggers and targets. s-S models have been applied to explain inertia in a variety of microeconomic settings, including money demand, cash management, pricing, durable goods, and investment. In macroeconomics, the principal application has been to provide microfoundations for price stickiness and thereby the real effects of money. This is the menu cost model of price stickiness.

**Microeconomics: the basic idea**

The hallmark of the s-S policy is the combination of inaction and discrete adjustment. The basic idea can be simply illustrated in a static setting. Consider an agent who must choose \( x \) to minimize some twice differentiable, concave payoff function \( \pi(x) \). The agent is endowed with a value \( x_0 \). The wrinkle is that there is a fixed cost \( k \) to changing \( x \) from its initial value. The optimal policy which balances the costs and benefits of adjustment is illustrated in Figure 1. If \( x_0 \) is less than \( S_L \) or greater than \( S_H \), the benefit of adjusting to \( S^* \) outweighs the fixed cost of adjustment \( k \). If \( x_0 \) is between \( S_L \) and \( S_H \), inaction is optimal, and consequently \([S_L, S_H]\) is referred to as the range of inaction. The points \( S_L \) and \( S_H \) are, respectively,
the upper and lower adjustment triggers. $S^*$ is the adjustment target.

Figure 1

An s$-$S policy

The combination of inaction and discrete adjustment is a direct result of the fixed cost of adjustment $k$. If instead the cost of adjustment were some twice differentiable convex function $c(x - x_0)$ with $c(0) = c'(0) = 0$, then there would be no inaction. Since the marginal cost of adjustment is zero at $x_0$, it would always be optimal to move closer to $S^*$.

One of the immediate lessons of Figure 1 is that the range of inaction $[S_L, S_H]$ may be large even if the fixed cost $k$ is small. This is because the payoff function is normally very flat in the neighbourhood of $S^*$. Formally, if $k$ is small we may apply Taylor's theorem and approximate $\pi(x)$ in the neighbourhood of $S^*$ by a quadratic $\pi(S^*) + \frac{1}{2} \pi''(S^*) (x - S^*)^2$.

Recall $S^*$ is the optimal choice so the first-order term is zero. $S_L$ and $S_H$ are the points at which this payoff function is equal to $\pi(S^*) - k$. Solving for $S_L$ and $S_H$ yields...
The size of the range of inaction is increasing in the adjustment cost and decreasing in the concavity of the loss function. Here second order adjustment costs are sufficient to generate a first-order range of inaction (Mankiw, 1985).

One-sided rules

Adding exogenous forces that act on \( x \) makes the problem dynamic. If the increments to \( x \) in the absence of adjustment are Markov, then the optimal trigger-target strategy will be stationary. The literature considers two cases. The first is monotonic drift in \( x \). This leads to ‘one-sided’ s-S rules. Agents let \( x \) drift until it passes a trigger \( s \) and then reset it to some value \( S \). One-sided rules arise naturally in inventory theory (Arrow, Harris and Marschak, 1951), money demand (Baumol, 1952) and pricing under inflation (Sheshinski and Weiss, 1977). Scarf (1959) provides a general proof of the optimality of one-sided s-S policies, requiring only that \( \pi \) is concave.

The canonical model is due to Sheshinski and Weiss. In their model, time is continuous and indexed by \( t \). They interpret \( x = \ln p_i - \ln P \) as the log difference between a firm's price \( p_i \) and a price index \( P \). Payoffs therefore depend on the firm's relative price \( p_i/p \). They assume that the price index grows at rate \( g \) and that the firm discounts future payoffs at a rate \( \rho \). Let \( V \) denote the profits of a firm that has just paid the fixed cost of adjustment and must choose a new price. The firm's optimization problem becomes:

\[
V = \max_{\ln S, T} \int_0^T \pi (\ln S - gt) e^{-\rho t} dt - \frac{e^{-\rho T}}{1 - e^{-\rho T}}.
\]

Here \( \ln S \) is natural logarithm of the target price \( S \), and \( T \) is the time between successive price adjustments. The adjustment trigger \( S = Se^{-gT} \). The first order conditions are:

\[
\int_0^T \pi' (\ln S - gt) e^{-\rho t} dt = 0, \quad \text{and} \quad \pi(\ln S) = \rho (V - k).
\]

The first equation says that the present value of marginal losses over the cycle should be set to zero. If the firm did not discount profits and the loss function were quadratic, this would mean that the trigger \( S \) and target \( s \) would be symmetrically placed about the static optimal price. With discounting the firm backloads losses; \( S \) is closer to the optimum than \( s \).

The second equation says that, at the trigger, the instantaneous profit is equal to the cost of delaying the next cycle.

Most of the comparative statics of this model are similar to those of the static model outlined above. An increase in the cost of adjustment \( k \), an increase in the rate of inflation \( g \), or a reduction in the concavity of \( \pi \) causes the target \( S \) to rise and the trigger \( s \) to fall. One somewhat surprising result is that an increase in \( g \) has an ambiguous effect on the frequency of adjustment. For given s-S bands an increase in \( g \) increases the frequency of adjustment. The widening of the bands, however, works in the opposite direction.

Two-sided rules

If we relax the assumption that the shocks to \( x \) are monotonic, then the optimal policy will involve two triggers, one above and one below the target. Such two-sided rules have been used to study cash management (Miller and Orr, 1966), pricing (Barro, 1972), durable consumption (Grossman and Laroque, 1990) and investment (Abel and Eberly, 1994).

As an example of a two-sided model, take the static example from the beginning of this section and assume that \( x \) follows a Brownian motion in the absence of adjustment. In this dynamic model, the agent would not necessarily adjust to the static optimum; the shape of the profit function and the drift of the shock may cause the agent to pick a target on one
One entirely new effect is that of the variance of the shock to $x$ on the adjustment policy. If $x$ follows a driftless Brownian motion, then an increase in the variance of $x$ leads to wider bands and to more frequent adjustment. The intuition is simple. If the agent keeps the bands fixed, then the increase in the variance of $x$ makes adjustment more frequent. The costs of adjustment rise relative the benefits. Wider bands are optimal. If the agent widens the bands in proportion to the standard deviation of the shock, the frequency of adjustment is unchanged but the benefits to adjustment rise. More frequent adjustment is optimal.

The widening of the bands in this case reflects an option value to waiting. $s$-$S$ adjustment is like exercising an option: the greater is uncertainty, the more this option must be in the money. Dixit (1991) shows that, given this option value, fourth-order adjustment costs lead to a first-order range of inaction.

Macroeconomic models

The work of Blinder (1981) and Caplin (1985) inspired interest in the aggregate implications of $s$-$S$ policies. Blinder provided several examples that illustrate the difficulty of aggregating $s$-$S$ policies and the potential complexity of the resulting dynamics. Caplin demonstrated that the $s$-$S$ model of inventories can explain the commonly observed finding in the inventory literature that production is more volatile than sales, an observation that is at odds with the production smoothing model of inventories (the idea is that the discreteness of orders in the $s$-$S$ model adds to the variability in demand). In recent years, a large body of research has examined the relationship between microeconomic frictions and aggregate dynamics. Two themes run through this literature. The first is a need to surmount difficult modelling issues brought on by the heterogeneity inherent in discrete adjustment. The second is that aggregate dynamics may look very different from the microeconomic dynamics.

The curse of dimensionality

The main difficulty encountered in constructing aggregate models of with $s$-$S$ behaviour is that the cross-sectional distribution of agents’ deviations from their optimum becomes a state variable. This distribution determines how many agents are near their triggers and hence the amount of adjustment that will take place in the near future. To handle the high dimension of this distribution, current models follow one of three approaches. Some, like Caplin and Spulber (1987), Caplin and Leahy (1991, 1997), Danziger (1999) and Gertler and Leahy (2006) make distributional assumptions that reduce the number of state variables. Others, like Blinder (1981), Bertola and Caballero (1990), and Caballero and Engel (1991: 1999), ignore equilibrium considerations and construct aggregates by integrating across actions of isolated individuals facing possibly correlated shocks. A third group, Dotsey, King and Wolman (1999), Willis (2002), and Caplin and Leahy (2006), solve stochastic general equilibrium models, employing approximations that reduce dimensionality.

The Caplin–Spulber model

The Caplin–Spulber model illustrates a few basic lessons in $s$-$S$ aggregation. Three log-linear relationships form the backbone of the model: the aggregate price index $p$ is the average of individual prices $p_i$; output $y$ equals real balances $m - p$; and a firm's optimal price $p^*$ rises with the price level and with real balances, $p^* - p = \alpha(m - p)$. Caplin and Spulber close the model with three assumptions: $m$ is continuous and monotonically increasing; firms follow one-sided $s$-$S$ pricing policies (when $p_i - p^*$ falls to $s$, it is raised to $S$) and the initial distribution of relative prices is uniform between $s$ and $S$.

The surprising result is that money is neutral in this setting in spite of the fact that all prices adjusted infrequently. The reason is simple. Output can only change if the distribution of prices shifts relative to the money supply. As the money supply increases, firms' prices tend to fall relative to $p^*$. The few firms that hit $s$ adjust to $S$. In this way, firms rearrange themselves within the interval $(s, S)$. Given the uniformity assumption, the distribution of $p_i - p^*$ is unchanged. The price index moves with the money supply because a small number of firms change their prices by a large amount.

The Caplin–Spulber model makes two important points. First, discrete adjustment at the microeconomic level does not necessarily imply discrete adjustment at the macroeconomic level. Heterogeneity in adjustment times tends to smooth macroeconomic dynamics. Second, the aggregate implications of $s$-$S$ dynamics depend on the evolution of the distribution of idiosyncratic deviations from the optimum. In this case, the distribution does not change, and the $s$-$S$ model looks exactly like its frictionless counterpart.

The Caplin–Leahy model

Caplin and Leahy (1991) make three simple amendments to the model of Caplin and Spulber: they assume that money is non-monotonic and follows a Brownian motion, that firms
follow symmetric, two-sided pricing policies, and that the initial distribution of prices is uniform within a range equal to the distance between the trigger and the target. In this setting, they show that the distribution retains this shape. It rises and falls within the range of inaction like an elevator.

The Caplin–Leahy model provides an example of an economy in which the distribution of idiosyncratic deviations changes over time. The model also illustrates a new phenomenon: the state-dependence of the effects of aggregate shocks. When the distribution of prices is interior to the range of inaction, shocks to the money supply shift the distribution and output changes. When the distribution of prices reaches the edge of the range of inaction, further movements in the money supply cause price adjustment. The distribution of deviations rearranges itself as in the Caplin–Spulber model and money is neutral.

### The Bertola–Caballero–Engel model

In a series of papers, Bertola, Caballero and Engel develop a very flexible framework for modeling aggregate and distributional dynamics with idiosyncratic shocks. Caballero and Engel (1991) consider prices and one-sided adjustment, and Bertola and Caballero (1990) consider durables and the two-sided adjustment. In this discussion, I will focus on durables and two-sided adjustment.

The model takes the neoclassical model without adjustment costs to be its benchmark. This neoclassical model would predict that an individual would like to hold a quantity $X_i^*(z_i)$ where $z_i$ is a vector of individual characteristics. They then postulate that individuals follow s-S policies: if $X_i - X_i^* \notin (S_L, S_H)$ then the individual adjusts his holdings so that $X_i - X_i^* = S^n_i$. They assume that innovations in $X_i^*$ are i.i.d. across agents $i$ and over time, and are characterized by a stochastic matrix $P_t$, where $P_t$ may depend on the aggregate state of the economy at date $t$. Since $P_t$ has a finite number of states, the $X_i - X_i^*$ take on a finite number of values; denote these deviations by $\tilde{X}_i$. The stochastic matrix $P_t$ and the s-S adjustment policy, induce transitions on the $\tilde{X}_i$. Denote these transitions by the stochastic matrix $\tilde{P}_t$.

This model provides a simple accounting of aggregate dynamics. Let $X_t$ denote the aggregate holdings of durables and let the column vector $f_t$ denote the cross-sectional density of the $\tilde{X}_i$. Then $f_t = \int f_t^* \, \text{d}i + f_t^\#$, and $f_{t+1} = f_{t} \tilde{P}_{t+1}$. In this view, s-S dynamics provide a theory of the error term in the neoclassical model. Deviations from the neoclassical model are associated with fluctuations in the density $f$.

The model allows one to consider the relative roles of idiosyncratic and common shocks. Shocks that are common across firms tend to shift $f$ as they do in the model of Caplin and Leahy. Idiosyncratic shocks, however, tend to mute the effects of aggregate shocks. If only idiosyncratic shocks are present, $f_t$ settles down to an ergodic density of $\tilde{P}$. If idiosyncratic shocks dominate, the microeconomic frictions are lost in the aggregate like in the model of Caplin and Spulber.

Caballero (1993) applies this framework to show that an aggregate s-S model may look like a partial adjustment model. A shock causes some agents to adjust and leaves others near the adjustment trigger. The result is that subsequent idiosyncratic shocks lead to further adjustment.

Like Caplin and Spulber and Bertola and Caballero, Golosov and Lucas (2004) emphasize the fact that the firms that adjust in an s-S model are those with the greatest desire to adjust. This differentiates s-S models from models in which the time between price adjustments is fixed such as the Taylor or Calvo models of price adjustment.

### Equilibrium interactions

The simplicity of the Bertola–Caballero–Engel model comes from the absence of equilibrium interactions. The question arises whether the introduction of equilibrium interactions would enhance or limit the differences between the s-S model and its frictionless counterpart. As usual, the answer is “it depends”.

On the one hand, Thomas (2002) shows that endogenous prices may blunt s-S dynamics. If an unusually large number of people are about to purchase a car, the price of cars should rise, thereby dissuading some agents from making purchases. Endogenous prices movements therefore tend to smooth any deviations of the s-S model from the frictionless neoclassical benchmark. Caplin and Leahy (2004) argue that in a one-sided model the aggregate dynamics become observationally equivalent to a model without adjustment costs.

On the other hand, Ball and Romer (1990) argue that in the presence of strategic complementarities, non-adjustment by some agents can encourage non-adjustment by others. For example, if due to increasing returns the profitability of investment by any single firm is increasing in aggregate investment, then each firm may forgo investment because others have decided to forgo investment. Strategic complementarities may therefore cause the range of inaction to widen, allowing for greater differences from the frictionless benchmark.

s-S models remain an active area of research. At the microeconomic level, recent work has shown how s-S frictions may trap information leading to interesting boom–bust cycles (Caplin and Leahy, 2006) and how adverse selection may amplify s-S frictions (House and Leahy, 2004). At the macroeconomic level, work progresses on the importance of fixed costs in explaining price inertia (Golosov and Lucas, 2003; Gertler and Leahy, 2006; Midrigan, 2006).

The Stability and Growth Pact was designed in 1997 and implemented with the inception of the euro in 1999. An innovative tool in essence, it provides, first, a practical definition of the concept of fiscal sustainability by imposing a ceiling of three per cent and 60 per cent respectively on the budget deficit and public debt. Second, it offers guidelines for governments’ public finances. Third, it offers a way to coordinate national public finances to achieve an optimal fiscal–monetary policy mix within the Eurozone. Even before some countries breached the Pact, the economic literature argued about its rationales.
respectively, no more than three per cent of GDP and 60 per cent of GDP. When, in May 1998 the European Union was deciding which of the EU–15 countries would enter into the EMU in light of the Treaty of Maastricht criteria, some countries, including Germany, would have failed to qualify under the debt criterion. Since then, the debt criterion has been interpreted in terms of trend rather than level in the Treaty of Maastricht, and as a consequence in the Treaty of Amsterdam. The nature of the SGP thus changed within a year of its ratification and a year before its implementation. \textit{De facto} the rule was then to abide by the deficit criterion, leaving the debt criterion to be interpreted in trend. The change in the interpretation of the Treaty of Maastricht resulted in a change in the interpretation of the Treaty of Amsterdam, weakening its original double objective.

What happens when a country does not abide by the three per cent rule? If it is a first violation, the country will have to make a non-interest-bearing deposit with the European Commission. The amount of this deposit comprises a fixed component equal to 0.2 per cent of GDP, and a variable component linked to the size of the deficit. Each following year the Council may decide to intensify the sanctions by requiring an additional deposit, though the annual amount of deposits may not exceed the upper limit of 0.5 per cent of GDP. A deposit is converted into a fine if, in the view of the Council, the excessive deficit has not been corrected after two years. After three consecutive years of violation, the country will see its three deposits become a fine. While the three per cent limit might seem tight, the probability that a country will fail to abide by the Pact for three years in a row, and thus be fined, was originally perceived as low. However, revised numbers from Eurostat indicate that Greece has always been above the three per cent deficit ceiling since its entry into the EMU in 2001. Additionally, Portugal's deficit was greater than three per cent in 2001, 2004 and 2005, Germany's deficits exceeded three per cent from 2002 to 2005, France's deficits exceeded three per cent from 2002 to 2004, and Italy, the UK and the Netherlands breached the three per cent rule in 2004. Further, the deposit rules were not enforced. Not only did Portugal not have to make a deposit, but France and Germany were not fined. The credibility of the SGP was dramatically weakened for the second time.

On 20 March 2005 the European Union decided to try to improve the credibility of the Pact: the Council adopted a report entitled ‘Improving the Implementation of the Stability and Growth Pact’ (Council of the European Union, 2005). The report was endorsed by the European Council in its conclusions of 22 March, and is now an integral part of the SGP. On 27 June 2005 two additional regulations amended Regulations 1466/97 and 1467/97 (Council of the European Union, 1997b; 1997c). The European Council unanimously agreed to introduce some flexibility into the SGP, creating a \textit{de facto} SGP II. This flexibility was particularly introduced via the concept of ‘relevant factors’, which are country-specific. Examples of relevant factors are: (a) budgetary efforts towards increasing or maintaining at a high level financial contributions to foster international solidarity and to achieve European policy goals (notably the unification of Europe if this has a detrimental effect on the growth and fiscal burden of a Member State), (b) structural reforms (for example, pensions, social security), (c) policies supporting R&D, and (d) medium-term budgetary efforts (consolidating during good economic times, a reduction in debt levels, and an increase in public investment). The European Council is the final judge of the relevance of a given factor.

In the meantime, the European Union introduced a ‘code of conduct’ to counterbalance the new flexibility that had been introduced. This code of conduct established a country-specific Medium Term budgetary Objective (MTO) that serves as the actual deficit target around which some flexibility is allowed so long as the country abides by the three per cent reference value. To better understand the
The rationales for a supra-national fiscal rule

One of the major goals of the SGP was to make fiscal discipline a permanent feature of the EMU. Safeguarding sound government finances was regarded as a means to strengthen the conditions for price stability in the Eurozone. However, it was also recognized that the loss by individual countries of the exchange rate instrument in the EMU must be offset by automatic fiscal stabilizers at the national level to help economies adjust to asymmetric shocks. The three per cent deficit limit was calculated under the assumption that the long run average nominal GDP growth rate is five per cent, whereas the long-run inflation rate is two per cent.

Beetsma (2001) provided a summary of the different arguments in favour of a fiscal rule. Arguments in support of a Europe-wide fiscal rule are of three types: benefits to domestic governments; benefits to other governments; and collective benefits.

Benefits to domestic governments

The main benefit to domestic governments, namely, public finance sustainability, has been studied by several researchers, including Amador (2000), Ballabriga and Martinez-Mongay (2005), Bohn (1995), Mongelli (1999), Nielsen (1992), and Perotti, Strauch and von Hagen (1998). The SGP aims at ensuring the sustainability of EU public finances, and hence is supposed to prevent governments hampering growth through unsustainable fiscal policies. For illustration purposes, it should be noticed that the primary balance as a percentage of GDP is close to zero or even positive (a surplus) for most of the euro area members. Thus, what pushes countries like France, and Germany above the three per cent deficit ceiling seems to be, primarily, interest payments on debt.

Does Europe really need a fiscal rule to prevent unsustainable domestic public finances? If the answer is ‘yes’, it is because financial markets do not work properly. If government bond yields include risk premia, increasing indebtedness may cause bond yields to rise, thus raising the cost of borrowing and imposing discipline on governments. Market discipline of this kind may be especially relevant and important in the EMU, in which governments of the Member States can issue debt but do not have the possibility of monetizing and inflating away excessive debt. Spreads between European bonds have narrowed considerably since 1991 for the Eurozone members. Bernoth, von Hagen and Schuknecht (2004) explain that, for Deutschmark/euro denominated bonds, EMU membership reduces the linear effect of debt on default risk premia. Accordingly, EMU members enjoy a lower risk premium than before, but this benefit declines with the size of public debt compared with Germany's. This is consistent with the view that markets anticipate fiscal support for EMU countries in financial distress unless these countries had previously been highly undisciplined. Thus, the disciplinary function of credit markets still exists. If the domestic benefit provided by the SGP to governments is not striking, does the SGP discipline governments in their relationships with others, or ease the coordination of fiscal policies between governments?
A first issue is the likelihood of free-riding behaviours: the fear that governments would run higher deficits in a monetary union. Indeed, under the uncovered interest parity assumption, the understanding was that countries would run deficits that would be financed partly by the Eurozone through an overall rise in the Eurozone bonds interest rate. Undeniably, a country not belonging to a monetary union and running a high deficit will have to face a rise in its domestic interest rate. In a monetary union and integrated capital market, a country running a high deficit will face a much lower rise in its interest rate since it is now equalized at the European level. This may create the incentive for some countries to free-ride on others. If every country behaves this way, on the one hand the overall interest rate rises, and on the other hand the Eurozone faces a greater risk of public finance unsustainability. In the extreme scenario, Eichengreen and Wyplosz (1998) argue that the financial turmoil triggered by a default on the debt of any member country would have significant cross-border effects. In this context, focusing his discussion of free-riding and the SGP on the effects of centralized monetary policy combined with decentralized fiscal policy, Uhlig (2002) regards the SGP as necessary in preventing free-riding in the form of excessively high deficits.

The second issue is moral hazard, which differs from free-riding to the extent that it is ‘post-contractual opportunism’. In other words, once countries belong to the EMU, countries’ loss functions change: without the SGP, governments could weigh more the use of fiscal policies to increase the likelihood of a re-election rather than keeping their public finances in line with the Maastricht guidelines. Dixit (2001) and Dixit and Lambertini (2001) demonstrate that fiscal discretion leads to equilibrium levels of output and inflation very different from Pareto-optimal choices. The SGP should thus prevent countries from changing their attitudes once within the Eurozone.

**Collective benefits**

Collective benefits of the SGP are at least threefold: the coordination of domestic fiscal policies; the policy-mix argument; and the reinforcement of the ECB’s credibility. First, there is the question of fiscal coordination among member countries. A lack of coordination could lead to asymmetric economic shocks on both the aggregate demand and aggregate supply in every country due to large differences in fiscal policies. The coordination of fiscal policies is intended to eliminate those large differences in fiscal policies across countries, and thus implicitly create a Europe-like fiscal policy. The coordination argument is different from the policy-mix argument in the sense that it addresses only the coordination of fiscal policies, whereas the policy-mix argument addresses the question of the coordination of the European monetary policy to a European-like fiscal policy.

Second, Beetsma (2001) and Issing (2002) analyse the policy-mix argument and claim that the advent of a central monetary authority was important in establishing the correct mix of fiscal and monetary policy within the Eurozone. Article 99(3) of the Treaty establishing the European Community stipulates: ‘In order to ensure closer coordination of economic policies and sustained convergence of the economic performances of the Member States, the Council shall, on the basis of reports submitted by the Commission, monitor economic developments in each of the Member States’ (Treaty establishing the European Community, 2002). Beetsma and Uhlig (1999) build a model of centralized monetary
policymaking and decentralized fiscal policymaking and find that a monetary union combined with an appropriately designed fiscal rule will be strictly preferred to fiscal autonomy, as there are benefits to coordination of a Europe-wide monetary policy with a Europe-wide fiscal policy.

The third reason is the maintenance of the credibility of the European Central Bank (ECB) through insuring its primacy as a monetary authority. As noted by Buti and van den Noord (2004, p. 6), the EMU is, ‘[commonly] seen as a regime of monetary leadership where fiscal policy is to support the central bank in its task to keep inflation in check’. This power is drawn from the following European Council resolution which accompanies the Pact: ‘[it] is also necessary to ensure that national budgetary policies support stability oriented monetary policies’ (Buti and van den Noord, 2004, p. 6). Around the time that the Maastricht Treaty was drafted, Beetsma and Bovenberg (1999) showed that the European budgetary situation could undermine the credibility of the future European Central Bank. If a country's fiscal situation becomes unsustainable, other countries might be forced to bail out the insolvent national government. Alternatively, the European Central Bank could be forced to monetize national debts, and thereby create additional inflation in the EU although this would be forbidden in theory by the statutes of the ECB. In this regard, the SGP is a secondary safety device.

Institutional design

Formally, the SGP consists of three elements: a political commitment, a preventive element, and a dissuasive element.

The political commitment

Peer support and peer pressure are an integral part of the Stability and Growth Pact: the Council and the Commission are expected to motivate countries to adhere to the pact, and make public their positions and decisions at all appropriate stages of SGP procedure. The idea is to make the SGP more transparent. Member States may also establish a committee of experts to advise them on the main macroeconomic projections, a notion that has roots in the economic literature (Wyplosz, 2005). With this aim, Council Regulation 1466/97 reinforces the multilateral examination of budget positions and the coordination of economic policies.

The SGP foresees the submission of all Member States to stability and convergence programmes. Stability and convergence programmes must present information on the adjustment path and the expected path of the general government debt ratio, as well as the main assumptions made about expected economic development. New to SGP II and in line with the recommendations of the literature, structural reforms are encouraged by the possibility of taking them into account on the path towards adjustment.

The preventive arm of the SGP

The preventive arm of the Pact was, for the first time, given real substance with the implementation of the Medium Term budgetary Objective (MTO). In the 1997 version of the SGP, the MTO was the same for every country: a close-to-balance or surplus budget. Since 2005 the MTO has been given a new
stability and growth pact: The New Palgrave Dictionary of Economics

definition and is part of a broader new addition to the SGP: the code of conduct. Member States have to define a specific MTO in cyclically adjusted terms. Thus, cycles are now taken into consideration. As recommended by the literature, country specificities must be taken into account. This new device means that surpluses from periods of economic growth are required to be used for debt and deficit reduction. The goals of the MTO are threefold. The first is to provide a margin with respect to the three per cent of GDP deficit ceiling. This margin is calculated by taking into account the past output volatility and budgetary sensitivity to output fluctuations of each Member State. The second goal is fiscal sustainability, for instance, taking into account the economic and budgetary impact of aging populations. Influenced by the economic literature (Blanchard and Giavazzi, 2004; Buti, Eijffinger and Franco, 2003; Fatas, 2005), the third goal is to take into account the need for public investment and represents the structural side of the SGP. The MTOs are revised every four years or whenever a major reform is implemented.

The Council also has the leeway to issue an ‘early warning’ to Member States before an excessive deficit has occurred. Articles 6(2) and 10(2) of Council Regulation 1466/97 state that

In the event that the Council identifies significant divergence of the budgetary position from the medium-term budgetary objective, or the adjustment path towards it, it shall, with a view to giving early warning in order to prevent the occurrence of an excessive deficit, address, in accordance with Article 103 (4) a recommendation to the Member State concerned to take the necessary adjustment measures.

The dissuasive element

If a country breaches the three per cent value for three consecutive years, it is considered to be in violation of the SGP. In order to dissuade countries from excessive deficits, Council Regulation 1467/97 establishes the Excessive Deficit Procedure (EDP). When the council decides that an excessive deficit exists, it makes recommendations to the Member State and establishes a deadline of six months (raised from four) for corrective policies to be implemented. If a Member State fails to implement the policies based on the Council’s decisions, the Council imposes sanctions (deposits, and then fines), which are levied within ten months of the first report of an excessive deficit. A country cannot avoid the deposits, and ultimately the fine, unless the Council decides to abrogate some or all of the sanctions. Abrogation depends on the significance of the progress made by the participating Member State concerned in correcting the excessive deficit, if the breach has resulted from an unusual event or a major economic decline (that is, an annual decline in real GDP of at least two per cent), or if the country’s deficit is due to ‘relevant factors’. Any fines already imposed are not reimbursable. Interest on the deposits lodged with the Commission, and the yield from fines, are distributed among Member States without an excessive deficit, in proportion to their share in the total GNP of eligible Member States.

Assessing the Pact

The economic literature and the Pact
Before the creation of the SGP, the economic literature reflected on the need of a fiscal rule for Europe. In 1997 this fiscal rule materialized into the SGP. Since then, the literature has addressed criticisms to the scientific justifications of the specific design of the SGP, as well as the proposed alternatives. Most of the justifications covered by the literature are inscribed in the following notions: sustainability of public finances; free-riding and moral hazard; coordination and policy mix; and finally the credibility of the ECB.

As for sustainability, the literature is divided with respect to the actual effects of the SGP. Prior to the SGP, financial markets played an active role in disciplining governments, and this still holds true (Bernoth, von Hagen and Schuknecht, 2004). Moreover, some authors challenge the arbitrariness of the definition of sustainability implicit in the SGP (the 3 per cent–60 per cent rule). On the one hand, since budget composition is different across countries, De Grauwe (2003) argues that countries should be able to choose their own debt target instead of the 60 per cent ceiling, and as a consequence have different deficit targets. On the other hand, Coeure and Pisani-Ferry (2005) call for a better concept of sustainability, including, for example, pension regimes. This is something that has been addressed in the amended version of the SGP through the notion of ‘relevant factors’, one of them being the change in pension expenditures.

As for free-riding, the SGP may prevent it (Warin and Wolff, 2005), but it seems not to prevent moral hazard. Indeed, although included in the definition of the Pact, the dissuasive arm seems to malfunction due to moral hazard behaviours: De Haan, Berger and Jansen (2003) explain that this is, likely, one of the reasons why some countries – Germany and France, for instance – decide to put more emphasis on solving their internal troubles by relaxing their fiscal policies instead of strictly abiding by the letter of the SGP. The SGP should prevent countries from changing their attitudes once within the Eurozone, but a recent literature on the political budget cycle (PBC) and the SGP explains that incumbent governments within the Eurozone display an inclination to raise public expenditure, and thus deficits, before an election, although they have to abide by the SGP (Mink and de Haan, 2005). Buti and van den Noord (2003) analyse the fiscal policies over the 1999–2002 period and find some evidence of expansionary fiscal policies motivated by near-term elections. This result is confirmed by von Hagen (2003) who concludes that there is evidence that fiscal policies were used during the period 1998–2002 before elections. Those results mean that the SGP does not seem to prevent moral hazard behaviours.

As for coordination, the SGP may not represent the optimal means of dealing with this problem. Eichengreen (1990), Cohen (1990), and Branson (1990) study the necessity for a federal budget to augment national budgets. MacDougall (1977), De Grauwe (1990), Italianer and Vanheukelen (1993), and Bryson (1994) analyse the need for a centralized budget as a way of establishing automatic stabilizers with income transfers from better-off to worse-off countries.

As for the ECB's credibility, every EMU member enjoys a lower risk premium than before the creation of the euro, which can be explained by many reasons, such as the liquidity of the market and the improved credibility for the central bank in charge of the European monetary policy. Did the SGP play a role? Since Germany and France did not abide by the SGP for some years, it is difficult to grant this benefit exclusively to the SGP.

In this context, the SGP has had mixed results. The amended version of 2005 embodies some of the changes called for by the economic literature. The lack of flexibility was one of the main criticisms. For instance, Cooper and Kempf (2000) call for some flexibility at the fiscal level, as the ECB lacks the
tools necessary for stabilization in the presence of country-specific shocks. The new definition of the MTO based on country specificities seems to go into this direction, although this is misleading. Indeed, the MTO in SGP I was ignored by the countries which considered only the three per cent of GDP reference value. Its new definition, based on country specificities, is now at the core of the assessment of countries’ fiscal policies. In other words, it seems that for national policies what matters is no longer three per cent but their specific medium-term objectives, by definition lower than three per cent. In this regard, the new preventive arm seems to be tighter than the original SGP, and hence less flexible. Flexibility refers to the idea of an optimal fiscal policy even though it can be above the three per cent deficit limit. In order to target this optimal fiscal policy and prevent at the same time the existence of a political budget cycle, authors such as Wyplosz (2005), Beetsma and Debrun (2005), Annet, Decressin and Deppler (2005), and Marinheiro (2005) argue for the strong version of institutional reform – the creation of an independent Fiscal Policy Committee (FPC), and a reconfiguring of the debt targets so that they are established, country by country, on a basis of the starting position. This would not automatically mean the end of a fiscal rule in Europe, but it would mean the end of the SGP. However, SGP II seems to go in this direction. Indeed, it allows countries to decide whether they need an independent committee to scrutinize their domestic fiscal policy. In fact, this independent committee is not the same as the FPC: the FPC could decide an optimal fiscal policy above the three per cent deficit limit, which is not the case with a national independent committee.

Another solution to introduce some flexibility without renegotiating the Treaty of Amsterdam, as well as giving some weight back to the debt criterion, is proposed by Pisani-Ferry (2002): allowing countries to opt out of the Excessive Deficit Procedure based on the deficit, and abide by the 60 per cent of GDP debt criterion. In this spirit, a country can have a deficit greater than three per cent as long as its debt is below 60 per cent. But before we consider other amendments, what is the future of the Pact from an institutional perspective?

The future of the Pact

The changes produced by SGP II to SGP I are twofold and concern both the preventive and dissuasive arms of the Pact. First, there is new definition of the medium-term objective (preventive arm). However, it is acceptable if countries do not abide by the medium-term objective as long as they do not go over the reference value of three per cent: regulation 1466/97 explains,

[in] order to enhance the growth-oriented nature of the Pact, major structural reforms which have direct long-term cost-saving effects, including by raising potential growth, and therefore a verifiable impact on the long-term sustainability of public finances, should be taken into account when defining the adjustment path to the medium-term budgetary objective for countries that have not yet reached this objective and in allowing a temporary deviation from this objective for countries that have already reached it.

This amendment does not relax the reference value of three per cent, but relaxes the constraint imposed by the definition of the medium-term budgetary objective. The amendment adds: ‘in order not to hamper structural reforms that unequivocally improve the long-term sustainability of public finances, special
Attention should be paid to pension reforms introducing a multipillar system that includes a mandatory, fully funded pillar, because these reforms entail a short-term deterioration of public finances during the implementation period.

The second change was to the dissuasive arm and deals with exceptional circumstances. The dissuasive arm is looser than it was. The European Commission is asked to prepare a report in case of a breach of the deficit reference value by a Member State. If the breach is not justified by an economic downturn (a recession of at least two per cent of GDP) or an exceptional external event, countries have to make deposits to the European Commission that will be transformed into fines in the third consecutive year if a country could not abide by the reference value for three years in a row. The amended regulation loosens the constraint by introducing the notion of relevant factors. Moreover, before asking for deposits when a country breaches the deficit reference value for the first or second time, the Commission should look at the medium-term economic position of a country, at relevant factors, and at the overall quality of public finances.

In the long run, the most important question in assessing the effects of SGP II versus SGP I is to know whether the preventive arm – tighter than under SGP I – will outweigh the loosening of the dissuasive arm. The answer is in the hands of national governments. In retrospect, the SGP does not seem to provide an ideal answer to the branches of the literature studying the potential need for a fiscal rule. This is not surprising, since the SGP is, by its nature, as much a politically designed rule extending the Treaty of Maastricht as an economically designed one.

stable population theory

Abstract

A population's age structure and growth are determined by rates of fertility, mortality and migration. Stable population theory provides a widely useful mathematical framework, described here, that connects a fixed set of rates to the population dynamics they generate. This theory makes it possible to trace causes and consequences of population change, to establish methods for estimating rates, and to make projections of future population. Much of the power of stable theory rests on the fact that the key features of population dynamics with fixed rates can be generalized, as discussed here, to rates that vary over time.

Article

Demographers are centrally concerned with the relationship between a population's age structure and its rates of mortality, fertility and immigration. Alfred Lotka (Sharpe and Lotka, 1911; Lotka, 1939) devised the fundamental mathematical form of this relationship for a population with no migration, in the event that age-specific mortality and fertility do not change over time.

Renewal equation

Lotka dealt primarily with females; we shall say more about males shortly. Mortality is described by an instantaneous mortality rate \( \mu_x \) at each age \( x \), and determines the probability \( l(x) \) of surviving from birth to age \( x \), as 
\[
l(x) = \exp\left( - \int_0^x ds \mu(s) \right).
\]
Demographers refer to \( l(x) \) as survivorship. Fertility is...

described by the rate \( m(a) \) of female births per female of age \( a \). The goal of the theory is to track
changes in population number and age composition over time. Suppose that we know the numbers of
females at all ages at some initial time that we denote as \( t = 0 \). Writing \( B(t) \) for the rate at which females
are born to the total population at any later time \( t > 0 \), Lotka derived what is called the ‘renewal equation’,

\[
B(t) = \int_0^t ds l(s) m(s) B(t - s) + h(t).
\]

To understand this equation, note first that the number of females \( n(s, t) \) at age \( s \) at time \( t \) must be simply
the number of survivors, \( l(s) B(t - s) \), of the \( B(t - s) \) females born at time \( t - s \). Thus, the first term on
the right side of the equation sums births to females whose ages range from zero to \( t \), and who were born
at any time between zero and \( t \). The second term \( h(t) \) represents births to all females who were alive at
the initial time \( t = 0 \), and whose ages are therefore greater than \( t \). As time passes, the females whose
children are counted in \( h(t) \) get older and eventually die. Thus after a long time passes (that is, for large
values of \( t \)) only the first term on the right of the renewal equation remains. Lotka found that the
solutions to this simpler equation are of a particular form that describes what is called a stable
population.

Classical stable theory

A **stable population** has an unchanging age structure and a constant exponential growth rate \( r \); both
structure and growth rate are determined by vital rates (mortality, fertility). In a stable population, births
at time \( t - a \) must differ from births at time \( t \) by an exponential factor in the growth rate,

\[
B(t - a) = e^{-ra} B(t).
\]

Also, a stable population obeys the renewal equation at long times \( t \) when the term
\( h(t) \) is zero. Inserting the above exponential relationship into the renewal equation shows that the growth
rate \( r \) satisfies what is called Lotka's **characteristic equation**,

\[
1 = \int_0^\infty da l(a) m(a) e^{-ra}.
\]

In a stable population, the number of females at age \( s \) at time \( t \) is \( n(s, t) = l(s) B(t - s) = l(s) e^{-rs} B(t) \).
Hence the proportion of a stable population that is between ages \( a \) and \( a + da \) in a stable population is

\[
u(a) = c l(a) e^{-ra},
\]

with
The per-capita birth rate (also called the crude birth rate) in a stable population is \( b = \int_0^\infty da \mu(a) u(a) \), and the per-capita death rate (also called the crude death rate) in a stable population is \( d = \int_0^\infty da \mu(a) u(a) \). The stable growth rate is \( r = \frac{b - d}{b} \) (as may be shown by using the relationship \( \mu(a) = -\frac{1}{b} \int \frac{il(a)}{da} \) in \( d \) and integrating by parts).

Given unchanging vital rates and any initial population in the full renewal equation, Lotka showed that the population obtained by solving the renewal equation must eventually approach a stable population whose growth rate is determined by the characteristic equation. This result explains the adjective stable in the term, stable age distribution. Lotka's original proof was put on a secure mathematical footing by Feller (1941; 1971); such stability is characteristic of many populations that undergo mortality and renewal (including, for example, light bulbs or laptop computers that die at a rate that depends on their age and must therefore be replaced at some rate). The property of stability of the age distribution when mortality and fertility are constant in time is known as ‘demographic strong ergodicity’.

In Lotka's classical theory of demography, male births are accounted for by noting that the human sex ratio at birth is remarkably constant over time and place, close to 1.05 male births for every female birth, except in cases where deliberate preference for one or the other sex leads to an excess mortality of the less favoured sex. Thus the numbers of males born are computed simply as a constant multiple of the number of females born. Male age structure will obviously become stable along with the female age structure, but male mortality and thus survivorship are usually different from female.

In practice, the renewal equation, in which time is a continuous variable, is often replaced by a discrete-time version in which time advances in discrete units. In that case the age composition of a population is represented by a vector of population numbers in successive discrete age classes, and the renewal equation is replaced by a matrix recursion. Leslie (1945) formulated and analysed the properties of the discrete equation, which has much the same properties as the continuous version. Coale (1972), working with time as a continuous variable, and Keyfitz (1977), working with time as a discrete or a continuous variable, provide authoritative discussions of the mathematics and application of stable population theory.

**Applying classical stable theory**

Stable theory and the characteristic equation yield powerful, fundamental insights into the relationship between mortality, fertility, population growth rate and age structure. We mention a few important examples here. The fact that a stable population's age structure is proportional to \( l(a)e^{-ra} \) shows that a population's age pyramid is steeper for faster growing populations and shallower for low-mortality populations. Economists are often interested in the proportions of a population at young (usually under 20 yrs), working (20 to 65 yrs) and old (over 65 yrs) ages, and in the dependency ratio (the sum of young and old divided by the number working). With mortality fixed, the dependency ratio for a stable population theory.
population is high when the growth rate $r$ is either large and negative (fewer young, many old) or large and positive (many young, fewer old), and there is an optimal growth rate at which dependency ratio is minimized. With growth rate fixed, the dependency ratio increases when mortality declines because more people survive to reach old age. These properties of stable populations carry over qualitatively to real populations, illuminating the effects of changes in mortality and fertility on population composition. In particular many industrialized countries in the 21st century have small positive or even negative growth rates as well as low mortality; today's populations thus have a larger fraction of older individuals and a smaller fraction of young than the higher-fertility and lower-mortality populations of the 19th and early 20th centuries. Changes in population age structure play an important role in the theory of economic demography, especially in understanding the role of transfers between different age segments of a population (Lee, 1994).

In stable theory, the contribution of fertility to population growth rate is described by the net replacement rate,

$$\text{NRR} = \int_0^\infty d\alpha \lambda(a) m(a),$$

which is the expected lifetime reproduction of a female. A stable population grows ($r > 0$), declines ($r < 0$) or is stationary depending on whether the NRR is greater than, less than, or equal to one. For any given pattern of mortality the condition $\text{NRR} = 1$ defines replacement fertility, the fertility rate at which $r = 0$. The generation time of a stable population is the average number of years over which a cohort of mothers produces its daughters, and is defined as

$$T = \int_0^\infty d\alpha \lambda(a) m(a) e^{-r\alpha}.$$

Generation times in contemporary populations are set primarily by the age pattern of reproduction. Historically generation times have ranged from 20 to 25 years for human populations, being on the lower end in high-fertility populations that have a high growth rate.

Stable population theory has found wide application in ecology and evolutionary biology, as discussed extensively by Caswell (2001). In the biological context, the stable population growth rate $r$ is often used to measure the fitness (in a Darwinian sense) of a particular biological combination of fertility and mortality. Another useful characterization of fertility and mortality patterns is given by the reproductive value $v(a)$ of an individual of age $a$ in a stable population (Fisher, 1930).
Clearly $v(a)$ is the discounted present value of an individual's future reproduction after age $a$, using the discount rate $r$. The characteristic equation tells us that $v(0) = 1$, so the reproductive value measures the future contribution of an individual of age $a$ relative to a newborn. In evolutionary theory, and in some questions in economic demography, we are interested in the effect on population growth rate of a change in either mortality or fertility at a particular age. An increase in fertility at age $a$ changes $r$ by an amount proportional to the reproductive value $v(a)$, whereas an increase in mortality at age $a$ changes $r$ by an amount proportional to the product $l(a)e^{-ra}v(a)$.

An elegant and important concept derived from stable theory is that of population momentum (Keyfitz, 1971). Suppose that a stable population is growing at some rate $r > 0$ and that the population makes an instantaneous transition to replacement fertility. Stable theory implies that with this reduced fertility the population will eventually become stable and stationary with growth rate $r = 0$. Keyfitz asked: what is the ratio of the size of the final stationary population to the size of the population just before the fertility transition occurs? The answer is that the ratio equals *population momentum*. Write $v_0(a)$ for the reproductive value in the final stationary population, $T_0$ for the generation time in the final stationary population, and $u(a)$ for the stable structure of the initially growing population. Then Keyfitz's population momentum equals $\frac{1}{T_0} \int_0^\infty da v_0(a) u(a)$. In the real world, fertility transitions take time and so actual momentum is generally larger than Keyfitz's momentum, as shown by Li and Tuljapurkar (1999).

Stable theory has also been extended to include the effects of migration, with much attention focused on the effects of immigration into low-fertility populations. Arthur and Espenshade (1988) and Feichtinger and Steinmann (1992) analyse the case where a stream of immigrants of known age distribution and total number is added annually to a population with below-replacement fertility. This case is relevant to a number of industrialized countries. Over time, the population's age structure will again converge to a stable age structure that is determined jointly by the age structure of the immigrant flow, the vital rates of the resident population, and the rate at which immigrants' vital rates converge to those of the residents. Feichtinger and Steinmann point out that the general theory of stable populations with immigration is closely connected with the theory of manpower systems and other social processes; for a review of the latter see Vassiliou (1997).

The concepts and mathematics of stable theory are relevant to the dynamics of populations that are structured by variables other than age. In demography, we may be interested in the joint distribution of age and parity (a female's parity is the number of offspring that she has had), or of age and health status. In biological applications, we may be concerned with a stage variable (for example, size or developmental state) rather than with age: this is especially the case for plants, insects and other organisms in which age is not directly observable in nature, or in which vital rates depend directly on size or state rather than on age. In such cases, Lotka's renewal arguments can nonetheless be applied, except that we must keep track of the distribution of individuals according to both their age and their
Stable population theory: The New Palgrave Dictionary of Economics

Stage. Vital rates now include mortality and fertility as function of age and stage, as well as rates at which individuals move between stages during the course of life. It should be obvious that such stage-based demography is relevant to economic analyses of the human life cycle in which we are interested in the transitions made by individuals between stages such as marriage, divorce and employment. The stable theory of stage-based demography parallels the theory we describe here, and an account of the biological theory is given by Caswell (2001).

Stable theory has been an essential component of successful efforts by demographers to create widely applicable models of vital rates, as nicely discussed by Preston, Heuveline and Guillot (2000). The authors also describe an extension of stable theory, in which a population's different age segments change at different rates over time. Thus, if the growth rate of individuals aged \( a \) at time \( t \) is \( r(a, t) \), the population density of individuals at age \( a + b \) at a later time \( t + b \) is given by

\[
n(a + b, t + b) = n(a, t) \frac{l(a + b)}{l(a)} \times \exp \left( \int_0^b ds r(a + s, t + s) \right).
\]

This expression allows us to use observations at different times on population structures (such as censuses or surveys) to estimate the growth rates of particular cohorts. Since populations in the real world are rarely stable, this approach is often useful.

**Demographic weak ergodicity**

Ansley Coale (1957) pointed out that mortality and fertility rates in practice will vary with time, violating the assumptions of strong demographic ergodicity and calling into question the use of classical stable theory. He argued, however, that human populations should forget their more remote history, in the sense that today's population composition should be most strongly influenced by the recent rather than the distant past. Lopez (1961; 1967) provided a mathematical framework for this argument by defining *demographic weak ergodicity*: if mortality and fertility rates change with time in some arbitrary (but demographically sensible) way, and two populations with distinct initial age structures are subject to the same sequence of changing rates, then as time goes by the age structures of these two populations will become proportional. Lopez's original proof has been strengthened and extended in more recent work, as discussed for example by Tuljapurkar (1982). An important consequence of demographic weak ergodicity is that we are justified in focusing attention on relatively recent changes in mortality and fertility as being the key to current and future age structures.

**Stochastic stable theory**

The work of Coale and Lopez provided the impetus for a powerful generalization of stable theory to cases when mortality and fertility rates change with time in a stochastic fashion. Analysis of historical mortality and fertility rates for any real population reveals that these rates change with time. Some
changes are slow and secular, as has been true for the 20th century decline in mortality and for the transition to low fertility in some parts of the world. But many changes in rates occur over time intervals of a generation or less and are often quickly reversed: 20th century examples include fertility swings in industrialized countries, and short-term (decadal or faster) variability in age-specific mortality rates. Cohen (1976) formulated a mathematical description of such variability for a discrete-time population model in which fertility and mortality rates vary over time in response to some underlying stochastic process. (Cohen's original model assumed a finite-state Markov process but his results have been extended to many other stochastic processes.) The vital rates (mortality, fertility) vary over time but have a stationary probability distribution. A central assumption on the variability in rates is that any initial population structure (for example, with only children present, or only adults present) will eventually lead to a population in which every age class is represented. Given this condition, Cohen showed that, if the same random sequence of vital rates is applied to two populations with different initial age structures, the two populations will change subsequently so that their age structures become proportional over time. Thus the stochastic sequence of mortality and fertility rates generates a stationary stochastic sequence of population age structures that is maintained over time. This property is called \textit{demographic stochastic weak ergodicity}. Let $X(t)$ denote the time sequence of vital rates and $Y(t)$ the time sequence of population structures. Then there is a joint stationary probability distribution of these two quantities. The stationary stochastic sequence of age structures is a \textit{time-varying stable population}.

The property of stochastic weak ergodicity allows demographers to focus attention on the time-varying stable population. We note here some useful properties of this kind of stable population; see Tuljapurkar (1990) and Caswell (2001) for further discussion. The growth rate $r$ of a classical stable population is replaced here by a long-run stochastic growth rate that satisfies a stochastic analog of the Lotka characteristic equation. The age structure itself can be described in terms of its moments, means, variances, covariances and autocorrelations. Variability over time in population structure reflects both the time-averages of mortality and fertility and the variances and covariances of these vital rates over time. Finally, stochastic theory allows us to characterize population trajectories in terms of probabilities of future events; for example, we can compute the probability that a dependency ratio will become unusually high or low over some specified time interval. Stochastic stable theory has been useful in demographic applications, especially to forecasting and fiscal problems (see below), and in a variety of ecological applications.

\section*{Population forecasts}

The age structures of human populations can be effectively described, analysed, and even projected with reasonable accuracy using classical one-sex renewal theory. In many situations demographers are called upon to make extremely long-term forecasts of population number and composition; for example, the United States Social Security Administration's trustees require a 75-year forecast. In most forecasts made by institutions such as census bureaus or the United Nations, experts first make a set of alternative projections of mortality, fertility and immigration, and then generate projections along these alternative futures. These alternative futures are referred to as scenarios. In most cases, the vital rates in these projected scenarios settle to constant values after some initial period of time, often over a generation.
stable population theory: The New Palgrave Dictionary of Economics

length or so. Correspondingly, the long-run forecast populations always approach classical stable populations that correspond to the alternative long-run rates.

Stochastic stable population theory generalizes this forecasting approach considerably by projecting vital rates as non-stationary stochastic processes. In most cases, the stochastic variability in the rates is fixed or changes very slowly, and there is a long-run slow secular change in the time-average vital rates. With vital rates projected in this way it is possible to generate stochastic population forecasts. At long times, these forecasted population structures usually approach stable time-varying populations. A major advantage of using stochastic stable theory is that probabilistic projections can be made of population structures, dependency ratios, and associated quantities of policy interest (Lee and Tuljapurkar, 2000).

Heinrich von Stackelberg was born on 31 October 1905, in Kudinowo, near Moscow, where his father was the director of a factory. The homeland of the family was the Baltic state of Estonia, although his mother was born in Argentina of Spanish descent. The family escaped the Russian revolution, retiring first to Yalta in the Crimea, and afterwards to Germany. They initially settled in Ratibor, Silesia but moved to Cologne in 1923. He completed his high school education in Cologne, studied economics at the University of Cologne, obtaining his ‘Diplomvolkswirt’ (master of economics) in 1927, ‘Dr. rer.pol.’ in 1930, and his habilitation in 1935.

He began his scientific career in 1928 as an assistant professor at the University of Cologne (1928–35). From 1935 until 1941 he was ‘Dozent’ and ‘ausserordentlicher Professor’ (associate professor) at the University of Berlin, and from 1941 until 1944 full professor at the University of Bonn. During World War II he was for some time drafted to military service. In 1944 and 1945 he held a guest professorship at the University of Madrid. He died at the early age of 41 in Madrid on 12 October 1946.

Stackelberg was the most gifted theoretical economist in Germany during his time. His habilitation thesis *Marktform und Gleichgewicht* (1934) has had a lasting influence on price theory. ‘Stackelberg asymmetric duopoly’ is known all over the world. His contributions to Austrian capital theory are the basis for all modern extensions of this theory. His textbook *Grundzüge der theoretischen Volkswirtschaftslehre* (1943) was the first ‘modern’ introduction to economics in the sense that it is based on a coherent theory of household and firm behaviour. Moreover, Stackelberg contributed to several other fields: cost theory, exchange rate theory, saving theory and others. In Germany he was one of the few leading economists who introduced mathematics into economics and took up the Anglo-Saxon approach in price and cost theory (Edgeworth, Marshall, Hicks, Harrod, Chamberlin and others).

The difficulty of oligopoly theory consists in the fact that the oligopolists are in a game theoretic situation which, in general, cannot be put into the form of a pure maximum problem. Stackelberg’s seminal idea was that this can nevertheless be done if – in the case of a duopoly – one firm takes a ‘dependent’ position (i.e. takes the actual price or production of the other firm as given) and the other an ‘independent one (i.e. knows this behaviour and fixes its price or production accordingly so that it maximizes its profits or other utility indices). If both firms wish to be in the ‘dependent’ position, a Cournot-type equilibrium results; on the other hand if both firms wish to be in the ‘independent’

position, a contradiction arises since each firm assumes a behaviour of the other which is incompatible with its actual behaviour. If they nevertheless fix their prices (or production) at that level, a ‘Bowley’-type oligopoly solution, as Stackelberg calls it, would emerge. Since it is unclear which position the firms will take, Stackelberg considered the oligopoly as a market form without equilibrium. Marktform und Gleichgewicht (1934) is comparable with Chamberlin's The Theory of Monopolistic Competition (1933) and Joan Robinson's The Economics of Imperfect Competition (1933), but goes further in the analysis and in mathematical rigour.

Stackelberg accepted Austrian capital theory, which emphasizes the time structure of production (‘zeitlicher Aufbau der Produktion’). The main drawback of this theory is that one of its basic concepts, namely the average gestation period, could not be well defined and measured for a modern interdependent economy. In ‘Kapital und Zins in der stationären Verkehrswirtschaft’ (1941) Stackelberg suggests the following solution. In a simple economy where the original factor input takes place in period O and the product ripens by nature (such as in the production of wood), the subsistence fund S, the yearly income (=harvest) Y, the interest factor $q=1+r$, where $r$=rate of interest, and the gestation period $T$ satisfy the relation $S=Y/q^T$. Stackelberg defines an economy as equivalent to this simple economy, if they correspond with respect to $S$, $Y$ and $r$, where $S$ is identified with labour income $L$. Thus the average gestation period may be calculated by $T=(\log Y – \log L)/\log q$.

In the article ‘Beitrag zur Theorie des individuellen Sparens’ (1939), Stackelberg deals with the problem: why does a household save? What are the effects of interest rate expectations on household saving? He took up the conceptual framework of Hicks and Allen (1934) and applied it to the allocation of expenditures in the time space. He derived Böhm-Bawerk's law of under-evaluation of future commodities from the law of declining marginal rates of substitution and showed how the optimal allocation of expenditure in time depends on it.

Stackelberg was a neoclassical economist. In his opinion, Keynes really added nothing new to available economic knowledge. He also considered Keynes's interest rate theory as a special case of Böhm-Bawerk's theory of exchange of present against future commodities (see ‘Zins und Liquidität’, 1947). Stackelberg kept intimate relations with that group of German economists (Walter Eucken, Erwin v. Beckerath and others) who during the war prepared the transition of the German economy to a free enterprise system. In spite of his untimely death, his influence especially on economic theory in Germany was most important in the sense that he initiated the reorientation of German economic thinking to the Anglo-Saxon approach. His very original contributions to economic theory have had a lasting effect.

Stakhanovism was a movement begun in the Soviet Union in 1935 to increase labour productivity by the popularization of work techniques reputedly initiated by workers themselves. On 31 August 1935, Aleksei Grigorevich Stakhanov, a 30-year-old miner in the Donets Basin, cut 102 tons of coal during his six-hour shift. This amount represented 14 times his quota, and within a few days was hailed by Pravda as a world record. Anxious to celebrate and reward individuals’ achievements in production that could serve as stimuli to other workers, the Soviet Union's Communist Party launched the Stakhanovite movement, or Stakhanovism. The title ‘Stakhanovite’, conferred on workers and peasants who set production records or otherwise demonstrated mastery of their assigned tasks, quickly superseded that of ‘shock worker’ (udarnik). Day by day throughout the autumn of 1935, the campaign intensified, culminating in an All-Union Conference of Stakhanovites in industry and transportation which met in the Kremlin in late November. Outstanding Stakhanovites mounted the podium to recount how, defying their quotas and often the scepticism of fellow workers and bosses, they applied new techniques of production to achieve stupendous results for which they were rewarded with wages that reached dizzying heights. Stalin captured the upbeat mood of the conference when, by way of explaining how such records were possible only in the ‘land of socialism’, he uttered the phrase, ‘Life has become better, and happier too.’ Widely disseminated, and even set to song, Stalin's words served as the motto of the movement.

The year 1936 was declared a Stakhanovite year. Competitions among workers during designated Stakhanovite months, ten-day periods (dekady), and shifts spread the movement everywhere in the Soviet Union. Not a single place of work was without its Stakhanovites. Even the Gulag got into the act. The highest proportion of Stakhanovites could be found in the extractive industries, the energy sector, and railway transportation, where upwards of 40 per cent of all workers were so designated by August 1936. Young male workers who had passed technical training courses, were classified as at least semi-
skilled and had an average of three to five years experience were most likely to be represented among Stakhanovites. However, what was characteristic in industry was not the case in agriculture, where the most prominent Stakhanovites were women. They included Pasha Angelina – brigade leader of the first all-female tractor brigade – and Maria Demchenko, the sugar-beet cultivator. The enormous publicity surrounding these and other female collective- and state-farm workers suggests a continuation of the party’s efforts, begun during collectivization, to forge an alliance with rural women against the previously dominant patriarchy of peasant families. Lending support to this interpretation is the rather frequent mention in rural female Stakhanovites’ testimonials of having been orphans and of overcoming the resistance of unenlightened husbands.

Stakhanovism encompassed lessons about not only how to work but how to live. In addition to providing a model for success on the shop floor, in the mine, or in the field, it conjured up images of the good life. Many of the qualities Stakhanovites were supposed to exhibit at work – cleanliness, neatness, punctuality, preparedness, and a keenness for learning – were applicable at home, too. These qualities were associated with kulturnost (‘culturedness’), the acquisition of which marked an individual as a New Soviet Man or Woman. Advertisements for perfume in journals intended for Stakhanovites, articles about Stakhanovites on shopping sprees, photographs of Stakhanovites sharing their happiness with their families, newsreels showing them moving into comfortable apartments and driving new automobiles presented to them as gifts, all symbolized kulturnost. Wives of male Stakhanovites had an important part to play in the movement as helpmates preparing nutritious meals, keeping their apartments clean and comfortable, and otherwise creating a cultured environment in the home so that their husbands were well rested and eager to work with great energy. It was also important to demonstrate that Stakhanovites were admired by their workmates and considered worthy of holding public office.

Stakhanovites, however, were not necessarily popular. Even before the raising of output norms in early 1936, workers who had not been favoured with the best conditions and consequently struggled to fulfil their norms expressed resentment of Stakhanovites by verbally and even physically abusing them. Foremen and engineers, only too well aware that ‘recordmania’ and the provision of special conditions for Stakhanovites created disruptions in production and bottlenecks in supplies, also on occasion ‘sabotaged’ the movement. At least that was the accusation made against many who often served as scapegoats for the failure of Stakhanovism to fulfil its promise of unleashing the productive forces of the country. Thus, at least in an indirect way, Stakhanovism fed the Terror of 1936–8.

In the course of those years, quite a few Stakhanovites received special educational training followed by promotion into the ranks of management; others were sent on tours of worksites where they demonstrated their skills; many became deputies in the Supreme Soviets of the USSR and its constituent republics. Eventually, Stakhanovism was routinized, becoming merely another task for party and trade union committees to carry out. It continued into the war and even enjoyed something of a revival in the post-war years when it was exported to eastern Europe. Stakhanov himself served in a number of honorific administrative positions in the coal-mining industry before descending into alcoholism and disability. When he died in 1977 he was all but forgotten, although the eastern Ukrainian town of Kadiyevka (Lugansk oblast) where he had worked and set his record had its name changed to Stakhanov. The 50th anniversary of Stakhanovism in 1985 was observed in the Soviet Union with an outpouring of popular and scholarly literature, museum displays, lectures, and special exhibitions, all of which were intended to inspire the ‘Stakhanovites of the 1980s’. It is hard to imagine Stakhanovism inspiring anything in the post-Soviet era except perhaps ridicule.

Abstract

This article describes the economic working arrangements put in place in the Soviet Union in the early 1930s by Stalin from the vantage point of Mises’ and Hayek’s scepticism about the feasibility of socialism. It describes the high-level management of the economy, the dictator's curse, the ad hoc nature of planning, the handling of principal–agent problems, the management of worker morale, the manner in which investment was maximized, the dictator's aversion to rules, and the use of coercion to achieve economic goals. Stalin's use of forced labour in his Gulag system is described as coercion failure.

Article

‘Stalinism’ refers to a political–economic system of state ownership and administrative-resource allocation directed by a monopoly political party (in Stalin's case, the Politburo of the Central Committee of the Communist Party, or Stalin himself), which combines economic incentives and ‘repression’ to achieve its economic and political goals (Gregory, 2004). Stalinism was first created in the Soviet Union as Stalin gained totalitarian authority and has subsequently been practised in modified forms by dictators in China (Mao), Cuba (Castro), North Korea (Kim Jong Il), Iraq (Saddam Hussein) and Cambodia (Pol Pot). ‘Early’ Stalinism dates from the expulsion from ruling circles of Stalin's last significant opposition in 1929 and 1930, when Stalin still had to build majorities within the Politburo (Khlevnyuk, 1996). ‘High Stalinism’ dates from late 1934 until his death in March 1953, when Stalin's decisions could no longer be challenged and his top officials carried out orders rather than participated in collective decisions. By the mid-1930s, the Politburo had ceased to meet regularly, and the party and state were run by informal groups appointed directly by Stalin. Stalinism is distinguished from the ‘administrative-command’ system of the post-Stalin era by the latter's less extreme use of repression and by its collective leadership.

The economic policy of Stalinism was marked by extremely high rates of capital accumulation in heavy industry and defence, with lesser priority for consumer goods and services. Nevertheless, there were investment cycles both in Stalin's Russia and throughout the Soviet empire, even though investment was dictated politically rather than by market forces. Although some interpret these investment cycles as temporary bouts of moderation, Stalin deliberately reduced investment when he feared that low real wages would harm work effort or, worse, lead to uncontrollable civil unrest. Stalin used his secret police to gauge the mood of workers and peasants for this purpose.

Although Stalin's predecessor, V.I. Lenin, established the institutions of terror, such as a special secret police for political enemies and an arbitrary system of ‘socialist legality’, it was Stalin who initiated ‘mass operations’ against his enemies. In January 1930, he ordered the arrest, deportation, and execution of kulaks (wealthier peasants and virtually any perceived regime opponent). In this ‘dekulakization’ campaign, more than two million peasants were deported to ‘special settlements’ or to the ‘corrective labour camps’ of the Gulag. The term ‘Gulag’ denotes the Main Administration of Camps under the jurisdiction of the interior ministry. Stalin used the assassination of the Leningrad party boss in December of 1934 to purge the party and state leadership of remaining political enemies. Their executions were pronounced at the Moscow show trials, the first being the 1936 trial of G. Zinoviev and L. Kamenev, expelled Politburo members and opponents of Stalin. The purge of the party elite broadened into ‘mass operations’, or the Great Terror, in July 1937 initiated by telegrams from Stalin and operational plans by NKVD head, N. Ezhov, which set execution and imprisonment quotas for 65 regions. The NKVD was the Peoples’ Commissariat for Internal Affairs, which was charged with carrying out terror operations. The Great Terror was tightly controlled by Stalin from start to finish. Although the original quotas called for 70,000 executions, almost 700,000 executions took place between July 1937 and November 1938. Although various theories exist as to why Stalin ordered these mass executions, it appears that he wished to create a new generation of party leaders to replace the ‘Old Bolsheviks’ who had lost their revolutionary fervour, and also wished to rid the Soviet Union of ‘socially harmful’ classes, who could have formed fifth columns during the Second World War.

After the Great Terror, Stalin used ‘lesser terror’, whereby he imposed criminal penalties on huge numbers of ordinary people for workplace violations, such as theft of state or...
Stalin as dictator

From approximately 1932 until his death Stalin was a true dictator: he had his way on every matter and was not afraid to abuse and humiliate his associates (Rees, 2004; Gorlizki and Khlevnyuk, 2004). As Khlevnyuk (2001a, p. 325, emphasis added), concluded, 'Stalin himself was not merely a symbol of the regime but the leading figure who made the principal decisions and initiated all state actions of any significance.' After 1930, Stalin increasingly bypassed formal procedures as reflected in the declining frequency of Politburo meetings (Rees and Watson, 1997, p. 12) and the use of ad hoc subcommittees that he personally appointed (Wheatcroft 2004, p. 91). Stalin continued to bind his associates into complicity by requiring each Politburo member to approve his decisions once he had made them (Gorlizki and Khlevnyuk, 2004).

Despite his dominance, Stalin faced massive principal–agent problems with his associates. His correspondence is full of concern about ‘paper fulfilment’ and of angry calls for monitoring fulfilment and increased responsibility for designated officials (Gregory, 2004, pp. 165, 266).

The erosion of collective rule is consistent with Hayek’s (1944) insight that the rise of a sole dictator is inevitable in such an environment. Stalin's ascendency is explained by the need for a tie-breaker as the Politburo members quarrelled, but, more importantly, by the fact that Stalin was more ambitious, brutal and controlled than his rivals. There were no ‘moderates’ or ‘extremists’ within the Politburo after 1930. Stalin did not have to confront major ideological or policy differences. The divisions that did exist were on lines of narrow self-interest based on departmental position.

Stalin made top-level appointments personally, was deeply suspicious of professional administrators and technocrats, and trusted only a few old Bolsheviks. Stalin was particularly concerned about rent seeking by those within his narrow circle who represented branch or territorial interests, ‘who cause us to deceive each other’ (Khlevnyuk et al., 2001, p. 80), and ‘who turn our Bolshevik party into a conglomerate of branch groups’ (Rees and Watson, 1997, p. 16).

Planning under the Stalinist system was quite different from its textbook description. The state planning agency, Gosplan, prepared only highly aggregated plans, stating: ‘Gosplan is not a supply organization and cannot take responsibility either for centralized specification of orders by product type or by customer or the regional distribution of products’ (cited in Gregory, 2004, p. 139). Gosplan refused to plan actual transactions, labelling them ‘syndicate work’ (Belova and Gregory, 2002, p. 271). Gosplan only reluctantly represented the state in inter-ministerial conflicts, claiming that ‘we are simply not equipped to deal with such matters’ (Belova and Gregory, 2002, p. 271). In short, after its 1929 purge and subsequent politicization, Gosplan limited its exposure by doing as little as possible. The ultimate power to direct resources belonged to the dictator. Stalin did not want a planning board with immense powers or numerous staff. He did not trust information from those accountable for results, a phenomenon Wintrobe (1998) labelled the ‘dictator's curse’. Truth-telling was the specialized task of Gosplan and other agencies such as the NKVD, which became Stalin's solution to the wider principal–agent problem (Belova and Gregory, 2002, pp. 269–73).

Hayek’s (1944, p. 82) assertion that a totalitarian system ‘cannot tie itself down in advance to general and formal rules that prevent arbitrariness… It must constantly decide questions which cannot be answered by formal principles only’ was true of Stalinist practice. There were few formal rules; the rules that existed were subject to override. Fresh guidelines were issued to plan each new year or quarter, rather than general planning rules being carried over. Ministries operated without corporate-governance charters (Gregory and Markovich, 2002, pp. 793–4). ‘Administrative’ enforcement was encouraged through appeals to vertical superiors (Belova, 2001). Planning procedures were complicated, contradictory, and confusing (Markевич, 2003). Enterprise usually received a few output and assortment assignments midway through the plan period, while secondary targets for costs and productivity were worked out retrospectively for reporting purposes. All plans, labelled ‘draft’ or ‘preliminary’, were no more than informal agreements which could be changed subsequently by virtually any superior. The ‘correcting’ and ‘finalizing’ of plans was a never-ending process; the ‘final’ plan remained always on the horizon (Markевич, 2003).

Resources were allocated in the course of the ‘battle for the plan’ during which superiors were barraged by requests to intervene. Intervention was generally arbitrary but was based on some implicit rules of thumb, such as the priority of heavy industry and the military: ‘All orders for the Ministry of Defense must be fulfilled exactly according to the schedule not allowing any delays’ (Gregory, 2004, pp. 160–1). Plan interventions created havoc for producers. The most important industrial leader of the 1930s expressed his frustration as follows: ‘They give us every day decree upon decree; each one is stronger and without foundation’ (Khlevnyuk, 1993, p. 32).

Stalin himself favoured such ad hoc administrative allocation: ‘Only bureaucrats can think that planning work ends with the creation of the plan. The creation of the plan is only the beginning. The real direction of the plan develops only after putting the plan together’ (Stalin, 1937, p. 413; emphasis added). Ad hoc allocation could not have been better designed for the exercise of political influence. Everything was tentative and subject to arbitrary change by someone higher up in the chain of command. Savvy politicians like Stalin would have been able to weigh the political benefits of satisfying an influential regional or industrial leader.

Stalin's unwillingness to bind himself in advance to rules cascaded down through the political system, preventing the emergence of a ‘law-governed’ economy. The commitment...
failure outlined by Kornai, Maskin and Roland (2003) – the predatory principle forcing agents to break formal rules so as to exploit them – seems to fit the Stalin model. In the Soviet case producers could break rules citing the threat to production from the rule, while superiors reserved the right to punish hapless scapegoats for breaking the same rules. It was the power to live outside formal rules that sentenced Stalin and his Politburo to lives of toil, drudgery and tedium (Gregory, 2004, pp. 68–72). Threats of resignation and pleas for lengthy vacations were commonplace. A representative Politburo meeting, held on 5 March 1932, had 69 participants and 171 points on its agenda (Khlevnyuk et al., 1995, p. 232). The greatest burden fell on Stalin who in 1934, a typical year, spent 1,700 hours in official meetings, the equivalent of more than 200 eight-hour days (Khlevnyuk, 1996, pp. 190–1). Virtually every communication requested a decision from him.

**Accumulation and consumption**

Dictators could aim for economic growth (Olson, 1993; Glaeser et al., 2004) or for self-enrichment, or share rents to build loyalty and political power (Wintrobe, 1998). Stalin was clearly obsessed with accumulation (hardly a surprise given Marx's emphasis on accumulation), which was captured in the growth models of Preobrazhenskii and Fel'dman in the early Soviet period (Elich, 1960; Spulber, 1964). At the core of Stalin's strategy to ‘build socialism’ were massive programmes for the hydroelectric dams, machinery complexes, vehicle works, blast furnaces, railways, and canals that were included on its itemized ‘title lists’ of approved projects.

Although Politburo meetings in the 1930s left few formal minutes, records reveal that the Politburo consistently set the nominal investment budget, grain collections, and foreign exchange, three variables related to investment (Gregory, 2004, chs 4 and 5). The investment budget allotted ‘investment rubles’ to industrial and regional agencies for construction and machinery, although no one appeared to know the real investment that resulted. Grain collections were designed to contribute to a budget surplus through the excess of state sale prices over purchase prices. Stalin personally directed foreign exchange to foreign capital goods rather than the luxury goods sometimes demanded by the Bolshevik elite. If Stalin's goal was indeed to maximize investment, two facts are, at first glance, confusing. First, Stalin was extremely concerned about consumption. In Stalin's words, the ‘provisioning of workers’ was one of ‘the most contested issues’ before the Politburo, and trade was ‘the most complicated ministry’ (Gregory, 2004, pp. 93–4). Stalin personally ordered consumer goods to cities where labour productivity was declining (Gregory, 2004, ch. 4). The Politburo decided retail trade plans, prices, assortment, and even the opening of new stores. The second confusing fact is that Stalin reduced the nominal investment budget on two occasions, in 1933 and 1937 (Davies, 2001). Such evidence can be interpreted either as unstable dictatorial preference or as a consistent rule of thumb to decide the volume of investment. Stalin's capacity for calculation, patience, and self-control suggest the stable preferences approach is correct.

Figure 1 illustrates the model that Stalin and his Politburo used to set investment and consumption. The figure captures the Marxian concept of the surplus product, the gap between output and consumption, as the outcome of a distributive struggle. The model has theoretical precursors in Schrettl (1982; 1984), and is set out more fully by Gregory (2004, ch. 4). It belongs to a general class of models in which a ruler's freedom of action is circumscribed by social 'tolerance limits' (Kornai, 1980, pp. 211–14) or a revolution or disorder constraint (Acemoglu and Robinson, 2000). If the Politburo increased investment too much, it risked provoking the workers to provide less effort or even rebel.
In the Stalinist system, the demand for labour was always enough for full employment and all able-bodied persons were required by law to work (Granick, 1987); thus, employment, \( N \), was fixed exogenously; individual effort, \( e \), was variable, so total effort, \( E = e \cdot \bar{N} \), was variable although employment was not. Total output, \( Q \), depended on total effort, \( E \). Total effort varied with the real wage, \( w \), as follows. The aggregate wage bill \( W \), the consumer goods received by workers, is measured along the vertical axis in the same units as output, and is proportional to the real wage given that employment is fixed, that is, \( W = w \cdot \bar{N} \). There is a reservation wage, analogous to a tolerance limit or disorder constraint, below which effort is zero; there is also a ‘fair’ wage at which effort is maximized. This effort curve bears some resemblance to Akerlof (1984) as applied at the micro-level. As the economy moves from the fair wage to the reservation wage, effort declines; at the lower limit unrest threatens to boil over into strikes and rebellion. Thus the effort curve intersects the horizontal axis at the reservation wage and becomes vertical at the fair wage. Effort also depends on the level of repression or coercion, \( C \), discussed below. To maximize effort, the dictator would pay the fair wage and get the maximum output, but this would not maximize the surplus. To maximize the surplus, \( Q - W \), he would choose the intermediate wage, effort, and output levels denoted \( W^* \), \( E^* \), and \( Q^* \).

An effort curve of this shape makes the consequences of plan mistakes asymmetric: paying the workers too little could be much worse than paying them too much. Paying workers too little not only cuts effort but also risks outright confrontation with the state. An investment-maximizing dictator must tread a fine line between the pursuit of investment and the
Stalin managed worker morale and effort in two ways. When investment and consumption were about right in the aggregate, plan mistakes were taken care of by reallocating consumer goods to those left short. In the case of aggregate mistakes, when too much investment threatened to provoke the workers, investment was cut back, such as in 1933 and 1937. In this sense, Stalin's behaviour was stable and consistent, given the constraints that he perceived.

The fair wage was set by a mass psychology that was unpredictable and hard to manipulate. If workers concluded from the propaganda of economic successes that they were being cheated, the fair wage would rise, forcing the Politburo to cut investment back. Stalin used the vast informant network of the NKVD to monitor protests, strikes, anti-Soviet statements, and factory-wall graffiti, and eavesdrop to gauge mass opinion (Berelovich, 2000). Stalin had obvious political motives to do this, but within our framework wages and fairness lay at the cross-hairs of politics and economics.

Figure 1 suggests other options. Stalin and his closest subordinates could seek to manipulate the effort curve by offering ideological rewards in place of material payoffs. The attempt to transform *homo economicus* into *homo sovieticus* led, however, to a vicious circle of wage equalization and declining productivity (Kuromiya, 1988; Davies, 1996). The Stakhanovite movement, the most publicized mobilization campaign of the 1930s, was driven by progressive piece rates that permitted participating workers to drive up their incomes by overfulfilling norms (Davies and Khlevnyuk, 2002). Stalin abandoned it because it tended to raise fair-wage aspirations among non-participating workers, and also threatened inflation (Gregory, 2004, pp. 104–6). Stalin also saw targeted rationing as a way to force accumulation without a loss of effort of high-priority workers: 'He who does not work *on industrialization* shall not eat' (cited in Gregory, 2004, p. 98; emphasis added). Finely targeted rationing, however, required a massive bureaucracy and proved to be a blunt instrument (Davies and Khlevnyuk, 1999).

**Coercion and accumulation**

The dictator could also use coercion to cause workers to lower their reservation wage without reducing effort. As long as coercion displaces the effort curve in Figure 1 downward while leaving the production curve undisturbed, the surplus is increased and coercion is ‘successful’. Stalin conducted three notable experiments with coercion to foster accumulation: the forced collectivization of the peasantry, the criminalization of workplace behaviour, and the use of forced labour.

Politically, collectivization aimed to impose Soviet power in the countryside and eliminate the stratum of richer peasants. Economically, collectivization was to give the state agricultural products at low state-dictated delivery prices, which could be sold domestically and abroad for a profit. In a word, collectivization’s aim was to lower peasant living standards while controlling their effort administratively. Collectivization was triggered by the peasants’ perceived unwillingness to contribute sufficiently to investment-led industrialization (Wheatcroft and Davies, 2002; Davies and Wheatcroft, 2004). The collective farms enabled Moscow to replace local decision making with central plans on sown acreage and obligatory deliveries. Acreage expanded but yields collapsed, while the share delivered to the state increased. Excessive procurements, bad weather, and plan errors combined to strip the countryside of grain; first the livestock were slaughtered, then the farmers themselves starved, threatened by severe punishments including death for theft of agricultural products. Davies and Wheatcroft (2004) dispel Conquest’s (1987) notion that Stalin manufactured the famine of 1932/33 to kill class enemies; rather they show an inept leadership subsequently trying to ameliorate the effects of its own bungling.

In 1932/33, Stalin intentionally directed food to those able to work in the fields and denied it to those already hospitalized by hunger (Davies and Wheatcroft, 2004, ch. 13). Ellman (2000) has also applied the entitlement theory of Sen (1983) to the 1946/7 famine and shows that the role of the state was essentially negative: it again selected those who died by denying them entitlements. Thus, concentrating grain stocks in the hands of the Soviet state actually increased the number of deaths. The 5.5 million–6.5 million famine deaths in 1932/33 far exceeded deaths in pre-revolutionary famines (Davies and Wheatcroft, 2004, pp. 402–3).

A variety of studies, including Millar (1974), conclude that collectivization did not increase the ‘agricultural surplus’ defined as the gap between the value of output produced in agriculture and output consumed in agriculture, due to the need to shift investment resources into agriculture to make up for the loss of animal draft power slaughtered during collectivization.

As the 1940s began, Stalin redirected coercion from specific class enemies to the entire public-sector work force. A battery of intimidating laws criminalized workplace violations which had previously been punished by administrative sanctions within the enterprise. The law of 26 June 1940 (Kozlov, 2004, vol. 1) made absenteeism, defined as any 20 minutes’ unauthorized absence or even idling on the job, a criminal offence, punishable by up to six months’ corrective labour with a 25 per cent reduction in pay. Repeat offences counted as unauthorized quitting, punishable by two to four months’ imprisonment. Enterprise managers were made criminally liable for failure to report worker violations. In August 1940 the minimum sentence for petty theft at work and ‘hooliganism’ was set at one year’s imprisonment. The notorious decree of June 1947 raised the minimum sentence for any theft of state property to five and seven years imprisonment. These punitive laws remained on the books until Stalin died.

A report prepared as background for Khrushchev’s secret de-Stalinization speech of February 1956 (Kozlov, 2004, vol. 1, statistical appendix) shows that from 1940 through June 1955 a total of 35.8 million persons were sentenced for criminal offences. With repeat offenders not allowed for, this would represent about one-third of the adult population of roughly 100 million. Of the 35.8 million, 15.1 million were imprisoned and a quarter of a million were executed. These laws placed cumulative totals of millions of people in prisons...

and camps outside of the 'civilian' workforce. The goal of lesser terror was to increase the effort for the same real wage by criminally punishing work indiscipline. Unlike collectivization, there have been no decisive evaluations of the success or failure of these draconian policies. What is known is that they fell into misuse and were formally removed after Stalin's death. If they had been successful, they would have been retained.

The Gulag

Collectivization, the Great Terror, the repression of state employees in the 1940s, and the arrests of 'national contingents' created huge flows into the Gulag, the interior ministry's chief administration of labour camps, created in 1930 to manage camps which at their peak housed more than 2.5 million inmates. Similar numbers of deportees were confined to labour settlements in the remote interior. The forced labourers were engaged in forestry, mining and construction, where they made up substantial shares of employment, but never more than about three per cent of the total workforce including farm workers (Khlevnyuk, 2001; 2003). The cumulative total of persons sentenced to the Gulag in the course of its existence, probably in excess of 20 million, remains the subject of debate. The Gulag's own central catalogs are inconsistent (Kozlov, 2004, vol. 2); it appears that even the Gulag did not know the correct number.

Political repression strategy (collectivization, terror, war) rather than economics dictated the Gulag's development, but, once created, the Gulag represented a tempting source of cheap labour. The Gulag's consistent economic raison d'être was to explore and colonize regions that were resource-rich but inhospitable, since forced labour could be ordered around the country at will (Khlevnyuk, 2003). Subsistence wages combined with the enforcement of effort through close supervision were supposed to promote the low-cost accumulation depicted in Figure 2.

Figure 2
‘Failed’ coercion?
The primacy of politics over economics is shown by the fact that the NKVD and its successor the MVD (the Ministry for Internal Affairs) did not lobby for expansion. The NKVD projected a shrinking number of inmates for the third five-year plan (1938–42), just as the first victims of Stalin's Great Terror began to flood in (Gregory, 2003, p. 4). In the late 1940s Gulag officials proposed to release all but the most dangerous prisoners from camps (Tikhonov, 2003), but this was unacceptable to Stalin. In 1953, within three months of Stalin's death, MVD chief Lavrentiy Beria released one and a half million prisoners, 60 per cent of the Gulag's inmates according to a plan prepared five years earlier. The MVD was increasingly alarmed by the Gulag's economic and social costs. Its economic costs were reflected in growing financial deficits; the social costs were measured by high rates of recidivism. Although the camps were supposed to segregate hardened criminals from youth offenders, the camps were mixing bowls and the high turnover spread the culture and mores of camp life throughout society.

Hopes for huge profits from the Gulag were quickly dashed. In the Far Eastern camps (Nordlander, 2003) early optimism about huge surpluses in gold mining was replaced by pessimism as output per inmate fell precipitously. The fact the White Sea–Baltic Canal (Morukov, 2003) was finished on time and on budget stimulated high expectations, until its major construction flaws became apparent. The Gulag leaders underestimated the risks of building Noril'sk (Borodkin and Ertz, 2003) and exposed the illusions that inmates could be coerced into supplying effort without economic rewards (Ertz, 2003).

By the post-war years, Gulag officials had concluded that the camps were operating at a loss. Labour productivity was much lower than that of free workers, while guarding detainees was very expensive; in 1950 there was one guard to ten inmates, leading to the widespread practice of 'unguarded' prison contingents. Prisoners formed protective networks and actually operated a number of camps (Heinzen, 2004). The arsenal of punishments was not sufficient to motivate prisoners, and trade-offs were complicated: prisoners placed on reduced rations for failing to meet work quotas could not work effectively. The most effective incentive systems, such as early release for exemplary work, deprived the Gulag of its best workers. Material incentives played an ever larger role in motivating penal labour (Borodkin and Ertz, 2003; 2005; Ertz, 2005). In the last years of the Gulag, prisoners were paid civilian wages (albeit at lower scales) and the distinctions between penal and free labour became blurred.

Evaluating repression

Effective coercion requires that penalties be accurately assessed and targeted, and that the agents of repression be well informed about offenders and the costs of their crimes. The relationship between true effort and punishment was ‘noisy’, and oppressive law could do little more than ensure that workers or inmates were physically at work and did not steal too much. Agricultural controllers could order the collective farms to sow more land but could not assess whether the land was being farmed efficiently (Davies and Wheatcroft, 2004). In industry, attempts to pin ‘normal’ effort down to objective technological criteria proved fruitless (Davies and Khlevnyuk, 2002, p. 877; Filtzer, 2002, pp. 232–41).

The investigation of low effort could yield an error of Type I that punished the innocent, or a Type II error that acquitted the guilty. Type I errors are reflected in the high rates of penalization that condemned hard workers along with neer-do-wells, drunks and thieves. Virtually every worker became liable to prosecution for some offence, including one-time and accidental violations. Rational managers might wish to prosecute only problem workers and repeat offenders, but the laws penalized even petty offences, and managers who failed to report offences were threatened with the same. As a result, the innocent were bundled along with the guilty in extraordinarily large numbers.
In March 1937, Nikolai Ezhov, Stalin's chief instrument of the Great Terror, told his officials to expect some innocent victims. Better that ten innocent people should suffer than one spy get away. When you chop wood, chips fly (Montefiore, 2003, p. 194). The attitude of Vyacheslav Molotov, Stalin's prime minister (interviewed by Chuev, 1991, p. 416) was, 'never mind if extra heads fall', even when one of those 'heads' was that of his own wife. Type II errors were evidenced by the fact that, although penalization rates were very high, offending rates were even higher (Filtzer, 2002, pp. 167–8). A judicial system that was supposed to 'make the chips fly' somehow failed to chop the wood. The combination of severe penalization and low conviction probability for the guilty is consistent with high-cost policing and justice administration (Becker, 1968, p. 184); the high rate of conviction of innocents, however, is a cost of the dictator's efforts to achieve a lower rate of offending than society was willing to tolerate (Djankov et al., 2003). Although the Gulag did not generate an internal surplus, it could have displaced the effort curve of civilian workers if they expected the Gulag wage as their punishment for low effort. But if workers expect Type I errors, they will be punished regardless of effort; if they expect to benefit from Type II errors, they can shirk without fear.

Error rates were not exogenous. They were fashioned by the counteractions of those threatened, who could take steps to reduce their risks. Workers and managers diverted effort from production into mutual insurance: since the threat was shared among them, they could agree to cover up each other's shortcomings. Post-war managers tolerated lateness and absence to maintain goodwill, and underreported such violations, while pursuing quitters who undermined morale and the factory's capacity to fulfil the plan (Filtzer, 2002). The rural police and courts pooled risks with the rural community in sheltering the young offenders who had deserted factories or technical schools (Kozlov, 2004, vol. I). Mutual insurance tended to cut the individual risk of punishment. Regional party officials defied even the most powerful central organizations to protect their own (Harris, 1999, pp. 156–63). High-level patrons could protect the most egregious embezzlers (Belova, 2001).

Figure 2 explains the phenomenon of 'failed coercion'. The threat of punishment raised the 'noise' of the system as managers and regional officials reported false results and formed mutual protection networks, shifting the output–effort curve down. The leftward movement of the effort curve captures the diversion of activity from production to the avoidance of repression. Failed coercion reduces the surplus and lowers output. Faced with widespread enforcement failures at lower levels, Stalin forced the legal system, local party offices, and the militia to increase arrest and conviction rates or suffer penalties themselves. The most common method of forcing repression was to distribute quotas by region and profession to officials at lower levels (Kozlov, 2004, vol. 1). In the Great Terror of 1937/38 local officials had to work feverishly to achieve a set number of confessions per day (Vatlin, 2004). To fulfil such plans the police officials imputed individual guilt from increasingly trivial differences in behaviour. Whether or not these measures reduced the Type II errors, they seem likely to have encouraged false denunciation and confession and so added to the errors of Type I.

After Stalin

Stalin's successors reverted to collective leadership and toned down repression. They also inherited an economy in secular decline. Thus, the story of the post-Stalin leadership is that of unsuccessful attempts to reform the Stalinist system without altering its basic characteristics, other than mass repression.

standards of living (historical trends)

Richard H. Steckel
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Social scientists generally agree on the considerable value of measuring and investigating long-term trends and socio-economic differences in the standard of living or quality of life. Over the past two centuries, researchers have refined the methodology for making such assessments but economic historians continue to be challenged by lack of raw data before the early 20th century. While it is impossible to assemble a comprehensive picture, useful information is available about changes or differences in GDP per capita and life expectancy from the early 19th century onward. It was during this era that large differences across countries and regions appeared.

Methodology

Research specialists agree that the standard of living has many elements, such as material goods and services, health, socio-economic fluidity, education, inequality, and political and religious freedom. Opinions differ on the precise measures to be used within each category and on the weights that should be attached to each. Health, for example, is measurable by length of life, morbidity (illness or disability) and physical fitness. Conceivably, one might attempt comparisons using all feasible measures, but this is expensive and time-consuming, and in any event good measures within categories are often highly correlated.

Weighting is a contentious issue in any attempt to summarize the standard of living, or otherwise compress diverse measures into a single number. Economists and other social scientists know that tastes are individualistic and diverse but they recognize general tendencies. Here I consider the available historical information on material standards and health.

Material aspects

Measure

The most widely used measure of the material standard of living is Gross Domestic Product (GDP) per capita, adjusted for changes in the price level (inflation or deflation). This measure reflects only economic activities that flow through markets, omitting productive endeavours unrecorded in market exchanges, such as preparing meals at home or maintenance done by the homeowner. It ignores work effort required to produce income and does not consider conditions surrounding the work environment, which might affect health and safety. Crime, pollution and congestion, which many people consider important issues affecting their quality of life, are also excluded from GDP. Moreover, technological change, relative prices and tastes affect the course of GDP and the products and services that it includes, which creates what economists call an ‘index number’ problem that is not readily solvable.
standards of living (historical trends): The New Palgrave Dictionary of Economics

Nevertheless most economists believe that real GDP per capita does summarize or otherwise quantify important aspects of the average availability of goods and services.

**Time trends**

Table 1 shows the course of the material standard of living in the United States from 1820 to 1998. Over this period of 178 years real GDP per capita increased by 21.7 times, or an average of 1.73 per cent per year. Although the evidence available to estimate GDP directly is meagre, this rate of increase was probably many times higher than experienced during the colonial period. This conclusion is justified by considering the implications of extrapolating the level observed in 1820 ($1,257) backward in time at the growth rate measured since 1820 (1.73 per cent). Under this supposition, real per capita GDP would have doubled every 40 years (halved every 40 years going backward in time) and so by the mid-1700s there would have been insufficient income to support life. Because the cheapest diet able to sustain good health would have cost nearly $500 per year, the tentative assumption of modern economic growth contradicts what actually happened. Moreover, historical evidence suggests that important ingredients of modern economic growth, such as technological change and human and physical capital, accumulated relatively slowly during the colonial period.

**Cycles**

Although real GDP per capita is given for only seven dates in Table 1, it is apparent that economic progress has been uneven over time. If annual or quarterly data were given, it would show that business cycles have been a major feature of the economic landscape since industrialization began in the 1820s. By far the worst downturn in US history occurred during the Great Depression of the 1930s, when real per capita GDP declined by approximately one-third and the unemployment rate reached 25 per cent.

**Regions**

The aggregate numbers also disguise regional differences in the standard of living. In 1840 personal income per capita was twice as high in the Northeast as in the North Central States. Regional divergence increased after the Civil War when the South Atlantic became the nation's poorest region, attaining only one-third of the living standards in the Northeast. Regional convergence occurred in the 20th century, and industrialization in the South significantly improved the region's economic standing after the Second World War.

**Health**

**Life expectancy**

Two measures of health are widely used in economic history: life expectancy at birth (or average length of life) and average height, which measures nutritional conditions during the growing years. Table 2 shows that life expectancy has approximately doubled since the mid-19th century, reaching 76.7 years in 1998. If depressions and recessions have adversely affected the material standard of living, epidemics have been a major cause of sudden declines in health in the past. Fluctuations during the 19th century are evident from the table, but as a rule growth rates in health have been considerably less volatile than those for GDP, particularly during the 20th century.

Childhood mortality greatly affects life expectancy, which was low in the mid-1800s substantially because mortality rates were very high for this age group. For example, roughly one child in five born alive in 1850 did not survive to age one, but today the infant mortality rate is less than one per cent. The period since 1850 has witnessed a significant shift in deaths from early childhood to old age. At the same time, the major causes of death have shifted from infectious diseases originating with germs or micro-organisms to degenerative processes that are affected by lifestyle choices such as diet, smoking and exercise.

Time trends

The largest gains were concentrated in the first half of the 20th century, when life expectancy increased from 47.8 years in 1900 to 68.2 years in 1950. Factors behind the growing longevity include the ascent of the germ theory of disease, programmes of public health and personal hygiene, better medical technology, higher incomes, better diets, more education, and the emergence of health insurance.

Explanations

Numerous important medical developments contributed to improving health. The research of Pasteur and Koch was particularly influential in leading to acceptance of the germ theory in the late 1800s. Prior to their work, many diseases were thought to have arisen from miasmas or vapours created by rotting vegetation. Thus, swamps were accurately viewed as unhealthy, but not because they were home to mosquitoes and malaria. The germ theory gave public health measures a sound scientific basis, and shortly thereafter cities began cost-effective measures to remove garbage, purify water supplies, and process sewage. The notion that ‘cleanliness was next to Godliness’ also emerged in the home, where bathing and the washing of clothes, dishes and floors became routine.

The discovery of Salvarsan in 1910 was the first use of an antibiotic (for syphilis), which meant that the drug was effective in altering the course of a disease. This was an important medical event, but broad-spectrum antibiotics were not available until the middle of the century. The most famous of these early drugs was penicillin, which was not manufactured in large quantities until the 1940s. Much of the gain in life expectancy was attained before chemotherapy and a host of other medical technologies were widely available. A cornerstone of improving health from the late 1800s to the middle of the 20th century was therefore prevention of disease by reducing exposure to pathogens. Also important were improvements...
in immune systems created by better diets and by vaccination against diseases such as smallpox and diphtheria.

Heights

Since the early 1980s, historians have increasingly used average heights to assess health aspects of the standard of living. Average height is a good proxy for the nutritional status of a population because height at a particular age reflects an individual's history of net nutrition, or diet minus claims on the diet made by work (or physical activity) and disease. The growth of poorly nourished children may cease, and repeated bouts of biological stress — whether from food deprivation, hard work, or disease — often leads to stunting or a reduction in adult height. The average heights of children and of adults in countries around the world are highly correlated with their life expectancy at birth and with the log of the per capita GDP in the country where they live.

Applications

This interpretation for average heights has led to their use in the study of the health of slaves, health inequality, living standards during industrialization, and trends in mortality. The first important results in the ‘new anthropometric history’ dealt with the nutrition and health of Americans slaves as determined from stature recorded for identification purposes on slave manifests required in the coastwise slave trade. The subject of slave health has been a contentious issue among historians, in part because vital statistics and nutrition information were never systematically collected for slaves (or for the vast majority of the American population in the mid-19th century, for that matter). Yet the height data showed that children were astonishingly small and malnourished while working slaves were remarkably well fed. Adolescent slaves grew rapidly as teenagers and were reasonably well-off in nutritional aspects of health.

Time trends

Table 3 shows the time pattern in height of native-born American men obtained in historical periods from military muster rolls, and for men and women in recent decades from the National Health and Nutrition Examination Surveys. This historical trend is notable for the tall stature during the colonial period, the mid-19th century decline, and the surge in heights of the 20th century. Comparisons of average heights from military organizations in Europe show that Americans were taller by two to three inches. Behind this achievement were a relatively good diet, little exposure to epidemic disease, and relative equality in the distribution of wealth. Americans could choose their foods from the best of European and Western Hemisphere plants and animals, and this dietary diversity combined with favourable weather meant that Americans never had to contend with harvest failures. Thus, even the poor were reasonably well fed in colonial America.

Loss of stature began in the second quarter of the 19th century when the transportation revolution of canals, steamboats and railways brought people into greater contact with diseases. The rise of public schools meant that children were newly exposed to major diseases such as whooping cough, diphtheria, and scarlet fever. Food prices also rose during the 1830s and growing inequality in the distribution of income or wealth accompanied industrialization. Business depressions, which were most hazardous for the health of those who were already poor, also emerged with industrialization. The Civil War of the 1860s and its troop movements further spread disease and disrupted food production and distribution. A large volume of immigration also brought new varieties of disease to the United States at a time when urbanization brought a growing proportion of the population into closer contact with contagious diseases. Estimates of life expectancy among adults at ages 20, 30 and 50, which was assembled from family histories, also declined in the middle of the 19th century.

In the 20th century, heights grew most rapidly for those born between 1910 and 1950, an era when public health and personal hygiene took vigorous hold, incomes rose rapidly and there was reduced congestion in housing. The latter part of the era also witnessed a larger share of income or wealth going to the lower portion of the distribution, implying that the incomes of the less well-off were rising relatively rapidly. Note that most of the rise in heights occurred before modern antibiotics were available, which means that disease prevention was a more significant cause of improving health than the ability to alter its course after onset. The growing control that humans have exercised over their environment, particularly increased food supply and reduced exposure to disease, may be leading to biological (but not genetic) evolution of humans with more durable vital organ systems, larger body size, and later onset of chronic diseases.

Recent stagnation

Between the middle of the 20th century and the present, however, the average heights of American men have stagnated, increasing by only a small fraction of an inch over the since the 1950s. Table 3 refers to the native born, so recent increases in immigration cannot account for the stagnation. In the absence of other information, one might be tempted to suppose that environmental conditions for growth are so good that most Americans have simply reached their genetic potential for growth. Unlike in the United States, heights and life expectancy have continued to grow in Europe, which has the same genetic stock as that from which most Americans descend. By the 1970s several American health indicators had fallen behind those in Norway, Sweden, the Netherlands and Denmark. While American heights were essentially flat after the 1970s, heights continued to grow significantly in Europe. The Dutch men are now the tallest, averaging six feet, about two inches more than American men. Lagging heights leads to questions about the adequacy of health care and lifestyle choices in America. As discussed below, it is doubtful that lack of resource commitment to health care is the problem because America invests a greater share of GDP than

the Netherlands. Greater inequality and less access to health care could be important factors in the difference. But access to health care alone, whether due to low income or lack of insurance coverage, may not be the only issues – health insurance coverage must be used regularly and wisely. In this regard, Dutch mothers are known for regular pre- and post-natal checkups, which are important for early childhood health.

Note that significant differences in health and the quality of life follow from these height patterns. The comparisons are not part of an odd contest that emphasizes height, nor is ‘big’ per se assumed to be beautiful. Instead, we know that, on average, stunted growth has functional implications for longevity, cognitive development and work capacity. Children who fail to grow adequately are often sick, suffer learning impairments and have a lower quality of life. Growth failure in childhood has a long reach into adulthood because individuals whose growth has been stunted are at greater risk of death from heart disease, diabetes and some types of cancer. Therefore it is important to know why Americans are falling behind.

International perspective

Per capita GDP comparisons

Table 4 places American economic performance in perspective relative to other countries. In 1820 the United States was fifth in world ranking, roughly 30 per cent below the leaders (United Kingdom and the Netherlands), but still two to three times better off than the poorest sections of the globe. It is notable that in 1820 the richest country (the Netherlands at $1,821) was approximately 4.4 times better off than the poorest (Africa at $418), but by 1950 the ratio of richest to poorest had widened to 21.8 ($9,561 in the United States versus $439 in China), which is roughly the level it is today (in 1998, it was $27,331 in the United States versus $1,368 in Africa). These calculations underestimate the growing disparity in the material standard of living because several African countries today fall significantly below the average, whereas it is unlikely that they did so in 1820 because GDP for the continent as a whole was close to the level of subsistence.

Per capita GDP growth

It is clear that the poorer countries are better off today than they were in 1820 (by 3.3 times in both Africa and India). At the simplest level, the explanation is that the countries that are now rich grew much faster after 1820. The last column of Table 4 shows that Japan realized the most spectacular gain, climbing from approximately the world average in 1820 to the fifth richest today, with more than a thirtyfold increase in real per capita GDP. All countries that are rich today had rapid increases in their material standard of living, realizing more than tenfold increases since 1820. The underlying reasons for this diversity of economic success is a central question in the field of economic history.

Life expectancy

Table 5 shows that disparities in life expectancy have been much less than those in per capita GDP. In 1820 all countries were bunched in the range of 21 to 41 years, with Germany at the top and India at the bottom, giving a ratio of less than two to one. It is doubtful that any country or region has had a life expectancy below 20 years for long periods of time because death rates would have exceeded any plausible upper limit for birth rates, leading to population implosion. The 20th century witnessed a compression in life expectancies across countries, with the ratio of levels in 1999 being 1.56 (81 in Japan versus 52 in Africa). Japan has also been a spectacular performer in health, increasing life expectancy from 34 years in 1820 to 81 years in 1999. Among poor unhealthy countries, health aspects of the standard of living have improved more rapidly than the material standard of living relative to the world average. Because many public health measures are cheap and effective, it has been easier to extend life than it has been to promote material prosperity, which has numerous complicated causes.

Figure 1 compares stature in the United States and the United Kingdom. Americans were very tall by global standards in the early 19th century as a result of their rich and varied diets, low population density, and relative equality of wealth. Unlike other countries that have been studied (France, the Netherlands, Sweden, Germany, Japan and Australia), both the United States and the UK suffered significant height declines during industrialization (as defined primarily by the achievement of modern economic growth) in the 19th century. Note, however, that the amount and timing of the height decline in the UK has been the subject of a lively debate. See for example the February 1993 issue of the *Economic History Review* for papers by Roderick Floud, Kenneth Wachter and John Komlos; only the Floud–Wachter figures are given here.

Figure 1
Average height of soldiers in Britain and of native-born American soldiers, 1710–1970. *Sources*: Steckel (2006, Fig. 12) and Floud, Wachter and Gregory (1990, Table 4.8).

One may speculate that the timing of the declines shown in the Figure 1 is probably more coincidental than emblematic of linkage among similar causal factors across the two countries. While it is possible that growing trade and commerce spread disease, as in the United States, it is more likely that a major culprit in the UK was rapid urbanization and associated increased in exposure to diseases. This conclusion is reached by noting that urban-born men were substantially shorter than the rural-born, and between the periods of 1800–30 and 1830–70 the share of the British population living in urban areas leaped from 38.7 per cent to 54.1 per cent.

State capture and corruption in transition economies

Konstantin Sonin
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

State capture by industrial lobbyists is a significant obstacle to normal economic development of formerly command (socialist) economies, at both the local and the national levels. It is prevalent in transition economics because of an excessively concentrated industrial structure and low labour mobility, both horizontal and vertical, a high level of discretion of public officials in economic affairs, and generally weak political institutions. Most of these features might be traced back to the pre-transition legacy.

Article

In an ideal democratic society, citizens determine economic policy by a direct voting procedure or by selecting appropriate candidates at polls. In the real world, economic policy is affected either directly by self-interested elected officials or bureaucrats, or indirectly by special interests such as industrial lobbyists or even large individual enterprises. The actual channels of the (primarily negative) influence of special interests on economic policy are called ‘state capture’. In most contexts, state capture necessarily involves ‘corruption’, that is, abuse of public office for private gain.

In any single instance of state capture, there are winners and losers. Typically, winners are politically important or simply large firms or whole industries and bureaucrats that receive favours from those
firms. On the losing side, there are small, politically unimportant businesses, and, ultimately, the public interest and consumer welfare. For transition economies, the overall growth rate of the enterprise sector is estimated to be ten per cent lower in a capture state than in a state where the effect is less pronounced (Hellman, Jones and Kaufmann, 2003).

The principal characteristics of transition economies, as related to the issue of state capture, are an excessively concentrated industrial structure inherited from the planned economy, a high level of discretion of public officials with respect to economic policy, weak institutions of political control such as party system or independent media, suboptimal allocation of authority between government layers, and low labour mobility, both horizontal and vertical. In short, all of these factors might be traced to the command economy legacy, one-party political system, and legal system subordinated to political authorities, which were characteristic for most now-in-transition countries in the mid-1980s.

In transition economies, political channels that transmit information and, if necessary, money from firms and other special interests to politicians are not only less efficient but also less institutionalized. Furthermore, conceptualization of a specific exchange, both by parties to the transaction and by a student of transition, might vary widely. For example, what is considered as a fully legal lobbying activity or campaign contribution in an OECD country might be thought of as a bribe or even outright extortion in some other economy.

**Theory and transition specifics**

A bureaucrat's ability to extract bribes, the manifest form of corruption, is primarily determined by her ability to create rents by shaping the playing field for business (Rose-Ackerman, 1999; Shleifer and Vishny, 1993). In a perfect analogy with a monopolist's behaviour, if a certain kind of business activity requires obtaining a licence from a regulating body, the bureaucrat who is able to collect kickbacks for granting a licence has incentives to keep the number of licences issued less than socially optimal, thus increasing the ‘price’ of those licences that are actually issued. Furthermore, this provides incentives for bureaucrats to create new rent-seeking opportunities by introducing as much licensing and regulation as possible. A monopolistic bureaucrat sets a lower bribe level than a chain of successive monopolies, but the total volume of bribes is obviously higher, and so the impact on social welfare of centralized versus decentralized corruption is ambiguous.

Typically, special interests, through the channels of state capture, seek protection from competition such as barriers to entry to the local market. At the international level, protection usually takes the form of either import quotas or tariff protection. At the local level, it takes the form of licensing, small-scale regulation, and preferential treatment such as tax exemptions granted to individual firms. State capture, as a stable, long-standing relationship between existing businesses and incumbent politicians, has adverse effects on business and politics. In business, state capture prevents innovation by new or potential entrants, and, as a result, by the incumbent firms as well, and thus constrains market development. In politics, it decreases the chances of challengers to mount an aggressive campaign against an incumbent, which in turn reduces the electoral accountability of incumbents.

It is possible to further refine the concept of state capture. Hellman, Jones, and Kaufmann (2003), based on their econometric analysis of a large sample of firms in transition economies, argue that is helpful to distinguish state capture from influence by special interests and administrative corruption, with each of
State capture and corruption in transition economies: The New Palgrave Dictionary of Economics

The three forms of business involvement in politics having distinct causes and consequences. In this refined definition, state capture is the process by which firms shape rules of the game through semi-institutionalized bribes paid to public officials and politicians; influence is the same process without direct transfers (this category corresponds to costly ‘informational lobbying’ à la Grossman and Helpman, 2001); and administrative corruption encompasses all ‘petty’ forms of bribery related to law enforcement and regulation.

Political power and economic power

At the beginning of the transition, most of the political institutions that help to mitigate agency problems in the developed world such as independent courts and media, grass-roots political parties, and an institutionalized civil society were virtually non-existent. Inadequate provision of basic public goods such as property rights protection and enforcement of contracts, which are crucial for economic development, forced economic agents to seek alternative tools, for example by supplementing their productive investment with investment in private protection. For large businesses, state capture was a potentially powerful tool. In this view, bribes to bureaucrats or other forms of privately financed purchase of a public good becomes a strategy of an economic agent to increase efficiency and predictability in his business relations.

A specific feature of many transition economies, as compared with developing countries with a similar level of GDP per capita, is that they have been left with the remnants of the command economy with its highly centralized industry. The effect was more pronounced in industrially developed countries such as Russia or Slovakia, and less in countries such as Vietnam or Albania.

The existence of enterprises with very large employment levels produced a specific form of state capture. The managers of large enterprises, regardless of whether they were profitable, have a large menu of political instruments in their hands from which to choose. In particular, they could either rely on ties inherited from the times of the plan, or operate in a newly formed web of quasi-market exchanges including various forms of barter (Gaddy and Ickes, 2002). In Russian practice, quasi-market exchanges have often relied on government power to set individual tax rates and energy tariffs for enterprises. In the Hellman, Jones, and Kaufmann (2003) classification this often amounts to influence, not state capture, as government intervention is caused not by direct bribery, but by a complex chain of exchanges made possible by agents’ participation in the same social network. The downside of this phenomenon is that inefficient enterprises are not driven out of the market, and at the same time provide political pressure to deter entry of new enterprises.

Proponents of ‘big bang’ reforms argued that establishing the rule of law, including institutions of property rights protection, requires the creation of a ‘grass-roots’ demand for the rule of law. In practice, it meant that the former state property should first go into the hands of private owners, and only then would those owners become natural proponents of a system of property rights protection. With the high degree of concentration present in transition economies, and with undeveloped factor markets, this forecast (from private ownership to demand for the rule of law to property rights) has not been borne out. The rich – the beneficiaries of early privatization – have obvious incentives to protecting their property privately, for example via state capture. Consequently, they do not have incentives to lobby for the establishment of well-working state institutions such as independent courts or efficient bureaucrats.
Instead, they seek to increase their political influence and modify the existing state institutions so that resources and wealth continue to be redistributed in their favour (Polishchuk and Savvateev, 2004; Sonin, 2003). (This is an example of how the Coase theorem is not valid when there are wealth effects.) In Russia, the country that entered transition after the longest period of Communist rule, and was the most industrialized of the transition economies, a decade after economic reforms were launched most of the productive assets were concentrated in the hands of a few individuals, the so-called oligarchs (see Oligarchs). In part, it is an efficiency requirement that, when property rights are poorly protected, control rights over assets become concentrated: the larger a single owner's share is, the greater her incentives are to pursue improvements, such as in corporate governance. (Recent cross-country studies show that the worse the general protection and enforcement of property rights are, the greater is the concentration of control rights.) On the other hand, wealth inequality very often imposes heavy costs on the economy, primarily because it produces widespread inequality of opportunity. Still, the main problem is that the oligarchs who rely on state capture for protection of their property rights and enforcement of contracts do not form a natural constituency for the rule of law. This effect is especially strong when economic inequality is accompanied by underdeveloped democratic institutions, which is typically the case in formerly Communist countries.

Decentralization and interjurisdictional mobility

A critical check on the extent of state capture comes from institutions of federalism. The traditional approach to fiscal federalism focused on externalities in the provision of public goods that arise from preference heterogeneity in different jurisdictions. In the 1990s, a new approach emerged emphasizing the accountability of government officials (agency problems) at both the central and the local levels (for example, Qian and Weingast, 1997; see also Bardhan and Mookherjee, 2006). All former command economies started transition with an overly centralized government structure, and faced the problem of optimal reallocation of economic and political authority.

The effect of decentralization on state capture is twofold. First, more authority allocated to the local level makes the agency problem at this level less prevalent, thus increasing accountability and reducing corruption. On the other hand, special interests might have much more influence over local government bodies; therefore, shifting authority downward might make state capture both more desirable and easier to achieve. In Bardhan and Mookherjee (2006) a reallocation of authority towards local government has a number of consequences. First, the amount of bribes collected by the central government decreases; second, local governments become captured by local special interests. Since local capture might be more easily supported by a social network, the total amount of bribes in the economy declines. However, since corruption at the central level is more money-based, the special interests are less entrenched than at the local level, and thus local capture brings more economic inefficiency. Ultimately, decentralization, while reducing bribe-based corruption measures, reduces economic efficiency.

Starting with Tiebout (1956), interjurisdictional mobility has been considered a major constraint on the local governments’ power to abuse their prerogatives. When mobility is high and subjects can relocate from a jurisdiction with a predatory or hostile government, the local government's monopoly power over laws, regulation, and their execution is compromised. (See Slinko, Yakovlev and Zhuravskaya, 2005, for unique evidence on political capture at the local level.) Since the capacity to extract bribes is increasing
in the bureaucrats’ power to manipulate regulation, high mobility – of both firms and individuals – would force local governments to compete in providing a business-friendly environment. For a local government, the incentives to devote resources to, for example, fighting corruption, increase with the resources devoted by neighbouring governments.

The endless transition

In most transition countries, the transition from the command economy started in the late 1980s and early 1990s. It might be argued that most of the economic problems they face are no longer those of transition, but those of economic development.

Since the transition began, fear of the Leviathan state has been swiftly replaced by the fear of the capture state, where large and powerful businesses tilt the playing field through bribery, media ownership, huge campaign contributions, and direct participation in politics. Lurid stories told about some extreme forms of capture, such as the use of corrupt secret service and police officers against business competitors, have crowded out images of millions perishing in forced-labour camps or dying in numerous famines caused by Communist economic management. There is a false sense of symmetry between the state manipulating its subjects and subjects manipulating the state: while the former has proved to be dangerous on a large scale, the second is a mere obstacle to economic development. There are several ways to deal with this obstacle. A backward-looking way is through restoration of the repressive capacity of the state. Another is through the development of political and civic institutions that may put a check on elected officials and bureaucrats, and through the institutionalization of business influence on politics in an efficient way.

state space models

Andrew Harvey
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The state space form opens the way to the statistical treatment of a wide range of dynamic models in a unified framework. For models formulated in unobserved components it offers algorithms for filtering, signal extraction and prediction. Data irregularities can be handled and recent work on computational methods has extended the range of nonlinear and non-Gaussian models that can be adopted for practical use.

Article

State space models is a rather loose term given to time series models, usually formulated in terms of unobserved components, that make use of the state space form for their statistical treatment. At the simplest level, structural time series models (STMs) are set up in terms of components such as trends and cycles that have a direct interpretation. Signal extraction, or smoothing, provides a description of these features that is model-based and hence avoids the ad hoc nature of procedures such as moving averages and the Hodrick–Prescott filter. While smoothing uses all the observations in the sample, filtering yields estimates at a given point in time that are constructed only from observations available at that time. For key time series, filtered estimates form the basis for ‘nowcasting’ in that they give an indication of the current state of the economy and the direction in which it is moving. They also
State space models: The New Palgrave Dictionary of Economics

provide the starting point for forecasts of future observations and components.

Local level model

A simple model with permanent and transitory components illustrates the basic ideas of filtering and smoothing. Suppose that the observations consist of a random walk component plus a random irregular term, that is

\[ y_t = \mu_t + \varepsilon_t, \quad \varepsilon_t \sim NID(0, \sigma_\varepsilon^2), \quad t = 1, \ldots, T \]

(1)

and

\[ \mu_t = \mu_{t-1} + \eta_t, \quad \eta_t \sim NID(0, \sigma_\eta^2), \]

(2)

where the irregular and level disturbances, \( \varepsilon_t \) and \( \eta_t \), respectively, are mutually independent and the notation \( NID(0, \sigma^2) \) denotes normally and independently distributed with mean zero and variance \( \sigma^2 \). The signal–noise ratio, \( q = \sigma_\eta^2 / \sigma_\varepsilon^2 \), plays the key role in determining how observations should be weighted for prediction and signal extraction. In a large sample, filtering is equivalent to a simple exponentially weighted moving average; the higher \( q \) is, the more past observations are discounted. When \( q \) is zero, the level is constant and all observations have the same weight. The reduced form of the model has the first differences following a first-order moving average process, that is

\[ \Delta y_t = \xi_t + \theta \xi_{t-1}, \quad \xi_t \sim NID(0, \sigma_\xi^2) \]

where \( \theta = [(q^2 + 4q)^{1/2} - 2 - q] / 2 \). This produces the same forecasts. However, the structural form in (1) also yields nowcasts and smoothed estimates of the level, \( \mu_t \), throughout the series. In the middle of a large sample, the smoothed estimates are approximately equal to
while the filtered estimates are

\[
(1 + \theta) \sum_{j \geq 0} (-\theta)^j y_{t-j}, \ q > 0.
\]

At the end of the sample this estimate also yields the forecast of future levels and future observations. Note that, although the above expressions are useful for displaying the weighting of the observations, finite sample computation is best done by a simple forward recursion for filtering and a subsequent backward one for smoothing.

**State space form**

The state space form (SSF) is a simple device whereby a dynamic model is written in terms of just two equations. The model in (1) and (2) is a special case. The general linear SSF applies to a multivariate time series, \( y_t \), containing \( N \) elements. These observable variables are related to an \( m \times 1 \) vector, \( \alpha_t \), known as the *state vector*, through a *measurement equation*

\[
y_t = Z_t \alpha_t + d_t + \varepsilon_t, \quad t = 1, ..., T
\]

where \( Z_t \) is an \( N \times m \) matrix, \( d_t \) is an \( N \times 1 \) vector and \( \varepsilon_t \) is an \( N \times 1 \) vector of serially uncorrelated disturbances with mean zero and covariance matrix \( H_t \). In general the elements of \( \alpha_t \) are not observable. However, they are assumed to be generated by a first-order Markov process,

\[
\alpha_t = T_t \alpha_{t-1} + c_t + R_t \eta_t, \quad t = 1, ..., T
\]
where $T_t$ is an $m \times m$ matrix, $c_t$ is an $m \times 1$ vector, $R_t$ is an $m \times g$ matrix and $\eta_t$ is a $g \times 1$ vector of serially uncorrelated disturbances with mean zero and covariance matrix, $Q_t$. Equation (6) is the *transition equation*. The specification of the system is completed by assuming that the initial state vector, $\alpha_0$, has a mean of $a_0$ and a covariance matrix $P_0$, and that the disturbances $\varepsilon_t$ and $\eta_t$ are uncorrelated with the initial state. The disturbances are often assumed to be uncorrelated with each other in all time periods, though this assumption may be relaxed to allow contemporaneous correlation, the consequence being a slight complication in some of the filtering formulae. The definition of $\alpha_t$ for any particular statistical model is determined by construction. Its elements may or may not be identifiable with components that have a substantive interpretation, for example as a trend or a seasonal. From the technical point of view, the aim of the state space formulation is to set up $\alpha_t$ in such a way that it contains all the relevant information on the system at time $t$ and that it does so by having as small a number of elements as possible. The SSF is not, in general, unique. The Kalman filter (KF) is a recursive procedure for computing the optimal estimator of the state vector at time $t$, based on the observations up to and including $y_t$. In a Gaussian model, the disturbances $\varepsilon_t$ and $\eta_t$, and the initial state, are all normally distributed. Because a normal distribution is characterized by its first two moments, the Kalman filter can be interpreted as updating the mean and covariance matrix of the conditional distribution of the state vector as new observations become available. The conditional mean minimizes the mean square error and when viewed as a rule for all realizations it is the minimum mean square error estimator (MMSE). Since the conditional covariance matrix does not depend on the observations, it is the unconditional MSE matrix of the MMSE. When the normality assumption is dropped, the KF is still optimal in the sense that it minimizes the mean square error within the class of all linear estimators. Given initial conditions, $a_0$ and $P_0$, the Kalman filter delivers the optimal estimator of the state vector as each new observation becomes available. When all $T$ observations have been processed, it yields the optimal estimator of the current state vector based on the full information set. When the initial conditions cannot be specified a diffuse prior is often placed on the initial state. This amounts to setting $P_0 = \kappa I$, and letting the scalar $\kappa$ go to infinity. Stable algorithms for handling diffuse priors are set out in Durbin and Koopman (2001).

Prediction is carried out straightforwardly by running the KF without updating. Mean square errors of the forecasts are produced at the same time. Smoothing is carried out by a backward filter initialized with the estimates delivered by the KF at time $T$. The aim is to compute the optimal estimator of the state vector at time $t$ using information made available after time $t$ as well as before. Efficient smoothing algorithms are described in Durbin and Koopman (2001, pp. 70–3). The weights are implicit, but Koopman and Harvey (2003) give an algorithm for computing and displaying them at any point in time. The state space smoother is far more general than the classic Wiener–Kolomogorov (WK) filter. The WK filter computes weights explicitly and for simple models it is possible to obtain expressions for the estimator in the middle of a doubly infinite sample without too much difficulty. Formula (3) is a case in point. However, the WK filter is limited to time-invariant models and even here it has no computational advantages over the state space fixed-interval smoothing algorithm. In the second edition of his celebrated text describing the WK filter, Whittle (1984, p. xi) writes ‘In its preoccupation with the stationary case and generating function methods, the 1963 text essentially missed the fruitful concept of
state structure. This … has now come to dominate the subject.’

The system matrices $Z_t, H_t, T_t, R_t$ and $Q_t$ may depend on a set of unknown parameters, and one of the main statistical tasks will often be the estimation of these parameters. Thus in the random walk plus noise model, (1), the parameters $\sigma_n^2$ and $\sigma_\varepsilon^2$ will usually be unknown. As a by-product, the KF produces a vector of prediction errors or innovations and in a Gaussian model these can be used to construct a likelihood function that can be maximized numerically with respect to the unknown parameters.

Since the state vector is a vector of random variables, a Bayesian interpretation of the Kalman filter as a way of updating a Gaussian prior distribution on the state to give a posterior is quite natural. The mechanics of filtering, smoothing and prediction are the same irrespective of whether the overall framework is Bayesian or classical. Smoothing gives the mean and variance of the state, conditional on all the observations. For the classical statistician, the conditional mean is the MMSE, while for the Bayesian it minimizes the expected loss for a symmetric loss function. With a quadratic loss function, the expected loss is given by the conditional variance. The real differences between classical and Bayesian treatments arise when the parameters are unknown. In a Bayesian framework, the hyperparameters, as they are often called, are random variables. The development of simulation techniques based on Markov chain Monte Carlo (MCMC) has now made a full Bayesian treatment a feasible proposition. This means that it is possible to simulate a distribution for the state that takes account of hyperparameter uncertainty.

**Applications**

The use of unobserved components opens up a new range of possibilities for economic modelling. Furthermore, it provides insights and a unified approach to many other problems. The examples below give a flavour.

The local linear trend model generalizes (1) by the introduction of a stochastic slope, $\beta_t$, which itself follows a random walk. Thus

$$
\mu_t = \mu_{t-1} + \beta_{t-1} + \eta_t, \eta_t \sim NID(0, \sigma_n^2), \beta_t = \beta_{t-1} + \zeta_t, \zeta_t \sim NID(0, \sigma_\zeta^2),
$$

(7)

where the irregular, level and slope disturbances, $\varepsilon_t$, $\eta_t$, and $\zeta_t$, respectively, are mutually independent. If both variances $\sigma_n^2$ and $\sigma_\zeta^2$ are zero, the trend is deterministic. When only $\sigma_\zeta^2$ is zero, the slope is fixed and the trend reduces to a random walk with drift. Allowing $\sigma_\zeta^2$ to be positive but setting $\sigma_n^2$ to zero gives an integrated random walk trend, which when estimated tends to be relatively smooth.

Signal extraction of the trend by setting the signal–noise ratio, $q = \sigma_\zeta^2 / \sigma_\varepsilon^2$, to 1/1600 gives the Hodrick–Prescott filter for quarterly data. Adding a cyclical component to (1) provides a vehicle for detrending based on a model the parameters of which can be estimated from the data.
Orphanides and van Norden (2002) have recently stressed the importance of tracking the output gap in \textit{real time}. Given the parameter estimates, real time estimation of components such as the output gap is just an exercise in filtering. However, as new observations become available the estimate of the gap at a particular point in time can be improved by smoothing. Harvey, Trimbur and van Dijk (2007) adopt a Bayesian approach which has the advantage of giving the full distribution of the output gap. Statistics such as the probability that the output gap is increasing are readily calculated. Following Kuttner (1994), Harvey, Trimbur and van Dijk (2007) also construct an unobserved components model relating the output gap to inflation in what is effectively a Phillips curve relationship.

A number of authors, beginning with Sargent (1989), have estimated the structural parameters of dynamic stochastic general equilibrium (DSGE) models using state space methods. The linear rational expectations model is first solved for the reduced-form state equation in its predetermined variables. Once this has been done, the model is put in state space form and the parameters are estimated by maximum likelihood. Alternatively a Bayesian approach can be adopted; see Smets and Wouter (2003, p. 1138).

\textbf{Data irregularities}

Some of the most striking benefits of the structural approach to time series modelling become apparent only when we start to consider more complex problems. In particular, the SSF offers considerable flexibility with regard to dealing with data irregularities, such as missing observations and observations at mixed frequencies. Missing observations are easily handled in the SSF simply by omitting the updating equations while retaining the prediction equations. Filtering and smoothing then go through automatically and the likelihood function is constructed using prediction errors corresponding to actual observations. With flow variables, such as income, the issue is one of temporal aggregation. This may be dealt with by the introduction of a cumulator variable into the state. The study by Harvey and Chung (2000) on the measurement of British unemployment provides an illustration of how mixed frequencies are handled and how using an auxiliary series can improve the efficiency of nowcasting and forecasting a target series. The challenge was how to obtain timely estimates of the underlying change in unemployment. Estimates of the numbers of unemployed according to the International Labor Organization (ILO) definition are given by the Labour Force Survey (LFS), which consists of a rotating sample of approximately 60,000 households. These estimates have been published on a quarterly basis since the spring of 1992, but from 1984 to 1991 estimates were available for the spring quarter only. Another measure of unemployment, based on administrative sources, is the number of people claiming unemployment benefit. This measure, known as the claimant count, is available monthly, with very little delay and is an exact figure. It does not provide a figure corresponding to the ILO definition, but it moves roughly in the same way as the LFS figure. The first problem is how to extract the best estimate of the underlying monthly change in a series which is subject to sampling error and which may not have been recorded every month. The second is how to use a related series to improve this estimate. These two issues are of general importance, for example in the measurement of the underlying rate of inflation or the way in which monthly figures on industrial production might be used to produce more timely estimates of national income. State space methods deal with the mixed frequencies in the target series, with the rather complicated error structure coming from the rotating sample (see Pfeffermann, 1991) and
state space models: The New Palgrave Dictionary of Economics

Continuous time

Continuous time STMs observed at discrete intervals can easily be put in SSF (see Harvey, 1989, ch. 9). An important case is the continuous time version of (7) where the smoothed trend is a cubic spline. Setting up such a model for a cubic spline enables the smoothness parameter to be estimated by maximum likelihood and the fact that irregularly spaced data may be handled means that it can be used to fit a nonlinear function to cross-sectional data. The model can easily be extended, for example to include other components, and it can be compared with alternative models using standard statistical criteria (see Kohn, Ansley and Wong, 1992).

Nonlinear and non-Gaussian models

Some of the most exciting recent developments in time series have been in nonlinear and non-Gaussian models. For example, it is possible to fit STMs with heavy-tailed distributions on the disturbances, thereby making them robust with respect to outliers and structural breaks. Similarly, non-Gaussian models, designed to deal with count data and qualitative observations, can be set up with stochastic components. In the general formulation of a state space model, the distribution of the observations is specified conditional on the current state and past observations, that is

$$p(y_t|a_t, Y_{t-1}), \quad t = 1, \ldots, T$$

(8)

where $Y_{t-1} = \{y_{t-1}, y_{t-2}, \ldots\}$. Similarly the distribution of the current state is specified conditional on the previous state and observations so that

$$p(a_t|a_{t-1}, Y_{t-1}).$$

(9)

The initial distribution of the state is given as $p(a_0)$. In a linear Gaussian model the conditional distribution in (8) and (9) are characterized by their first two moments and so they are specified by the measurement and transition equations. The Kalman filter updates the mean and covariance matrix of the state. In more general models, computer-intensive methods, using techniques such as importance sampling, have to be applied (see Durbin and Koopman, 2001). Within a Bayesian framework, methods are normally based on MCMC. Particle filtering is often used for signal extraction; see the review in
The use of state space methods highlights a fundamental distinction in time series models between those motivated by description and those set up to deal directly with forecasting. This is epitomized by the contrast between STMs on the one hand and autoregressions and autoregressive-integrated-moving average (ARIMA) models on the other. In a linear Gaussian world, the reduced form of an STM is an ARIMA model and questions regarding the merits of STMs for forecasting revolve round the gains, or losses, from the implied restrictions on the reduced form and the guidance, or lack of it, given to the selection of a suitable model (see the discussion in Harvey, 2006). Once nonlinearity and non-Gaussianity enter the picture, the two approaches can be very different. Models motivated solely by forecasting tend to be set up in terms of a distribution for the current observations conditional on past observations rather than in terms of components. For example, changing variance can be captured by a model from the generalized autoregressive conditional heteroscedasticity (GARCH) class, where conditional variance is a function of past observations, as opposed to a stochastic volatility (SV) model in which the variance is a dynamic unobserved component. The readings in Shephard (2005) describe SV models and discuss the use of computationally intensive methods for estimating them.

The realization that the statistical treatment of a wide range of dynamic models can be dealt with directly in a unified framework is important. For engineers, using state space methods is a natural way to proceed. For many economists, brought up with regression and autoregression, state space is an alien concept. This is changing. State space methods are now becoming an important part of the toolkit of econometricians and economists.

state-dependent preferences

Edi Karni

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

State-dependent preferences pertains to situations involving decision making in the face of uncertainty, in which the states resolving the uncertainty are of direct concern to the decision maker, and affect his or her evaluation of the consequences. The presence of state-dependent preferences raises fundamental issues concerning the representation of the decision maker’s preference relations and, in particular, the definition and interpretation of subjective probabilities. These difficulties are explained and an approach to resolving them is discussed.

Article

Theories of individual decision making under uncertainty pertain to situations in which a choice of a course of action, by itself, does not determine the outcome. To formulate these theories Savage (1954) introduced what has become the standard analytical framework. It consists of three sets: a set $S$, of states of the world (or states, for short); an arbitrary set $C$, of consequences; and the set $F$, of all the functions from the set of states to the set of consequences. Elements of $F$, referred to as ‘acts’, represent courses of action, consequences describe anything that may happen to a person, and states are the resolutions of uncertainty, that is, ‘a description of the world so complete that, if true and known, the consequences of every action would be known’ (Arrow, 1971, p. 45). Decision makers are characterized by preference relations, $\succeq$, on $F$. With few exceptions, preference relations are taken to be complete (that is, for all $f$ and $g$ in $F$, either $f \succeq g$ or $g \succeq f$) and transitive binary relations on $F$. The symbols $f \succeq g$ have the interpretation ‘the course of action $f$ is preferred or indifferent to the course of action $g$’. The strict preference relation, $\succ$, and the indifference relation, $\sim$, are the asymmetric and symmetric parts of $\succeq$, respectively.
respectively.
To speak loosely, a preference relation is state-dependent when the prevailing state of nature is itself of
direct concern to the decision maker. For example, taking out a health insurance policy is choosing an
action whose consequences – the indemnities – depend on the realization of the decision maker's state of
health. In this example, the state is the decision maker's state of health. It affects the decision maker's
well-being directly, and indirectly, through the payoff prescribed by the health insurance policy. The
preference relation may display ordinal state dependence, in which case the underlying state may affect
the decision maker's preferences by altering his ordinal ranking of the consequences; or cardinal state
dependence, by altering his risk attitudes; or both.
To define state dependence formally, it is convenient to adopt the model of Anscombe and Aumann
(1963). In this model the state space is finite, and the consequences are lotteries, that is, probability
distributions that assign strictly positive probability to a finite number of outcomes. Denote by \( L(X) \) the
set of lotteries on an arbitrary set, \( X \), of possible outcomes. Given a preference relation \( \succeq \) on \( F \); a state
\( s \); and \( f, f', g, g' \) in \( F \), define a preference relation on \( F \) conditional on \( s \), \( \succeq_s \), by
\( f \succeq_s f' \) if \( g \succeq g' \)
whenever \( f(s) = g(s) \), \( f'(s) = g'(s) \) and \( g(s') = g'(s') \) for all \( s' \in S - \{ s \} \). Because acts are functions,
\( f(s) \) is defined uniquely. Thus \( \succeq_s \) defines a preference relation on \( L(X) \) conditional on \( s \). This induced
preference relation is also denoted by \( \succeq_s \).
A state \( s \in S \) is said to be null if \( \succeq_s \) for all \( f, f' \in F \), otherwise it is non-null.
Definition. A preference relation \( \succeq \) on \( F \) is state dependent if \( \succeq_s \neq \succeq_{s'} \) for some non-null \( s \) and \( s' \) in
\( S \).
Because consequences are lotteries, if a preference relation \( \succeq \) on \( F \) displays state dependence, then \( \succeq_s \)
and \( \succeq_{s'} \) must differ on the ranking of some lotteries in \( L(X) \). This may be due to distinct attitudes
toward risk and/or distinct ordering of outcomes, that is, degenerate lotteries that assign the given
outcomes probability one. Circumstances in which the dependence of the decision maker's preferences
on the state constitutes an indispensable feature of the decision problem include the choice of health
insurance coverage (see Arrow, 1974; Karni, 1985); the choice of flight insurance coverage (see Eisner
and Strotz, 1961); the choice of optimal consumption and life insurance plans in the face of uncertain
life span (see Yaari, 1965; Karni and Zilcha 1985); and the provision of collective protection (see Cook
and Graham, 1977).

Subjective expected utility representations

Preferences among acts are a matter of personal judgement, presumably combining the decision maker's
valuation of the consequences and his or her beliefs regarding the likely realization of alternative events
(that is, subsets of the state space). Subjective expected utility theory pertains to preference relations
whose structures allow the decision maker's valuations of the consequences to be expressed numerically,
by a utility function; his or her beliefs to be quantified by a (subjective) probability measure on the set of
states; and the acts to be evaluated by the expectations of the utility of the corresponding consequences
with respect to the subjective probability. In other words, the theory depicts the decision makers’ choice
among alternative acts as expected utility maximizing behaviour.
By the classic von Neumann–Morgenstern expected utility theorem, \( \succeq \) on \( F \) satisfies the axioms of expected utility theory (that is, \( \succeq \) is a complete and transitive binary relation satisfying the Archimedean and independence axioms) if and only if there exist real-valued functions \( w(\cdot, s) \) on \( X \), \( s \in S \), such that for all \( f, g \in F \),

\[
f \succeq g \iff \sum_{s \in S} \sum_{x \in X} w(x, s) f(x, s) \geq \sum_{s \in S} \sum_{x \in X} w(x, s) g(x, s).
\]

Furthermore, the functions \( \{w(\cdot, s) \mid s \in S\} \) are unique up to cardinal unit comparable transformation. (That is, if some other utility functions \( \{w'(\cdot, s) \mid s \in S\} \) represent \( \succeq \) on \( F \), in the sense of equation (1), there exit \( b > 0 \) and real numbers \( a(s) \), one for each state, such that \( w'(s) = bw(s) + a(s) \) for all \( s \in S \).) The function \( w(\cdot, \cdot) \) captures the decision maker's valuation of the outcomes and his or her beliefs about the likely realization of the states. The axioms of expected utility theory do not imply a unique decomposition of \( w \) into subjective probability distribution on \( S \) and utility on outcome-state pairs. Indeed, let \( p(s), s \in S \), be any list of positive numbers that sum up to 1, where \( p(s) = 0 \) if and only if \( s \) is null. Define \( u(x, s) = w(x, s) / p(s) \) for all non-null \( s \in S \) and all \( x \in X \), and \( u(x, s) = \bar{u} \) if \( s \) is null. Then, by equation (1), \( \succeq \) is represented by \( \sum_{s \in S} p(s) \sum_{x \in X} u(x, s) f(x, s) \). The question is as follows: are there additional conditions that would imply a unique decomposition of \( w(x,s) \) into a product of utility representing the (possibly state-dependent) valuation of the outcomes and probabilities representing beliefs that govern the decision maker's choice among acts?

Anscombe and Aumann (1963) show that a preference relation is non-trivial (that is, \( f > g \) for some \( f, g \in F \)) satisfying the axioms of expected utility theory and state independence, that is, \( \succeq s = \succeq s' \), for all non-null \( s, s' \in S \) if and only if there exist a real-valued function, \( u \), on \( X \), and a subjective probability distribution, \( \pi \), on \( S \) such that, for all \( f, g \in F \),

\[
f \succeq g \iff \sum_{s \in S} \pi(s) \sum_{x \in X} u(x, s) f(x, s) \geq \sum_{s \in S} \pi(s) \sum_{x \in X} u(x, s) g(x, s).
\]

Moreover, \( u \) is unique up to positive linear transformation, and \( \pi \) is unique satisfying \( \pi(s) = 0 \) if and only if \( s \) is null.

The subjective expected utility representation (2) separates risk attitudes, represented by the utility function, from beliefs, represented by the subjective probabilities. However, the uniqueness of the probabilities depends crucially on the premise that constant acts are constant utility acts. This premise is
not implied by the axioms. In particular, state-independent preferences do not imply state-independent utility function. To see why, let $\gamma$ be a strictly positive real-valued function on $S$ and

$$\Gamma = \sum_{s \in S} \gamma(s) \pi(s).$$

Define $\tilde{u}(x, s) = u(x) / \gamma(s)$, for all $x \in X$ and $s \in S$, and let $\tilde{\pi}(s) = \gamma(s) \pi(s) / \Gamma$, for all $s \in S$. Then, by equation (2) and the uniqueness of $u$, for all $f, g \in F$,

$$f \succeq g \iff \sum_{s \in S} \tilde{\pi}(s) \sum_{x \in X} \tilde{u}(x, s) f(x, s) \geq \sum_{s \in S} \tilde{\pi}(s) \sum_{x \in X} \tilde{u}(x, s) g(x, s).$$

(3)

Thus, the utility–probability pair $(\tilde{u}, \tilde{\pi})$ induces a subjective expected utility representation of $\succeq$ that is equivalent to the one induced by the pair $(u, \pi)$. There are infinitely many distinct utility-probability pairs that represent the same preference relation in the sense of equation (2). Moreover, because $\pi$ and $\tilde{\pi}$ are distinct, even if beliefs exist a priori and are coherent enough to allow their representation by probabilities, it is not evident which of the infinitely many probability distributions consistent with $\succeq$ actually represents the decision makers beliefs. But if the probabilities that figure in the representation are meaningless, there seems to be no compelling reason to prefer the expected utility representation (2) over the more general additive representation (1). On the contrary, because the additive representation does not require that the preferences be state independent, it is applicable to the analysis of problems, such as the demand for health and life insurance, in which the assumption of state-independent preferences is clearly inadequate.

### Hypothetical preferences and subjective expected utility representations of state-dependent preferences

An alternative analytical framework, introduced by Karni and Schmeidler (1981), postulates the existence of a preference relation on hypothetical lotteries, whose prizes are outcome-state pairs. This preference relation is assumed to satisfy the axioms of expected utility and to be consistent with the actual preference relation on acts. Because the hypothetical lotteries imply distinct, hence incompatible, marginal distributions on the state space, preferences among such lotteries are introspective and may be expressed verbally only as hypothetical choices. Decision makers are supposed to be able to conceive of such hypothetical lotteries and to invoke, for the purpose of their evaluation, the same mental processes that govern their actual decisions.

To express these ideas formally, denote by $L(X \times S)$ the set of all probability distributions on $X \times S$ that assign strictly positive probabilities to a finite number of outcome-state pairs. A lottery $\ell \in L(X \times S)$ is said to be non-degenerate if $\sum_{y \in X} \ell(y, s) > 0$ for all $s \in S$. Denote by $\succeq$ an introspective preference relation on $L(X \times S)$. For each $s \in S$, define the conditional introspective preferences, $\succeq_s$, on $L(X \times S)$ analogously to the definition of $\succeq$ (that is, $\ell \succeq_s \ell'$ if and only if $\ell \succeq \ell'$, for all $\ell, \ell' \in L(X \times S)$ such that $\ell'(\cdot, s') = \ell'(\cdot, s')$ for all $s' \in S - \{s\}$).
To speak loosely, the introspective preference relation \( \widehat{\succeq} \) and the actual preference relation \( \succeq \) are consistent if they are induced by the same utilities. Formally, define a mapping, \( H \), from \( L(X \times S) \) to \( F \) as follows: For each non-degenerate \( \mathcal{E} \in L(X \times S) \), let \( H(\mathcal{E})(x, s) = \mathcal{E}(x, s) / \sum_{y \in X} \mathcal{E}(y, s) \), for all \( (x, s) \in X \times S \). A state \( s \) is said to be obviously null if \( f \succeq s f' \) for all \( f \) and \( f' \) in \( F \) and there are \( \mathcal{E}, \mathcal{E}' \in L(X \times S) \) such that \( \mathcal{E} \succeq_s \mathcal{E}' \). A state \( s \) is obviously non-null if \( f > s g \) for some \( f \) and \( g \). A state \( s \) is essential if there are \( \mathcal{E} \) and \( \mathcal{E}' \) in \( L(X \times S) \) such that \( \mathcal{E} \succeq_s \mathcal{E}' \).

**Strong consistency:** For all \( s \in S \) and non-degenerate \( \mathcal{E} \) and \( \mathcal{E}' \) in \( L(X \times S) \), \( H(\mathcal{E}) \succeq_s H(\mathcal{E}') \) implies \( \mathcal{E} \succeq_s \mathcal{E}' \), and if \( s \) is obviously non-null, then \( \mathcal{E} \succeq_s \mathcal{E}' \) implies \( H(\mathcal{E}) \succeq_s H(\mathcal{E}') \).

**Theorem** (Karni and Schmeidler, 1981): Let \( \succeq \) be a non-trivial binary relation on \( F \) and \( \widehat{\succeq} \) a binary relation on \( L(X \times S) \). Then each of the two relations satisfies the axioms of expected utility and jointly they satisfy strong consistency if and only if there exist a real-valued function, \( u \), on \( X \times S \) and a probability distribution, \( \pi \), on \( S \) such that, for all \( f \) and \( g \) in \( F \),

\[
f \succeq g \iff \sum_{s \in S} \pi(s) \sum_{x \in X} u(x, s) f(x, s) \succeq \sum_{s \in S} \pi(s) \sum_{x \in X} u(x, s) g(x, s)
\]

(4)

and, for all \( \mathcal{E} \) and \( \mathcal{E}' \) in \( L(X \times S) \),

\[
\mathcal{E} \widehat{\succeq} \mathcal{E}' \iff \sum_{s \in S} \sum_{x \in X} u(x, s) \mathcal{E}(x, s) \succeq \sum_{s \in S} \sum_{x \in X} u(x, s) \mathcal{E}'(x, s).
\]

(5)

Moreover, the function \( u \) is unique up to cardinal unit comparable transformation, the probability \( \pi \) restricted to the event of all essential states is unique, and for \( s \) obviously null \( \pi(s) = 0 \) and for \( s \) obviously non-null \( \pi(s) > 0 \).

The subjective expected utility representation in (4) applies whether the preference relation, \( \succeq \), is state-dependent or state-independent. Furthermore, as Karni and Mongin (2000) observed, because the utility function is identified using hypothetical lotteries, the probability measure \( \pi \) in the representation theorem above quantifies the decision maker’s beliefs. A similar result in a somewhat different framework is proved in Karni (2003); a probabilistically sophisticated version of this approach appears in Grant and Karni (2004).

A weaker version of this result, based on restricting the consistency condition to a subset of hypothetical lotteries that have the same marginal distribution on \( S \), due to Karni, Schmeidler and Vind (1983), yields
a subjective expected utility representation with state-dependent preferences. Wakker (1987) has extended the theory of Karni, Schmeidler and Vind (1983) to include the case in which the set of consequences is a connected topological space. However, the arbitrary choice of the subset of hypothetical lotteries renders the probabilities in these works arbitrary. Other theories that yield subjective expected utility representations invoke preferences on conditional acts (that is, preference relations over the set of acts conditional on events). Fishburn (1973) and Karni (2007) advanced such theories assuming consequence sets that have distinct structures. Skiadas (1997) proposed a non-expected utility model, based on hypothetical preferences, that yield a representation with state-dependent preferences. In this model, acts and states are primitive concepts, and preferences are defined on act-event pairs. For any such pair the consequences (utilities) represent the decision maker's expression of his holistic valuation of the act. The decision maker is not supposed to be aware whether or not the given event occurred; hence, his evaluation of the act reflects, in part, his anticipated feelings, such as disappointment aversion.

Moral hazard and state-dependent preferences

Drèze (D1961; 1987) and Karni (2006) present distinct theories of individual decision making under uncertainty with moral hazard and state-dependent preferences. Both assume that decision makers can exercise some control over the likely realization of events. Drèze does not specify the means by which this control is exercised, relying instead on their manifestation in the decision maker's choice behaviour. In particular, departing from Anscombe and Aumann's (1963) 'reversal of order' assumption, Drèze assumes that decision makers strictly prefer that the uncertainty of the lottery payoff be resolved before that of the acts, presumably to allow them to exploit this information by taking action to affect the likely realization of the underlying states. Drèze obtains a unique separation of state-dependent utilities from a set of probability distributions over the set of states of nature. Choice is represented as expected utility maximizing behaviour where the expected utility associated with any given act is itself the maximal expected utility with respect to the probabilities in the set. Karni (2005b) replaces the state space with a set of effects – phenomena on which decision makers can place bets and whose realization they can influence by their actions. In Karni's theory the choice set consists of action-bet pairs. Actions affect the decision maker's well-being directly (for example, actions may correspond to levels of effort) and indirectly (through their impact on the decision maker's beliefs); bets are functions from effects to monetary payoffs. Karni gives necessary and sufficient conditions for the existence of subjective expected utility representations with unique, action-dependent, subjective probabilities; effect-dependent utility functions representing the evaluation of wealth; and a distinct function that captures the direct impact of the choice of action on the decision maker's well-being.

Attitudes toward risk

As with state-independent preferences, the economic analysis of many decision problems involving state-dependent preferences requires measures of risk aversion. Such measures are developed in Karni (1985).

statistical decision theory

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Decision-making can be done scientifically. One can assemble the available information in a form directly usable in decision-making, mathematically assess the consequences of decisions, and combine both to reach optimal decisions. This article discusses the basis of such scientific decision-making, explaining the key concepts of utility, prior information, and maximization of expected utility. Statistical decision theory enlarges the framework of decision-making to include ‘choice among statistical procedures’. We introduce and contrast the competing Bayesian and frequentist approaches to statistical decision theory.

Article

Decision theory is the science of making optimal decisions in the face of uncertainty. Statistical decision theory is concerned with the making of decisions when in the presence of statistical knowledge (data) which sheds light on some of the uncertainties involved in the decision problem. The generality of these definitions is such that decision theory (we drop the qualifier ‘statistical’ for convenience) formally encompasses an enormous range of problems and disciplines. Any attempt at a general review of decision theory is thus doomed; all that can be done is to present a description of some of the underlying ideas.

Decision theory operates by breaking a problem down into specific components, which can be mathematically or probabilistically modelled and combined with a suitable optimality principle to determine the best decision. Section 1 describes the most useful breakdown of a decision problem – that into actions, a utility function, prior information and data. Section 2 considers the most important optimality principle for reaching a decision – the Bayes principle. The frequentist approach to decision theory is discussed in Section 3, with the minimax principle mentioned as a special case. Section 4 compares the various approaches. The history of decision theory is difficult to pin down, because virtually any historical mathematically
formulated decision problem could be called an example of decision theory. Also, it can be difficult to distinguish between true decision theory and formally related mathematical devices such as least squares estimation. Decision theory became clearly formulated as a science through work of John von Neumann and Oscar Morgenstern, culminating in their book *Theory of Games and Economic Behavior* (1944), and Abraham Wald, culminating in his book *Statistical Decision Functions* (1950). (The books do discuss some of the earlier history of decision theory.) General introductions to decision theory can be found, at an advanced level, in Blackwell and Girshick (1954) and Savage (1954); at an intermediate level in Raiffa and Schlaifer (1961), Ferguson (1967), De Groot (1970), Berger (1985), and French and Rios Insua (2000); and at a basic level in Raiffa (1968), Lindley (1985), and Winkler (1972).

### 1 Elements of a decision problem

In a decision problem, the most basic concept is that of an action \( a \). The set of all possible actions that can be taken will be denoted by \( A \). Any decision problem will typically involve an unknown quantity or quantities; this unknown element will be denoted by \( \theta \).

*Example 1:* A company receives a shipment of parts from a supplier, and must decide whether to accept the shipment or to reject the shipment (and return it to the supplier as unsatisfactory). The two possible actions being contemplated are:

- \( a_1 \): accept the shipment,
- \( a_2 \): reject the shipment.

Thus \( A = \{a_1, a_2\} \). The uncertain quantity which is crucial to a correct decision is:

- \( \theta \): the proportion of defective parts in the shipment.

Clearly action \( a_1 \) is desirable when \( \theta \) is small enough, while \( a_2 \) is desirable otherwise.

The key idea in decision theory is to attempt a quantification of the gain or loss in taking possible actions. Since the gain or loss will usually depend upon \( \theta \) as well as the action \( a \) taken, it is typically represented as a function of both. In economics this function is generally called the *utility function*, following the work of Frank Ramsey in the 1920s, and is denoted by \( U(\theta, a) \). It is to be understood as the gain achieved if action \( a \) is taken and \( \theta \) obtains. (The scale for measuring ‘gain’ will be discussed later.) In the statistical literature it is customary to talk in terms of loss instead of gain, with typical notation \( L(\theta, a) \) for the loss function. Loss is just negative gain, so defining \( L(\theta, a) = -U(\theta, a) \) results in effective equivalence between the two formulations (whatever maximizes utility will minimize loss).

*Example 1 (continued):* The company determines its utility function to be given by:

\[
U(\theta, a_1) = 1 - 10\theta, \quad U(\theta, a_2) = -0.1.
\]

To understand how these might be developed, note that if \( a_2 \) is chosen the shipment will be returned to the supplier and a new shipment sent out. This new shipment must then be processed, all of which takes time and money. The overall cost of this eventuality is determined to be 0.1 (on the scale being used). The associated utility is \(-0.1\) (a loss is a negative gain). Note that this cost is fixed: that is, it does not depend on \( \theta \).
When \( a_1 \) is chosen, quite different considerations arise. The parts will be utilized with, say, gain of 1 if none is defective. Each defective part will cause a reduction in income by a certain amount, however, so that the true overall gain will be 1 reduced by a linear function of the proportion of defectives. \( U(\theta, a_1) \) is precisely of this form. The various constants in \( U(\theta, a_1) \) and \( U(\theta, a_2) \) are chosen to reflect the various importance of the associated costs.

The scale chosen for a utility function turns out to be essentially unimportant, so that any convenient choice can be made. If the gain or loss is monetary, a suitable monetary unit often can provide a natural scale. Note, however, that utility functions can be defined for any type of gain or loss, not just monetary. Thus, in ex 1, the use of defective parts could lead to faulty final products from the company, and affect the overall quality image or prestige of the company. Such considerations are not easily stated in monetary terms, yet can be important to include in the overall construction of the utility function. (For more general discussion of the construction of utility functions, see Berger, 1985.)

The other important component of a decision problem is the information available about \( \theta \). This information will often arise from several sources, substantially complicating the job of mathematical modelling. We content ourselves here with consideration of the standard statistical scenario where there are available (a) data, \( X \), from a statistical experiment relating to \( \theta \); and (b) background or prior information about \( \theta \), to be denoted by \( \pi (\theta) \). Note that either of these components could be absent.

The data, \( X \), is typically modelled as arising from some probability density \( p_\theta (X) \). This, of course, is to be interpreted as the probability (or probability density) of the particular data value when \( \theta \) obtains.

**Example 1 (continued):** It is typically too expensive (or impossible) to test all parts in a shipment for defects, so that a statistical sampling plan is employed instead. This generally consists of selecting, say, \( n \) random parts from the shipment, and testing only these for defects. If \( X \) is used to denote the number of defective parts found in the tested sample, and if \( n \) is fairly small compared with the total shipment size, then it is well known that \( p_\theta (X) \) is approximately the binomial density:

\[
   p_\theta (X) = \frac{n!}{X! (n-X)!} \theta^X (1-\theta)^{n-X}.
\]

The prior information about \( \theta \) is typically also described by a probability density \( \pi (\theta) \). This density is the probability (or mass) given to each possible value of \( \theta \) in the light of beliefs as to which values of \( \theta \) are most likely.

**Example 1 (continued):** The company has been receiving a steady stream of shipments from this supplier and has recorded estimates of the proportion of defectives for each shipment. The records show that 30 per cent of the shipments had \( \theta \) between 0.0 and 0.025, 22 per cent of the shipments had \( \theta \) between 0.025 and 0.05, 15 per cent had \( \theta \) between 0.05 and 0.075, 11 per cent had \( \theta \) between 0.075 and 0.10, 13 per cent had \( \theta \) between 0.10 and 0.15, and the remaining 9 per cent had \( \theta \) bigger than 0.15. Treating the varying \( \theta \) as random, a probability density which provides a good fit to these percentages is the beta (1,14) density given (for \( 0 \leq \theta \leq 1 \)) by:

\[
   \pi (\theta) = 14 (1-\theta)^{13}.
\]
(For example, the probability that a random $\theta$ from this density is between 0.0 and 0.025 can be calculated to be 0.30, agreeing exactly with the observed 30 per cent.) It is very reasonable to treat $\theta$ for the current shipment as a random variable from this density, which we will thus take as the prior density.

2 Bayesian decision theory

When $\theta$ is known, it is a trivial matter to find the optimal action: simply maximize the gain by maximizing $U(\theta, a)$ over $a$. When $\theta$ is unknown, the natural generalization is to first ‘average’ $U(\theta, a)$ over $\theta$, and then maximize over $a$. The correct method of ‘averaging over $\theta$’ is to determine the overall probability density of $\theta$, to be denoted $\pi^*(\theta)$ (and to be described shortly), and then consider the Bayesian expected utility:

$$U^*(a) = E^\pi^* [U(\theta, a)] = \int U(\theta, a) \pi^*(\theta) d\theta.$$  

(This last expression assumes that $\theta$ is a continuous variable taking values in an interval of numbers. If it can assume only one of a discrete set of values, then this integral should be replaced by a sum over the possible values.) Maximizing $U^*(a)$ over $a$ will yield the optimal Bayes action, to be denoted by $a^*$.

Example 1 (continued): Initially, assume that no data, $X$, are available from a sampling inspection of the current shipment. Then the only information about $\theta$ is that contained in the prior $\pi(\theta)$; $\pi^*(\theta)$ will thus be identified with $\pi(\theta) = 14(1 - \theta)^{13}$. Calculation yields:

$$U^*(a_1) = \int_0^1 (1 - 10\theta) \ 14(1 - \theta)^{13} d\theta = 0.33, \ U^*(a_2) = \int_0^1 (-0.1) \ 14(1 - \theta)^{13} d\theta = -0.1.$$  

Since $U^*(a_1) > U^*(a_2)$, the Bayes action is $a_1$, to accept the shipment.

When data, $X$, are available, in addition to the prior information, the overall probability density $\pi^*$ for $\theta$ must combine the two sources of information. This is done by Baye's theorem (from Bayes, 1763), which gives the overall density, usually called the posterior density, as:

$$\pi^*(\theta) = p_B(X) \cdot \pi(\theta) / m(X),$$  

where:
(or a summation over $\theta$ if $\theta$ assumes only a discrete set of values), and $p_\theta(X)$ is the probability density for the experiment with the observed values of the data $X$ inserted.

**Example 1 (continued):** Suppose a sample of $n = 20$ items is tested, out of which $X = 3$ defectives are observed. Calculation gives that the posterior density of $\theta$ is:

$$
\pi^*(\theta) = p_\theta(3) \cdot \pi(\theta) / m(3) = \left[ \frac{20!}{3!17!} \theta^3 (1 - \theta)^{17} \right] \cdot \left[ 14 (1 - \theta)^{13} \right] / m(3) = (185, 504) \theta^3 (1 - \theta)^{30},
$$

which can be recognized as the beta (4,31) density. This density describes the location of $\theta$ in the light of all available information. The Bayesian expected utilities of $a_1$ and $a_2$ are thus:

$$
U^*(a_1) = \int_0^1 (1 - 10\theta) \pi^*(\theta) d\theta = \int_0^1 (1 - 10\theta)(185, 504) \theta^3 (1 - \theta)^{30} d\theta = -0.14,
$$

and

$$
U^*(a_2) = \int_0^1 (-0.1) \pi^*(\theta) d\theta = -0.1.
$$

Clearly $a_2$ now has the largest expected utility and should be the action chosen; in other words, the lot of parts should be rejected.

### 3 Frequentist decision theory

An alternative approach to statistical decision theory arises from taking a ‘long run’ perspective. The idea is to imagine repeating the decision problem a large number of times, and to develop a decision strategy which will be optimal in terms of some long-run criterion. This is called the frequentist approach, and is essentially due to Neyman, Pearson and Wald (see Neyman and Pearson, 1933; Neyman, 1977; Wald, 1950).

To formalize the above idea, let $d(X)$ denote a decision strategy or decision rule. The notation reflects the fact that we are imaging repetitions of the decision problem which will yield possibly different data $X$, and must
To therefore specify the action to be taken for any possible $X$. The utility of using $d(X)$ when $\theta$ obtains is thus $U(\theta, d(X))$. The statistical literature almost exclusively works with loss functions instead of utility functions; for consistency with this literature we will thus use the loss function $L(\theta, d) = -U(\theta, d)$. (Of course, we want to minimize loss.)

The first step in a frequentist evaluation is to compute the risk function (expected loss over $X$) of $d$, given by:

$$R(\theta, d) = E_\theta \left\{ L(\theta, d(X)) \right\} = \int L(\theta, d(X)) \, p_\theta(X) \, dX.$$  

(Again, this integral should be a summation if $X$ is discrete valued.) For a fixed $\theta$ this risk indicates how well $d(X)$ would perform if utilized repeatedly for data arising from the probability density $p_\theta(X)$. For various common choices of $L$ this yields familiar statistical quantities. For instance, when $L$ is 0 or 1, according to whether or not a correct decision is made in a two action hypothesis testing problem, the risk becomes the ‘probabilities of type I or type II errors’. When $L$ is 0 or 1, according to whether or not an interval $d(X)$ contains $\theta$, the risk is $1 -$ minus the ‘coverage probability function’ for the confidence procedure $d(X)$. When $d(X)$ is an estimate of $\theta$ and $L(\theta, d) = (\theta - d)^2$, the risk is the ‘mean squared error’ commonly considered in many econometric studies. (If the estimator $d(X)$ is unbiased, then this mean squared error is also the variance function for $d$.)

**Example 2:** Example 1, involving acceptance or rejection of the shipment, is somewhat too complicated to handle here from the frequentist perspective; we thus consider the simpler problem of merely estimating $\theta$ (the proportion of defective parts in the shipment). Assume that loss in estimation is measured by squared error; that is:

$$L(\theta, d(X)) = [\theta - d(X)]^2.$$

A natural estimate of $\theta$, based on $X$ (the number of defectives from a sample of size $n$), is the sample proportion of defectives $d_1(X) = X / n$. For this decision rule (or estimator), the risk function when $X$ has the binomial distribution discussed earlier (so that $X$ takes only the discrete values $0,1,2, \ldots n$) is given by:

$$R(\theta, d) = \sum_{X=0}^{n} \left( \theta - \frac{X}{n} \right)^2 p_\theta(X) = \theta(1 - \theta) / n.$$  

The second step of a frequentist analysis is to select some criterion for defining optimal risk functions (and hence optimal decision rules). One of the most common criteria is the minimax principle, which is based on consideration of the maximum possible risk:
This indicates the worst possible performance of \( d(X) \) in repeated use, and hence has some appeal as a criterion based on a cautious attitude. Using this criterion, an optimal decision rule is, of course, defined as one which minimizes \( R^*(d) \), and is called a \textit{minimax decision rule}.

\textit{Example 2 (continued):} It is easy to see that:

\[
R^*(d_1) = \max_{\theta} R(\theta, d_1) = \max_{\theta} \frac{\theta(1 - \theta)}{n} = \frac{1}{4n}.
\]

However, \( d_1 \) is not the minimax decision rule. Indeed, the minimax decision rule turns out to be:

\[
d_2(X) = \left( X + \sqrt{\frac{n}{2}} \right) / \left( n + \sqrt{n} \right),
\]

which has \( R^*(d_2) = 1 / [4(1 + \sqrt{n})^2] \) (compare with Berger, 1985, p. 354). The minimax criterion here is essentially the same as the minimax criterion in game theory. Indeed, the frequentist decision problem can be considered to be a zero-sum two-person game with the statistician as player II (choosing \( d(X) \)), an inimical ‘nature’ as player I (choosing \( \theta \)), and payoff (to player I) of \( R(\theta, d) \). (Of course, it is rather unnatural to assume that nature is inimical in its choice of \( \theta \).) (For further discussion of this relationship, see Berger, 1985, ch. 5.)

Minimax optimality is but one of several criteria that are used in frequentist decision theory. Another common criterion is the invariance principle, which calls for finding the best decision rule in the class of rules which are ‘invariant’ under certain mathematical transformations of the decision problem. (See Berger, 1985, ch. 6, for discussion.)

There also exist very general and elegant theorems which characterize the class of acceptable decision rules. The formal term used is ‘admissible’: a decision rule, \( d \), is \textit{admissible} if there is no decision rule, \( d^* \), with \( R(\theta, d^*) \leq R(\theta, d) \), the inequality being strict for some \( \theta \). If such a \( d^* \) exists, then \( d \) is said to be \textit{inadmissible}, and one has obvious cause to question its use. Very common decision rules, such as the least squares estimator in three or more dimensional normal estimation problems (with sum of squares error loss), can turn out rather astonishingly to be inadmissible, so this avenue of investigation has had a substantial impact on decision theory. A general discussion, with references, can be found in Berger (1985).

4 Comparison of approaches
For solving a real decision problem, there is little doubt that the Bayesian approach is best. It incorporates all the available information (including the prior information, $\pi(\theta)$, which the frequentist approach ignores), and it tends to be easier than the frequentist approach by an order of magnitude. Maximizing $U^*(a)$ over all actions is generally much easier than minimizing something like $R^*(d)$ over all decision rules; the point is that, in some sense, the frequentist approach needlessly complicates the issue by forcing consideration of the right thing to do for each possible $X$, while the Bayesian worries only about what to do for the actual data $X$ that are observed. There are also fundamental axiomatic developments (see, Ramsey, 1931; Savage, 1954; and Fishburn, 1981, for a general review) which show that only the Bayesian approach is consistent with plausible axioms of rational behaviour. Basically, the arguments are that situations can be constructed in which the follower of any non-Bayesian approach, say the minimax analyst, will be assured of inferior results. Sometimes, however, decision theory is used as a formal framework for investigating the performance of statistical procedures, and then the situation is less clear. In Example 2, for instance, we used decision theory mainly as a method to formulate rigorously the problem of estimating a binomial proportion $\theta$. If one is developing a statistical rule, $d(X)$, to be used for binomial estimation problems in general, then its repeated performance for varying $X$ is certainly of interest. Furthermore, so the argument goes, prior information may be unavailable or inaccessible in problems where routine statistical analyses (such as estimating a binomial proportion $\theta$) are to be performed, precluding use of the Bayesian approach. The Bayesian reply to these arguments is that (a) optimal performance for each $X$ alone will guarantee good performance in repeated use, negating the need to consider frequentist measures explicitly; and (b) even when prior information is unavailable or cannot be used, a Bayesian analysis can still be performed with so-called objective prior densities: see Bernardo and Smith (1994), and Berger (2006).

Example 2 (continued): If no prior information about $\theta$ is available, one might well say that choosing $\pi(\theta) = 1$ reflects this lack of knowledge about $\theta$. A Bayesian analysis (calculating the posterior density and choosing the action with smallest Bayesian expected squared error loss) yields, as the optimal estimate for $\theta$ when $X$ is observed:

$$d_2(X) = (X + 1) / (n + 2).$$

This estimate is considerably more attractive than, say, the minimax rule $d_2(X)$ (see Berger, 1985, p. 375).

In practical applications of decision theory, it is the Bayesian approach which is dominant, yet the frequentist approach retains considerable appeal among theoreticians. A general consensus on the controversy appears quite remote at this time. This author sides with the Bayesian approach in the above debate, while recognizing that there are some situations in which the frequentist approach might be useful. For an extensive discussion of these issues, see Berger (1985); Chernoff and Moses (1959) provide an insightful introduction.

statistical discrimination

Andrea Moro
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Statistical discrimination is a theory of inequality between demographic groups based on stereotypes that do not arise from prejudice or racial and gender bias. When rational, information-seeking decision makers use aggregate group characteristics, such as group averages, to evaluate individual personal characteristics, individuals belonging to different groups may be treated differently even if they share identical observable characteristics in every other aspect. Discrimination can be the agents' efficient response to asymmetric beliefs, or discriminatory outcomes may display an element of inefficiency: the disadvantaged group could perform better if beliefs were not asymmetric across groups (but beliefs are asymmetric because the disadvantaged are not performing as well as the dominant group).

Article

Statistical discrimination is a theory of inequality between demographic groups based on stereotypes that do not arise from prejudice or racial and gender bias. It occurs when rational, information-seeking decision makers use aggregate group characteristics to evaluate relevant personal characteristics of the individuals with whom they interact. Because group-level statistics, such as group averages, are used as a proxy for the individual variables, individuals belonging to different groups may be treated differently even if they share
identical observable characteristics in every other aspect. Some examples may help clarify the concept.

- When an insurance company chooses life insurance premia, the customer's likelihood of dying is one of the most relevant variables affecting the company profitability. A seemingly irrelevant proxy, gender, is highly correlated with death frequencies at every age. It is therefore optimal for the company to adopt a policy setting different premia for men and women who share similar characteristics.

- Employers usually place value on job attachment, for reasons such as the costs of specific human capital investment. Historically, women have had lower labour market attachment than men, perhaps because of a higher propensity to be involved directly in child-rearing. In evaluating workers with otherwise identical characteristics, employers may prefer to hire male over identical female candidates. This is because employers assess probabilistically higher profitability from hiring a man.

- Highway police are often accused of searching cars driven by minorities more frequently than other cars. While such a policy may be viewed as unfair, it may not be the outcome of prejudice if police officers hold (perhaps biased) beliefs that minorities are more likely to engage in criminal activities. They use such beliefs to maximize the probability of arrest over a given time frame.

All of the above examples share the following features: the decision maker a) is a rational utility maximizing agent engaged in perfecting the available information; b) has incomplete information about some outcome-relevant individual characteristics; and c) holds asymmetric beliefs regarding the average value of relevant variables across groups. These beliefs can be interpreted as stereotypes.

The examples are also different in one important aspect. In the first example, differences in the company's beliefs are rooted in a 'technological', exogenous difference between groups, the death frequencies. In the other examples, asymmetric beliefs may feed back into differences in the type of behaviour that generates them. To clarify: it is possible that, because employers are less likely to hire women in jobs that require labour market attachment, then women are more likely to be involved in child-rearing than men, and are less prone to acquire the skills that are necessary to seek and perform well in those jobs, confirming the asymmetric belief that employers hold regarding labour
market attachment. In this case, beliefs are endogenous, or self-confirming. The distinction between these two sources of inequality is important. In the first case, discrimination is the agents' efficient response to asymmetric beliefs. In the second case, discriminatory outcomes may display an element of inefficiency: the disadvantaged group could perform better if beliefs were not asymmetric across groups (but beliefs are asymmetric because the disadvantaged are not performing as well as the dominant group).

We proceed by presenting in greater detail two additional labour-market-related examples of these two flavours of statistical discrimination.

**Discrimination when the quality of information differs exogenously across groups**

Consider the example of an employer that does not observe with certainty the skill level of her prospective employees. The population of workers of a given group has a skill distribution $\Phi$. Workers draw from $\Phi$ their skill $p$, which is assumed to be equal to the value of their product when employed. Employers know the distribution, but only observe a noisy signal of productivity, $s = p + e$, where $e$ is a zero-mean error distributed according to $\Phi_e$. The employer infers $p$ from $s$ using the available information. In equilibrium, if the labour market is competitive and all employers share the same type of information, workers are paid according to their expected productivity conditional on the value of the signal. It can be shown that if $\Phi$ is a normal distribution, with mean $\mu$ and standard deviation $\sigma$, and if the error is also normal, with mean 0 and variance $\sigma_e$, then, using conditional expectations, the employers' best estimate of $p$ is a weighted average of the workers' signal and the population average, with weights that depend on the relative size of the variance of the skill and the error distribution (see Phelps, 1972). Formally, the expected worker's productivity conditional on the signal is:

$$E(p|s) = \frac{\sigma_e^2}{\sigma^2 + \sigma_e^2} p + \frac{\sigma^2}{\sigma^2 + \sigma_e^2} s$$

Intuitively, if the signal is very noisy (that is, if the variance of $e$ is very high),
the expected conditional value of workers productivity is close to the population average regardless of the signal's value. On the other extreme, if the signal is very precise ($\sigma_e$ is close to zero), then the signal provides a precise estimate of the worker's ability.

If workers belong to two identifiable demographic groups, then it is rational for the employer to condition her inference also on the group identity of the worker. Suppose for example that the signal emitted by minorities is ‘noisier’ than the signal of non-minorities (perhaps because tests are race-biased). Then it follows that minorities with high signals will receive lower wages than same-signal workers from the dominant group, and the opposite happens to workers with low signals.

While this model is capable of explaining differential treatment for same-signal workers from different groups, on average workers of the two groups receive the same wage, which is equal to the average productivity $\mu$. Group differences between groups' average wages can be obtained by extending the model to include employers' risk aversion (Aigner and Cain, 1977), or workers' pre-market investment in human capital (Lundberg and Startz, 1983). All of these approaches still require the assumption of some form of exogenous group difference, for instance in the signal's quality, an assumption which has been questioned.

**Equilibrium discrimination with ex-ante identical groups**

Recognizing these limitations, Arrow (1973) proposed an alternative model where inequality occurs even with identical groups' fundamentals. In his model, employers' asymmetric beliefs about members of different groups are self-confirming.

A formalization of this approach is presented in Coate and Loury (1993). There are two job-tasks, a simple task that anybody can perform, and a complex task requiring skills that can only be acquired through prior costly investment in human capital. Workers are heterogeneous in the cost of investment, but the cost distribution is the same across groups. There is a linear technology: each worker has the same productivity in the low-skill job, but workers have zero productivity in the high-skill job if they made no investment in human capital. If they do invest, their productivity is higher in the high-skill job than in the low-skill job. Wages are set exogenously and the high-skill job is paid with higher wages than the simple job. Employers do not observe skill level, and assign workers to tasks according to
an imperfect signal that is correlated with investment (this may be viewed as the outcome of a test where the likelihood of receiving a higher grade is higher for workers that have invested in human capital). No differences in the quality or informativeness of the test across groups need to be assumed. The task assignment depends on the expected skill, which depends both on the individual signal and on the group average, for reasons identical to those outlined in Phelps's model above, and formalized in equation (1). The optimal task assignment rule is to set a threshold and assign all workers with signals above such a threshold to the high-skill job, and workers below that threshold to the low-skill job. The marginal worker, with a signal equal to the threshold, has an expected productivity in the high-skill job identical to her productivity in the low-skill job.

A crucial feature of the model is that human capital investment provides a positive informational externality: investing not only helps a worker's own chances of being assigned to the high-skill job, but also increases the probability of being qualified to perform the high-skill job for every member of her group. This externality may generate multiple equilibria with different fractions of aggregate human capital investment.

For an intuition on how equilibria may be characterized, consider a model with only one group of workers. Suppose that in equilibrium only a few workers acquire human capital. In this case, employers' assessment of the probability that a worker has invested in human capital, given her signal, will be low even if the signal is relatively high. This is because Bayes's rule implies that the posterior probability of one worker having invested in human capital is increasing with the prior – the group's aggregate investment, (in equation (1) the workers' expected productivity depends on the group's average). Therefore, the optimal threshold for task assignment is set relatively high. Because it is difficult to obtain a high-skill job, the expected wage gain from investing is small, so only the few workers with relatively low cost of investment will acquire human capital, which confirms the original assumption that few workers invest.

There may also be equilibria with a high fraction of workers acquiring human capital. In such equilibria, employers will set a lower threshold in order to assign workers to a high-skill job relative to the low-investment equilibrium. Because high-skill jobs are more accessible, this task assignment rule provides higher returns to investment in human capital, which is a necessary condition to support this as an equilibrium. Note that the threshold cannot be too low, because if the high-skill job becomes too easily accessible, there are no
incentives to invest in human capital. Turning to the two-group model, all outcomes where both groups replicate one of the equilibria of the one-group model are equilibria of the two-group model. These symmetric equilibria display no inequality. However, if the base model displays multiple equilibria, and if groups coordinate on equilibria with different fractions of workers investing in human capital, the group with lower investment will exhibit lower average wages, a higher fraction of workers employed in the low-skill job, and a higher threshold required for assignment to the high-skilled job.

While such a model illustrates the possibility for inequality to arise even when groups are \textit{ex ante} identical, it cannot predict which group will be discriminated against, or why a symmetric equilibrium was not selected. The linearity of the technology implies that groups are treated separately, as if they were living in different islands: expected marginal productivities of workers depend only on their own signal and on the aggregate investment of their own group. Therefore, in this environment, statistical discrimination exists because of a \textit{coordination failure}: the disadvantaged group fails to coordinate on the ‘good’ equilibrium, but the dominant group has nothing to lose if the disadvantaged group could solve the coordination failure.

A version of the model with a more general technology provides an alternative source of discrimination in which groups have conflicting interests (Moro and Norman, 2004). Consider a production function exhibiting a complementarity between tasks. Then, the marginal product of a worker in each task is affected by aggregate investment in human capital in both groups. Specifically, the expected marginal product in the high-skill job of a given worker depends negatively on aggregate investment in human capital from members of the other group. This is because when more members of the other group acquire human capital, the higher aggregate availability of skills decreases the marginal product of a skilled worker. Hence, incentives to acquire skills decrease when more members of the other group acquire skills. The complementarity generates incentives for groups to \textit{specialize}, and asymmetric equilibria may exist even if there is a unique symmetric equilibrium. While there is an element of self-fulfilling prophecy, asymmetric equilibria here are the result of specialization rather than coordination failure. In such equilibria, the discriminated group cannot coordinate on a better outcome without a simultaneous coordination on a worse outcome by the other group: the dominant group always gains from discrimination. While in this model there always exist symmetric equilibria, group size is a relevant
factor, and the roles of the two groups can be reversed only if group sizes are identical.

**Empirical evidence of statistical discrimination**

There is a vast body of literature documenting racial and gender wage inequality. (See the bibliographies for the articles in this *Dictionary* on black-white labour market inequality in the United States, and women's work and wages.) In such literature, group differences that cannot be explained by differences in observable characteristics are attributed to prejudicial preferences, and little attention has been devoted to testing whether statistical discrimination plays a role in determining such differences. The main problem is to find ways to identify, using available data, to what extent group differences are caused by prejudicial attitudes, or by asymmetric beliefs (self-confirming or otherwise) and incentives.

Altonji and Pierret (2001) observe that if firms statistically discriminate, then as firms learn over time about workers' productivity, differences on the observed variables should fall over time. The data supports this proposition. Another example of an ‘outcome-based’ approach in the identification of the source of discrimination is the study by Knowles, Persico and Todd (2001), testing discrimination against minorities in motor vehicle searches by police officers. They find no evidence of racial animus in the data.

Attempts to identify different sources of discrimination include experimental or quasi-experimental data. (See Anderson, Fryer and Holt, 2006 for a survey of the literature, which also includes sources from the psychology literature.) A different approach is to estimate statistical discrimination models directly. Moro (2003) finds that adverse equilibrium selection did not play a role in exacerbating wage inequality during the last part of the 20th century. Fang (2006) estimates a statistical discrimination model to assess the prevalence of a signalling component to the college wage premium. While the estimates match wage distributions reasonably well, they are not designed to answer questions about model validation.

statistical inference

Abstract

Economic facts are typically established by means of statistical inference, which is concerned with how data supporting general claims about the world deduced from economic models should be calculated. Normally statistical inference proceeds by either estimation (point or interval) or testing. There is no general agreement on how statistical inference should be performed, but in some common situations there is good agreement about the numerical results. Of the three main schools – named after Fisher; Neyman, Pearson and Wald (NPW); and Bayes – the Bayesian alone is logically coherent.

Article

Deduction is the process whereby we pass from a general statement to a particular case: the reverse procedure, from the particular to the general, is variously called induction, or inference. Statistical inference is ordinarily understood to involve repetition or averaging, as when an inference is made about a population on the basis of a sample drawn from it. Economic facts are typically established by means of statistical inference. Economists construct a model of the world and deduce from it implications for the real world. These are checked against the available data, leading to some degree of support for the model. Statistical inference is concerned with how this support should be calculated.

Statistical inference incorporates a parameter $\theta$ which describes the model. In the simplest cases $\theta$ is a real number but in many models it is a set of numbers or even a function. The other basic element is the
data \( x \) being observations made on the actual economic system. So \( \theta \) corresponds to the general element and \( x \) to the particular. The model describes how the data follow from the parameter value. This is usually in the form of a probability distribution \( p(x|\theta) \): the probability of \( x \), given the value of \( \theta \). The problem of statistical inference is to make some statement about \( \theta \) given the value of \( x \). A simple example is provided by a model that says one variable \( y \) has linear regression on another \( z \), the regression line having equation \( y = \alpha + \beta z \) and the parameter being the pair \((\alpha, \beta) = \theta\). Data may then be collected for several pairs \((y_i, z_i), i = 1, 2, ..., n\) and an inference made about \( \theta \). The probability specification will ordinarily be that, for any \( z \), \( y \) is normally distributed about \( \alpha + \beta z \) with constant variance \( \sigma^2 \). If \( \sigma^2 \) is unknown then it will need to be included with \( \alpha \) and \( \beta \) in \( \theta \).

Two types of inference statement are ordinarily made about \( \theta \): estimation and testing. The main distinction being that in testing some values of \( \theta \) are singled out for special consideration, whereas in estimation all values of \( \theta \) are treated equally. In the regression example, the hypothesis may be made that \( z \) does not affect \( y \) in the sense that \( \beta = 0 \). It would then be usual to test the hypothesis \( \beta = 0 \). In estimation, on the other hand, \( \beta = 0 \) plays no special role and the reasonable values of \( \beta \) on the basis of \( x \) are required. Estimation takes two forms, point and interval. In the former \( \theta \) is estimated by a single number, the point estimate; or in the multidimensional case by a set of numbers. In the latter an interval, or region, of values of \( \theta \) which are reasonably supported by the data is given. In the regression example

\[
b = \frac{\sum (y_i - \bar{y})(z_i - \bar{z})}{\sum (z_i - \bar{z})^2}
\]

is the least-squares point estimate of \( \beta \), \( y \) and \( z \) being the means of the \( y \)- and \( z \)-values respectively. An interval estimate would be of the form \( b \pm ts \), where \( s \) is the standard deviation evaluated from the data and \( t \) is the value obtained from Student's \( t \)-distribution. Point estimates are usually inadequate because they do not include any expression of the uncertainty that exists about the parameter: interval estimates are much to be preferred and usually, as in the regression case, start with the point estimate \( b \) and construct the interval about it. Interval estimates and tests are often related by the fact that the interval contains those parameter values which would not be judged significant were a test of that value to be carried out.

There is no general agreement on how statistical inference should be performed though, in some common situations, there is good agreement about the numerical results. It is possible to recognize three main schools named after Fisher; Neyman, Pearson and Wald (NPW); and Bayes. The Fisherian school is the least formalized and is the one most favoured by scientists, especially those on the biological side, in medicine and agriculture. Because of its lack of a strict mathematical structure it is the hardest to describe succinctly, yet, because of this it is often the easiest to use. The name is entirely apposite since it is essentially the creation of one man, R.A. Fisher (1925, 1935). Estimation is based on the log-likelihood function \( L(\theta) = \log p(x|\theta) \). Here \( p(x|\theta) \), the probability of data \( x \) given parameter \( \theta \), is considered as a function of \( \theta \) for the observed values of the data, now considered as fixed. A point estimate of \( \theta \) is provided by the maximum likelihood value \( \hat{\theta} \), that maximizes, over \( \theta \), \( L(\theta) \). The precision of \( \hat{\theta} \) can be found using minus the second derivative of \( L(\theta) \) at \( \hat{\theta} \). An interval
estimate is then of the form \( \hat{\theta} \pm s \), where \( s \) depends on the measure of precision. Extensions to the multi-dimensional dimensional case are readily available and, although cases are known where the method is unsatisfactory, it often works extremely well and is deservedly popular. In the case of normal means, maximum likelihood and least-squares estimates agree. A Fisherian test of the hypothesis that \( \theta \) is equal to a specified value \( \theta_0 \) is found by constructing a statistic \( t(x) \) from the data \( x \) and calculating the probability, were \( \theta = \theta_0 \), of getting the value of \( t(x) \) observed, or more extreme. This probability is called the significance level: the smaller it is, the more doubt is cast on \( \theta \) having the value \( \theta_0 \). The best-known example is the \( F \)-test for the equality of means in an analysis of variance. It is typical of the Fisherian approach that few rules are available for the choice of the statistic \( t(x) \). His genius was enough to produce reasonable answers in important cases. Often \( t(x) \) is based on a point estimate of \( \theta \).

In some ways NPW is a formalized version of Fisher's approach. It has been much developed in the United States, though even there much applied work is Fisherian and it is the theoreticians who espouse NPW. There are many good expositions: for example, Lehmann (1959, 1983). Statistical inferences are thought of as decisions about \( \theta \) and the merit of a decision is expressed in terms of a loss function measuring how bad the decision is when the true value is \( \theta \). If \( t(x) \) is a point estimate of the real parameter \( \theta \), squared error \( (t(x) - \theta)^2 \) is the loss function ordinarily used, the loss diminishing the nearer the estimate is to the true value. In testing, the decisions are to reject or to accept the null value \( \theta_0 \) being tested. The simplest loss function is zero for a correct decision and some constant, positive value for each incorrect one. The probability of rejection of \( \hat{\theta} = \theta_0 \) when in fact it is true is typically the significance level in Fisher's approach. Having the concept of a decision and a loss function, it becomes possible to ask the question, what is the best decision (estimate or test)? The criterion used to answer this is the expected loss, the expectation being over the data values according to the probability specification \( p(x|\theta) \). Thus, for point estimate \( t(x) \), the expected loss is \( \int (t(x) - \theta)^2 p(x|\theta) \, dx \). The problem then is to choose \( t(x) \) to minimize this function. There is a substantial difficulty in that this expected loss depends on \( \theta \), which is unknown. Consequently additional criteria have to be used in order to select the optimum decision. For example, the decisions may be restrained in some way, as when a point estimate is restricted to be unbiased. A basic result is that the only sensible decisions are those which arise from the following procedure. Select a probability distribution \( p(\theta) \) for \( \theta \) and minimize the expected loss obtained by averaging over both \( x \) and \( \theta \) – in the point estimation case, \( \int \int (t(x) - \theta)^2 p(x|\theta) \, p(\theta) \, dx \, d\theta \). This expectation being a number, the minimization is usually possible without ambiguity. However, the choice of \( p(\theta) \) remains to be made. It is important to notice that in NPW theory the distribution of \( \theta \) is merely introduced as a device for producing a reasonable decision (the technical term is ‘admissible’) and is not necessarily held to express opinions about \( \theta \).

The third system of inference is named, quite inappropriately, after the discoverer of Bayes's,' theorem. Laplace was the first significant user. Inference is a passage from the special \( x \) to the general \( \theta \) on the basis of a model \( p(x|\theta) \) going in the opposite direction, from \( \theta \) to \( x \). In the Bayesian view, inference is similarly accomplished by a probability distribution \( p(\theta|x) \) of \( \theta \), given \( x \). The two distributions are related by Bayes's,' theorem, \( p(\theta|x) \propto p(x|\theta) \, p(\theta) \), where \( p(\theta) \) is a distribution for \( \theta \)

NPW and Bayes are similar in their introduction of probabilities for \( \theta \). A basic difference is that the Bayesian approach recognizes \( p(\theta) \) as a statement of belief about \( \theta \), and not, as does NPW, just as a technical device. With this strong statement about \( p(\theta) \) both \( x \) and \( \theta \) have probabilities attached and the full
force of the probability calculus can be employed: in particular, to make the inference \( p(\theta|x) \). Now the inference is couched, not in terms of estimates or tests, but by means of a probability distribution. If \( p(\theta|x) \) is centred around \( t(x) \), say as its mean, then \( t(x) \) may be conveniently thought of as a point estimate of \( \theta \). If \( \theta_0 \) is of special interest \( p(\theta_0|x) \) may be used as a test of the hypothesis that \( \theta = \theta_0 \).

But the full inference is the distribution \( p(\theta|x) \). Consequently, once the big step of introducing \( p(\theta) \) has been made, the inference problem is solved by use of the probability calculus: no other considerations are needed. For example, typically \( \theta \) is multi-dimensional \( \theta = (\theta_1, \theta_2, \ldots, \theta_m) \) and only a few parameters are of interest, the remainder are called nuisance parameters. If only \( \theta_1 \) matters, inferences about it are easily made by the marginal distribution \( p(\theta_1|x) \) found by integrating out the nuisance parameters from \( p(\theta|x) \). The regression example above for slope \( \beta \) (\( \alpha \) and \( \sigma^2 \) being nuisance) provides an illustration.

Until World War I, Bayesian and non-Bayesian views had alternated in popularity, but the work of R.A. Fisher was so influential that it led to an almost complete suppression of the Bayesian view, which was reinforced by the work of Neyman, Pearson and Wald. Savage (1954) renewed interest in the Bayesian approach by providing it with its axiomatic structure, following Ramsey (1931) whose original ideas had lain unappreciated. Savage was much influenced by the work of de Finetti (his most accessible work is 1974/5) who provided a new view of probability that has had considerable impact upon subsequent thinking. Today the three disciplines lie uneasily together.

The Bayesian approach is the most formalized of the three inferential methods because everything is expressed within the single framework of the probability calculus, which is itself very well formalized. It has been relatively little used largely because of the perceived difficulty of assigning a distribution to \( \theta \). An important property of this method is that it is easily extended to include decision-making. As with NPW theory, a class of decisions \( d \) is introduced together with a loss function \( l(d, \theta) \) expressing the loss in selecting \( d \) when \( \theta \) obtains, and choosing that decision \( d \) that minimizes the expected (over \( \theta \) ) loss \( \int l(d, \theta) p(\theta|x) \, d\theta \), using the inference \( p(\theta|x) \). (This is in contrast to the NPW approach, using the expectation over \( x \).)

There are two basic differences between the Bayesian paradigm and the other two. These concern the logical structure, and the likelihood principle. Both the Fisherian and NPW paradigms tackle an inference problem by thinking of several, apparently sensible procedures, investigating their properties and choosing that procedure which overall has the best properties. Fisher's work on maximum likelihood and its demonstrated superiority to the method of moments provides an example. In neither of these approaches are there general procedures: for example, there is no way known of constructing an interval estimate. Within NPW, Wald did introduce the minimax principle but it is generally unsatisfactory in the inference context and has not been used in practice. Against this, the techniques that are available, like maximum likelihood and analysis of variance, are easy to use and interpret (though the interpretation is often wrong: see equations (1) and (2) below). The lack of a formal structure has enabled statisticians to extemporize and come up with valuable concepts and techniques that are of substantial practical value though sometimes with weak justifications. The Bayesian paradigm proceeds differently. It begins by laying down reasonable, elementary properties to be demanded of an inference and then, by deduction, discovers which procedures have these properties. In that sense it is the complete opposite of the Fisherian and NPW views that start with the procedures. It is the method used in other branches of mathematics where the basic properties provide the axioms for the subsequent, logical development.

Though there are important variants, all the axiom systems proposed lead to the result that the only inference procedures satisfying them are those that use probability: that the only sensible inference for \( \theta \), given \( x \), is a probability statement about \( \theta \), given \( x \). The Bayesian position is therefore a deduction from simple requirements about our inferences. NPW comes near to recognizing this in its technical introduction of \( p(\theta) \). The Fisherian view never addresses the problem.

The second difference between the Bayesian and other views involves the likelihood principle. The model provides \( P(x|\theta) \) which, for fixed \( \theta \), is a probability for \( x \). Considered as a function of \( \theta \) for fixed \( x \), it is called the likelihood for \( \theta \) (given \( x \)). It was an important contribution of Fisher’s to emphasize the distinction between the probability and likelihood aspects, and to show us, for example, in the maximum likelihood estimate, the importance of the likelihood function. However, Fisher did not consider the likelihood to be the only tool for inference. In a significance test, based on a statistic \( t(x) \), he used the significance level, which is an integral over values of \( x \) giving more extreme values to \( t \) than that observed, for the tested value \( \theta_0 \). Clearly this cannot be calculated from the likelihood function which holds \( x \) fixed and varies \( \theta \). NPW uses the expected (over \( x \)) loss and therefore does not use the likelihood function. On the other hand, the only feature of the data used in a Bayesian procedure is the likelihood, supplementing it with the distribution for \( \theta \). The likelihood principle says that if two data sets, \( x \) and \( y \), have the same likelihood, then the inferences from \( x \) and \( y \) should be the same. Most statistical procedures in common use today violate the principle, but Bayesian procedures do not. The latter part of that statement is clearly true from Bayes’s theorem which, in order to calculate the inference, uses only the likelihood. Here is an example of its violation when an unbiased estimate is used.

Given \( \theta \), \( x \) is a random sample from a population in which each value is either 1 or 0 with probabilities \( \theta \) and \( 1 - \theta \). In one case the sample is selected to be of size \( n \) and \( r \) of the values are found to be 1. In the second case, \( r \) is chosen and the population sampled until \( r \) 1’s have been observed, the total sample being of size \( n \). In each case the likelihood is \( \theta^r(1 - \theta)^n-r \) and so, by the likelihood principle, the inferences should be the same. However, in the first case the unbiased estimate of \( \theta \) based on \( (r, n) \) is the familiar \( r/n \): in the second case it is \( (r - 1)/(n - 1) \). Significance tests of \( \theta = 1/2 \), say, are different in the two cases because ‘more extreme’ in one case means more extreme values of \( r \) for fixed \( n \), and in the other more extreme values of \( n \) for fixed \( r \). There are many impressive arguments in favour of the likelihood principle, even outside the Bayesian paradigm, yet it is not accepted by most statisticians and almost all inferential procedures used today violate it: maximum likelihood estimation is the obvious exception.

There is another interesting consequence of the axiomatic, Bayesian approach leading to the probabilistic form of inference, and that is that any non-probabilistic inference will somewhere violate the basic properties set out in the axioms. Indeed, it is true that every non-Bayesian procedure has a counter-example where it behaves in an absurd fashion. In illustration let \( (l(x), u(x)) \) be a confidence interval for \( \theta \) at level \( \alpha \) based on data \( x \). The precise meaning of this is that

\[
p(l(x) < \theta < u(x)|\theta) = \alpha, \quad \text{for all } \theta.
\]  

(1)
Notice that this is a probability statement about \( x \), given \( \theta \), based on \( p(x|\theta) \). In words, the probability that the random interval \((l(x),u(x))\) contains \( \theta \) is \( \alpha \), for all given \( \theta \). It is easy to produce examples for \( x \) in which the interval is the whole line; \( l(x) = -\infty, \ u(x) = \infty \), and \( \alpha = 0.95 \). Here we are 95 per cent confident that \( \theta \) is real. This is absurd in the case of the observed \( x \), although it is true that for 95 per cent of \( x \)'s the statement will be true. Contrast this with the Bayesian statement that

\[
p(l(x) < \theta < u(x)|x) = \alpha, \text{ for all } x,
\]

based on \( p(\theta|x) \). This is about \( \theta \), given \( x \): in words, the probability is \( \alpha \) that \( \theta \) lies between \( l(x) \) and \( u(x) \). Clearly, with \( \alpha < 1 \), it could never happen that the interval is the whole real line.

A key ingredient in any form of inference is clearly probability, whose laws are well understood. But there is considerable dispute over the interpretation of probability: disputes which have practical consequences. There are two broad groups: subjective and frequentist views. In the subjective view, a probability is an expression of the subject's belief. Thus (2) expresses a belief that \( \theta \) lies between the numbers \( l(x) \) and \( u(x) \). In the frequentist view, probabilities are related to observed frequencies. Thus (1) says that the frequency with which the interval contains \( \theta \) is \( \alpha \). The latter are objective, in the sense that the frequencies can be objectively observed by all subjects. The great majority of statisticians today adopt the frequency view, claiming an objectivity for their methods. Most Bayesians hold to the subjective approach, claiming that economists have to express beliefs about the system they are discussing. It is undoubtedly true that many users of statistics think of the frequency statements, like (1), as belief statements, like (2). It had been thought that the two views were opposites but de Finetti showed that the frequentist view of probability is a special case of the subjective view, namely when the data are believed to be exchangeable. The values \( x_1, x_2, \ldots, x_n \) are exchangeable if their probability distribution is invariant under permutation of the \( x \)'s. A random sample from a population would ordinarily be judged to possess this invariance. The case mentioned earlier where each \( x_i \) is either 1 or 0, with probabilities \( \theta \) and \( 1-\theta \) respectively, is the standard example. Here \( \theta \) is a frequency probability, or chance, about which there are beliefs \( p(\theta) \) changed by the data \( x \) to new beliefs \( p(\theta|x) \).

Resistance to the Bayesian approach and subjective probability has centred around the genuine difficulty of assessing beliefs, especially when there is little knowledge of the parameter. Rather than face the formidable, and perhaps impossible, task of measuring belief, statisticians have concentrated on frequentist methods, sometimes ignoring their defects. A related difficulty with the subjective approach is the lack of objectivity in the sense that two subjects may, on the basis of the same data, have different beliefs. The Bayesian response is that this reflects reality and if each economist were to express all his beliefs probabilistically, we would have a clearer appreciation of the situation; and, in any case, different beliefs come together with increasing amounts of data. This is why observational studies are so important. Economics is predominantly frequentist but does have a substantial school, particularly in econometrics, of the Bayesian persuasion. The close connection between that view and decision-making...
makes it more attractive to the economist than to the laboratory scientist who sees himself as acquiring
knowledge, not making decisions.
Inference that is statistical, involving repetition, is naturally allied to the frequency view: whereas
inference, in general, has no frequency basis. But de Finetti’s observation connecting exchangeability
(which is essentially a finite, frequentist property) with subjectivity shows that the Bayesian view
embraces both statistical and non-statistical inference. Consequently, the subjective, Bayesian paradigm
has enormous potential, encompassing almost all problems of passing from the special to the general.
The guilt (corresponding to $\theta$) of a defendant in a law court on the basis of evidence $x$ is an example.
The likelihood principle says that the only relevant features are the probabilities of the evidence on the
assumptions of innocence, and of guilt. Whether this potential will be realized depends in large part on
overcoming the practical difficulties of assessment of beliefs.
Statistical inference depends on a probability specification $P(x|\theta)$ for data $x$, given parameter $\theta$. If
NPW it uses, in addition, a loss function: if Bayesian it introduces an additional probability specification
for $\theta$, $p(\theta)$. An important topic studies how the inference is affected by changes in any of the
specifications. The inference is said to be robust if the change has little effect on it. For example, it is
usual to choose $P(x|\theta)$ to be normal, largely because this assumption is relatively easy to handle and
leads to many, simple and powerful answers. We might ask what happens if the normal is replaced by
the very similar Student’s $t$-distribution with its rather longer tails. For the mean $\mu$ of the normal, the
sample mean is, by any standard, an excellent point estimate of $\mu$: a trimmed mean, in which a few
extreme observations are discarded, is not quite as good but is still reasonable. With the $t$-distribution
however, the situation is reversed and the trimmed mean behaves better than the sample mean. The
former is more robust. Of recent years a lot of work has been put into the study of robust inference
procedures to replace less robust ones like least squares.
The scientist who is able to plan his experiment, either in the laboratory or in the field, has a much
simpler inference problem than the economist who, almost entirely, has to rely on data that have arisen
naturally instead of being planned. The planned experiment can take cognizance of factors additional to
those the scientist is directly interested in. This can be done either by explicitly including them in the
experiment, or by a suitable randomization procedure that has a high chance of eliminating any
unwanted effects. The economist is usually denied both opportunities, though sometimes extra factors
can be included. The inference procedure should therefore recognize uncertainties that the laboratory
experiment has eliminated. This is not always done and inference in economics remains less satisfactory
than in other sciences. The concept of causation is harder to understand in economics. In the regression
of $y$ on $z$ above, it is easy to think of $z$ causing changes in $y$: but it may be that changes in $y$ and $z$ are
both caused by related fluctuations in a third variable $w$. The attempt by econometricians to avoid this
difficulty by including many variables has led to complexities of interpretation due to the high
dimensionality of the problem.
Statistical inference is ordinarily thought of as a passage from data $x$ to parameter $\theta$ but there is another
form in which the inference is from past data $x$ to future observations $y$, with no explicit reference to a
parameter. This is often called prediction, and the obvious application is to time series with
$x = (x_1, x_2, \ldots, x_n), x_i$ being the value of some quantity at time $t_i$ and $y = x_{n+1}^\prime$; so that the quantity has
been observed up to time $t_n$ and it is required to predict its value at $t_{n+1}$. The usual way to proceed is to
model the time series in some parametric form involving $\theta$ and to infer the value of $\theta$ on the basis of
The model will specify $p(y|x, \theta)$ and one possibility is to predict $y$ using $p(y|x, \hat{\theta})$, where $\hat{\theta}$ is a point estimate of $\theta$. In the Bayesian view, $p(y|x)$ is directly available for prediction, where $p(y|x) = \int p(y|x, \theta) p(\theta|x) d\theta$, using standard probability calculations. It is arguable that all practical inference problems are of this type and that the model, and $\theta$, are only introduced as a means of solving them.

Many statistical procedures are complicated and require extensive computations: in some cases, one does not even know how to find a procedure. One possibility is to use approximation techniques and find a procedure which loses only little information in comparison with the optimum method and yet is simple. Asymptotic methods often provide such approximations. Data often consist of a random sample, or of a time series $(x_1, x_2, \ldots, x_n)$ involving $n$ observations. It is often possible to study the limiting behaviour as $n$ increases without limit. For example, with random samples, the maximum likelihood estimate $\hat{\theta}$ is asymptotically normally distributed with mean equal to the true value and variance $\sigma^2/n$, with $\sigma^2$ calculable in terms of the second derivative of the loglikelihood. Although this is only true as $n$ goes to infinity, it can be used to produce a 95 per cent confidence interval for $\theta$ of the form $\hat{\theta} \pm 1.96\sigma / \sqrt{n}$. This is then an approximation, for large $n$, to the exact interval. Asymptotic methods have been very successful though it is often difficult to know how fast the limit is approached and whether a particular $n$ is large or not. Stirling's asymptotic formula is remarkably accurate for $n$ as low as 3. Some asymptotic results are not realized until $n$ is well into the thousands.

The present position in statistical inference is historically interesting. The bulk of practitioners use well-established methods like least squares, analysis of variance, maximum likelihood and significance tests: all broadly within the Fisherian school and chosen for their proven usefulness rather than their logical coherence. If asked about their rigorous justification most of these people would refer to ideas of the NPW type: least-squares estimates are best, linear unbiased; $F$-tests have high power and maximum likelihood values are asymptotically optimal. Yet these justifications are far from satisfactory: the only logically coherent system is the Bayesian one which disagrees with the NPW notions, largely because of their violation of the likelihood principle. The practitioner is most reluctant to adopt this logical approach because of its apparent impracticality. The impracticality is largely an illusion and current work is energetically overcoming it. So the next few decades should be interesting as the various theories get amended and one emerges triumphant, or some new ideas avoid the contradictions. Whatever happens, inference will surely remain one of the most important of subjects, simply because of the ubiquity of inference problems in all aspects of human endeavour.

Statistical mechanics is a branch of physics which studies the aggregate behaviour of large populations of objects, typically atoms. A canonical question in statistical mechanics is how magnets can appear in nature. A magnet is a piece of iron with the property that atoms tend on average to be spinning up or down; the greater the lopsidedness the stronger the magnet. (Spin is binary.) While one explanation would be that there is simply a tendency for individual atoms to spin one way rather than another, the remarkable finding in the physics literature is that interdependences in spin probabilities between the atoms can, when strong enough, themselves be a source of magnetization. Classic structures of this type include the Ising and Currie–Weiss models (cf. Ellis, 1985).

Economists, of course, have no interest in the physics of such systems. On the other hand, the
mathematics of statistical mechanics has proven to be useful for a number of modelling contexts. As illustrated by the magnetism example, statistical mechanics models provide a language for modelling interacting populations. The mathematical models of statistical mechanics are sometimes called ‘interacting particle systems’ or ‘random fields’, where the latter term refers to interdependent populations with arbitrary index sets, as opposed to a variables indexed by time. It is the mathematics of statistical mechanics models that economists have found valuable in studying the evolution of populations.

Statistical mechanics models are useful to economists as these methods provide a framework for linking microeconomic specifications to macroeconomic outcomes. A key feature of a statistical mechanical system is that, even though the individual elements may be unpredictable, order appears at an aggregate level. At one level this is an unsurprising property; laws of large numbers provide a similar linkage. However, in statistical mechanics models properties can emerge at an aggregate level that are not describable at the individual level. Magnetism is one example of this as it is a feature of a system, not an individual element; the existence of aggregate properties without individual analogues is sometimes known as ‘emergence’. Emergent properties are in fact why statistical mechanics models appear to be such an intriguing set of tools for economists since they suggest that there may be aspects of macroeconomic outcomes that are not reducible to the microeconomic specification from which they derive. As such, emergence is a way to make progress on understanding aggregate behaviour in the presence of heterogeneous agents. This is especially important in light of results by Hugo Sonnenschein and others that show that the Arrow–Debreu type general equilibrium framework does not, by itself, impose many restrictions on which data can be observed. (See aggregate demand theory and aggregation (theory) for the basic results and different efforts to overcome this lack of empirical content to general equilibrium theory.) In order to produce empirical implications, statistical mechanics models impose stronger (and in many ways different) restrictions on individual interrelationships than are found in Arrow–Debreu models, so in this sense are clearly less general. What is interesting is that the aggregate properties of statistical mechanics models often do not depend on details of the interaction structure, a property known as ‘universality’.

The general structure of statistical mechanics models may be understood as follows. Consider a population of elements $\omega_i$, where $i$ is an element of some arbitrary index set $I$. Let $\sim$ denote vector all elements in the population and $\sim i$ denote all the elements of the population other than $i$. Concretely, each $\omega_i$ may be thought of as an individual choice. A statistical mechanics model is specified by the set of probability measures

$$
\mu(\omega|\omega_{\sim i})
$$

for all $i$. These probability measures describe how each element of a system behaves given the behaviour of other elements. Following our example, (1) can be interpreted as describing the probabilities of a
given person's choice given the choices of others. The objective of the analysis of the system is to understand the joint probability measures for the entire system,

\[ \mu(\omega), \]

(2)

that are compatible with the conditional probability measures (1). Thus, the goal of the exercise is to understand the probability measure for the population of choices given the conditional decision structure for each choice. Stated this way, one can see how statistical mechanics models are conceptually similar to various game-theory models, an idea found in Blume (1993), who uses statistical mechanics methods to study the convergence properties of populations in which individual agents interact with their neighbours via a sequence of coordination games.

This formulation of statistical mechanics models, with conditional probability measures representing the micro-level description of the system, and associated joint probability measures the macro-level or equilibrium description of the system, also illustrates an important difference between physics and economics reasoning. For the physicist, treating conditional probability measures as primitive objects in modelling is natural. One does not ask ‘why’ one atom's behaviour reacts to other atoms. In contrast, conditional probabilities are not natural modelling primitives to an economist. The microeconomic foundations of a model (that is, the specification of preferences, technology, beliefs and possibly institutional framework) produce conditional probabilities as descriptions of how individuals behave in the environment. Hence, one does not start by taking as a given a conditional probability description that imposes the requirement that the likelihood that an individual student drops out of high school is an increasing function of the drop-out decisions of other students. Rather, one specifies a decision problem for the student in which peer influence matters, possibly through a direct desire to conform or via information communicated by the decisions of others. This decision problem will have a probabilistic structure in which the individual outcome \( \omega_i \) depends on others in the population, just as in the standard statistical mechanics case, but the form of this dependence is derivative from the specification of the decision problem. A defect of a number of economic models using statistical mechanics is the tendency to follow the physics literature and treat (1) as an appropriate way to formulate microfoundations. Dynamic versions of statistical mechanics models are usually modelled in continuous time. One considers the process \( \omega_i(t) \) and, unlike the atemporal case, probabilities are assigned to at each point in time to the probability of a change in the current value. Operationally, this means that for sufficiently small \( \delta \)

\[ \mu(\omega_i(t + \delta)|\omega_i(t + \delta) \neq \omega_i(t)) = f(\omega_i(t), \omega_i(t))\delta + o(\delta). \]

(3)
What this means is that at each $t$ there is a small probability that $\omega_i(t)$ will change value; such a change is known as a flip when the support of $\omega_i(t)$ is binary. This probability is modelled as depending on the current value of element $i$ as well as on the current (time $t$) configuration of the rest of the population. Since time is continuous whereas the index set is countable, the probability that two elements change at the same time is 0 when the change probabilities are independent. Systems of this type lead to the question of the existence and nature of invariant or limiting probability measures for the population, that is, the study of

$$\lim_{t \to \infty} \mu(\omega(t)|\omega(0)).$$

Discrete time systems can of course be defined analogously; for such systems a typical element is $\omega_{i,t}$. In such cases, it perhaps most natural to assume that changes in the individual elements of the system are simultaneous.

The conditional probability structure described by (1) can lead to very complicated calculations for the joint probabilities (2). In the interests of analytical tractability, physicists have developed a set of methods referred to as mean field analyses. These methods typically involve replacing the conditioning elements in (1) with their expected values, that is

$$\mu(\omega_i|E(\omega_{-i})).$$

A range of results exist on how mean field approximation relate to the original probabilities models they approximate. From the perspective of economic reasoning, mean field approximations have a substantive economic interpretation as they implicitly mean that agents make decisions based on their beliefs about the behaviours of others rather than the behaviours themselves. Brock and Durlauf (2001a) develop an environment in which the equilibrium set of choices, modelled as an expectational form of a noncooperative (that is, Nash) equilibrium, turns out to the mean field approximation of a model that is interpretable as a social planning equilibrium in which the planner determines all choices, accounting for complementarities in payoffs across individuals.

Properties

Existence
The first question one naturally asks for environments of the type described concerns the existence of a joint or invariant probability measure over the population of elements in which conditional probabilities for the behaviours of the elements have been specified. Existence results of this type differ from classic results such as the Kolmogorov extension theorem in that they concern the relationship between conditional probabilities and joint probabilities, rather than the relationship (as occurs in the Kolmogorov case) between joint probabilities measured on finite sets of elements versus an infinite collection that represents the union of the various elements. Liggett (1985; 1991) provides a comprehensive survey of results. These results are quite technical but do not, in my judgement, require conditions that appear to be reasonable from the perspective of socio-economic systems, at least in the sense that they do not seem to have any interesting behavioural content.

Uniqueness or multiplicity

The existence of a joint or invariant measure says nothing about how many such measures exist. When there are multiple measures compatible with the conditional probabilities, the system is said to be nonergodic. Notice that for the dynamical models the uniqueness question involves the dependence of the invariant measure on the initial configuration on \( \omega(0) \) or \( \omega \). Heuristically, for atemporal models, nonergodicity is thus the probabilistic analog to multiple equilibria, whereas for temporal models nonergodicity is the probabilistic analog to multiple steady states.

One of the fascinating features of statistical mechanics models is their capacity to exhibit nonergodicity in nontrivial cases. Specifically, nonergodicity can occur when the various direct and indirect connections between individuals in a population create sufficient aggregate interdependence across agents. As such statistical mechanics models use richer interactions structure than appear, for example in conventional time series models. To see this, consider a Markov chain

\[
\Pr(\omega_t = 1|\omega_{t-1} = 1) \neq 1 \text{ and } \Pr(\omega_t = 0|\omega_{t-1} = 0) \neq 1,
\]

then \( \lim_{j \to \infty} \Pr(\omega_{t+j}|\omega) \) will not depend on \( \omega_0 \). However, suppose that \( j = Q \), that is, the index set is the set of integers so that we are considering the evolution of a countable collection of elements. Suppose further that the system has a local Markov property of the form

\[
\Pr(\omega_{i,t}|\omega_{\sim t-1}) = \Pr(\omega_{i,t}|\omega_{i-1,t-1, \sim i+1,t-1}).
\]

In words, the behaviour of a particular \( \omega_{i,t} \) depends on its value at \( t-1 \) as well as its ‘nearest neighbours’. In this case, it is possible that \( \lim_{j \to \infty} \Pr(\omega_{i,t+j}|\omega) \) does depend on \( \omega \) even though no conditional probability \( \Pr(\omega_{i,t}|\omega_{i-1,t-1, \sim i+1,t-1}) \) equals 1. The reason for this is that, in the case of an evolving set of interacting Markov processes, there are many indirect connections. For example, the realization of \( \omega_{i-2,t-2} \) will affect \( \omega_{i,t} \) because of its effect on \( \omega_{i-1,t-1} \); no analogous property exists when there is a single element at each point in time. In fact, the number of elements at time \( t-k \) that affect \( \omega_{i,t} \) is, in this example, growing in \( k \). This does not mean that such a system necessarily has multiple invariant measures, merely that it can when there is sufficient sensitivity of

\[
\Pr(\omega_{i,t}|\omega_{\sim t-1}) = \Pr(\omega_{i,t}|\omega_{i-1,t}, \omega_{i,t-1}, \omega_{i+1,t-1})
\]

to the realizations of \( \omega_{i-1,t-1} \) and \( \omega_{i+1,t-1} \). For many statistical mechanics models, this dependence can be reduced to a single parameter. For example, a dynamic version of the Ising model may be written...
statistical mechanics: The New Palgrave Dictionary of Economics

so $J$ fully characterizes the degree of dependence in the system. In statistical mechanics models, one often finds threshold effects, that is, when $J$ is below some $J < \tilde{J}$, the system exhibits a unique invariant measure whereas, if $J > \tilde{J}$, multiple measures exist.

Applications

The earliest uses of statistical mechanics models in economics appear to be Follmer (1974) and Allen (1982). Follmer analyses the question of when idiosyncratic preference shocks affect aggregate prices. He models these shocks as binary and shows that, if the shocks obey nearest neighbour-type interdependence, then it is possible for the shocks to affect the aggregate price level. This occurs specifically if the interdependences are strong enough to produce multiple invariant measures, that is, the law of large numbers breaks down for the shocks. Allen (1982) applies statistical mechanics ideas to the diffusion of technical change.

Statistical mechanics ideas were largely dormant until the early 1990s, when a number of researchers independently began using the tools, often in very different contexts. One area where this work has proven valuable is game theory. Blume (1993; 1995) employed statistical mechanics methods to understand the role of different interactions structures in evolutionary game theory. Brock (1993) provides a wide-ranging exploration of the relationship between various types of statistical mechanics models and particular socio-economic environments, with particular attention to the difference between environments with and without a social planner.

Other authors have applied statistical mechanics to particular substantive contexts. Durlauf (1993) employs a discrete time model to study economic growth. For this work, the motivation was twofold: first, to formalize the idea that local spillover effects can create a development trap and, second, to identify how leading sectors can expand and thereby lead to a take-off to sustained industrialization and growth. Bak et al. (1993) analyse a model in which industrial demand linkages can cause idiosyncratic shocks to produce aggregate fluctuations. Kelly (1994) shows how these models can explain how shocks of different sizes lead to very different macroeconomic consequences. Other applications include financial market fluctuations (Horst, 2005), information transmission (Kosfeld, 2005), technical change (Auerswald et al., 2000) and trade networks and unemployment (Oomes, 2003).

Current theoretical research using statistical mechanics models has attempted to extend their use to more general specifications than have appeared in the physics and mathematics literatures. Brock and Durlauf (2006) extend various properties of statistical mechanics models to contexts where agents face more than two choices; the choices are not ordered so this approach creates links between statistical mechanics models and multinomial choice models in the various social sciences. Other authors have focused on continuous choice spaces (for example, Bisin, Horst and Özgür, 2006; Horst and Scheinkman, 2006). Ioannides (2006) considers how a range of alternative interaction structures affect aggregate outcomes. Bisin, Horst and Özgür, (2006) consider issues of self-consistent beliefs for different local interaction structures. Horst and Scheinkman (2006) consider the relationship between conditional probabilities of the form (1) and the underlying decision problems of agents, thus facilitating better microfoundations when these methods are used. These various directions seem promising in
allowing statistical mechanics methods to describe richer socio-economic environments. Researchers have also begun to bring statistical mechanics models to empirical work. The econometric analyses of statistical mechanics models of Brock and Durlauf (2001a; 2001b; 2006; 2007), Conley and Topa (2003) and Topa (2001) have begun to be studied. As initially discussed in Manski (1993), complicated identification problems exist in uncovering behavioural interdependences even when individual-level data are available. One important message from Brock and Durlauf (2001a; 2001b) is that the nonlinearities that are embedded in the probability structure of statistical mechanics models are important in overcoming what Manski has called the reflection problem. Further, Brock and Durlauf (2007) shows how the presence of multiple equilibria can be used to uncover behavioural interdependences in the presence of group level unobservables. Once one moves to econometric applications, it is essential to allow for richer forms of individual heterogeneity than are found in the various theoretical models. Indeed, most theoretical models assume that individual agents are described by the same conditional probability measure; one exception is Glaeser, Sacerdote and Scheinkman (1996). At this point, essentially nothing is known about the properties of statistical mechanics models in which empirically salient forms of heterogeneity have been introduced. For this reason, I believe that advances in the use of statistical mechanics methods in economic theory and econometrics will prove to be strong complementary.

Some statisticians and economists might find it surprising to learn that statistics and economics share common roots going back to ‘Political Arithmetic’ in the mid-17th century. The primary objective of this article is to revisit the common roots and trace the parallel development of both disciplines up to and including the 20th century, and to attempt to signpost certain methodological lessons that were missed along the way to the detriment of both disciplines. The emphasis is primarily on methodological developments, with less attention paid to institutional developments.

The close interrelationship between economics and statistics, going back to their common roots in ‘Political Arithmetic’, played a crucial role in availing the development of both disciplines during their practical knowledge (pre-academic) period. Political economy was first separated from political arithmetic and became an academic discipline – the first social science – at the end of the 18th century, partly as a result of political arithmetic losing credibility. Statistics emerged as a ‘cleansed’ version of political arithmetic, focusing on the collection and tabulation of data, and continued to develop within different disciplines including political economy, astronomy, geodesy, demography, medicine and biology; however, it did not become a separate academic discipline until the early 1900s. During the 19th century the development of statistics was institutionally nurtured and actively supported by the more empirically oriented political economists such as Thomas Malthus who helped to create section F of the Royal Society, called ‘Economic Science and Statistics’, and subsequently to found the Statistical Society of London. The teaching of statistics was introduced into the university curriculum in the 1890s, primarily in economics departments (see Walker, 1929).

The close relationship between economics and statistics was strained in the first half of the 20th century, as the descriptive statistics tradition, associated with Karl Pearson, was being transformed into modern (frequentist) statistical inference in the hands of Fisher (1922, 1925, 1935a, 1956) and Neyman and Pearson (1933), and Neyman (1935, 1950, 1952). During the second half of the 20th century this relationship eventually settled into a form of uneasy coexistence. At the dawn of the 21st century there is a need to bring the two disciplines closer together by implementing certain methodological lessons overlooked during the development of modern statistics.

1 The 17th century: political arithmetic, the promising beginnings

If one defines statistics broadly as ‘the subject matter of collecting, displaying and analysing data’, the roots of the subject are traditionally traced back to John Graunt's (1620–74) Natural and Political Observations upon the Bills of Mortality, published in 1662 (see Hald, 1990; Stigler, 1986), the first systematic study of demographic data on birth and death records in English cities. Graunt detected surprising regularities stretching back over several decades in a number of numerical aggregates, such as the male/female ratio, fertility rates, death rates by age and location, infant mortality rates, incidence of new diseases and epidemics, and so on. On the basis of these apparent regularities, Graunt proceeded to draw certain tentative inferences and discuss their implications for important public policy issues. Hald summarized the impact of this path-breaking book as follows:

Graunt's book had immense influence. Bills of mortality similar to the London bills were introduced in other cities, for example, Paris in 1667. Graunt's methods of statistical analysis were adopted by Petty, King and Davenant in England; Vauban in France; by Struyck in the Netherlands; and somewhat later by Sussmilch in Germany. Ultimately, these endeavours led to the establishment of governmental statistical offices. Graunt's investigation on the stability of the sex ratio was continued by Arthuthnott and Nicolas Bernoulli. (Hald, 1990, p. 103)

Graunt's book had close affinities in both content and objectives to several works by his close friend
William Petty (1623–87) on ‘Political Arithmetick’ published during the 1670s and 1680s; Graunt and Petty are considered joint founders of the ‘political arithmetic’ tradition (Redman, 1997). The fact that Graunt had no academic credentials and published only the single book led to some speculation in the 1690s, which has persisted to this day, that Petty was the real author of *The Bills of Mortality*. The current prevailing view (see Greenwood, 1948; Kreager, 1988) is that Petty's potential influence on Graunt's book is marginal at best. Stone aptly summarizes this view as follows:

Graunt was the author of the book associated with his name. More than likely, he discussed it with his friend; Petty may have encouraged him to write it, contributed certain passages, helped obtaining the Bills for the county parish … at Romsey, the church in which Petty's baptism is recorded and in which he is buried; he may even have suggested the means of interpolating the numbers of survivors between childhood and old age. But all this does not amount to joint let alone sole authorship. (Stone, 1997, p. 224)

Hull (1899), one of Petty's earliest biographers and publisher of his works, made a strong case against Petty being the author of the ‘Bills of Mortality’ by comparing his methodological approach to that of Graunt:

Graunt exhibits a patience in investigation, a care in checking his results in every possible way, a reserve in making inferences, and a caution about mistaking calculation for enumeration, which do not characterize Petty's work to a like degree. The spirit of their work is often different when no question of calculation enters. Petty sometimes appears to be seeking figures that will support a conclusion which he has already reached; Graunt uses his numerical data as a basis for conclusions, declining to go beyond them. He is thus a more careful statistician than Petty, but he is not an economist at all. (Hull, 1899, pp. xlix and lxxv)

Both Graunt and Petty used limited data to draw conclusions and make predictions about the broader populations, exposing themselves to severe criticisms as to the appropriateness and reliability of such inferences. For instance, using data on christenings and burials in a single county parish in London, they would conjure up estimates of the population of London (which included more than 130 parishes), and then on the basis of those estimates, and certain contestable assumptions concerning mortality and fertility rates, proceed to project estimates of the population of the whole of England. The essential difference between their approaches is that Graunt put enough emphasis on discussing the possible *sources of error* in the collection and compilation of his data, as well as in his assumptions, enabling the reader to assess the reliability (at least qualitatively) of his inferences. Petty, in contrast, was more prone to err on the side of political expediency by drawing inferences that would appeal to the political powers of his time (see Stone, 1997).

Graunt and Petty considered statistical analysis a way to draw *inductive inferences* from observational data, analogous to performing experiments in the physical sciences (see Hull, 1899, p. lxv). Political arithmetic stressed the importance of a new method of quantitative measurement – ‘the art of reasoning by figures upon things relating to the government’ – and was instrumental in the development of both
statistics and economics (see Redman, 1997, p. 143). The timing of this emphasis on quantitative measurement and the collecting of data was not coincidental. The empiricist turn pioneered by Francis Bacon (1561–1626) had a crucial impact on intellectual circles such as the London Philosophical Society and the British Association, with which Graunt and Petty were associated – these circles included Robert Boyle, John Wallis, John Wilkins, Samuel Hartlib, Christopher Wren and Isaac Newton. As summarized by Letwin:

The scientific method erected by Bacon rested on two main pillars: natural history, that is, the collection of all possible facts about nature, and induction, a careful logical movement from those facts of nature to the laws of nature. (Letwin, 1965, p. 131)

Graunt and Petty were also influenced by philosopher John Locke (1632–1704), through personal contact. Locke was the founder the British empiricist tradition, which continued with George Berkeley (1685–1753) and David Hume (1711–76). Indeed, all three philosophers wrote extensively on political economy as it relates to empirical economic phenomena, and Locke is credited with the first use of the most important example of analytical thinking in economics, the demand-supply reasoning in determining price (see Routh, 1975).

Graunt's and Petty's successors in the political arithmetic tradition, Gregory King (1648–1712) and Charles Davenant (1656–1714) continued to emphasize the importance of collecting data as the only objective way to frame and assess sound economic policies. Their efforts extended the pioneering results of Grant and Petty and provided an improved basis for some of the original predictions (such as the population of England), but they did not provide any new methodological insights into the analysis of the statistical regularities originally enunciated by Graunt. The enhanced data collection led to discussions of how certain economic variables should be measured over time, and a new literature on index numbers was pioneered by William Fleetwood (1656–1723). The roots of national income accounting, which eventually led to the current standardized macro-data time series, can be traced back to the efforts of these early pioneers in political arithmetic (see Stone, 1997).

According to Hald:

His [Graunt's] life table was given a probabilistic interpretation by the brothers Huygens; improved life tables were constructed by de Witt in the Netherlands and by Halley in England and used for the computation of life annuities. The life table became a basic tool in medical statistics, demography, and actuarial science. (Hald, 1990, p. 1034)

The improved life tables, with proper probabilistic underpinnings, were to break away from the main political arithmetic and become part of a statistical/probabilistic tradition that would develop independently in Europe in the next two centuries, giving rise to a new literature on life tables and insurance mathematics (see Hald, 1990).

A methodological digression. This was a crucial methodological development for data analysis because it was the first attempt to provide probabilistic underpinnings to Graunt's statistical regularities. Unfortunately, the introduction of probability in the life tables was of limited scope and had no impact on the broader development of political arithmetic, which was growing during the 18th century without
any concerns for any probabilistic underpinnings. Without such underpinnings, however, one cannot
distinguish between real regularities and artifacts.

2 The 18th century: the demise of political arithmetic

At the dawn of the 18th century political arithmetic promised a way to provide an objective basis for
more reliable framing and assessment of economic and social policies. As described by Petty, the
method of political arithmetic replaces the use of ‘comparative superlative words, and intellectual
arguments’ with ‘number, weight, or measure; to use only arguments of sense; and to consider only such
causes as have visible foundations in nature, leaving those that depend on the mutable minds, opinions,
appetites, and passions of particular men, to the consideration of others’ (Hull, 1899, p. 244).

English political institutions, including the House of Commons, the House of Lords and the monarchy,
took full advantage of the newly established methods of political arithmetic and encouraged, as well as
financed, the collection of new data as needed to consider specific questions of policy (see Hoppit,
1996). Putting these methods to the (almost exclusive) service of policy framing by politicians carried
with it a crucial danger for major abuse. An inherent problem for social scientists in general has always
been to distinguish between inferences relying on sound scientific considerations and those motivated by
political or social preferences and leanings.

The combination of (a) the absence of sound probabilistic foundations that would enable one to
distinguish between real regularities and artefacts, and (b) the inbuilt motivation to abuse data in an
attempt to make a case for one’s favourite policies, led inevitably to extravagant and unwarranted
speculations, predictions and claims. These indulgences eventually resulted in the methods of political
arithmetic losing credibility. The extent of the damage was such that Greenwood, in reviewing ‘Medical
Statistics from Graunt to Farr’, argued:

One may fairly say on the evidence here summarized that the eighteenth-century political
arithmeticians of England made no advance whatever upon the position reached by
Graunt, Petty and King. They were second-rate imitators of men of genius. (Greenwood,
1948, p. 49)

An important component of the evidence provided by Greenwood was the ‘population controversy’,
which often involved idle speculation in predicting the population of England. This speculation began
with Graunt with a lot of cautionary notes attached, but it continued into the 18th century with much less
concern about the possible errors that could vitiate such inferences. The discussions were from two
opposing schools of thought: the pessimists, who claimed that the population was decreasing, and the
optimists, who argued the opposite: their conflicting arguments were based on the same bills of mortality
popularized by Graunt. Neither side had reliable evidence for its predictions because the data provided
no sound basis for reliable inference. All predictions involved highly conjectural assumptions of fertility
and mortality rates, the average number of people living in each house, and so on. The acrimonious
arguments between the two sides revealed the purely speculative foundations of all such claims and
contributed significantly to the eventual demise of political economy (see Glass, 1973, for a detailed
review).
The above quotation from Greenwood might be considered today as an exaggeration, but it describes accurately the prevailing perception at the end of the 18th century. An unfortunate consequence of disparaging the methods of political arithmetic was the widely held interpretation that it provided decisive evidence for the ineffectiveness of Bacon's *inductive method*. Indeed, one can argue that this cause was instrumental in the timing of the emergence of *political economy* at the end of the 18th century, as the first social science to break away from political arithmetic. Adam Smith (1723–90) declared: ‘I have no great faith in political arithmetick’ (1776, p. 534). James Steuart (1712–80) was even more critical:

> Instead of appealing to political arithmetic as a check on the conclusions of political economy, it would often be more reasonable to have recourse to political economy as a check on the extravagances of political arithmetic. (quoted by Redman, 1997)

During the late 18th century, political economy defined itself by contrasting its methods with those of political arithmetic, arguing that it did not rely only on tables and figures in conjunction with idle speculation, but was concerned with the theoretical issues, causes and explanations underlying the process that generated such data. Political economists contrasted their primarily deductive methods to the discredited inductive methods utilized by political arithmeticians. As argued by Hilts:

> Of importance to the history of statistics in England was the fact that the political economists were fully conscious of their deductive proclivities and saw political economy as methodologically distinct from the inductive science of statistics. (Hilts, 1978, p. 23)

At this point it should be emphasized that the terms induction and deduction had different connotations during the 18th century, and care should be taken when interpreting some of the claims of that period (see Redman, 1997). Despite the criticisms by leading political economists of the inductive method, broadly understood as using the data as a basis of inference, the tradition of collecting, compiling and charting data as well as drawing inferences concerning broad tendencies on such a basis, continued to grow throughout the 18th and 19th centuries, and was influential in the development of political economy. Some political economists such as Thomas Malthus (1766–1834) and John McCulloch (1789–1864) continued to rely on the British empiricist tradition of using data as a basis of inference, but were at great pains to separate themselves from the 18th century's discredited political arithmetic tradition. Indeed, the leading political economists of that period, including Adam Smith and David Ricardo (1772–1823), used historical data extensively in support of their theories, conclusions and policy recommendations developed by deductive arguments (see Backhouse, 2002a).

At the close of the 18th century, the only bright methodological advance in the withering tradition of political arithmetic was provided by William Playfair's (1759–1823) *The Commercial and Political Atlas*, published in 1786. This book elevated the analysis of tabulated data to a more sophisticated level by introducing the power of graphical techniques in displaying and analysing data. Playfair introduced several innovating techniques such as hachure, shading, colour coding, and grids with major and minor divisions of both axes to render the statistical regularities in the data even more transparent. In a certain sense, the graphical techniques introduced by Playfair made certain empirical regularities more
transparent and rendered certain conclusions easier to draw. The graphs in this book represent economic
time series, measuring primarily English trade (imports/exports) with other countries during the 18th
century. Indeed, Playfair's writings were mainly on political economy; his first book, *Regulation of the*
*Interest of Money*, was published in 1785 (see Harrison, 2004).

In what follows the developments in probability theory will be discussed only when they pertain to the
probabilistic underpinnings of statistical analysis; for a more detailed and balanced discussion see Hald
(1990; 1998; 2007). The probabilistic underpinnings literature on probability developed independently
from political arithmetic in England, and there was no interaction between the two until the mid-19th
century.

Viewed from today's vantage point, the primary problem with Grant's inferences based on data
pertaining to a single parish in London, was how 'representative' the data were for the population of
London as a whole, which included more than 130 other parishes. This problem was formalized much
later in terms of whether the data can be realistically viewed as a 'random sample' from the population
of London. Defining what a random sample is, however, requires probability theory, which was not
adequately understood until the late 19th century (see Peirce, 1878).

*Jacob Bernoulli.* The first important result relating to the probabilistic underpinnings of statistical
regularities was Jacob Bernoulli's (1654–1705) Law of Large Numbers (LLN), published posthumously
in 1713 by his nephew Nicolas Bernoulli (1687–1759). Bernoulli's theorem showed that *under certain*
*circumstances*, the relative frequency of the occurrence of a certain event $A$, say

$$
\bar{X} = \frac{1}{n} \sum_{i=1}^{n} X_i = \frac{m}{n} \quad (m \text{ occurrences of } \{X_i=1\} \text{ and } n-m \text{ occurrences of } \{X_i=0\} \text{ in } n \text{ trials})
$$

provides an estimate of the probability $P(A) = p$ whose accuracy increases as $n$ goes to infinity. In modern terminology $\bar{X}$ constitutes a
consistent estimator of $p$. Bernoulli went on to use this result in an attempt to provide an interval
estimator of the form: $p$ is in $(\bar{X} \pm \varepsilon)$ for some $\varepsilon > 0$, but his estimator was rather crude (see Hald, 1990).

*A methodological digression.* The *circumstances* assumed by Bernoulli were specified in terms of the
trials being *independent and identically distributed* (IID). It turned out that the same probabilistic
assumption defines the notion of a *random sample* mentioned in relation to the probabilistic
underpinnings concerning Graunt's statistical regularities, though the two literatures were developing
independently. The role of these probabilistic underpinnings was not made explicit, however, until the
early 1920s (see Section 4.2). Indeed, the role of the IID assumptions is often misunderstood to this day.
For instance, Hilts argues:

Mathematically the theorem stated [LLN], in very simplified language, that an event
which occurs with a certain probability, appears with a frequency approaching that
probability as the number of observations is increased. (Hilts, 1973, p. 209)

Strictly speaking, the LLN says nothing of a sort, because, unless the trials are IID, the result does *not*
follow. This insight was clearly articulated by Uspensky:

It should, however, be borne in mind that little, if any, value can be attached to the
practical applications of Bernoulli's theorem, unless the conditions presupposed in this
theorem are at least approximately fulfilled: independence of trials and constant
Laplace. The first successful attempt to integrate data analysis with the probabilistic underpinnings should be credited to Pierre-Simon Laplace (1749–1827), a famous French mathematician and astronomer, and Thomas Bayes (1702–61), a British mathematician and Presbyterian minister. In papers published in 1764 and 1765 (see Hald, 2007) respectively, they proposed the first inverse probability (posterior-based) interval for \( p \) for the form \( p \) of the form ‘\( p \) is in \( \mu \pm [\varepsilon(\mu)] \)’ for some \( \varepsilon > 0 \), by assuming a prior distribution \( p \sim U(0,1) \) that is \( p \) is a uniformly distributed random variable (see Hacking, 1975). This gave rise to the inverse probability approach (known today as the Bayesian approach) to statistical inference, which was to dominate statistical induction until the 1920s, before the Fisherian revolution. In 1812 Laplace (see Hald, 2007) also provided the first frequentist interval estimator of \( p \) of the form \( p \) is in \( \bar{x} \pm \varepsilon \) for some \( \varepsilon > 0 \). The difference between this result and a similar result by Bernoulli is that Laplace used a more accurate approximation based on convergence in distribution as the basis of his result; the first central limit theorem supplying an asymptotic approximation of the binomial by the Normal distribution (see Hald, 1990).

3 The 19th century: political economy and statistics

The demise of political arithmetic by the early 19th century was instrumental in contributing to the creation of two separate fields: political economy and statistics. Political economy was created to provide more reasoned explanations for the causes and contributing factors giving rise to economic phenomena. Statistics was demarcated by the narrowing down of the scope of political arithmetic in an attempt to cleanse it from the unwarranted speculation that undermined its credibility during the 18th century.

3.1 The Statistical Society of London

Given their common roots, the first institution created to foster the development of the field of statistics, the Statistical Society of London, was created in 1834 with the active participation of several political economists, including Thomas Malthus and Richard Jones (1790–1855), who, together with John Drinkwater (1801–51), Henry Hallam (1777–1859) and Charles Babbage (1791–1871), were to found the Society after some prompting from Quetelet, who visited England in 1833. Other political economists who played very active roles in the early stages of the Society included Thomas Tooke (1774–1858), John R. McCulloch (1789–1864) and Nassau Senior (1790–1864). The first council included notable personalities such as Earl FitzWilliam (1748–1833), William Whewell (1794–1866), G. R. Porter (1792–1852) and Samuel Jones-Loyd (1796–1883).

In an attempt to protect themselves from the disrepute on speculation based on data brought about by political arithmeticians, the new society was founded upon the explicit promise to put the emphasis, not on inference, but upon the collection and tabulation of data of relevance to the state. The founding document stated:
The Statistical Society of London has been established for the purposes of procuring, arranging, and publishing Facts calculated to illustrate the condition and prospects of the Society. (Journal of the Statistical Society of London, 1834, p. 1)

The seal on the cover of the Journal of the Statistical Society of London (JSSL) was a wheatsheaf around which was written ‘aliis exterendum’ (‘to be threshed by others’). That is, the aim of the society is to painstakingly gather the facts and let others draw whatever conclusions might be warranted:

The Statistical Society will consider it to be the first and most essential rule of its conduct to exclude carefully all Opinions from its transactions and publications – to confine its attention rigorously to facts – and, as far as it may be found possible, to facts which can be stated numerically and arranged in tables. (JSSL, 1834, pp. 1–2)

Of particular interest is the way the statement of the aims of the society separated statistics from political economy:

The Science of Statistics differs from Political Economy because although it has the same end in view, it does not discuss causes, nor reason upon probable effects; it seeks only to collect, arrange, and compare, that class of facts which alone can form the basis of correct conclusions with respect to social and political government. (JSSL, 1834, p. 2)

The overwhelming majority of the published papers in the JSSL were in the political arithmetic tradition of Graunt, relating primarily to economic, medical and demographic data, with two major improvements: ameliorated methods for the collection and tabulation of data giving rise to more accurate and reliable data, and more careful reasoning being used to yield less questionable inferences. This is particularly true for data relating to life tables and mortality rates associated with epidemics. The best examples of such an output are given by William Farr (1807–83), who is considered to be the founder of medical statistics because his analysis of such data contributed to medical advances and crucial changes in policies concerning public health (see Greenwood, 1948). For a more extensive discussion of the methodological and institutional developments associated with data collection and tabulation in England and France see Schweber (2006) and Desrosières (1998).

By the 1850s it became apparent that the early founding declaration of the society to publish papers that stay away from ‘Opinions’ – drawing conclusions on the basis of data – was unrealistic, unattainable and unjustifiable in the minds of the members of the society. Despite this initial promise, slowly but surely JSSL publications began to go beyond the mere reporting and tabulation of data relating to economic, political, demographic, medical, moral and intellectual issues, including poverty figures and education statistics. The motto ‘aliis exterendum’ was removed in 1857 from their seal to reflect the new vision of the society (see RSS, 1934).

3.2 The probabilistic underpinnings in the 19th century

During the early 19th century, a completely separate tradition in statistical analysis of data was being
developed in Europe (mainly in France and Germany) in the fields of astronomy and geodesy. This literature was developing completely independently of political arithmetic, but by the 1840s the two traditions had merged in the hands of Adolphe Quetelet (1796–1874): see Porter (1986).

Legendre and Gauss. In the early 19th century the analysis of astronomical and geodesic data by Adrien-Marie Legendre (1752–1833), Carl Friedrich Gauss (1777–1855) and Laplace introduced curve-fitting as a method to summarize the information in data (see Farebrother, 1999). In modern notation the simplest form of curve-fitting can be expressed in the form of a linear model $y = X\beta + \varepsilon$, where $y := (y_1, y_2, \ldots, y_n)$ and $X := (x_1, x_2, \ldots, x_n)$ denote a vector and a matrix of observations, respectively, $\beta := (\beta_1, \beta_2, \ldots, \beta_m)$ a vector of unknown parameters and $\varepsilon := (\varepsilon_1, \varepsilon_2, \ldots, \varepsilon_n)$ a vector of errors. Legendre (1805) is credited with inventing least squares as a mathematical approximation method, by proposing the minimization of $\varepsilon(\beta) = (y - X\beta)^T(y - X\beta)$ as a way to estimate $\beta$. Gauss (1809) should be credited with providing the probabilistic underpinnings for this estimation problem by transforming the mathematical approximation error into a generic statistical error:

$$\varepsilon_k(x_k, m) = \varepsilon_k \sim \text{NIID}(0, \sigma^2), \ k = 1, 2, \ldots, n, \ldots, (1)$$

where NIID($0, \sigma^2$) stands for ‘Normal, Independent and Identically Distributed with mean 0 and variance $\sigma^2$’. Laplace provided the first justification of the Normality assumption based on the central limit theorem in 1812 (see Hald, 2007). What makes Gauss's contribution all-important from today's vantage point is that the probabilistic assumptions in (1) provide the framework that enables one to assess the reliability of inference. Ironically, Gauss's embedding of the mathematical approximation problem into a statistical model is rarely appreciated as the major contribution that it is (see Spanos, 2008). Instead, what Gauss is widely credited with is the celebrated Gauss-Markov theorem (see Section 4.6).

Quetelet. The ‘law of error’ was elevated to a most important method in analysing social phenomena by Adolphe Quetelet (1796–1874), a Belgian astronomer and polymath, in the 1840s. His statistical analysis of data differed in that his methods were integrated with the probabilistic underpinnings that were lacking in the analysis of political arithmeticians; his probabilistic perspective was primarily influenced by the work of Joseph Fourier (1768–1830), a French mathematician and physicist. Quetelet's most important contribution was to explicate Graunt's regularities in terms of the notion of probabilistic (chance) regularity which combined the unpredictability at the individual level with the abiding regularity at the aggregate level. By fitting the Normal curve over the histogram of a great variety of social data, his objective was to eliminate ‘accidental’ influences and determine the average physical and intellectual features of a human population, including normal and abnormal behaviour. His modus operandi was the notion of the ‘average man’ (see Desrosières, 1998). The ‘average man’ began as a simple way of summarizing the systematic characteristic of a population, but in some of Quetelet's later work, ‘average man’ is presented as an ideal type, and any deviations from this ideal were interpreted as
errors of nature.

A methodological digression. In addition to the substantive issues raised by his approach to ‘social physics’ (see Cournot, 1843), the methodological underpinnings of Quetelet’s statistical analysis were rather weak. When the Normal curve is fitted over a histogram of data \( x := (x_1, x_2, \ldots, x_n) \) in an attempt to summarize the statistical regularities, one implicitly assumes that data \( x \) constitutes a realization of an IID process \( \{X_k, k = 1, 2, \ldots, n, \ldots\} \) (see Spanos, 1999): these are highly questionable assumptions for most of the data used in Quetelet (1942). The concern to evaluate the precision (reliability) of an inference, introduced earlier by Laplace and Gauss, was absent from Quetelet’s work. Hence, his analysis of statistical regularities did not give rise to any more reliable inferences than those of the political arithmetic tradition a century earlier; the necessity to assess the validity of the premises (NIID assumptions) for inductive inference was not clearly understood at the time.

3.3 The ‘mathematical’ turn

In the last quarter of the 19th century there was a concerted effort to render both statistics and economics more rigorous by introducing the language of mathematics into both disciplines. In statistics this effort was spearheaded by Edgeworth, Galton and Pearson and in economics by Edgeworth, Jevons, Walras and Irving Fisher. The mathematical turn of this period was motivated by the strong desire to emulate the physical sciences and introduce quantification into these fields, which involved both calculus and probability theory (see Backhouse, 2002a; 2002b).

Galton. Quetelet’s use of the Normal curve to analyse social data had a powerful influence on Francis Galton (1822–1911), who provided a different interpretation to the ‘law of error’. Galton (1869) interpreted the variation around the mean, not as errors from the ideal type, but as the very essence of nature’s variability. Using this variability he introduced the notions of regression and correlation in the 1890s as a way to determine relationships between different data series \( \{(x_k, y_k), k = 1, 2, \ldots, n\} \).

Regression and correlation opened the door for providing statistical explanations which revolutionized statistical modelling in the biological and social sciences (see Porter, 1986). Retrospectively, Galton was the founder of the biometrics tradition, which had a great influence on the development of statistics in the 20th century in the hands of Karl Pearson (1857–1936) and Udny Yule (1871–1951).

Pearson significantly extended the summarization of data in the form of smoothing histograms, by introducing a whole family of new frequency curves – known today as the Pearson family – to supplement the Normal curve, and applied these techniques extensively to biological data, with notable success. He also provided clear probabilistic underpinnings for Galton’s regression and correlation methods. Yule (1897) established a crucial link between the Legendre–Gauss least-squares and the linear regression model, by showing that least-squares can be used to estimate the parameters of linear regression, bringing together two seemingly unrelated literatures (see Spanos, 1999). This was an important breakthrough that, unfortunately, also introduced a confusion between two different perspectives on empirical modelling: curve-fitting as a mathematical approximation method, and the probabilistic perspective where regression is viewed as a purely probabilistic concept defined in terms of the first moment of a conditional distribution (see Stigler, 1986; Spanos, 2008). Yule published a highly influential textbook in statistics in 1911 in which he successfully blended the biometric with the
Of particular interest for the fundamental interaction between statistics and economics is the case of Francis Edgeworth (1845–1926), primarily an economist. His mathematical self-training enabled him to provide a bridge between the theory of errors tradition going back to Gauss and Laplace, the biometric tradition of Galton and Pearson, and the more traditional economic statistics of the 19th century focusing on economic time series data and index numbers. His direct influence on statistics, however, was rather limited because the style and mathematical level of his writings were too demanding for the statisticians of the late 19th century. Bowley (1928), ‘at the request of the Council prepared a summary of his mathematical work which may have served to make his achievement known to a wider circle’ (see RSS, 1934, p. 238). Edgeworth contributed crucially to the mathematization of economics and the theory of index numbers (see Backhouse, 2002b).

William Stanley Jevons (1835–82), English economist and logician. In his book *The Theory of Political Economy* (1871), he used calculus to formulate the marginal utility theory of value, and the notion of partial equilibrium, which provided the foundation for the marginalist revolution in economics (see Backhouse, 2002a).

Léon Walras (1834–1910) was a French mathematical economist, one of the protagonists in the marginalist revolution and the innovator of general equilibrium theory. His perspective on the use of mathematics in economics was greatly influenced by Augustin Cournot (1801–77), a French philosopher, mathematician and economist. Cournot is credited with the notion of functional relationships among economic variables, which led him to the supply and demand curves (see Backhouse, 2002a).

In the United States the process of mathematization began somewhat later with Irving Fisher (1867–1947), who followed in the footsteps of Walras, Jevons and Edgeworth in introducing mathematics into economics and making significant contributions to the theory of index numbers (see Backhouse, 2002b). These early pioneers in the mathematization of economics shared a vision of using statistics to provide pertinent empirical foundations to economics (see Moore, 1908). Fisher described this goal as a life-long ambition:

> I have valued statistics as an instrument to help fulfill one of the great ambitions of my life, namely, to do what I could toward making economics into a genuine science. (Fisher, 1947, p. 74)

The same vision was clearly articulated much earlier by Jevons:

> The deductive science of Economics must be verified and rendered useful by the purely empirical science of statistics. (Jevons, 1871, p. 12)

Indeed, Neville Keynes attributed to *statistics* a much greater role in the quantification of economics than hitherto:

> The functions of statistics in economic enquiries are: … descriptive, … to suggest
empirical laws, which may or may not be capable of subsequent deductive explanation, …
to supplement deductive reasoning by checking its results, and submitting them to the test
of experience, … the elucidation and interpretation of particular concrete phenomena, …

At the dawn of 20th century, pioneers such as Moore (1908; 1911), who aspired to help in securing
empirical foundations for economics, had several advantages – for example, the institutionalization
of the collection and compilation of economic data via the establishment of government statistical offices,
the systematic development of index numbers, and so on. The mathematization of economics provided
them with economic models amenable to empirical enquiry (see Backhouse, 2002a; 2002b). In addition,
at the end of the 19th century there were several developments in statistical methods, including least-
square curve-fitting, regression, correlation, periodogram analysis and trend modelling that seemed
tailor-made for analysing economic data (see Mills, 1924; Stigler, 1954; Heckman, 1992; Hendry and
Morgan, 1995).

4 The 20th century: a strained relationship

To enliven the discussion of the tension created in the 1920s between economic statistics and statistical
inference, the account below refers to the confrontation between the two protagonists who represented
the different perspectives, Bowley and Fisher.

4.1 Economic statistics as against statistical inference

The early 20th century statistics scene was dominated by Karl Pearson (1857–1936) and his research in
biology at the Galton Laboratory established in 1904. Pearson's research at this laboratory consolidated
the biometrics tradition, whose primary outlet was the in-house journal Biometrika. Pearson established
the department of ‘Applied Statistics’ at University College in 1911, which, at the time, was the only
place one could study for a degree in statistics (see Walker, 1958).

Arthur Bowley (1869–1957) was a typical successful ‘economic statistician’ of the early 20th century
who authored one of the earliest textbooks in statistics, Elements of Statistics (1901), while a part-time
lecturer at the London School of Economics. Bowley understood statistics as comprising two different
but interrelated components, the arithmetic and the mathematical. The former was concerned with
statistical techniques as they relate to measurement, compilation, interpolation, tabulation and plotting of
data, as well as the construction of index numbers; this constitutes Part I – General Elementary
Methods, and comprises the first 258 pages of Bowley (1902). The mathematical dimension (Part II –
The Application of the Theory of Probability to Statistics, the last 74 pages of Bowley, 1902) was
concerned with the use of probability theory in minimizing and evaluating the errors associated with
particular inferences. The last 12 pages of Bowley (1902) are devoted to a discussion of ‘regression and
correlation’ as expounded by Pearson (1896) and Yule (1897).

Bowley (1906) illustrated what he meant by ‘errors’ using the ‘probable error’ for the arithmetic average

---

\[ \bar{x}_n = \frac{1}{n} \sum_{k=1}^{n} x_k \] of the data \((x_1, x_2, \ldots, x_n)\) as:

\[
\bar{x} \pm SD(\bar{x}),
\]

with \(SD(\bar{x})\) denoting the standard deviation of \(\bar{x}\). Taking the Normal distribution as an example he argued that the claim in (2) can be interpreted as saying that ‘the chance that a given observation should be within this distance of the true average is 2:1’ (1906, p. 549). This interpretation can be best understood as based on a Bayesian credible interval evaluation, instead of a frequentist confidence interval developed in the 1930s.

From this perspective, Bowley interpreted the work of Pearson and Edgeworth as concerned with providing different ways to evaluate these ‘probable errors’ (for example, \(SD(\bar{x})\)) using either a fitted frequency curve or an asymptotic approximation, respectively (see Bowley, 1906, p. 550). It is interesting to note that in the 5th edition of Bowley’s statistics book, published in 1926, Part II increased threefold to 210 pages, but contains no reference to Fisher’s work, which, at the time, was well on its way to transform Karl Pearson’s descriptive statistics into modern statistical inference.

Ronald Fisher (1893–1962) pioneered a recasting of statistics (1915; 1921; 1922), moving away from the Edgeworth–Pearson reliance on large sample approximations based on inverse probability (Bayesian) methods, and focusing on finite sample frequentist inference relying on sampling distributions. This recasting was initially inspired by Gossett’s (1908) derivation of the student’s t distribution for a given sample size \(n\). Fisher made this recasting explicit in his 1921 paper by severely criticizing the inverse probability (Bayesian) approach and articulating a more complete picture of his approach to statistical inference in his 1922 classic paper.

In the early 1920s Bowley was a professor of statistics (second in fame only to Karl Pearson) at the London School of Economics (LSE), known primarily for his contributions in the area of survey sampling, and Fisher was a young statistician at Rothamstead Agricultural Station trying to make sense of a 200-year accumulation of experimental data. Bowley was aware of Fisher's early work: we know that in 1924 Bowley requested and promptly received Fisher's offprints for the LSE library (see Box, 1978, p. 171). Moreover, by some accident of faith, the two were neighbours at Harpenden, interacting socially as bridge companions (see Box, 1978, p. 85). Indeed, Bowley encouraged Fisher to publish his correction of Pearson’s (1900) evaluation of degrees of freedom associated with his goodness-of-fit test (see Fisher, 1922a).

The next academic encounter between the professor and the young aspiring statistician was in 1929 when Fisher applied for an academic position in Social Biology at the LSE, but was turned down in favour of Lancelot Hogben (see Box, 1978, p. 202). Fisher's first academic position was at University College as Professor of Eugenics, in 1933. The tension between their different perspectives on statistics became public in their first showdown at Fisher's presentation to the Royal Statistical Society in 18 December 1934 entitled ‘The Logic of Inductive Inference’, where he attempted to explain his published work on recasting the problem of statistical induction since his 1922 paper. Bowley was appointed to
move the traditional vote of thanks and open the discussion, and after some begrudging thanks for Fisher's 'contributions to statistics in general' – by then Fisher's 1925 book had made him famous – he went on to disparage his new approach to statistical inference based on the likelihood function by describing it as abstruse, arbitrary and misleading. His comments were predominantly sarcastic and discourteous, and went as far as to accuse Fisher of giving insufficient credit to Edgeworth (see Fisher, 1935, pp. 55–7). The litany of churlish comments and currish remarks continued with the rest of the old guard: Isserlis, Irwin and the philosopher Wolf (1935, pp. 57–64), who was brought in by Bowley to undermine Fisher's philosophical discussion on induction. Jeffreys complained about Fisher's criticisms of the Bayesian approach (1935, pp. 70–2). To Fisher's support came Egon Pearson, Neyman and, to a lesser extent, Bartlett. Pearson (1935, pp. 64–5) argued that:

When these ideas [on statistical induction] were fully understood … it would be realized that statistical science owed a very great deal to the stimulus Professor Fisher had provided in many directions. (Pearson, 1935, pp. 64–5)

Neyman was equally supportive, praising Fisher's path-breaking contributions, and explaining Bowley's reaction to Fisher's critical review of the traditional view of statistics as understandable attachment to old ideas (1935, p. 73). Fisher, in his reply to Bowley and the old guard, was equally contemptuous:

The acerbity, to use no stronger term, with which the customary vote of thanks has been moved and seconded … does not, I confess, surprise me. From the fact that thirteen years have elapsed between the publication, by the Royal Society, of my first rough outline of the developments, which are the subject of to-day's discussion, and the occurrence of that discussion itself, it is a fair inference that some at least of the Society's authorities on matters theoretical viewed these developments with disfavour, and admitted with reluctance. … However true it may be that Professor Bowley is left very much where he was, the quotations show at least that Dr. Neyman and myself have not been left in his company. … For the rest, I find that Professor Bowley is offended with me for 'introducing misleading ideas'. He does not, however, find it necessary to demonstrate that any such idea is, in fact, misleading. It must be inferred that my real crime, in the eyes of his academic eminence, must be that of 'introducing ideas'. (Fisher, 1935, pp. 76–82)

Fisher's reference to 'his academic eminence', although containing a dose of sarcasm, it was not totally out of place. Bowley became a member of the Council of the Royal Statistical Society as early as 1898, served as its Vice-President in 1907–8 and again in 1912–14, and President in 1938–40. He was awarded the society's highest honour, the Guy Medal in gold, in 1935; he received the Guy in silver as early as 1895. In contrast, Fisher had no academic position until 1933, and even that came with the humiliating stipulation that he would not teach statistics from his new position as Professor of Eugenics at University College (see Box, 1978, p. 258).

Fisher made it clear that he associated the ‘old guard’ in statistics with Bowley-type economic statistics:
Statistical methods are essential to social studies, and it is principally by the aid of such methods that these studies may be raised to the rank of sciences. This particular dependence of social studies upon statistical methods has led to the unfortunate misapprehension that statistics is to be regarded as a branch of economics, whereas in truth methods adequate to the treatment of economic data, in so far as these exist, have mostly been developed in the study of biology and the other sciences. (Fisher, 1925, p. 2)

The unbridgeable gap between Bowley and the ‘old guard’ on one side, and Fisher, Neyman and Pearson on the other, was apparent six months earlier when Bowley was assigned the same role for Neyman's first presentation. Despite the fact that Neyman began his presentation by praising Bowley for his earlier contributions to survey sampling methods, he grouped him with Fisher and accused him of the same abstruseness:

I am not certain whether to ask for an explanation or to cast a doubt. It is suggested in the paper that the work is difficult to follow and I may be one of those who have been misled by it. I can only say I have read it at the time it appeared and since, and I have read Dr Neyman's elucidation of it yesterday with great care. I am referring to Dr Neyman's confidence limits. I am not at all sure that the ‘confidence’ is not a ‘confidence trick’.

(Neyman, 1934, pp. 608–9)

His ‘confidence trick’ remark is not very surprising in view of Bowley's own interpretation of (2) in inverse probabilistic (Bayesian) terms. Predictably, Egon Pearson and Fisher came to Neyman's rescue from the rebukes of old guard. Retrospectively, Bowley's charge of abstruseness, levelled at both Fisher and Neyman, might best be explained in terms of David Hume's (1711–76) ‘tongue in cheek’ comment two centuries earlier:

The greater part of mankind may be divided into two classes; that of shallow thinkers, who fall short of the truth; and that of abstruse thinkers, who go beyond it. The latter class are by far the most rare; and I may add, by far the most useful and valuable. They suggest hints, at least, and start difficulties, which they want, perhaps, skill to pursue; but which may produce fine discoveries, when handled by men who have a more just way of thinking. •…• All people of shallow thought are apt to decry even those of solid understanding, as abstruse thinkers, and metaphysicians, and refiners; and never will allow any thing to be just which is beyond their own weak conceptions. (Hume, 1987, pp. 253–4)

In summary, the pioneering work of Fisher, Egon Pearson and Neyman, was largely ignored by the Royal Statistical Society (RSS) establishment until the early 1930s. By 1933 it was difficult to ignore their contributions, published primarily in other journals, and the ‘establishment’ of the RSS decided to display its tolerance to their work by creating ‘the Industrial and Agricultural Research Section’, under the auspices of which both papers by Neyman and Fisher were presented in 1934 and 1935 respectively. In their centennial volume published in 1934, the RSS acknowledged the development of ‘mathematical
statistics’, referring to Galton, Edgeworth, Karl Pearson, Yule and Bowley as the main pioneers, and listed the most important contributions in this sub-field which appeared in its *Journal* during the period 1909–33, but the three important papers by Fisher (1922a; 1922b; 1924) are conspicuously absent from that list. The list itself is dominated by contributions in vital, commercial, financial and labour statistics (see RSS, 1934, pp. 208–23). There is only one reference to Egon Pearson, for his 1933 paper ‘Control and Standardization of Quality of Manufactured Products’ – the very paper used as self-justification by the RSS in creating the new section. It is interesting to note that by the late 1920s the revolutionary nature of Fisher's new approach to statistics was clearly recognized by many. Tippet (1931) was one of the earliest textbook attempts to blend the earlier results on regression and correlation within Fisher's new approach. In the United States, Hotelling (1930) articulated a most elucidating perspective on Fisher's approach.

4.2 The Fisher–Neyman–Pearson approach

The main methods of the Fisher–Neyman–Pearson (F–N–P) approach to statistical inference, point estimation, hypothesis testing and interval estimation, were in place by the late 1930s. The first complete textbook discussion of this approach, properly integrated with its probabilistic underpinnings, was given by Cramer (1946). The methodological discussions concerning the form of inductive reasoning underlying the new frequentist approach, however, were to linger on until the 1960s and beyond; see the exchange between Fisher (1955), Pearson (1955) and Neyman (1956).

One of the most crucial insights of the F–N–P approach to statistical inference, which set it apart from previous approaches to statistics, was the explicit specification of the premises of statistical induction in terms of the notion of a *statistical model*:

> The postulate of randomness thus resolves itself into the question, ‘Of what population is this a random sample?’ which must frequently be asked by every practical statistician. (Fisher, 1922, p. 313)

He defined the initial choice of the statistical model in the context of which the data will be interpreted as a ‘representative sample’ as the problem of *specification*, emphasizing the fact that: ‘the adequacy of our choice may be tested *posteriori*’ (1922, p. 314). Indeed, the first three tests discussed in Fisher (1925, pp. 78–94) are misspecification (M-S) tests for the Normality, Independence and Identically Distributed assumptions. Fisher (1922; 1925; 1935), and later Neyman (1938/1952; 1950), emphasized the importance of both model specification and validation vis-à-vis the data:

> Guessing and then verifying the ‘chance mechanism’, the repeated operations of which produces the observed frequencies. (Neyman 1977, p. 99)

Pearson (1931a, 1931b) was among the first to discuss the implications of non-Normality as well as develop M-S tests for it; see Lehmann (1999) for the early concern about the consequences of misspecification in the 1920s.
The F–N–P discernments concerning statistical model specification, M-S testing, and respecification can be summarized in the form of what might be called the F–N–P perspective (articulated in Spanos, 2006a) which can be summarized as follows:

1. Every statistical (inductive) inference is based on certain premises, in the form of (a) a statistical model $\mathcal{M}$ parameterizing the probabilistic structure of an observable stochastic process $\{Z_t, t \in \mathbb{N}\}$, and (b) a set of data $Z := (z_1, \ldots, z_n)$, viewed as a ‘typical realization’ of this process.

2. A statistical model is specified in terms of a complete and internally consistent set of probabilistic assumptions concerning the underlying stochastic process $\{Z_t, t \in \mathbb{N}\}$. For example, the Normal/linear regression model is specified in terms of assumptions [1]–[5] (Table 1) concerning the observable process $\{(\gamma_t | X_t = x_t), t \in \mathbb{N}\}$, and not the errors.

The Normal/linear regression model

Statistical GM: $\gamma_t = \beta_0 + \beta_1^T x_t + \nu_t, \quad t \in \mathbb{N},$

[1] Normality: $(\gamma_t | X_t = x_t) \sim \mathcal{N}(, , )$.

[2] Linearity: $E(\gamma_t | X_t = x_t) = \beta_0 + \beta_1^T x_t, \text{ linear in } x_t$.

[3] Homoskedasticity: $\text{Var}(\gamma_t | X_t = x_t) = \sigma^2$, free of $x_t$.

[4] Independence: $\{(\gamma_t | X_t = x_t), t \in \mathbb{N}\}$ an independent process.

[5] $t$-invariance: $\theta_t = (\beta_0, \beta_1, \sigma^2)$ do not change with $t$.

The importance of the F–N–P perspective stems from the fact that the statistical model enables one:

1. (i) to assess the validity (statistical adequacy) of the premises for inductive inference – by testing the assumptions using misspecification tests; and
2. (ii) to provide relevant error probabilities for appraising the reliability of the associated inference (see Spanos, 2006a).

It is well known that the reliability of any inference procedure depends crucially on the validity of the pre-specified statistical model vis-à-vis the data in question. The optimality of these procedures is defined by their capacity to give rise to valid inferences (trustworthiness), which is calibrated in terms of the associated error probabilities – how often these procedures lead to erroneous inferences (see Mayo, 1996). In the case of confidence interval estimation the calibration is usually gauged in terms of minimizing the coverage error probability: the probability that the interval does not contain the true value of the unknown parameter(s). In the case of hypothesis testing the calibration is ascertained in terms of minimizing the type II error probability – the probability of accepting the null hypothesis when false, for a given type I error probability (see Cox and Hinkley, 1974). It is also known, but often insufficiently appreciated, that when any of the model assumptions are invalid, the reliability of
inference is called into question (see Pearson, 1931a; Bartlett, 1935, for early discussions). Departures from the model assumptions will give rise to a discrepancy between the nominal error probabilities (valid premises), and the actual error probabilities (misspecified premises), giving rise to unreliable inferences (see Spanos and McGuirk, 2001, Spanos, 2005).

Although the nature of the F–N–P statistical induction became clear by the late 1930s, the form of the underlying inductive reasoning was clouded by a disagreement between the two protagonists (see Mayo, 2005). Fisher argued for ‘inductive inference’ spearheaded by his significance testing (see Fisher, 1955; 1956), and Neyman argued for ‘inductive behaviour’ based on Neyman–Pearson testing (see Neyman, 1956; Lehmann, 1993; Cox, 2006). Neither account, however, gave satisfactory answers to the question ‘when do data Z provide evidence for (or against) a hypothesis or a claim 𝐻?’ The pre-data error–probabilistic account of inference seemed inadequate for a post-data evaluation of the inference reached to provide a clear evidential interpretation of the results (see Hacking, 1965).

The F–N–P paradigm, in addition to (a) the pre-data as against post-data error probabilities, still grapples with some additional philosophical/methodological issues including (b) the fallacies of acceptance and rejection (for example statistical as against substantive significance), (c) double use of data, (d) statistical model selection (specification) as against model validation, (e) structural as against statistical models. These and other methodological issues have been extensively debated in other social sciences such as psychology and sociology (see Morrison and Henkel, 1970; Lieberman, 1971; Godambe and Sprott, 1971), but largely ignored in economics until recently.

Mayo (1996) argued convincingly that some of these chronic methodological issues and problems can be addressed by supplementing the Neyman–Pearson approach to testing (see Pearson, 1966) with a post-data assessment of inference based on severe testing reasoning. This extended frequentist approach to inference, called the error-statistical approach, has been used by Mayo (1991) to address (c), by Mayo and Spanos (2006) to address the fallacies of acceptance and rejection, and by Spanos (2006b; 2007) to deal with the issues (d) and (e), respectively.

4.3 Economic statistics in the early 20th century

In the 1930s applied economists were more keyed to Bowley's traditional view of economic statistics than to F–N–P statistical inference perspective. Indeed, Bowley was elected president (the first from Britain) of the Econometric Society for 1938–9. The more economics-oriented ‘statistics textbooks’ written in the 1920s and 1930s, including Bowley (1920/1926/1937), Mills (1924/1938), Ezekiel (1930), Davis and Nelson (1935) and Secrist (1930), largely ignored the new statistical inference paradigm. Their perspective was primarily one of ‘descriptive statistics’, supplemented with the Pearson–Yule curve-fitting perspective on correlation and regression, and certain additional focus on the analysis of time series data, including index numbers (see Persons, 1925).

Economic statistics, as exemplified in Mills (1924), provided the framework for the work at the National Bureau of Economic Research (NBER), of which Mills was a staff member. The empirical work on business cycles by Burns and Mitchell (1946) represents an excellent use of descriptive statistics in conjunction with graphical methods, as understood at the time. Their detailed, carefully crafted and painstaking statistical analysis of business cycles, however, suffers from the same crucial weakness as
all descriptive statistics: the premises for inductive inference (the underlying statistical model) is not explicitly specified, and as a result one cannot assess the reliability of inferences based on such statistics. For instance, without clearly specified probabilistic premises one can easily misidentify temporal dependence type cycles with regular business cycles (see Spanos, 1999).

The conventional wisdom at the time is summarized by Mills (1924) in the form of a distinction between 'statistical description vs. statistical induction'. In statistical description measures such as the sample mean $\bar{x} = \frac{1}{n} \sum_{k=1}^{n} x_k$, the sample variance $s^2_x = \frac{1}{n-1} \sum_{k=1}^{n} (x_k - \bar{x})^2$, the correlation $r = \frac{\sum_{k=1}^{n} (x_k - \bar{x})(y_k - \bar{y})}{\sqrt{\sum_{k=1}^{n} (x_k - \bar{x})^2 \sum_{k=1}^{n} (y_k - \bar{y})^2}}$, and so on, ‘provide just a summary for the data in hand’ and ‘may be used to perfect confidence, as accurate descriptions of the given characteristics’ (1924, p. 549). However, when the results are to be extended beyond the data in hand – statistical induction – their validity depends on certain inherent a priori assumptions such as (a) the ‘uniformity’ for the population and (b) the ‘representativeness’ of the sample (1924, pp. 550–2).

A methodological digression. Unfortunately, Mills's misleading argument concerning descriptive statistics lingers on even today. The reality is that there are appropriate and inappropriate summaries of the data, which depend on the inherent probabilistic structure of the data. For instance, if data $\{(x_k, y_k), k=1,...,n\}$ are trending, like most economic time series, the summary statistics $(\bar{x}, s^2_x, \bar{y}, s^2_y, r)$ represent artefacts – highly misleading descriptions of the features of the data in hand. When viewed in the context of a probabilistic framework, $(\bar{x}, s^2_x, \bar{y}, s^2_y, r)$ are unreliable estimators of $E(X_k), E(Y_k), Var(X_k), Var(Y_k), Corr(X_k, Y_k)$; they provide reliable and precise estimates only when certain probabilistic assumptions concerning the underlying the vector process $\{(X_k, Y_k), k \in \mathbb{N}\}$, such as independent and identically distributed (IID), are valid for the data in hand. Any departures from these premises require one to qualify the reliability and precision of these estimates. In an important sense one of Fisher's lasting contribution to statistics was to (a) make the IID assumptions explicit as part of the problem of specification, by formalizing Mills's a priori ‘uniformity’ and ‘representativeness’ assumptions, and (b) render them empirically testable. It is important to note that ignoring statistical adequacy is a very different criticism of Burns and Mitchell than that of Koopmans (1947); see below.

The paper by Yule (1926), entitled 'Why Do We Sometimes get Nonsense Correlations between time series?', provided a widely discussed wakeup call in economics, because it raised serious doubts about the appropriateness of the linear regression model when the data $\{(x_k, y_k), k=1,...,n\}$ constitute time series, by pointing out the risk of getting spurious results. As commented in Spanos (1989b), the source of the spurious (nonsense) correlation problem is statistical inadequacy (see Section 4.8 below). Yule's (1927) autoregressive (AR(p)) and Slutsky's (1927) moving average (MA(q)) models can be viewed as attempts to specify statistical models to capture the temporal dependence in time series data.

Stochastic processes. The AR(p) and MA(q) models were given proper probabilistic underpinnings by Wold (1938) using the newly developed theory of stochastic processes by Kolmogorov and Khitchin in the early 1930s (see Doob, 1953). This was a crucial and timely development in probability theory which extended significantly the intended scope of the F–N–P approach beyond the original IID framework, by introducing several dependence and heterogeneity concepts, such as Markov dependence,
4.4 The Econometric Society and the Cowles Commission

The vision statement of the Econometric Society founded in 1930 read:

Its main object shall be to promote studies that aim at a unification of the theoretical-quantitative and the empirical-quantitative approach to economic problems. (Frisch, 1933, p. 106)

The impression among quantitatively oriented economists in the early 1930s was that the F–N–P sampling theory methods were inextricably bound up with agricultural experimentation. It was generally believed that these methods are relevant only for analysing ‘random samples’ of experimental data, as Frisch argued:

In problems of the kind encountered when the data are the result of experiments which the investigator can control, the sampling theory may render very valuable services. Witness the eminent works of R.A. Fisher and Wishart on problems of agricultural experimentation. (Frisch, 1934, p. 6)

In place of the statisticians’ linear regression Frisch proposed his errors-in-variables scheme, which treated all observable variables symmetrically by decomposing them into a latent systematic (deterministic) component and a white-noise error with economic theory providing relationships among the systematic components. Fisher’s reaction to Frisch’s scheme was that economists were perpetuating a major confusion between ‘statistical’ regression coefficients and ‘coefficients in abstract economic laws’ (see Bennett, 1990, p. 305).

Tinbergen’s (1939) empirical modelling efforts were in the spirit of the Pearson–Yule curve-fitting tradition, which paid little attention to the validity of the premises of inference. In reviewing this work Keynes (1939) destructively criticized the use of regression in econometrics and raised numerous substantive and statistical problems, but not the reliability of inference problem (see Spanos, 2006a). The first attempt to bring together Frisch’s errors-in-variables scheme with Fisher’s linear regression model was made by Koopmans (1939), which had no success. Koopmans’ primary influence on econometrics was as a leading figure in the Cowles Commission in Chicago in the 1940s (see Heckman, 1992).

The first successful attempt to bring the F–N–P methods into econometrics modelling was made by Haavelmo (1944), who argued convincingly against the prevailing view that sampling methods are only applicable to random samples of experimental data (see Spanos, 1989a). Contrary to this view, the F–N–P perspective provides the proper framework for modelling time series data which exhibit both dependence and heterogeneity:

For no tool developed in the theory of statistics has any meaning … without being referred
to some stochastic scheme. (Haavelmo, 1944, p. iii)

… economists might get more useful and reliable information (and also fewer spurious results) out of their data by adopting more clearly formulated probabilistic models. (1944, p. 114)

The part of Haavelmo’s monograph that had the biggest impact on the development of econometrics was, however, the technical ‘solution’ to the simultaneity problem that was formalized and extended by the Cowles Commission in the form of the simultaneous equations model (SEM): see Koopmans, 1950. Despite the introduction of frequentist methods of inference by the Cowles Commission, the theory-driven specification of the structural model:

\[
\Gamma^T y_k = \Delta^T x_k + \epsilon_k, \quad k \in \mathbb{N},
\]

(using the traditional notation, see Spanos, 1986), leaves any inferences concerning the structural parameters \((\Gamma, \Delta, \Omega)\) highly susceptible to the unreliability of inference problem.

**Methodological digression.** The unreliability of inference arises primarily because it is often insufficiently appreciated that the statistical reliability of such inference depends crucially on the statistical adequacy of the (implicit) reduced form model:

\[
y_k = B^T x_k + u_k, \quad y_k \sim N(0, \Sigma), \quad k \in \mathbb{N}.
\]

That is, unless (4), viewed as multivariate linear regression model (assumptions [1]–[5] in Table 1 in vector form), is statistically adequate ([1]–[5] are valid for the data in question), any inference based on (3) is likely to be unreliable. Note that *identification* refers to being able to define the structural parameters \((\Gamma, \Delta, \Omega)\) uniquely in terms of the statistical parameters \((B, \Sigma)\). In practice (4) is not even estimated explicitly, let alone have its assumptions [1]–[5] tested thoroughly before drawing any inferences concerning \((\Gamma, \Delta, \Omega)\) (see Spanos, 1986; 1990). A more expedient way one that highlights the reliability issue, is to view (3) as a structural model which is embedded into the statistical model (4), giving rise to a special type of substantive information restrictions. Hence, the theory-dominated perspective of the Cowles Commission, despite the importance of the technical innovations introduced in dealing with simultaneity, has (inadvertently) undermined the problem of statistical adequacy in empirical modelling (see Spanos, 2006a). As argued by Heckman:

The Haavelmo–Cowles way of doing business – to postulate a class of models in advance
The Haavelmo program as interpreted by the Cowles Commission scholars refocused econometrics away from the act of empirical discovery and toward a sterile program of hypothesis testing and rigid imposition of a priori theory onto the data. (Heckman, 1992, pp. 883–4)

Koopmans (1947), in reviewing Burns and Mitchell (1946), criticized their focusing on the purely empirical nature of their results without any guidance from economic theory. He pronounced their empirical findings as representing the ‘Kepler stage’ of data analysis, in contrast to the ‘Newton stage’, where the original empirical regularities were given a structural (theoretical) interpretation using the law of universal gravitation (LUG). What Koopmans (1947) neglected to point out is that it was not the theory that guided Kepler to the regularities, but the statistical regularities exhibited by the data. Indeed, Kepler established these regularities 60 years before Newton was inspired by them to come up with his LUG. The Cowles Commission approach, which Koopmans misleadingly associates with the Newton stage, was equally (if not more) vulnerable to the reliability of inference problem. There is no reason to believe that the reduced form (4) implied by the structural form (3), which was specified in complete ignorance of the probabilistic structure of the data, will constitute a statistically adequate model. The specification of statistical models relying exclusively on substantive information is not conducive to reliable/precise inferences. The crucial difference between Kepler's empirical results and those in Burns and Mitchell (1946) and Klein (1950) – based largely on Koopmans's preferred approach – is that Kepler's constitute real statistical regularities in the sense that his estimated model of elliptical motion, viewed retrospectively in the context of the linear regression model (Table 1), is statistically adequate; assumptions [1]–[5] are valid for his original data (see Spanos, 2008).

### 4.5 Textbook econometrics: the Gauss–Markov perspective

The textbook approach to econometrics was largely shaped in the early 1960s by two very successful textbooks by Johnston (1963) and Goldberger (1964) by viewing the SEM as an extension/modification of the classical linear model. These textbooks demarcated the intended scope of econometrics to be the ‘quantification of theoretical relationships’, and reverted back to the ‘curve-fitting’ perspective of the Legendre–Gauss 19th century tradition, instead of adopting the F–N–P perspective (see Spanos, 1995; 2007).

The cornerstone of textbook econometrics is the so-called Gauss–Markov theorem, which is based on the linear model:

\[ y = X\beta + \epsilon, \ E(\epsilon) = 0, \ E(\epsilon\epsilon^T) = \sigma^2 I_n, \]

\[ (5) \]
where \( I_n \) is the identity matrix. In the context of (5), Gauss in 1823 (see Hald, 2007) proved that the least squares estimator \( \hat{\beta}_{LS} = (X^TX)^{-1}X^T y \) has minimum variance within the class of linear and unbiased estimators of \( \beta \). For the sake of historical accuracy it is important to point out that Markov had nothing to do with this theorem (see Neyman, 1952, p. 228). This theorem, and the perspective it exemplifies, provide the central axis around which textbook econometrics revolves (see Greene, 2003).

A methodological digression. Spanos (1986) challenged the traditional interpretation that the Gauss–Markov theorem provides a formal justification for least squares via the optimality of the estimators it gives rise to, arguing that the results of this theorem provide a poor basis for reliable and precise inference. This is primarily because the Gauss–Markov theorem yields the mean and variance of \( \hat{\beta}_{LS} \) but not its sampling distribution, that is \( \hat{\beta}_{LS} \sim D(\beta, \sigma^2(X^TX)^{-1}) \). Hence, even the simplest forms of inference, like testing \( H_0: \beta = 0 \) would require one to use either inequalities like Chebyshev's to approximate the relevant error probabilities (Spanos, 1999, pp. 550–2), or invoke asymptotic approximations; neither method would, in general, give rise to reliable and precise inferences (Spanos, 2006a, pp. 46–7).

The Gauss–Markov ‘curve-fitting’ perspective promotes ‘saving the theory’ by attributing the stochastic structure to the error term and favouring broad premises (weak assumptions) in an attempt to protect the inference from the perils of misspecification. This move, however, relegates the essentialness of ensuring the reliability and precision of inference. Weak assumptions, such as the Gauss–Markov assumptions in (5), do not guarantee reliable inferences, but they usually give rise to much less precise inferences than specific premises comprising assumptions such as [1]–[5] (Table 1): Spanos, 2006a. As perceptively noted by Heckman:

In many influential circles, ambiguity disguised as simplicity or ‘robustness’ is a virtue. The less said about what is implicitly assumed about a statistical model generating data, the less many economists seem to think is being assumed. The new credo is to let sleeping dogs lie. (Heckman, 1992, p. 882)

In addition, the ‘error-fixing’ strategies of the textbook approach, designed to deal with departures from the linearity, homoskedasticity, no-autocorrelation assumptions, do not usually address the reliability of inference problem (Spanos and McGuirk, 2001).

Some of the important technical developments in both econometrics and statistics since the 1980s, such as the generalized method of moments (see Hansen, 1982), as well as certain nonparametric (see Pagan and Ullah, 1999) and semiparametric methods (see Horowitz, 1998), are motivated by this Gauss–Markov perspective. These methods, although very useful for a number of different aspects of empirical modelling, do not provide the answer to statistical misspecification, and often compromise the reliability/precision of substantive inferences (see Spanos, 1999, pp. 553–5).

4.6 Demarcating the boundaries of modern statistics
As argued above, the F–N–P perspective has been largely ignored in empirical modelling in economics, despite the wholesale adoption of Fisher's estimation and the Neyman–Pearson testing methods. One of the primary obstacles has been the problem of blending the substantive subject matter and statistical information and their roles in empirical modelling. Many aspects of empirical modelling, in both the physical and social sciences, implicate both sources of information in a variety of functions, and others involve one or the other, more or less separately. For instance, the development of structural (theoretical) models is primarily based on substantive information; that activity, by its very nature, cannot be separated from the disciplines in question, but where does this leaves statistics? It renders the problem of demarcating its boundaries as a separate discipline extremely difficult (see Lehmann, 1990; Cox, 1990).

A methodological digression. Spanos (2006c) argued that the lessons learned in blending the substantive and statistical information in econometric modelling can help delineate the boundaries of statistics as a separate discipline. Certain aspects of empirical modelling, which focus on statistical information and are concerned with the nature and use of statistical models, can form a body of knowledge that is shared by all applied fields. Statistical model specification, the use of graphical techniques (going back to Playfair), misspecification (M-S) testing and respecification, together with the relevant inference procedures, constitute aspects of statistical modelling that can be developed generically without requiring any information concerning ‘what substantive variables the data \( Z \) quantify or represent’. All these aspects of empirical modelling belong to the realm of statistics and can be developed generically without any reference to substantive subject matter information. This, in a sense, will broaden the scope of modern statistics because the current literature and textbooks pay little attention to some of these aspects of modelling (see Cox and Hinkley, 1974).

The statistical and substantive information can be amalgamated, without compromising their integrity, by embedding structural models into adequate statistical models, which would provide the premises for statistical inference. That is, the substantive restrictions need to be thoroughly tested and accepted in the context of the statistical model in order for the resulting empirical model to enjoy both statistical and substantive meaning (see Spanos, 2006b; 2007).

4.7 The Box–Jenkins turn in statistics

An important development in statistics that had a lasting effect on econometrics and created a tension with textbook econometrics, was the publication of Box and Jenkins (1970). Building on the work of Wold (1938), they proposed a new statistical perspective on time series modelling which placed it within the F–N–P modelling framework where the premises of inference is specified by a statistical model. In addition to transforming descriptive time series analysis into statistical inference proper, the Box–Jenkins approach introduced several noteworthy innovations into empirical modelling that influenced empirical modelling in economics.

1. (i) Modelling begins with a family of statistical models in the form of the ARIMA(p,d,q):
where $v_t^* = \Delta^d v_t$, that was thought to capture adequately the temporal dependence and heterogeneity (including seasonality) in time series data.

2. (ii) Statistical modelling was viewed as an iterative process that involves several stages, identification, estimation, diagnostic checking, and prediction.

3. (iii) Diagnostic checks, based on the residuals from the fitted model, offered a way to detect model inadequacies with a view to improve the original model.

4. (iv) Exploratory data analysis (EDA) was legitimized as providing an effective way to select (identify) a model within the ARIMA(p,d,q) family.

5. (v) The deliberate choice of a more general specification in order to put the model ‘in jeopardy’ (see Box and Jenkins, 1970, p. 286) is exploited in assessing the adequacy of a selected model.

The Box–Jenkins approach constituted a major departure from the rigid textbook approach, where the model is assumed to be specified by economic theory in advance of any data. Indeed, the predictive success of the ARIMA(p,d,q) models in the 1970s exposed the statistical inadequacy of traditional econometric models, sending the message that econometric models could ignore the temporal dependence and heterogeneity of times series data at their peril (see Granger and Newbold, 1986).

The weaknesses of traditional econometric modelling techniques brought out by the Box–Jenkins modelling motivated several criticisms from within econometrics, including those by Hendry (1977) and Sims (1980), that led to the autoregressive distributed lag (ADL(p,q)) and the vector autoregressive (VAR(p)) family of models, respectively. The LSE tradition (see Hendry, 1993), embraced and extended the Box–Jenkins innovations (i)–(v), rendering the general-to-specific approach the backbone of its empirical modelling methodology (see Hendry, 1995).

4.8 Unit roots and cointegration

The Box–Jenkins ARIMA(p,d,q) modelling approach raised the question ‘how does one decide on the value of $d \geq 0$ in $\Delta^d y_t$, that is appropriate to induce stationarity?’ It turned out that the value of $d$ is related to the number of unit roots in the $AR(m)$ representation, $v_t = y_0 + \sum_{k=1}^{m} Y_k v_{t-k} + \epsilon_t$, of the underlying stochastic process $\{v_t, t \in \mathbb{N}\}$. Efforts to answer this question led to the unit root ‘revolution’, initiated by Dickey and Fuller (1979) in the statistics literature. This had an immediate impact on the econometrics literature, which generalized and extended the initial results in a number of different directions (see Phillips and Durlauf, 1986; Phillips, 1987). This literature eventually led to further important developments, which brought out a special relationship (cointegration) among unit root
processes and error-correction models (see Engle and Granger, 1987; Johansen, 1991; Hendry, 1995). A methodological digression. The (non-standard) sampling distribution results associated with unit roots were used by Phillips (1986) to shed light on the chronic problem of spurious regression raised by Yule (1926). This problem was revisited by Granger and Newbold (1974) using simulations of time series data \{(x_t, y_t), t=1,…,n\} generated by two uncorrelated Normal unit root processes:

\[ y_t = y_{t-1} + \epsilon_{1t}, \ x_t = x_{t-1} + \epsilon_{2t} \]

Their results demonstrated that when these data were used to estimate the linear regression model, \( y_t = \beta_0 + \beta_1 x_t + \mu_t \), the inferences based on the estimated model were completely unreliable. In particular, they noted a huge discrepancy between the nominal (\( \alpha = .05 \)) and actual (\( \hat{\alpha} = .76 \)) error probabilities when testing the hypothesis \( \beta_1=0 \).

In a very influential paper, Phillips (1986) explained this by deriving analytically the (non-standard) sampling distributions of the least-squares estimators (\( \hat{\beta}_0, \hat{\beta}_1 \)) under the above unit root scheme, showing how different they were from the assumed distributions. What was not sufficiently appreciated was that the discrepancy between the nominal and actual error probabilities is a classic symptom of unreliable inferences emanating from a statistically misspecified model, that is misspecification, due to ignoring the temporal dependence/heterogeneity in the data, is the real source of spurious regression. One would encounter similar unreliabilities when the data exhibit deterministic trends or/and Markov dependence, or/and non-Normalities (see Spanos and McGuirk, 2001, Spanos, 2005). Deriving the sampling distributions under all scenarios of possible misspecifications is impractical (there is an infinity of such scenarios), and does not address the unreliability of inference issue. What is needed is to respecify the original model to account for the disregarded information that gave rise to the detected departures. For instance, for the above Granger and Newbold data, if one were to estimate the dynamic linear regression model:

\[ y_t = \alpha_0 + \alpha_1 x_t + \alpha_2 x_{t-1} + \alpha_3 y_{t-1} + \epsilon_t, \ t \in N, \]

the above noted unreliabilities would disappear (see Spanos, 2001).
4.9 Recent developments in microeconometrics

Arguably, some of the most important developments in econometrics since 1980 have taken place in an area broadly described as microeconometrics (see Manski and MacFadden, 1981; Heckman and Singer, 1984; Cameron and Trivedi, 2005) for a recent textbook survey. This area includes discrete and limited dependent and duration models for cross-section data, as well as panel data models. The roots of these statistical models go back to the statistical literature on the probit/logit and analysis of variance models (see Agresti, 2002, ch. 16), but they have been generalized, extended and adapted for economic data. A welcome facet of microeconometrics is the specification of statistical models that often takes into consideration the probabilistic structure of the data (see Heckman, 2001). Unfortunately, this move does not often go far enough in securing statistical adequacy. This becomes apparent when one asks, ‘what are the probabilistic assumptions providing a complete specification for the probit/logit, duration and the fixed and random effect models?’ Without such complete specifications, one would not even know what potential errors to probe for to secure statistical adequacy.

While these developments in microeconometrics are of great importance, their potential value has been offset by the insufficient attention paid to the task of ensuring reliability and precision of inference. Their statistical results are still largely dominated by the Gauss–Markov perspective, in the sense that:

1. (i) the probabilistic structure of the models in question is specified, almost exclusively, in terms of unobservable error terms,
2. (ii) the error probabilistic assumptions are often vague and incomplete, and invariably involve non-testable orthogonality conditions,
3. (iii) the statistical analysis focuses primarily on constructing consistent and asymptotically Normal estimators, and
4. (iv) respecification is often confined to ‘error-fixing’.

In view of (i)–(iv), even questions of ensuring statistical adequacy cannot be posed unequivocally for these statistical models. Spanos (2006a; 2006d) proposed complete specifications for these statistical models in terms of probabilistic assumptions relating to the observable stochastic processes involved, but there is a long way to go to develop adequate misspecification testing and the respecification results needed to ensure the reliability and precision of inference when applying these statistical models to actual data.

5 Conclusion

The demise of political arithmetic by the end of the 18th century, due to the unreliability of the inferences its methods gave rise to, contains important lessons for both economics and statistics. Petty's attitude of ‘seeking figures that will support a conclusion already reached by other means’ lingers on in applied econometrics more than three centuries later. The problem then was that, in addition to the quality and the accuracy of data, the probabilistic underpinnings of establishing statistical regularities were completely lacking. Fisher's recasting of statistical induction has changed that, and it is now known
that the explicit specification of the statistical model enables one to (a) assess the validity of the premises for inductive inference, and (b) provide relevant error probabilities for assessing the reliability of ensuing inferences. It has taken several decades to understand how one can assess the model assumptions vis-à-vis the observed data using misspecification tests (see Spanos, 1999), but one hopes it will take less time before modellers understand the necessity to implement such tests with the required care and thoroughness to ensure the reliability of the resulting statistical inferences (see Spanos, 2006a).

The Box–Jenkins modelling approach exposed the inattention to statistical adequacy in traditional econometric modelling and strengthened the call for adopting the F–N–P perspective. This will bring modern statistical inference closer to econometrics to the benefit of both disciplines. Careful implementation of this perspective will certainly improve the reliability of empirical evidence in economics and other applied disciplines. Moreover, the ab initio separation of the statistical and substantive information can help demarcate and extend the intended scope of statistics. The error-statistical extension/modification of frequentist statistics (Mayo, 1996) can address some of the inveterate problems concerning inductive reasoning and broaden the intended scope of statistical inference in these disciplines by enabling one to consider questions of substantive adequacy, shedding light on causality issues, omitted variables and confounding effects (see Spanos, 2006b).

status and economics

Abstract

Social status both affects and is affected by earnings and wealth. Research on status examines status-seeking behaviour, and the impact of acquired and endowed status. Status characteristics such as wealth and education can be acquired; others such as beauty, gender, or race are endowed. Status hierarchies appear to waste resources, as agents expend effort and income acquiring position, but such social structures may also benefit societies.

Article

The study of status by economists is not new, although some find it surprising since status initially seems to be a purely social phenomenon. A person's status is a ranking in a hierarchy that is socially recognized. People may participate in a number of status hierarchies defined by the different social groups of which they are members. Status may be defined and recognized narrowly, as when it is based on skills or accomplishments, or widely, when it is valued and recognized by an entire society. People within a society may differ in their assessment of the importance of a given status characteristic, so consistent rankings may be impossible. Research on status has focused on several questions. Why do individuals value status? What kinds of status-seeking behaviours do we observe? Is status-seeking a good thing?

Status-seeking behaviour
Adam Smith (1759) noted that individuals are willing to expend effort to attain status, a practice that Veblen (1926), who coined the term ‘conspicuous consumption’, viewed as wasteful. Social psychologists study the subject, and have developed status characteristics theory. Status-seeking acts vary by culture, and include purchasing status goods or houses in the ‘right’ neighbourhood and seeking education that is not ‘useful’ (Veblen, 1926), as well as contributing money to charity (Getzner, 2000) and planning weddings that strain the family’s financial resources (Bloch, Vijayendra and Desai, 2004).

In these examples status-seeking is clearly ‘costly’ to the individual. Assessing the full impact of status also requires evaluating several possible indirect consequences of individuals’ status-seeking decisions. Bernheim (1994) models behaviour that is a costly signal about an individual’s social desirability. Agents possess unobservable characteristics and tastes for associating with others with whom they are similar. Individuals seek the esteem of others, where esteem is based on public perceptions of their types. The result is the development of social norms whereby individuals choose similar actions in order to increase their popularity. In this case, the underlying characteristics may have cultural value, for example, whether an individual is ‘selfish’ or ‘generous’. Sub-populations within a society might value these characteristics differently, however, resulting in different sets of social norms. This means that this type of status characteristic can only be ranked within its cultural context.

In other cases, the status characteristic may have value for its own sake in addition to its status value. Here returns to status are not based solely on an absolute level of status, but also on one's relative status ranking. Thus status-seeking becomes a contest where individuals are willing to incur costs in order to win. Positional externalities are inherent in the status contest since actions that increase one individual’s relative status decrease another’s. The resulting positional arms races generally reduce social welfare and probably account for much of Veblen's distaste for status-seeking behaviour.

Earnings or wealth are straightforward examples of this type of positional externality. As every department chair knows, people care not only about their absolute earnings but also about relative earnings. Bolton (1991) models bargaining with agents who care about their absolute and relative earnings and finds that this model organizes some experimental data better than a pure self-interest model. In the laboratory, subjects behave as if they care about relative earnings. Concern about relative earnings may explain why risk-averse individuals may make decisions that, on the surface, seem more consistent with risk-seeking behaviour (Robson, 1992.)

Fershtman, Murphy and Weiss (1996) argue that status-seeking can affect economic growth. They model social status as a reward for education-seeking in economic growth-enhancing occupations. If individuals differ only by ability or income, then awarding status to growth-enhancing occupations will increase growth. However, if individuals differ by both wealth and learning ability, the ‘wrong’ agents may acquire education; inefficiency arises because low-talent/high-income workers invest in education to obtain higher status occupations. This reduces wages in the high-status occupations and crowds out high-talent/low-income workers. In addition to the inefficient distribution of talent in the economy, status-seeking then reduces economic growth.

Endowed status

While the status characteristics discussed above result from decisions an individual makes and may be productivity related, this is not necessarily the case. Other status characteristics, such as race,
Artificial status. Even artificial status may act like a type of power in economic interactions. Ball et al. (2001) report results from experiments designed to control for productivity-related attributes and to isolate the effect of status. Status is awarded by the experimenters in order to ensure that all subjects recognize the relevant status characteristics. Half the participants are publicly awarded gold stars based on the sum of their answers to a trivia quiz, and then trade in experimental markets where the traders on one side of the market have stars, and those on the other side do not. They find that earnings average 15 per cent higher for the high-status traders, and that the pattern of higher earnings persists even when status is randomly awarded. Thye (2000) finds a similar result in a bargaining game. Kumru and Vesterlund (2005) use the same procedure to induce status differences, in a sequential voluntary contributions game. They find that low-status agents tend to mimic the decisions of high-status agents, which creates an incentive for high-status agents to raise their own contributions. This suggests that status may play a role in increasing welfare in games where the socially optimal outcome is not the equilibrium in a pure self-interest model of behaviour.

Beauty. Economists’ theory of incomplete information explains why costly status credentials that signal productivity may be linked to higher income. This occurs, for example, when job candidates with college degrees are preferred over those with no college education for jobs requiring no higher education-related skills. A systematic link between earnings and status characteristics that seem entirely unrelated to productivity, such as beauty, is more puzzling. For example, Hamermesh and Biddle's (1994) find a 15 per cent wage premium to more beautiful workers; this is consistent with status characteristics theory, but probably not with the marginal productivity theory of wages. Equally puzzling is Hamermesh and Parker's (2005) finding that more attractive faculty members earn higher teaching evaluations. In a trust-game experiment, Wilson and Eckel (2006) find that people are more likely to trust attractive people, although they are actually no more trustworthy than less attractive people. Other examples come from Solnick and Schweitzer (1999) on ultimatum games and Mulford et al. (1998) and Kahn, Hottes and Davis (1971) in Prisoner’s Dilemma games.

In an experimental study of employment, Mobius and Rosenblatt (2006) are able to decompose the positive effect of beauty into three mechanisms. More attractive people are more confident, and confidence increases productivity. If one holds confidence fixed, however, more attractive people are wrongly considered more able by employers, a stereotype that may result in hiring mistakes. Beautiful workers also may have better communication and social skills, which may be beneficial when tasks require working with others. The result concerning confidence may explain the higher evaluations of attractive teachers.

Gender. In almost all societies men hold higher status than women. In the United States, for example, women earn less money than men, even after attempting to control for productivity related attributes such as education (Altonji and Blank, 1999; Darity and Mason, 1998.) Experimental tasks can allow researchers to look at environments where productivity does not affect outcomes in any way. Earnings differentials persist even in these environments. Women also may face discrimination in hiring. Goldin and Rouse (2000) collect hiring data for symphony orchestra musicians where in some cases musicians
Women were auditioned from behind a screen. They find that women were more likely to be hired or advanced to the next round of auditions in the ‘blind’ condition and less likely than men to be advanced in the ‘non-blind’ condition.

Differential treatment by gender also exists in experimental bargaining games. Solnick (2001) and Eckel and Grossman (2001) conducted ultimatum bargaining games where subjects knew their opponents’ gender. Both studies find that offers made by men and women are about the same, while offers made to women are significantly lower than those made to men. Field experiments also find differences in bargaining by gender; women are initially offered higher prices in the market for cars (Ayers and Siegelman, 1995) and trading cards (List, 2004).

Race. Race is a form of status, and also follows the pattern of low status being related to low earnings. Even after controlling for productivity related attributes, African-Americans still earn less than whites (Altonji and Blank, 1999; Darity and Mason, 1998). Economic research on the motivations for race-related wage discrimination dates back to Becker (1957). Arrow (1972) argues that status in working environments is related to discrimination in yet another way. Conferring high status on some individuals can compensate for ‘nearness’ to individuals with whom an agent prefers not to associate. This hypothesis explains the result that highly educated African-Americans face a relatively larger wage gap. In this case education, another status characteristic, works against their earnings potential.

Any status characteristic needs to be observable in order to affect others’ behaviour. Since African-Americans have less education than whites on average, Arrow argues that using education as a criterion in employment screening can be an effective means of discrimination. Visual cues may form another basis for discrimination. Historically, skin colour was used as a signal of social status – since people who worked outside tended to tan, so lighter skin was a signal of wealth and high status. Arrow (1972) describes skin colour as a ‘cheap’ signal about race. Darity and Mason (1998) survey a number of studies on race and skin colour in the United States and find that even within races, darker skin colour is related to lower earnings. This suggests that race-related status hierarchies are not bilateral. Eckel and Wilson (2004) show subjects pictures of their opponents prior to playing a trust game. A different sample of subjects from the same subject pool evaluated the pictures for a number of characteristics. They find that trust and reciprocity are significantly related to skin colour as well as perceived ‘friendliness’ and ‘reliability’ of the recipients. Field experiments also find differences in bargaining by race; minorities are initially offered higher prices in the market for cars (Ayers and Siegelman, 1995) and trading cards (List, 2004).

Names. Names are a signal of status in societies where there is segmentation based on race or ethnicity. Bertrand and Mullianathan (2003) find that employers in the United States are less likely to call the sender of a résumé identified with an African-American sounding name than they are the sender of an identical resume with a white-sounding name. Fryer and Levitt (2004) calculate an index of ‘distinctively black’-sounding names, but once they control for other socio-economic variables, names are not associated with economic disadvantage. Fershtman and Gneezy (2001) conduct laboratory experiments in Israel that pair subjects with partners who have names that denote a distinctive Ashkenazic or Eastern Jewish heritage. They find that subjects with an Ashkenazic partner are three times more likely to make an efficient transfer in a trust game, although similar amounts are transferred in dictator games, regardless of the ethnic heritage of the recipient. This suggests that while people of
Ashkenazic heritage are of higher status, more highly educated, and, in the experiment, more trusted, they are not more worthy when it comes to income distributions in an experiment.

Discussion

Amidst all the evidence that status affects economic decision-making, the puzzle is: why? Discrimination research often focuses on two possible explanations, namely, animus and statistical discrimination. While animus seems a consistent explanation for preferring individuals endowed with high status, it is less compelling when considering status that can be obtained. Statistical discrimination is consistent with Bernheim's (1994) model of social norms; however, Goldin and Rouse's (2000) result that women are hired more frequently than men in a setting where gender is unknown, and less frequently when it is known, suggests that status may be an inaccurate proxy for a person's hidden attribute of interest.

Status may serve a role in helping to prevent coordination failures in games with multiple plausible outcomes. If all individuals use the strategy ‘defer to high-status individuals’ in a game such as the ‘battle of the sexes’, status can serve to largely eliminate dominated outcomes. Status may also provide a means of avoiding low payoff equilibrium outcomes in Prisoner's Dilemma type games. Kumru and Vesterlund's (2005) result that low-status individuals follow the behaviour of high-status leaders in public goods games suggests a positive role for status in guiding behaviour. Evolutionary arguments provide the most plausible explanation for the existence of status-related behaviour. Tastes that increase the likelihood that individuals survive and produce offspring are most likely to persist in a population. Among social animals the highest-ranking individual is generally the largest with size being linked to sexual maturity, strength and health. These high-status individuals generally enjoy preferential access to food and mates and produce a disproportionate number of society's offspring. Status hierarchies can also enhance the transmission of useful information if the prestige of high-status, successful individuals attracts close observation by others (Henrich and Gil-White, 2001). To the extent that status characteristics are passed along to offspring, this strategy produces a stronger ‘next generation’ than one without status hierarchies. This argument suggests that current tastes may result from what was a successful survival strategy for our distant ancestors. On the other hand, in most parts of the world humans have access to food and medical care that reduce the importance of status preference as a survival strategy. Given the inefficiencies that status-seeking produces, therefore, these tastes may no longer be optimal.

Steindl was born in Vienna on 14 April 1912. He studied economics in Vienna and received his Ph.D. working under Richard Strigl. He worked in the Austrian Institute for Economic Research (AIER) from 1935 to 1938, the year of his emigration to England. He was a lecturer at Balliol College, Oxford, from 1938 to 1941, and then a research worker at the Oxford Institute of Statistics. He worked there with Michal Kalecki, who left a lasting mark on his theoretical work. He returned to Austria in 1950. He was barred from teaching at the University of Vienna for ideological reasons and resumed his job at AIER, where he worked until his retirement in 1978. In 1970, however, the University of Vienna bestowed upon him a honorary professorship. He was visiting professor at Stanford University in 1974/5.

Steindl dealt with the economic problems of the size of firms (1945) and of the distribution of firms according to size (1965a). He explained the pattern of size distribution of firms by means of random processes (birth and death processes). Other fields of interest were education (1967) and technology (for example, 1980).

The research which may prove longest lasting is his work on the development and the present phase of capitalist economies. His main work (1952) deals with the tendency to stagnation of the mature capitalist economy. His point of departure was that oligopoly leads to increased profit margins and consequently to a fall in effective demand. The ensuing decline in the degree of capacity utilization causes ceteris paribus a lower level of investment and a decline in the rate of growth in mature capitalist economies. The slowing down of capital growth reduces further the utilization of capacity and leads to a cumulative process of declining growth. Steindl thus treats the utilization parameter differently from Kalecki, for whom it is a purely passive variable. Another difference consists in the explanation of the growth trend of the capitalist economy without having recourse to exogenous factors like innovations.

*Maturity and Stagnation in American Capitalism* was largely ignored during a period of high employment and intensive growth. Only when the old weaknesses of unemployment and stagnation...
reappeared did the book arouse wider interest and prove its lasting significance. The evolution of his ideas is shown in the introduction to (1976) and in the penetrating analysis both of present economic trends (for example, 1979; 1985a; 1985b) and of the present state of economics (1984).

Abstract

An 18th-century Scottish political economist, Steuart's interest in economic management, contrasting with the economic liberalism of Adam Smith, reflected his long exile on the European continent and his awareness of backward conditions generally. Believing that markets do not always clear, Steuart advocated import protection, subsidies for exports and agriculture, and public works to combat unemployment. He thought the resultant high taxation would encourage people to work hard to obtain the necessities of life. Whereas Smith ignored him in Wealth of Nations, Marx gave him his due in Capital, and in the 20th century his monetary theory was recognized by some as anticipating that of Keynes.

Biographical

The Steuart family owned two estates, Goodtrees, which is near Edinburgh, and Coltness on the outskirts of Glasgow. Goodtrees was the seat of Sir James Steuart, the second baronet, Solicitor-General and a member of the Union Parliament. Sir James married Anne Dalrymple, the eldest daughter of the Lord President of the Court of Session, by whom he had five children of whom James was the only son. James was born on 10 October 1713, presumably at Goodtrees.

James attended the Parish School at North Berwick, proceeding in due course to Edinburgh University
Steuart, Sir James (1713–1780) : The New Palgrave Dictionary of Economics

where he studied, inter alia, constitutional and Scots law. Thereafter James made the expected progression and passed the Bar examinations in 1735 at the age of 22.

Steuart became the third baronet in 1717 on the death of his father but did not spend time either enjoying his new status or his standing as an advocate. Rather he embarked upon a Foreign Tour (1735–40). It was during this period that he lost his remarkable mother, an event which may have affected his future fate.

Steuart travelled with a fellow advocate, Carnegie of Boysack, and the pair initially went to Holland where they pursued further study. But in due course they travelled through France, settling for a period in Avignon. Avignon was at this time a Papal Territory and a haven for those Scots who had been ‘out’ in the Jacobite Rebellion of 1715. It was here that Steuart met the Duke of Ormond, a fervent supporter of the Cause who in turn directed Steuart's steps to Madrid where he met the Earl Marischall, another of the architects of the ill-fated '15. It may have been the influence of these two men that directed Steuart's steps to Rome in the late 1730s. Steuart seems to have been captivated by the Old Pretender and his staff (there is very little mention of Prince Charles) and in a way which was to have a profound influence upon his future.

Steuart met Lord Elcho in Lyons, en route home, and it may be that he persuaded the future commander of the Prince's Life Guards to join the movement. In any event Steuart was active on behalf of the Jacobites after his return to Scotland in 1740 and it was because of this that he was sent to France as ambassador in 1745, following the success at Prestonpans. But after the battle of Culloden in April 1746 Steuart entered a long period of exile and to begin with maintained an active link with the Party. But the early 1750s saw a withdrawal from the Jacobite interest and Steuart, together with Lord Elcho, eventually settled in Angoulême where they lived in some style, with the support of Elcho's mother (Wemyss, 2003).

Steuart was bored, however, and it was probably significant that the exiled Parlement of Paris came to the locality in 1753. It was here that Steuart met Mercier de la Rivière, the latter-day Physiocrat so much admired by Adam Smith, with whom Steuart formed a long and lasting friendship. When the Parlement returned to Paris in 1754 Steuart followed where he was entertained by Mercier de Rivières and probably introduced to Montesquieu and Mirabeau.

The scientific opportunities were considerable, but in fact Steuart left Paris and France in 1755 to avoid compromising his position further in the event of hostilities with Britain. He left Paris in short before the dissemination of the Tableau économique. The first two books of the Principles were completed in the isolation of Tübingen (Germany) by August 1759. His work on the Policy of Grain and the Dissertation on the German Coin belong to this period.

The Steuart family left Tübingen in 1761 following Lord Barrington's successful attempt to have Steuart's son, also James, appointed as a coronet in the British Dragoons. They travelled west to Rotterdam and Antwerp before settling temporarily in the Spa. It was here that Steuart was arrested by the French authorities and subsequently imprisoned. The arrest was thought to be due to Steuart's close knowledge of the weakness of the French economy, although another gloss has been put upon the event by Paul Chamley. Chamley indicated that Steuart had been caught in the possession of plans for the invasion of Santo Domingo (Haiti): plans which had been prepared by Mercier de la Rivière, ‘who had a personal pecuniary interest in an English invasion of the island and may also have realised that it would do his friend Steuart no harm in the eyes of London if he were arrested by the French’ (Chamley, 1965, pp. 44–6; Skinner, in Steuart, 1998, vol. 1, pp. xlv–xlvi).
Steuart returned to England in 1763, the year of peace with France, under the mistaken belief that the British government had acted upon his behalf. Steuart did not in fact receive a pardon for past misdemeanours until 1771. But in the meantime he enjoyed the protection of Lord Barrington, sometime Secretary at War, whom he had first met on the Foreign Tour. After the frenetic period when he brought the *Principles* (1767) to completion, he pursued, or rather continued to pursue, work of an academic nature as the *Works* amply confirm. He also found time to write a series of letters on the American War (Raynor and Skinner, 1994) which are chiefly interesting for his suspicion of military victory and his advocacy of free trade with the Colonies whatever the outcome. These letters were written between 1775 and 1778.

Steuart was apparently a good neighbour, actively interested in the economic affairs of the locality (Lanarkshire) and in the politics of the region. Steuart died on 26 November 1780. He was interested in the family vault at Cambusnethan (Lanarkshire) which is now sadly in ruins. Coltness has been demolished apart from some remnants of the original stable block.

Steuart married Lady Frances Wemyss (Lord Elcho's sister) on 25 October 1743 and their son, also James, was born the following year. Sir James Steuart-Denham had a distinguished military career. He served mainly in Ireland and on his death in 1839 was the Senior General in the British army, notable for his reform of cavalry tactics. He married Alicia Blacker of Carrick but there were no children. (The name ‘Denham’ was added in 1773 following the transfer of the estate of Westshields to the third baronet on the death of Archibald Denham) (Skinner, 2006, p. 73).

**The Principles: methodology**

It should be noted that one of the most important features of Sir James Steuart's career was his extensive knowledge of the Continent. The Foreign Tour (1735–40) and exile as a result of his association with the Jacobites meant that by the end of the Seven Years’ War Sir James had spent almost half of his life in Europe. In this time he mastered four languages (French, German, Spanish and Italian), a fact which may help to explain Joseph Schumpeter's judgement that ‘there is something un-English (which is not merely Scottish) about his views and his mode of presentation’ (1954, p. 176n).

In the course of his travels Steuart visited a remarkable number of places which included Antwerp, Avignon, Brussels, Cadiz, Frankfurt, Leyden, Liège, Madrid, Paris, Rome, Rotterdam, Tübingen, Utrecht, Venice and Verona. He seems, moreover, consistently to have pursued experiences which were out of the common way. For example, when he settled at Angoulême he took advantage of his situation to visit Lyons and the surrounding country. During his residence in Tubingen, he undertook a tour of the schools in the Duchy of Württemburg. Earlier he had spent no less than 15 months in Spain where he was much struck by the irrigation schemes in Valencia, Mercia and Granada, the mosque in Cordoba and the painful consequences of the famine in Andalusia in the spring of 1737. In fact very little seems to have been lost on him and it is remarkable how often specific impressions found their way into the main body of the *Principles*. In his major book Steuart noted the economic consequences of the Seven Years’ War in Germany, the state of agriculture in Picardy, the arrangement of the kitchen gardens round Padua, and the problem of depopulation in the cities of the Austrian Netherlands.

Steuart drew attention to the difficulties under which he laboured in the preface to the *Principles* precisely because he thought they would be of interest to the reader. He pointed out that the ‘composition’ was the ‘successive labour of many years spent in travelling’ (1966, p. 304) during which...
he had examined different countries ‘constantly, with an eye to my own subject’:

I have attempted to draw information from every one with whom I have been acquainted: this however I found to be very difficult until I had attained to some previous knowledge of my subject. Such difficulties confirmed to me the justness of Lord Bacon's remark, that he who can draw information by forming proper questions, is already possessed of half the science. (1966, pp. 5–6)

Steuart wrote very much in the style of a man finding his way through a new field. This, added to the fact that nearly eight years separate the first and last books, presented obvious problems; problems of which Steuart was always conscious but which he viewed with very mixed feelings:

Had I been master of my subject on setting out, the arrangement of the whole would have been rendered more concise; but had this been the case, I should never had been able to go through the painful deduction which forms the whole train of my reasoning and upon which … the conviction it carries along with it in a great measure depends. (1966, p. 7)

Steuart sought to establish a system of thought whose content met the requirements of Newtonian methodology. The leading feature of Steuart's method is objective empiricism. He was thus entirely in accord with his friend Hume (Skinner, 2005) but like Hume, he recognized that the mere collection of facts was not of itself sufficient. The first step on the route to knowledge is the collection and description of facts; the second, the statement of certain ‘principles’ reached through a process of induction.

Steuart also recognized that the scientist can only advance by concerning ‘himself’ with cause and consequence, that is, by thinking deductively. He solved the problem of how to combine the two techniques by using induction to establish his basic hypotheses, or ‘principles’, and deduction for what Hasbach described as the ‘clarification of phenomena’ (1891).

Steuart was quite clear as to the techniques of reasoning to be employed. The rules were simple, if difficult to obey: observation, induction, deduction, verification. There remained the question of the technique to be followed in building up a body of knowledge and here Steuart's answer was equally clear. The scientist should begin with the simple (and thus apparently abstract) case and gradually take account of more and more complex (and thus ‘realistic’) cases. The first objective must be clarity and Steuart thus recognized that the attainment of the second, relevance, can only come about through the use of the abstraction in the early stages of study. He argued that in building up a body of knowledge:

Every branch of it must, in setting out, be treated with simplicity and all combinations not absolutely necessary must be banished from the theory. (1966, p. 227)

But, since the object is relevance and since the ‘more extensive any theory be made, the more it will be useful’, it follows that as we proceed ‘combinations will crowd in and every one of these must be attended to’ (1966, p. 227). Steuart always employed this technique in dealing with a body of knowledge; that is, he gradually builds up his argument in a series of steps which progressively increase in complexity.
At the same time, Steuart recognized that theoretical edifices constructed in this manner present the economist with particular difficulties which arise from the nature of the subject matter itself. In Steuart's view, the economist or social scientist can only show 'how consequences may follow from one another; to foretell what must follow is exceedingly difficult if not impossible' (1966, p. 365). While we can and must establish general principles these do not provide rules of behaviour which must always hold good. Steuart thus concluded (somewhat ironically, in the context of a critique of Hume's quantity theory) that:

I think I have discovered that in this, as in every other part of political economy, there is hardly such a thing as a general rule to be laid down’ (1966, p. 339)

Given the need for a systematic statement of particular principles, established in accordance with the discipline of an appropriate methodology, there remained the problem of establishing a useful ‘method’ in respect of the organization of the discourse as a whole.

The thing to be done is to fall upon a distinct method … by contriving a chain of ideas, which may be directed towards every part of the plan, and which at the same time, may be made to arise methodically from one another. (1966, p. 28)

Here again, Steuart followed Hume's lead. The ‘plan’ is contained in the first two books and is based upon a theory of economic development. Steuart's dominant theme was to be change and growth, and it is this which gives his work cohesion.

The historical perspective

Steuart opened his account with ‘society in the cradle’ before going on to trace the origins of, and the process of transition between, the various stages of the progress of man. In this context, Steuart made use of a theory of stages, now recognized as a piece of apparatus which was central to the work of the Scottish Historical School. He cites, for example, the Tartars and Indians as relatively primitive socio-economic types of organization (1966, p. 56) while concentrating primarily on the third and fourth stages – the stages of agriculture and commerce. In the former case, Steuart observed that those who lacked the means of subsistence could acquire it only through becoming dependent on those who owned it; in the latter, he noted that the situation was radically different in that all goods and services command a price. He concluded, in passages of quite striking clarity:

I deduce the origin of the great subordination under the feudal government, from the necessary dependence of the lower classes for their subsistence. They consumed the produce of the land, as the price of their subordination, not as the reward of their industry in making it produce.

He continued:

I deduce modern liberty from the independence of the same classes, by the introduction of

industry, and circulation of an adequate equivalent for every service. (1966, pp. 208–9).

Steuart also observed that ‘an opulent, bold and spirited people, having the fund of the Prince's wealth in their own hands, have it also in their own power, when it becomes strongly their inclination, to shake off his authority’ (1966, p. 216).

The alteration in the distribution of power which was reflected in the changing balance between proprietor and merchant led Steuart to the conclusion that ‘industry must give wealth and wealth will give power’ (1966, p. 213). As an earnest of this position, he drew attention (significantly in his Notes on Hume's History) to the reduced position of the Crown at the end of the reign of Elizabeth: a revolution which appears ‘quite natural when we set before us the causes which occasioned it. Wealth must give power; and industry, in a country of luxury, will throw it into the hands of the commons’ (1966, p. 213n).

It was perhaps for this reason that Steuart's French translator, Senovert (1789), advised his readers that of the advantages to be gained from a reading of the Principles, ‘Le premier sera de convaincre, sans doute, que la révolution qui s'opère sous nos yeux était dans l'ordre des choses nécessaires’ (1966, p. 24n). Senovert, in short, was convinced of the inevitability of the Revolution and believed that the Principles confirmed the point.

Economic analysis

To economists he has always been Sir James Steuart, because that is how he appears on the title page of his 1767 book. This is subtitled, An Essay on the Science of Domestic Policy in Free Nations, in which are particularly considered, Population, Agriculture, Trade Industry, Money, Coin, Interest, Circulation, Banks, Exchange, Public Credit and Taxes. It offers a detailed, comprehensive and often original account of the application of economic argument to this enormous range of questions.

The population theory with which the book opens anticipates much that Malthus went on to say, and Marx even suggested in the first volume of Capital that, ‘admirers of Malthus do not even know that the first edition of the latter's work on population contains, except in the purely declamatory part, very little but excerpts from Steuart’ (Marx, 1867, p. 333).

His analysis of the balance of payments has also been much admired. He went considerably further than Hume by incorporating a detailed analysis of the capital account, and this led him to the conclusion (among several where he differs from Hume) that a country with a persistent capital account deficit will be unable to find an equilibrium price level at which specie flows cease.

Steuart's travels on the Continent during his 18 years of exile from 1745 to 1763 acquainted him with monetary developments in Paris and Amsterdam, and this enriched his theoretical and empirical chapters on money and banking. But it is his analysis of economic policy which has attracted much modern attention. The contrast between his analysis and Smith's in The Wealth of Nations published just nine years later is especially marked. Steuart's years of exile had given him a detailed knowledge of economic and financial policy on the Continent, and in particular in France, Germany and Holland, and he advocated a degree of state intervention into every aspect of economic life, which contrasted sharply with the principles that Smith enunciated. Skinner (1981) has suggested that it was precisely Steuart's long years of residence on the Continent that led him to evolve a ‘system’ which was so much more
Steuart, Sir James (1713–1780) : The New Palgrave Dictionary of Economics

In his book, Steuart offers extensive and detailed advice to an idealized statesman, who is assumed to possess unlimited knowledge and whose ‘inclinations are always to be virtuous and benevolent’ (1966, p. 333). Steuart believed that markets do not always clear, and this was especially the case with the labour market, where there was always liable to be an imbalance between ‘demand’ and the supply of ‘work’. Manufacturers, merchants and workers sought to ‘consolidate’ any high living standards they temporarily achieved into permanently higher incomes, and they often achieved this by restricting competition. Once prices and wages were consolidated at high levels, employment necessarily suffered as soon as foreign manufacturers began to produce more cheaply. With these assumptions about the behaviour of workers and entrepreneurs, and the impotence or non-existence of corrective market forces, there was an extensive range of policies through which state intervention could be expected to increase wealth, welfare and employment.

As soon as domestic production became overpriced, imports would undermine domestic employment and the creation of wealth, and Steuart therefore proposed that ‘a branch of trade should be cut off’ where the Statesman shall find,

upon examining the whole chain of consequences, … the nation's wealth not at all increased, nor her trade encourages, in proportion to the damage at first incurred by the importation. (1966, p. 293)

In addition to protecting industry against imports, Steuart advocated export subsidies, because he saw the alternative to, for instance, subsidizing exports of fish by £250,000 so that what cost £1,000,000 could be sold overseas for £750,000, as the total loss of £750,000 of potential domestic output. Without the subsidy,

those employed in the fishery will starve; … the fish taken will either remain upon hand, or be sold by the proprietors at a great loss; they will be undone, and the nation for the future will lose the acquisition of £750,000 a year. (1966, pp. 256–7)

Steuart was also concerned that as industry and population grew, the price of subsistence would rise as the population forced farming onto inferior land, where ‘the progress of agriculture demands an additional expence’. In order to ‘preserve the intrinsic value of goods at the same standard as formerly; [the Statesman] must assist agriculture with his purse, in order that exportation may not be discouraged’ (1966, p. 200).

As well as seeking to avert the influence of agricultural diminishing returns by subsidizing agriculture in order to keep export costs down, Steuart actually proposed the setting up of a ‘policy of grain’ in ‘the Common Markets of England’, where the government would buy up all the grain that farmers were prepared to produce at ‘the minimum price expedient for the farmers’, and sell all that could be marketed at ‘the maximum price expedient for the wage-earners’, and store any excess in state granaries. Steuart actually drafted this anticipation of the European Economic Community's agricultural policies of the 1970s and the 1980s in 1759 while he was in exile in Tübingen.

Steuart also anticipated post-Second World War industrial policies, for he argued that a Statesman should not hesitate to intervene directly in the finance and management of any new undertaking where
he saw economic potential, and should

inquire into the capacity of those at the head of it; order their projects to be laid before him; and when he finds them reasonable and well planned, he ought to take unforeseen losses upon himself … the more care and expence he is at in setting the undertaking on foot, the more he has a right to direct the prosecution of it towards the general good. (1966, p. 391)

Steuart was a powerful advocate of public works to create employment whenever there was an excess supply of labour. The government should always finance the employment of ‘the deserving and the poor’, and they should be employed to extend a nation's social and economic infrastructure rather than for unproductive purposes:

If a thousand pounds are bestowed upon making a firework, a number of people are thereby employed, and gain a temporary livelihood. If the same sum is bestowed for making a canal for watering the fields of a province, a like number of people may reap the same benefit, and hitherto accounts stand even; but the firework played off, what remains, but the smoke and stink of the powder? Whereas the consequence of the canal is a perpetual fertility to a formerly barren soil. (1767, vol. 1, p. 519)

All these interventionist policies needed to be financed, and Steuart actually welcomed the high taxation this would entail. He argued that taxes redistribute income and wealth and create employment, for they advance the public good, by drawing from the rich, a fund sufficient to employ both the deserving and the poor in the service of the state. (1767, vol. 1, pp. 512–13)

They also increase the power and prestige of the Statesman, for

By taxes the Statesman is enriched, and by means of this wealth, he is enabled to keep his subjects in awe, and to preserve his dignity and consideration. (1966, p. 304)

Economists who believe in the efficacy of market forces have often been concerned that high taxation may have adverse supply side effects, but Steuart actually believed that taxation would often have favourable supply side effects. High taxes

may discourage idleness; and idleness will not be totally rooted out, until people be forced, in one way or other, to give up superfluity and days of recreation … When the hands employed are not diligent, the best expedient is to raise the price of their subsistence by taxing it. (1966, pp. 691–5)

Steuart was aware that this analysis of the social and economical benefits from high taxation would not be popular with his contemporaries, and that ‘the politics of my closet is very different from those of the
century in which I live’, but he comforted himself with the thought that ‘reason is reason’, and that in another century these startling opinions would be acknowledged as correct (1767, vol. 1, p. 514).

Steuart's industrial policies amount (as Eltis, 1986, has suggested) to the setting up of a corporate state with a social contract between producers who are protected against foreign competition and whose employment is guaranteed, and the state to whom they pay high taxes. Some of these are then returned to inefficient producers, while the rest furthers the state's social and political objectives.

In addition to welcoming high taxation as a tool for the finance of industrial policies, Steuart was an advocate of state banks which would issue paper money. By making money less scarce, he believed that they would reduce interest rates and so benefit industry and commerce. He argued that John Law's Mississippi Scheme could have been successful in France with only a few minor modifications in the manner it was set up and administered, and that this could have established the long-term rate of interest at two per cent in France.

The many kinds of government expenditure Steuart so strongly advocated could also be financed through borrowing, and here again Steuart was ahead of his time. He believed that in the limit, whatever a government could raise from taxation could be devoted to the payment of interest on public debt so that at a five per cent rate of interest, governments could borrow 20 times their tax revenues:

If no check be put on the augmentation of public debts, if they be allowed constantly to accumulate, and if the spirit of a nation can patiently submit to the natural consequences of such a plan, it must end in this, that all property, that is income, will be swallowed up in taxes; and these will be transferred to the creditors.

But even in that state of affairs where all property income is paid as interest to those who have lent to the government does not represent the limit of the state's power to borrow. It can go on to tax the recipients of debt interest and so provide the wherewithal to finance still further borrowing, for these taxes ‘may be mortgaged again to a new set of men, who will retain the denomination of creditors’ (1767, vol. 2, pp. 633–4). Some may doubt that governments can at the same time continue to borrow, and defraud those from whom they borrowed in the past by taxing away their interest so that this provides the finance for still further borrowing. Won't there be a refusal to go on lending to such governments? No, opines Steuart, because

The prospect of a second revolution of the same kind with the first would be very distant; and in matters of credit, which are constantly exposed to risk, such events being beyond the reach of calculation, are never taken into any man's account who has money to lend.

(1966, p. 647)

Hence Steuart was perceptive enough to appreciate that sovereigns (and sovereign governments) can continually defraud their creditors, while new lenders will still queue up to be defrauded because the prospect of this will be so distant and problematical that it has a negligible influence on the immediate willingness to lend.

Steuart's book was well received at first, but Smith, who believed that economies would make full use of their labour and capital in the complete absence of government-inspired employment policies, and at the
same time wholly distrusted the omniscience and benevolence of governments, greatly weakened Steuart's reputation as a serious economist by totally ignoring the existence of his book in *The Wealth of Nations*. Four years before its publication, he wrote that 'Without once mentioning [Steuart's book], I flatter myself, that every false principle in it, will meet with a clear and distinct confutation in mine' (1977, p. 164).

In the 19th century Marx gave Steuart his due, and there are 13 references to him in the first volume of *Capital*. Several 19th-century German economists have compared Steuart's historical and institutional approach to political economy favourably with Smith's deductive methodology, but most accolades to the richness and originality of Steuart's contribution only emerged after the Keynesian revolution. His monetary and employment theory have been much praised, most comprehensively by Vickers (1959), though Hutchison (1978) and Schumpeter (1954) have also recognized his Keynesian anticipations. Steuart's monetary theory has much more in common with Keynes than the mere proposition that sufficient monetary expansion will reduce interest rates to two per cent. In Steuart's argument, money expenditure is not closely linked to the money supply, for idle balances will often be freely held, and the price level depends upon

\[
\text{demand and competition … Let the specie of a country … be augmented or diminished, in ever so great a proportion, commodities will still rise and fall according to the principles of demand and competition … Let the quantity of coin be ever so much increased, it is the desire of spending it alone which will raise prices. (1966, pp. 344–5)}
\]

But Steuart's monetary and employment theory describe only one element of his thought which has anticipated modern developments. S.R. Sen, the distinguished Indian economic planner who published an important book on Steuart in 1957, commended him as 'the first Economic Adviser to the Government of India', praised his case for detailed intervention into every aspect of economic life and suggested that 'it would not be any great exaggeration to say that A.P. Lerner's chapter on functional finance seems almost a paraphrase of Steuart’ (Sen, 1957, p. 122). Twenty years later, Akhtar (1979), of the New York Federal Reserve Bank restated Steuart in 30 equations, and compared his growth theory favourably with Smith's.

The classical counter-revolution of the 1980s has, of course, challenged the case for detailed state intervention which became so fashionable after the Keynesian revolution, and Steuart's dirigisme has been criticized by Anderson and Tollison (1984). It will be evident that there has been a more extensive response to the interventionist political economy of Sir James Steuart in the 20th century than there was in his own time.

**Reception**

Contemporary reaction was mixed. Hume is said to have been critical of the ‘form and style’ of the book while James Boswell considered the work to be ‘irregular and fanciful’ (Skinner, 1966, p. xlvi). Hugh Blair wrote to Hume that ‘Sir James’ Book is the most ponderous piece of lumber that I have ever looked into’ (NLSms. 23153). One contemporary review was cautious, noting that:
We have no idea of a statesman having any connection with the affair, and we believe that the superiority which England has at present over all the world, in point of commerce, is owing to her excluding statesman from the executive part of all commercial concerns.  

(Critical Review 23 (1767), p. 412)

The Monthly Review (36, p. 464) went so far as to accuse Steuart of imbibing prejudices abroad ‘by no means consistent with the present state of England and the genius of Englishmen’. Steuart replied:

Can it be supposed, that during an absence of near twenty years, I should in my studies have all the while been modelling my speculations of English notions? If, from this work I have any merit at all, it is by divesting myself of English notions, so far as to be able to expose in a fair light the sentiments and policy of foreign nations, relatively to their own situation. (1966, pp. 4–5. This passage occurs in the second edition of the Principles, published in the Works)

But if Steuart did not fare well among at least some of the key figures of the Enlightenment (and later!) the situation was rather different upon the Continent and elsewhere. During the 1780s the text was twice translated into German while there was a French version in 1789. Kobayashi (in Steuart, 1998) has suggested that Steuard's model of ‘primitive accumulation’ may help to explain the popularity of his work in contemporary Ireland and Germany. Keith Tribe (1988, p. 133) on the other hand, noted that ‘until the final decade of the eighteenth century Sir James Steuart's Inquiry was better known and more frequently cited than Smith's Wealth of Nations’.

But perhaps the most intriguing link is with North America. The pirated Dublin edition of 1770 was circulated widely in the Colonies and attracted the attention of Alexander Hamilton who was naturally concerned about the economic prospects of the infant republic. Hamilton rejected Smith's ‘fuzzy philosophy' in favour of a policy of protection as a means of counterbalancing the competitive advantages of the British economy in the years following the Peace of Paris (1783). This perspective seems to have been widely shared, and is essentially a variant of Steuart's stage of ‘infant trade'.

Stewart was the most important early commentator on Adam Smith's work. He was born in Edinburgh in 1753 and died there in 1828. He was the brilliant and well-connected son of an Edinburgh professor and was destined for an academic career from the earliest age. Educated at Edinburgh and Glasgow Universities, Stewart was taught by Adam Ferguson and Thomas Reid and became a close acquaintance of Adam Smith. He was appointed to the Edinburgh Chair of Moral Philosophy on Ferguson's retirement in 1785 and held it until 1810, when ill-health forced his retirement. A charismatic and influential teacher, his vast erudition and synthetic skill was shaped by an acute sensitivity to the ideological responsibilities of the pedagogue. He was a prolific writer whose contemporary reputation was built on the first volume of his *Elements of the Philosophy of the Human Mind* (vol. 1, 1792; vol. 2, 1815; vol. 3, 1826) and its companion text book *Outlines of Moral Philosophy* (1793). These works circulated widely in the universities of Britain, America and the continent in the early 19th century and did much to establish Scottish Common Sense Philosophy as the most influential vehicle of elite education in the age of the American, French and Industrial Revolutions. Stewart's collected works were published posthumously in 1854–60.

Stewart's *Account of the Life and Writings of Adam Smith LL.D* (1793) was frequently republished, often as an introduction to Smith's works. He discussed the *Wealth of Nations* in relation to the *Theory of Moral Sentiments* and both in relation to Smith's abortive plan for publishing a theory of jurisprudence. At Edinburgh he lectured on the principles of government and political economy in 1800–8 to an influential group of students who were to do much to form Whig and Tory opinion in the early 19th century. These lectures were intended for publication but the manuscript was accidentally destroyed and never rewritten. Their substance can, however, by inferred from a posthumous text which was compiled from his notes and published with his collected works.

Stewart was the first academic to detach the study of political economy from that of the theory of
government and to treat each as a distinct branch of political science and it is in this methodological innovation rather than for any particular economic theory that his importance for political economy lies. His lectures were addressed to those ‘who study Political Economy with a view to the improvement of the theory of legislation’ (Stewart, vol. 9, p. 255). He defined political economy as the sum of ‘all those speculations which have for their object the happiness and improvement of Political Society’. This, not ‘the mistaken notions concerning Political Liberty which have been so widely disseminated in Europe by the writing of Mr. Locke’, was the only proper foundation on which a true science of government could be raised (Stewart, vol. 8, pp. 10, 23). In general, Stewart's lectures offered an intelligent, critical presentation of the arguments of the *Wealth of Nations* illuminated by occasional information about Smith's last thoughts, by a sustained and sympathetic reappraisal of the Physiocrats and by a persistent preoccupation with perfectibility, progress, and the gradual improvement of the British Constitution.

Sticky wages have become a widely utilized framework for modelling nominal wage stickiness and for assessing its macroeconomic consequences, including for the transmission of monetary shocks. This article provides a heuristic description of the staggered contracts model, motivates its salient features, and discusses its evolution.

Nominal wages are regarded as ‘sticky’ if they fail to adjust to the level that would prevail in an equilibrium with costless wage adjustment and full information. Modern analysis of sticky wages, including their allocative effects and policy implications, owes an enormous debt to Keynes (1936). Keynes believed that nominal wages were likely to adjust less rapidly than prices in response to nominal shocks. He inferred that real wages would move counter-cyclically, so that a monetary contraction would push up the real wage and reduce employment. Keynes applied his theory to explain the collapse of employment during the Great Depression, and also argued that wage stickiness had major implications for the choice of a monetary regime. But while Keynes's work is justly celebrated, it is important to recognize that the belief that nominal wage rigidities play a central role in the monetary transmission channel was held by some pre-eminent classical economists of the early 19th century, such as Henry Thornton.
In the wake of the Keynesian revolution, considerable interest developed in constructing quantitative models that incorporated the hallmarks of Keynes's framework, including sticky wages. A shortcoming of these early models was in their characterization of expectations as adaptive. By the mid-1970s, the first models incorporating sticky wages into a general equilibrium framework with rational expectations appeared in seminal work by Fisher (1977) and Gray (1976). These authors assumed that wages were set a fixed number of periods in advance, with the predetermined wage set so that the labour market was expected to clear at the 'maturity' of the contract. While a considerable innovation, the 'Fischer–Gray' contract formulation effectively constrained the real effects of monetary shocks to be no longer than the duration of the longest contract.

Taylor (1980) introduced staggered wage contracts as a mechanism for allowing monetary shocks to exert real effects lasting beyond the length of the longest contract, a feature he termed the 'contract multiplier'. Taylor's wage-contracting model was meant to be consistent with several empirical observations about wage-setting: (a) wages are typically set in nominal terms and remain unchanged for sustained periods; (b) wage-setting tends to be asynchronous across different groups of workers; and (c) workers appear to take the wages set by other workers into account when adjusting their own wage, as well as aggregate demand. (See Taylor, 1999, for a comprehensive survey of staggered contracting models.)

Specifically, Taylor divided workers into $N$ cohorts, and assumed that each cohort was constrained to adjust its contract wage at fixed intervals once every $N$ periods. To illustrate the key features accounting for a contract multiplier, it is helpful to consider the special case in which wage contracts last two periods. In this case, Taylor's model can be expressed as three equations:

\[
\begin{align*}
\bar{x}_T &= (1/2)^* (\bar{w}_T + E_T \bar{w}_{T+1}) + (1/2)^* g(\bar{y}_T + E_T \bar{y}_{T+1}) \\
\bar{w}_T &= (1/2)^* (\bar{x}_T + \bar{x}_{T-1}) \\
\bar{m}_T &= \bar{y}_T + \bar{w}_T
\end{align*}
\]
where variables are in logs, and $E_T$ denotes the conditional expectation operator. The first equation determines the contract wage $x_T$, which is the fixed wage each member of the cohort currently readjusting its wage receives over the life of the contract. The contract wage is specified as depending on average economy-wide wages expected over the contract life, and on current and future output (with the parameter $g$ determining the sensitivity). The second equation expresses the average economy-wide wage $w_T$ as a simple average of the contract wages still in effect. Finally, the model includes a simple quantity theory relation between the exogenous money stock $m_T$ and nominal demand (the price level is a constant markup over the average wage). If we substitute (2) into (1), it is evident that contract wages have both a forward- and a backward-looking component, with the latter playing a crucial role in allowing the model to generate persistence.

Solving Taylor's model for the contract wage yields:

$$x_T = h \times x_{T-1} + (1-h) \times m_T$$

$$h = (1 - g^{(1/2)})^{2/(1-g)}$$

(4)

where the money supply is assumed to follow a random walk. If $g$ is sufficiently small, the composite parameter $h$ is close to unity, implying that a monetary shock has a small initial effect on the contract wage (and on average wages or prices), and thus exerts a large and persistent effect on output; by contrast, $h$ approaches zero as $g$ approaches unity, consistent with monetary shocks exerting large immediate effects on wages and prices, but little effect on output. Importantly, since $g$ is assumed to be a free parameter, Taylor's model can rationalize an arbitrarily high degree of output persistence even if contracts last only two periods.

Taylor's staggered contracts model represented a major innovation in so far as it seemed to provide an empirically realistic model of monetary transmission within a rational expectations framework. However, while the staggered contracts framework became widely utilized for generating persistent responses to monetary shocks, the assumption that nominal wage stickiness was the primary source of monetary non-neutrality proved less durable. Thus, when Calvo (1983) developed an alternative staggered contracts framework that departed from Taylor's by specifying contract durations to be random, he assumed that prices rather than wages were sticky. This shift towards specifying sticky prices as the source of monetary non-neutrality was motivated by empirical evidence that appeared inconsistent with counter-cyclical real wages, and persisted until the late 1990s.

Some critiques, and the model's evolution

The staggered contracts model of Taylor and Calvo has evolved in response to several critiques. First, Fuhrer and Moore (1995) criticized its inability to account for inflation persistence or for the output costs of disinflation. In particular, while one-time changes in money could have persistent real effects,
These authors showed that permanent changes in money growth had fleeting effects on inflation and output. Two alternative approaches have emerged in response to this critique. One route has effectively embedded additional persistence into the contracting structure by assuming that some agents have adaptive expectations (as in Roberts, 1997) or that workers not receiving a signal to change their wage (or price) follow a mechanical indexation scheme (Christiano, Eichenbaum and Evans, 2005). An alternative approach adopted by Ball (1995) and Erceg and Levin (2003) retains rational expectations, but assumes that agents learn gradually about shocks. Either approach may account for inflation inertia and prolonged output losses due to disinflation; however, in the latter inflation persistence is not intrinsic as in the indexation schemes, but instead depends on features that determine the speed of learning (including policymaker credibility and transparency).

Chari, Kehoe and McGratten (2000) challenged the ability of Taylor-style contracts to generate a contract multiplier in a version with explicit micro-foundations. These authors argued that the key parameter ‘g’ in eq. (1) should not be regarded as a free parameter, since in their model it was determined by structural parameters characterizing tastes and technology; moreover, no reasonable calibration could account for a low enough value of ‘g’ to deliver a sizeable contract multiplier. This challenge spawned an expansive literature showing how it was possible to account for a sizeable contract multiplier in a more richly specified micro-founded model. While Chari, Kehoe and McGratten included only price rigidities, Erceg (1997) and Huang and Liu (2002) demonstrated that a combination of wage and price rigidities could help generate a substantial contract multiplier in a micro-founded setting in which workers acted as monopolistic competitors in the labour market and set wages in a staggered fashion; an extensive literature (including these authors) has shown that persistence may also be enhanced through various real rigidities.

Finally, Caplin and Spulber (1987) introduced state-dependent pricing into the staggered contracts framework, allowing agents to choose when to adjust their contracts rather than constraining them to adjust at exogenous intervals (‘time-dependent’ pricing). Their paper suggested that this innovation had pivotal implications for the monetary transmission mechanism: money could be neutral under some conditions. However, in subsequent analysis in a state-dependent framework with maximizing agents, Dotsey, King and Wolman (1999) found that the dynamic responses to a monetary policy shock were qualitatively similar to those of the standard Taylor model with time-dependent contracts.

In light of these critiques, the recent literature has tended to incorporate both wage and price rigidities within a micro-founded staggered contracts framework that allows for some form of inflation inertia. Christiano, Eichenbaum and Evans (2005) showed that such a model provides a good quantitative characterization of the responses of macro variables to a monetary policy shock. Importantly, the nearly acyclical empirical response of the real wage to a monetary policy shock has also helped renew support for incorporating sticky wages (as well as sticky prices) into macro models; with sticky prices alone, the real wage would be strongly pro-cyclical. Finally, interest in sticky wages has also been buttressed by the welfare analysis of Erceg, Henderson and Levin (2000). These authors showed that a combination of wage and price rigidities may account for the policymaker's apparent trade-off between stabilizing inflation and the output gap, and has important normative implications for the design of policy rules. A significant shortcoming of recent models is that their empirical support comes primarily from aggregate data. Moreover, current micro-founded sticky wage models appear deficient in their characterization of worker–firm attachments, and because they fail to take account of the sizeable costs...

of renegotiating labour contracts. Models that are developed to address such limitations may well have substantially different normative implications from current models, even if their dynamic properties remain similar.

Abstract

George Stigler combined technical competence, erudition, and wit. Stigler asked Frank Knight's question of how we know the goals of those we study. Early on, he offered a Knightian challenge to welfare economics, defending classical economic policy against the new orthodoxy. Later, he became an exponent of the orthodoxy. If goals are fixed, information is useful as a means to achieving them. Characterizing information as a commodity, Stigler described competitive equilibrium as a distribution of prices in a market. Policy advice is endogenous and we return to Adam Smith's analysis in which the philosopher is no better than those he studies.

George Stigler begins his autobiographical statement for the 1982 Nobel Prize in Economic Sciences (Stigler, 1983a) with these words:

I was born in Renton, a suburb of Seattle, Washington, in 1911. I was the only child of Joseph and Elizabeth Stigler, who had separately migrated to the United States at the end of the 19th century, my father from Bavaria and my mother from what was then Austria-
Hungary (and her mother was in fact Hungarian). I attended schools in Seattle through the University of Washington, from which I was graduated in 1931. I spent the next year at Northwestern University.

My main graduate training was received at the University of Chicago from which I received the Ph.D. in 1938. The University of Chicago then had three economists – each remarkable in his own way – under whose influence I came. Frank H. Knight was a powerful, sceptical philosopher, at that time vigorously debating Austrian capital theory but gradually losing interest in the details of economic theory. Jacob Viner was the logical disciplinarian, and equally the omniscient student of the history of economics. Henry Simons was the passionate spokesman for a rational, decentralized organization of the economy. I was equally influenced by two fellow students, W. Allen Wallis and Milton Friedman.

His statement ends this way:

I met my wife, Margaret L. Mack, at the University of Chicago. We were married in 1936. She died in 1970. I have three sons, Stephen (a statistician), David (a lawyer), and Joseph (a social worker). We are a close-knit family, and each summer we gather at a cottage on the Muskoka Lakes in Canada.

The Nobel Committee adds, ‘George J. Stigler died on December 1, 1991’.

What is not mentioned in the texts between these paragraphs are the honours. The presidency of the American Economic Association in 1964, of the History of Economics Society in 1977, and of the Mont Pelerin Society in 1977 along with the Nobel Prize in 1982 testify to a unique career. Specialist accounts focus on his contributions to the study of regulation (Peltzman, 1993), industrial organization (Demsetz, 1993) and the economics of science (Diamond, 2005). Biographical sketches by those who knew him well (Becker, 1993; Friedman, 1993; Wallis, 1993), as well as his 1988 Memoirs, attempt to link his life and work. Following his death, McCann and Perlman (1993) assessed Stigler's career; Longawa (1993) provided the bibliography. More than a decade later, we attempt to capture the permanent challenge of Stigler's work here.

Economists today, trained in a straightforward mathematical discipline, find it difficult to appreciate Stigler's combination of technical competence, scholarly erudition (Becker, 1993; Rosen, 1993; Rosenberg, 1993), and mordant wit (Friedland, 1993). The erudition is a serious problem. A student who has read neither Aristotle nor Bernard Mandeville may fail to appreciate the change of attitude between an article by Stigler that opened with a passage from Aristotle's Ethics (1943, p. 355) and his identification of revealed preference with the philosophy advanced in Mandeville's Fable of the Bees (1966, p. 68). Moreover, there is what Friedland calls ‘shyness’ and Friedman refers to as ‘sensitivity’. Stigler's 1988 autobiographical account spells out his contributions to the ongoing scientific discussion, but it hides virtuosity behind a veil of modesty.

Virtuosity and modesty
We begin with a contribution that is not discussed in Stigler's autobiography but which might have made the career of an ordinary scholar, what is known in the operations research literature as ‘Stigler's diet problem’. Given a scientific consensus on nutrients, what is the least-cost diet? We start with 9 nutrients and 77 foods. Recent accounts of Stigler's treatment remain appreciative:

Stigler used trial and error, and mathematical insight and agility to solve his (9\times77) set of inequalities. Based on cost and nutrient content, he was able to ‘weed’ the original 77 foods down to 15 as the eliminated foods were dominated by those in the list of 15. … Stigler's diet for 1939 data cost $39.93 per year. … Stigler's 1939 diet problem was the first ‘large-scale’ problem that was solved using the simplex method (Dantzig 1963 [pp. 551–67]). In 1947, nine clerks, using hand-operated desk calculators, pivoted away for 120 clerk-days and found the linear programming minimum cost of $39.69. Stigler knew what he was doing! (Garille and Gass, 2001, p. 2)

Authorities preface their judgement of the technical virtuosity of the performance with this judgement of the oddity of it all:

Stigler's diet problem is a prime example of an OR model that faithfully describes the real-world situation but whose solution validity is close to zero. As Stigler (1945, p. 312) cautioned: ‘No one recommends these diets for anyone, let alone everyone.’ (Garille and Gass, 2001, p. 2)

What was the effort about, then? Stigler explains when he compares his solution to those of ‘competent dieticians’ which cost two or three times as much as his:

The dieticians take account of the palatability of goods, variety of diet, prestige of various foods, and other cultural facets of consumption. … the particular judgments of the dieticians as to minimum palatability, variety, and prestige are at present highly personal and non-scientific, and should not be presented in the guise of being parts of a scientifically-determined budget. The second reason is that these cultural judgments, while they appear modest enough to government employees and even to college professors, can never be valid in such a general form. No one can now say with any certainty what the cultural requirements of a particular person may be … If the dieticians persist in presenting minimum diets, they should at least report separately the physical and cultural components of these diets. (1945, p. 314)

So, for Stigler, claims about the goals of individuals that had neither scientific nor philosophical weight were embedded in the dieticians’ solutions. At a minimum, he insisted, these claims should be made transparent.

Later editions of Stigler’s textbook discuss his contribution to linear programming:

This method of isolating products is intimately related to a method known as linear
To which he adds the footnote, ‘See almost any other book on economics’ and a reference to an article by Paul Samuelson on Frank Knight's theorem on linear programming.

We do not learn that Stigler's data and solution were the test case for George Dantzig to prove the worth of his simplex. Instead, we see played out Stigler's distaste for the economist who overemphasizes his own originality, a view reiterated in the essays on J.S. Mill's originality. There, too, Stigler endorsed Mill's stance of impartiality between ideas he created and those he adopted from others (1955; 1982, pp. 96–7).

We turn next to the problem that closes Stigler's diet paper – how we, as scientists, know the goals of individuals outside some very narrow physical sense.

Knight's discipline

Stigler's writings with an autobiographical component invariably stress the importance of Frank H. Knight as exemplar. In a self-assessment that is viewed sceptically by McCann and Perlman (1993), Stigler wrote ‘A more improbable Moses, if Knight would ever forgive the analogy, could not be designed’ (1988, p. 17). He stressed the impact of Knight's personal integrity, his life as a scholar who renounced money and fame as impediments to truth seeking (1988, p. 18). Is it then something of a surprise that the opening chapter in Memories of an Unregulated Economist asks ‘Are economists good people?’ Here, what worries Stigler most seems to have been the possibility that scholarship might be compromised by monetary rewards, specifically in the case of consulting. He thinks this is not so in his own case, but he recognizes that scholarship might also be influenced by sympathy for the client's case (1988, p. 133). Indeed, the idea that a statistician might be tempted by sympathy for the client is a concern in statistical consulting (Vardeman and Morris, 2003). Such ethical issues are rarely considered in economics.

Stigler was Knight's discipline for a long time. In his 1943 Economica review of Theory of Competitive Price (the partially completed 1946 Theory of Price), Lachmann pronounced the book to be a coherent version of Knight's distribution theory in which classical productive inputs are replaced by anonymous factors and cost is opportunity forgone. This view has triumphed so completely, outside perhaps of neo-Ricardian theorizing, that the radicalism of the Knight–Stigler position at the time is now largely forgotten.

In 1943 Stigler put forward a Knightian challenge to new welfare economics, defending classical economic policy against the new orthodoxy. First, he offered the objection:

Consider theft; our present policy toward this means of livelihood probably has adverse effects on the national income. Prevention of theft and punishment of thieves involves substantial expenditures for policemen, courts, jails, locks, insurance salesman, and the like. By compensating successful thieves for the amounts they would otherwise steal, we save these resources and hence secure a net gain. (If this policy leads to an undue increase in declarations of intent to steal, the retired successful thieves – who, after all, have
special talents in this direction – may be persuaded to assume the police functions.) (1943, p. 356)

Since it would ‘outrage our moral sensibilities to pay voluntary tribute to thieves’, something must be wrong. Stigler sketched the alternative:

The familiar admonition not to argue over differences in tastes \( \textit{de gustibus non est disputandum} \) leads not only to dull conversations but to bad sociology. It is one thing to recognize that we cannot \textit{prove}, by the usual tests of adequacy of proof, the superiority of honesty over deceit or the desirability of a more equal income distribution. But it is quite another thing to conclude that therefore ends of good policy are beyond the realm of scientific discussion.

For surely the primary requisite of a working social system is a consensus on ends. The individual members of the society must agree upon the major ends which that society is to seek. (1943, p. 357)

The 1943 paper is cited in the first edition of the full \textit{Theory of Price} as defending a Knightian consensus view of the law (Knight 1947, p. 62):

\[ \text{it is the fundamental tenet of those who believe in free discussion that matters of fact and logic can (eventually) be agreed upon by competent men of good will, that matters of taste cannot be ...} \] (1946, pp. 15–16)

Consensus in deep goals was as critical to policy as consensus about theory and fact was to science. The defence of new welfare economics was brief and devastating (Samuelson, 1943). Here is K.J. Arrow's judgment:

Professor Stigler has made it a burden of reproach to the new welfare economics that it does not take into account the consensus on ends. It is not clear from his discussion whether he regards the agreed-on ends as being obvious from introspection or casual observation … or as requiring special inquiry; his comments seem rather to incline in the former direction, in which case he lays himself open to Professor Samuelson's request for immediate enlightenment on various economic issues. (1951, pp. 83–4)

We find much of the Knightian spirit also in the 1946•minimum wage law article. Stigler did not reprint this article in the \textit{Citizen and the State}, where he described it mischievously as an example of how the misguided economist, lacking a market failure to correct, ‘lamented the intervention of the state’ (1975, p. x). The reader can predict the judgement about the topic but perhaps not the remedy. Given that minimum wage laws fail to ameliorate poverty, what should we do? The shared goal of equal treatment drives Stigler's results in a surprising direction:

One principle is fundamental in the amelioration of poverty; those who are equally in need

should be helped equally. If this principle is to be achieved, there must be an objective criterion of need; equality can never be achieved when many cases are judged (by many people) ‘on their merits’ … It is the corollary of this position that assistance should not be based upon occupation. The poor farmer, the poor shopkeeper, and the poor miner are on an equal footing. (1946, pp. 364–5).

Stigler endorsed a negative income tax in this context:

There is a great attractiveness in the proposal that we extend the personal income tax to the lowest income brackets with negative rates in these brackets. Such a scheme could achieve equality of treatment with what appears to be a (large) minimum of administrative machinery. (1946, p. 365)

Stigler's belief at the time that greater equality is a shared goal might explain his sharp reaction to 'suggestions' that he and Friedman tone down their egalitarianism in their joint study Roofs and Ceilings (Hammond and Hammond, 2006). The full history of 'natural experiments' in economics has yet to be written. When it is, the study of how the San Francisco housing market responded to the great earthquake (Friedman and Stigler, 1946) will take pride of place (Rockoff, 1991).

The work on regulation cited in the Nobel award falls between his Knightian and his Mandevillean periods. Neither electricity (Stigler and Friedland, 1962) nor securities regulation (Stigler, 1964) attained the articulated goals of regulation policy.

Mandeville’s disciple

Stigler renounced the procedure of imputing goals from articulated speech when his papers on regulation were collected:

It seems unfruitful, I am now persuaded, to conclude from the studies of the effects of various policies that those policies which did not achieve their announced goals, or had perverse effects (as with a minimum wage law), are simply mistakes of the society. A policy adopted and followed for long time, or followed by many difference states, could not usefully be described as a mistake: eventually its real effects would become known to interested groups. To say that such policies are mistaken is to say that one cannot explain them. (1976, p. x)

Ten years before, in the 1966 edition of The Theory of Price, Stigler tells the student about the ‘penetrating’ Bernard Mandeville, the philosopher of revealed preference. This is the passage he quotes:

I don't call things Pleasures which Men say are best, but such as they seem to be most pleased with; … John never cuts any Pudding, but just enough that you can't say he took none; this little Bit, after much chomping and chewing you see goes down with him like chopp'd Hay; after that he falls upon the Beef with a voracious Appetite, and crams
himself up to his Throat. Is it not provoking to hear John cry every Day that Pudding is all his Delight, and that he don't value the Beef of a Farthing? (1966, p. 68)

Instead of supposing policy goals are revealed in discussion, he now follows Mandeville in imputing goals from consequences (Stigler, 1971). So, regulatory capture is not a ‘failure’ of regulation, but is instead the very point of regulation.

An intriguing variation on Mandeville is presented in Stigler and Becker (1977). The title, ‘De Gustibus Non Est Disputandum’, teases Knight and the early Stigler. Stigler and Becker posit that individuals are homogeneous with respect to unobservable ends of life revealed in the material world by means of physical goods and other inputs. Attracting much attention as the first of a sequence of papers on rational addiction, the paper perhaps ought to be seen as an attempt to recover common goals in choice. Following the supposition that goals are better revealed in mute choices than articulated speech, in the Tanner Lectures (Stigler, 1982), Stigler now defends the sort of productivity ethics once denounced by Knight.

**Information as commodity**

In Stigler's judgement (and that of Becker), the 1961 article ‘Economics of Information’ was the most important of the contributions listed in the citation for the Nobel award. The problem is deceptively straightforward: how long will the rational consumer search for a lower price? From the claim that it pays to search more for higher-priced commodities, Stigler obtains the result that, the higher the price of a commodity, the lower is its percentage deviation from the central tendency. The importance of characterizing a competitive equilibrium in terms of a statistical distribution of prices instead of a point mass from ‘one price in the market’ is hard to overstate. This approach explains Stigler's scepticism regarding models of oligopoly that involve price movements in one direction but not another (1947; 1978). Stigler's insistence on the veil of language also helps explain why he maintains that we recover prices at which transactions were made even if they differ from reported prices (Stigler and Kindahl, 1970).

The implications that flow from Stigler's notion that information is a commodity extend to his theory of oligopoly (Stigler, 1964). Here, Stigler takes joint profit maximization as the default and explains oligopoly on the basis of the probability of detecting collusion. Now that the economics literature has rediscovered Adam Smith's principle of sympathetic behaviour as an explanation of group formation and cooperative behaviour (Sally, 2001), Stigler's argument that cooperation is the default in small groups reveals great prescience. Perhaps most unsettling to economists is the additional implication regarding the endogeneity of economic advice. For, if information is a commodity and economists provide information to clients, then we, too, are inside the economic process. This endogeneity of economic advice raises causality questions that are central to ‘Do Economists Matter?’ (Stigler, 1976). The issue here is whether our opinions are the cause or the effect? Now this is an identification problem!

**Science as consensus**

As we read the record, the Knightian emphasis on consensus underscores Stigler's view of scientific
practice. For Stigler, as for his teachers, the past of economics was part of what has been called the extended present. Indeed, Rosen (1993) and Rosenberg (1993) explain, perhaps more clearly than did Stigler himself, how Stigler drew inspiration from the past. What distinguishes him from Knight is the view that we might justifiably exclude views that are sufficiently far from the centre:

There is merit in excluding the lunatic from discourse. If a man tells me he is Napoleon, or that matter, Josephine, discussion would serve no purpose. … Occasionally the lone dissenter with the absurd view will prove to be right – a Galileo with a better scheme of the universe, a Babbage with a workable computer – but if we give each lunatic a full, meticulous hearing, we should be wasting vast time and effort. So long as we do not suppress the peaceful lunatic, we leave open the possibility that he may convince others that he is right.

••… The larger the group [with a common outlook], the more certain we can be that it is not insane in the sense of being divorced from apparent fact and plausible reasoning. (Stigler, 1975, pp. 3–4)

This view explains Stigler's reading of the Sraffian account of classical economics and the challenge offered by Samuel Hollander (Hollander, 1979; Stigler, 1990; Hollander, 1990). In the case of the Chicago reaction to Ronald Coase's ‘mistake’ in the discussion of externalities, the outcome differed. Stigler recounts how the response was to invite Coase to dinner to talk about the ‘mistake’ which, by the end of the evening, became the ‘Coase theorem’ (Stigler, 1988, pp. 75–8).

Stigler's confidence in the relationship between the size of the community asserting a factual claim and the probability that the claim is correct depends upon the independence of inquiry. Yet once we believe that common acceptance warrants belief, we violate the independence of acceptance upon which the probability claim rests. If we accept a result because it is widely accepted, can we really think the result is even more firmly established for the next ‘researcher’? This is, perhaps, the most significant weakness of Stigler's generation, the neglect of what in retrospect turn out to be game-theoretic issues. And here Stigler is particularly stubborn (Demsetz, 1993). One technical point at which game theory is missing occurs in Stigler's assertion (1966, pp. 94–5) that the institutional framework fails to affect the equilibrium in the case of auctions. Stigler's (1952) work on T.R. Malthus fails to appreciate Malthus's argument that William Godwin's proposal for communism would create a large-number prisoner's dilemma. Godwin himself came to understand Malthus's prisoner's dilemma argument (Godwin, 1801, p. 74).

If there is systematic error in one aspect of our understanding of the past, then our demand for coherence may well impose, as a general equilibrium condition, errors in all those aspects that are connected. So one error about the past leads to others. As evidence of how the Malthus error has cascaded, consider Stigler on the most famous characterization of economics: ‘[Malthus's] pessimism was the source for the characterization of economics as “the dismal science”’ (1988, p. 5). A great deal of scholarship has now demonstrated that this is precisely wrong (Persky, 1990; Levy, 2001; Peart and Levy, 2005).

Chicago School
Stigler's Nobel lecture (1983b) is an important defence of the progressive nature of economics. To make the progressive case, one needs to know how the discipline changes over time. In an important sense, the Chicago School doctrine of motivational homogeneity (Stigler and Becker, 1977) is a return to the classical economic doctrine of analytical egalitarianism against contending schools of thought that had focused instead on racial, ethnic or class differences. These latter accounts prevailed in early 20th-century economic analysis, and presupposed unequal economic competence (Peart and Levy, 2005). In early neoclassical economics, inferiority was adduced from claims about positive time preference (Peart, 2000). Stigler never succumbed to this temptation (Stigler, 1941, pp. 212–19; Stigler and Becker, 1977).

The Chicago defence of the egalitarian roots of classical economics in the face of racist claims by eugenicists and other ‘progressive’ ‘experts’ (Peart and Levy, 2005), suggests that, fundamentally, economics has hardly progressed in its foundational elements. We find the same defense of homogenous capacity in Adam Smith arguing against Plato, in J.S. Mill against Carlyle, and in Chicago. But perhaps this ought not to surprise economists. Whatever is important for policy will be contested. The answer to Samuelson's request, which Arrow echoed, then perhaps lies in considering whether ‘common ends’, policy goals, are recommended by those who believe themselves able to rule others or by those who believe themselves to be essentially the same as others. In his defence of equal capacity of economic agents, George Stigler will be remembered as second to none in the 20th century.

Joseph E. Stiglitz, 2001 Nobel Laureate in Economics, helped to create the theory of markets with asymmetric information and was one of the founders of modern development economics. He played a leading role in an intellectual revolution that changed the characterization of a market economy. In the new paradigm, the price system only imperfectly solves the information problem of scarcity because of the many other information problems that arise in the economy: the selection over hidden characteristics, the provision of incentives for hidden behaviours and for innovation, and the coordination of choices over institutions.

Article
Joseph E. Stiglitz helped to create the economics of information, which analyses equilibrium in markets in which there are asymmetries of information among the market participants. For that work, he received the Nobel Prize in Economics in 2001, jointly with George A. Akerlof and A. Michael Spence. Stiglitz’s work demonstrated the many and sometimes subtle ways in which markets can fail to lead to efficient outcomes. His work elucidated a broad set of phenomena that had largely been ignored before 1970 because they were outside the limits of the standard paradigm: incentive contracts, bankruptcy, quantity rationing, financial structure, equilibrium price distributions, innovation, and dysfunctional institutions. This work contributed to a paradigm shift in economics. In the new paradigm, the price system only imperfectly solves the information problem of scarcity because of the many other information problems that arise in the economy. Stiglitz has also proved central theorems in many fields: development economics, finance, trade theory, public economics, and industrial organization.

The broad plan from which much of Stiglitz’s work originates had two central goals. The first was to show that many of the implications of the standard neoclassical model do not remain valid once the assumption of perfect information is dropped. His famous paper on adverse selection (Rothschild and Stiglitz, 1976) opens with these words:

Economic theorists traditionally banish discussions of information to footnotes. Serious consideration of costs of communication, imperfect knowledge, and the like would, it is believed, complicate without informing.…”[T]his comforting myth is false. Some of the most important conclusions of economic theory are not robust to considerations of imperfect information. (1976, p. 629)
The second goal was to provide a better theoretical understanding of the workings of the economic system as a whole. As Stiglitz (2007) explains,

By the time I had finished my graduate studies, I had realized that the model of the economic system that was being taught – and that was at the center of policy analyses – was not a model of a modern capitalist economy. It was little more than a fancy version of a primitive agriculture exchange/production economy, slightly updated to include manufacturing – so long as there were diminishing returns. There was but a short distance between Ricardo and Walras, and between Walras and Samuelson.

…Capital was nothing more than seed that was harvested but not consumed…

…technology was stagnant (or at most exogenous).

A critical assumption of the standard neoclassical model is that there is a price for each quality of good in the market and for each action one would wish to contract for. Buyers have no problem ascertaining quality, and firms produce the quality that they have agreed to produce. Firms do not need to motivate their workers. Lenders do not worry about borrowers repaying. Owners do not worry about managers taking the right actions. Stiglitz in his lectures to students in the 1980s gave the example of a stylist cutting hair: in the standard model, there would be a price for each hair that he cut.

A real-life experiment that helped economists evaluate the standard neoclassical theory were the experiences with market socialism in Eastern Europe, in which government owned the firms but there was a manager of each firm whose job it was to maximize profits of that firm, facing market prices. Stiglitz (1994) argues that if the neoclassical model were an accurate characterization of a market economy, then market socialism would have been successful. Because of the importance of incentive problems and of non-price institutions (such as banks) within the economy, the inefficiencies that arose under market socialism were not accidents, but rather the inevitable consequence of (a) the limitations of the information contained in prices, and (b) the gap between the set of goods for which markets can practically exist and the much broader set of present and future goods and actions on which welfare depends.

Two ideas inform much of Stiglitz's work.

1. The 'control/information' system of market economies embraces far more than the price system of the neoclassical model. The exchange problem is intertwined with the process of selection over hidden characteristics, the provision of incentives for hidden behaviours and for innovation, and the coordination of choices over institutions.

2. Competitive equilibrium in economies with imperfect information and missing markets is not, in general, Pareto efficient. Market outcomes can be improved on by government intervention, e.g., taxes and subsidies. A simple illustration is that if the care that the insured take to avoid an accident is not observable to the insurance company, then commodities like fire extinguishers that decrease insured agents’ losses should be subsidized, while commodities like alcohol that increase their losses should be taxed (Greenwald and Stiglitz, 1986, p. 247).

Until Arrow's work on medical care (Arrow, 1963), the only reasons for a missing market that had been well explored were environmental externalities and the inability, or undesirability, to exclude from use (the problem of public goods). Stiglitz's contributions would help to radically broaden the understanding of the sources of externalities to include information externalities, group reputation effects, agglomeration effects, knowledge spillovers, and pecuniary externalities (see, for example, Greenwald and Stiglitz, 1986 on pecuniary externalities and Hoff, 2001 on coordination failures). In the process, Stiglitz's work would help to change the profession's understanding of capitalism, although the policy recommendations of economists did not change as much as Stiglitz had hoped.

Citations are an objective, if imperfect, measure of influence. Kim, Morse and Zingales (2006) compiled a list of the 146 articles published in economics journals from 1970 to 2002 that had received by June 2006 more than 500 citations from the ISI Web of Science/Social Science Citation Index. Six of Stiglitz's papers appear on this list (no other author has more). In descending order of number of citations, the papers are Stiglitz and Weiss (1981), Rothschild and Stiglitz (1970), Dixit and Stiglitz (1977), Shapiro and Stiglitz (1984), Rothschild and Stiglitz (1976), and Grossman and Stiglitz (1980). This article will place each of these papers in the context of Stiglitz's research programme.

### Biographical data

Stiglitz's early experiences shaped his lifelong professional interests in understanding how an economy handles risk, and in bringing economic theory to bear on real-world problems. Stiglitz was born in Gary, Indiana, a city marred, in his words, by 'huge inequality, poverty, and discrimination' (Stiglitz, 2007). He was the middle of three children. After the failure of an earlier business, his father became an independent insurance agent. One part of his job was to find new insurers for firms whose businesses had burned down and whose insurance policies had been cancelled. Stiglitz's mother worked in the family insurance business when Stiglitz was young and later taught elementary school in a low-income inner city neighbourhood of Gary. After retiring from elementary education, she worked in adult remedial education, where she encountered some of the same students whom she had taught as children in inner-city schools.

Stiglitz's genius was recognized early. In high school, he was assigned independent study in lieu of some of the regular classes, which he had outstripped. (His father apparently took
The economics of uncertainty

The economics of uncertainty is concerned with the principles that an individual uses in evaluating a random distribution of returns. Applications extend from how individuals allocate their portfolios between safe assets and risky assets, to how farmers allocate their land among different crops. The work in the 1960s by James Tobin and others equated an increase in risk with an increase in variance. Rothschild and Stiglitz (1970) set forth an alternative definition of an increase in risk. Comparing income distributions with the same mean, they proposed a definition that corresponded to a preference ordering among every expected-utility-maximizer with a concave utility function. This ordering was not the same as a ranking based on increases in variance. In a companion paper, Rothschild and Stiglitz (1971) demonstrated the usefulness of their definition in deriving comparative static results. They showed that such results depended on a simple criterion: the concavity or convexity of a ‘first-order condition’ characterizing the individual’s optimal decision with respect to the random variable that was the source of risk. That work unified work in an area that until then had been in great confusion.

The economics of information

In the 1960s, James Mirrlees (1971) began working on the problem of how a government could design an optimal tax schedule, taking into account that government can observe individuals’ incomes, but not their ability and effort. Given this asymmetry of information, the analytical problem is to distribute a given tax burden according to differences in ability to pay. Stiglitz recognized the similarities between this problem and the problems that arise in markets with asymmetric information. For example, insurance companies and banks want to design a menu of offers that will maximize their profits, taking into account that they do not know each individual’s risk of accident or bankruptcy and the care that an individual expends to avoid the insured for event. Employers want to design labour contracts to maximize productivity, taking into account that they do not know each individual’s risk of accident or bankruptcy and the care that an individual expends to avoid the insured for event. Stiglitz recognized the similarities between this problem and the problems that arise in markets with asymmetric information. For example, insurance companies and banks want to design a menu of offers that will maximize their profits, taking into account that they do not know each individual’s risk of accident or bankruptcy and the care that an individual expends to avoid the insured for event. Employers want to design labour contracts to maximize productivity, taking into account that they do not know each individual’s risk of accident or bankruptcy and the care that an individual expends to avoid the insured for event. Stiglitz recognized the similarities between this problem and the problems that arise in markets with asymmetric information.

Hidden characteristics

A selection problem arises whenever there is imperfect information about the characteristics of the items being transacted, and different sides of the transaction know different things (so information is asymmetric). This problem is pervasive. Rothschild and Stiglitz (1976) constructed a celebrated model of the insurance market in which individuals differ only in terms of their privately known risk type, and the insurance firms know the overall distribution of risks in the population. The model uses the canonical textbook apparatus of consumer choice – budget lines and indifference curves – but produces very surprising (and counter-Walrasian) results.

To illustrate Stiglitz's *modus operandi*—to begin with highly simplified models of particular markets that allow him to identify a general principle—I describe the Rothschild and Stiglitz (1976) model in detail.

Consider an individual whose situation is described by his income if he is lucky enough to avoid an accident ($W_{NA}$) and his income if an accident occurs ($W_A$). His initial endowment point E is $(W, W - d)$, where $d$ represents the damages incurred in the accident. An individual purchases insurance in order to alter his pattern of income across these two states of nature.

Begin with the benchmark case in which insurance companies know an individual’s probability of accident. Given this probability, let $\bar{W}$ denote his expected income. Then competitive equilibrium would be at a point A, illustrated in Figure 1, where the insurance company breaks even and the individual’s indifference curve, denoted $\bar{U}_L$, is tangent to the budget line. Since risk-averse individuals who are offered a break-even price for insurance will choose full insurance, the equilibrium is along the 45 degree line. The line that goes through the endowment point E and the point A is the locus of contracts at which an insurance company breaks even (‘the fair-odds line’).

Figure 1
Next, bring in asymmetric information. Suppose that individuals are of two types that differ in their accident probability, and each individual knows his own type. Given the differences in risks, the high-risk individual has lower expected wealth (denoted $\bar{W}$ in Figure 2) than the low-risk individual (denoted $\bar{W}$). If the insurance company could observe who was low-risk and who was high-risk, then, on the same reasoning as above, the equilibrium contracts would be at A and B in Figure 2. A higher accident probability gives rise to a flatter indifference curve (the two types' indifference curves satisfy the 'single crossing property'), and also to more costly insurance (a flatter fair-odds line). If, however, the insurance firms do not know the characteristics of individuals, then clearly they cannot offer contracts A and B. For in that case all individuals would claim they were the low-risk type and choose the contract A, and the insurance companies would not break even. Offers that survive the competitive process cannot specify a price at which customers choose to buy all the insurance they want, because the high-risk individuals would always purchase more insurance at that price than the low-risk individuals, and the insurance firms would not break even. Competitive offers of contracts instead consist of both a price and a quantity.

Figure 2

Consider then the price and quantity offer at point C in Figure 3, which would break even if all individuals purchased it (a ‘pooling’ contract). Rothschild and Stigliz demonstrate that this cannot be equilibrium. Any contract such as C’ in the shaded area in Figure 3 – with slightly less insurance coverage than C but at a lower price per dollar of coverage – would attract only the low-risk individuals. Given that, the contract C generates losses and would be withdrawn.

Figure 3
The only possible equilibrium, which is illustrated in Figure 4, is one in which the market distinguishes types by offering a contract B with complete coverage (which will be chosen by the high-risk individuals), and a contract D with partial insurance coverage (which the low-risk individuals prefer to full insurance at B and which the high-risk individuals do not prefer to full insurance at B). In this case, the market ‘solves’ the screening problem, but at the cost of foreclosing otherwise feasible and desirable exchanges.
If, however, there are so few high-risk types that low-risk individuals are strictly better off at a pooling contract, then there can be no competitive equilibrium at all! The pooling contract with full insurance breaks the candidate separating equilibrium, but a contract at a slightly lower price and lower quantity of insurance cream skims the low-risk individuals. Thus the contract with full insurance cannot break even and is withdrawn.

With these intuitive graphs, Rothschild and Stiglitz demonstrate the non-robustness to considerations of imperfect information of two central results of the neoclassical model – that equilibrium is characterized by supply equals demand, and that equilibrium always exists. In papers published over the next two decades, Stiglitz demonstrated how market responses to the screening problem could explain puzzles in equity, credit, and labour markets. For instance, in equity markets, when insiders in a firm have more information than outsiders, the controlling insiders' willingness to issue equity conveys a signal that says that on average the shares are overpriced. The market responds by lowering the price. This discourages
firms from issuing new shares and provides an explanation for the fact that firms have limited access to equity (Greenwood, Stiglitz and Weiss, 1984).

In credit markets, if prospective borrowers have more information than lenders about the riskiness of their investments, there are situations in which a lender will set his interest rate below the market-clearing rate. He will not wish to raise his interest rate to what the market will bear if an increase in the rate would lead the lowest-risk borrowers to drop out of the market and reduce the lender's expected return. In this case, credit rationing will occur, as demonstrated in Stiglitz and Weiss (1981).

In many markets, individuals can, at a cost, provide credible information about their characteristics. Then 'hidden characteristics' become public information. This led Stiglitz to examine the incentives to acquire and transmit information. A central point is that the private returns to the provision of information differ from the social returns; thus the level of information that is public in a signalling equilibrium has, in general, no efficiency properties. To see this, consider the following simple example from Stiglitz (1975).

Suppose that there are two ability types whose productivity is $AH$ and $AL$ (the more able can do in one hour what the less able take $AH/AL$ hours to do). Suppose a fraction of the population $p$ is high ability and a fraction $1-p$ is low ability. Ability is private information but, at a cost $C$, an individual can reveal it (as would occur, for instance, if there is a credential that only a high-ability type is able to obtain but that certifies a skill unrelated to productivity). Then there exist two equilibria – a separating equilibrium and a pooling equilibrium – if

$$AL < AH - C < pAH + (1-p)AL.$$ 

If all other high-ability types screen, then the first inequality implies that the remaining high-ability individual has an incentive to screen. In doing so, he earns more than his alternative wage in the screening equilibrium, $AL$. This establishes that a separating equilibrium exists.

However, if no other high-ability types screen, then both types are paid their average productivity, and the second inequality implies that the remaining high-ability individual has no incentive to screen. This establishes that a pooling equilibrium exists, as well, and that it Pareto dominates the separating equilibrium. In the separating equilibrium, each worker fails to take into account the effect of his decision to screen on the wage of unscreened individuals. Individual decisions create a diffuse externality.

The fact that the investor in information must obtain a positive expected private return from his information-gathering activities led Stiglitz to a fundamental result in finance. There had long been a theory, the efficient markets theory, which states that the observation of prices in capital markets suffices to reveal all relevant private information. Grossman and Stiglitz (1980) showed that the theory was incorrect: if information is costly and markets are competitive, then there must be an 'equilibrium degree of disequilibrium' – persistent discrepancies between prices and ‘fundamental values’ that provide incentives for individuals to obtain information. In capital markets, prices serve two functions: besides being used in the conventional way to clear markets, they also convey information. When individuals invest in information and thereby learn that the return to a security is going to be high (or low), they bid its price up (or down), and thus the price system makes that information publicly available. But if all information were publicly conveyed, there would be no incentives for individuals to invest in information.

Differential information can be a source of pure economic rents. Stiglitz argued that firms exploit that fact by creating 'noise'. Knowing that it is costly for customers to search, Salop and Stiglitz (1977) showed that stores can exploit that by varying their prices to extract rents from customers with high search costs. The market equilibrium prices serve to discriminate (imperfectly) among individuals with different search costs. These results overturned a standard theory, the law of the single price (a given commodity is sold at the same price in all stores). In a similar vein, Edlin and Stiglitz (1995) argued that managers will have an incentive to enhance asymmetries of information between them and rival managers and boards of directors, and thereby limit the scope for takeovers.

**Hidden actions and agency theory**

In the standard neoclassical model, there are no conflicts of interest between economic actors. Principal–agent theory introduces conflicts of interest by specifying actions that cannot be observed. In this theory, a principal, who delegates a task to an agent, designs a contract that makes payment depend on observable circumstances (for example, revenues) that are correlated with the desired, but unobservable, actions of the agent. Stephen Ross, James Mirrlees, and Joe Stiglitz contemporaneously developed principal–agent theory.

Stiglitz's initial contribution was stimulated by his observations in Kenya during parts of 1969–71. He analysed a puzzle that had been recognized at least since Alfred Marshall – the apparent inefficiency of the institution of sharecropping, which assigns the tenant only a share of the marginal return to his effort. Stiglitz (1974) showed that sharecropping could be advantageous to tenants and landlords because of the savings in monitoring costs compared to a wage system with costly monitoring, the increases in output compared with a wage system with imperfect monitoring, and the reduction in risk borne by tenants compared with a system where workers pay fixed land rents but do not have access to risk markets.

Four insights in this paper and Stiglitz's other work in principal–agent theory have been important for further developments in economics.

1. It is sometimes useful to take the *transaction*, rather than the *market*, as the unit of analysis.
2. There is a trade-off between incentives and insurance if the principal has greater ability to bear risk than the agent. Since the first-order effect of distorting incentives is zero, the provision of a small level of insurance is in this case always welfare-increasing.
3. The distribution of wealth influences the extent of agency problems, in both rich and poor countries.
4. Agency problems are pervasive in a complex modern economy. Agency theory has contributed to new theories of public finance, of corporate governance, and of positive political economy.

However, in many situations, incentive contracts cannot be written because an individual's individual contribution to output is not well observed. In that case, pure economic rents can play an important role in providing incentives, as in Shapiro and Stiglitz (1983). But integrating the idea of rents into a model of a competitive economy initially posed a puzzle. If price exceeds marginal cost, why doesn't competition lead to price-cutting?

An antecedent to Shapiro and Stiglitz (1984) was the model in Shapiro (1983) of rents as an incentive to quality that is unobservable at the time of purchase. In that model, firms develop a reputation for quality by the goods that they produce. The prospect of the loss of rents to a firm that ‘milks’ its reputation by selling at a high price less than the promised quality induces the firm to live up to consumers’ expectations. Competition does not lead to price-cutting because consumers come to learn that, if the price is too low, firms do not have an incentive to maintain their reputation, and therefore the offer of high-quality goods at a low price is not credible.

Shapiro and Stiglitz (1984) extends to a labour market the idea of rents as an incentive device for difficult-to-monitor effort. Workers in this model are identical (so there is no selection issue). Firms observe at random intervals whether a worker is working or shirking. To elicit effort, each firm would want to offer a higher wage than other firms so that, if it finds a worker shirking, it suffers a cost when he is fired. But if it benefited one firm to raise its wage, it would benefit all firms. This might seem like the dilemma where, if every spectator in the stadium stands up to get a better view, no one sees any better. But, when all employers raise their wages, those actions have a real effect on the economy: unemployment emerges since the higher wage rations firms’ demand for workers. Now a worker who is fired cannot immediately find another job. This makes job loss costly. Unemployment creates an incentive to work on the job rather than shirk, and so competitive equilibrium will be characterized by unemployment and pure labour rents.

Macroeconomics

Informational imperfections limit the scope of equity and credit markets, as well as insurance and labour markets. In a series of papers with Bruce Greenwald and Andrew Weiss (for example, Greenwald, Stiglitz and Weiss, 1984), Stiglitz drew out the implications for the fluctuations in output and employment that have characterized capitalism throughout its history. The central argument was this. Limitations in the scope of equity markets in the presence of significant bankruptcy costs lead firms to behave in a risk-averse manner. They pay attention to own risk, while traditional theory suggests that the only risk that firms should care about is the correlation with the stock market. Higher levels of investment or production entail increased debt, and, as debt is increased, the bankruptcy probability is increased. Firms will therefore produce and invest only up to the point where expected marginal returns equal expected marginal bankruptcy costs. This has four implications that contrast with what would occur with perfect markets:

1. Amplification of small shocks. Changes in the net worth of the firm or in the riskiness of the environment affect the production and investment decisions of the firm (in contrast to the standard theory). For a highly leveraged firm, small changes in demand can result in large changes in output and employment. Thus, disturbances to the economy tend to be amplified.
2. Persistence. If for some reason net worth is reduced at a given time, production falls in subsequent periods. Only gradually will production be restored to normal, as net worth builds up again.
3. Risk-averse banks. Banks are a specialized kind of firm whose production activity is making loans. A reduction in the net worth of banks and an increase in the riskiness of their environment will lead them to contract their output – that is, to make fewer loans, which has multiplier effects throughout the economy.
4. Worsening of the applicant pool for loans during a recession. For any given bankruptcy cost, there is a critical net worth such that, below that net worth, firms act in a risk-loving manner, and, above that net worth, in a risk-averse manner. If the economy moves into a recession and firms find their net worth decreases, good (that is, risk-averse) firms reduce their loan applications, bad (that is, risk-loving) firms increase their loan applications, so that there is an increasing proportion of bad (that is, low net worth) applicants. These effects may be so strong as to lead to a situation where banks make no loans at all!

During Stiglitz's tenure as Chief Economist of the World Bank, the contrast between his perspective on macroeconomics and the perspective based on well-functioning markets came to a head. These are two starkly different ways of looking at the world. If there are well-functioning markets, then opening up capital markets will lead to efficient outcomes. This view was identified with the US Treasury Department and the IMF in the 1990s. During the 1997–99 East Asian financial crisis, a condition of IMF financial support was that the East Asian economies adopt contractionary fiscal and monetary policies. The contractionary monetary policy would raise interest rates and, at some point, reverse private capital flows.
outflows and restore the ability of the East Asian countries to repay their foreign debts. It was argued that the basic reason for the East Asian financial crisis was lack of transparency, or corruption, in the business practices of these economies, which frightened away foreign investors.

In contrast, Furman and Stiglitz (1998) argued that a lack of transparency did not cause the crisis (although it aggravated the effects of the downturn once it began). They argued that small developing countries are financially fragile. There are pervasive externalities in banks’ and firms’ decisions to obtain short-term loans from abroad. Each bank and each firm takes the risk environment as given, and yet the aggregate set of decisions determines the risk of a financial crisis. This meant that some limits on free capital markets were appropriate in developing countries. Moreover, Furman and Stiglitz argued that policies that increased interest rates in the East Asian economies would greatly erode the net worth of debtors, and the erosion of their net worth would lead to a recession that could not easily be reversed.

Stiglitz’s views ultimately were influential. However, the openness of his conflict with the IMF and US Treasury frayed his relationships with many people in Washington and hastened his departure from the World Bank.

**Development economics**

Whereas macroeconomics remains split between different schools with contrasting views on the importance of market imperfections, the centrality of market imperfections in the field of development economics is not questioned. Before the development of the economics of information (and also the development of game theoretic models of political economy), economists lacked a broad framework for understanding of the sources of the imperfections in markets. Economists who tried to design policies to fit developing country markets generally assumed rigidities in markets, but did not explain them by reference to a choice-based perspective. Abhijit Banerjee (2001, p. 465) has characterized development economics in this era as the ‘ugly duckling’ of economics: ‘It was full of strange assumptions and contrary logic, and all the other [fields of] economics made fun of it.’

Stiglitz’s work in development economics played a major role in transforming the field. His models were important in establishing (a) that positive feedback mechanisms can give rise to multiple equilibria and underdevelopment traps; (b) that, because of the causes of market failures and constraints on growth vary greatly from setting to setting, analysis has to be done case by case; and (c) that non-market institutions need have no efficiency properties. Important applications of these ideas are below.

**Trade-off between diversity of goods and scale economies.** In a path-breaking model, Dixit and Stiglitz (1977) posed a question seemingly unrelated to development. This paper addressed the question: will a market solution yield the socially optimum kinds and quantities of commodities if there are multiple possible varieties of goods, each produced by a single firm with increasing returns to scale in production? The desire by consumers for diversity meant that there would be many firms, but not necessarily the optimal number. Dixit and Stiglitz used a modelling assumption that turned out to be very useful analytically. By assuming a continuum of goods, their set-up lets the modeller respect the discrete nature of many location decisions and yet analyse the model in terms of the behaviour of continuous variables like the share of manufacturing in a particular region.

This model became a building block in models in the new fields of endogenous growth theory and economic geography. To understand the flavour of this work, consider an economy with three sectors: a low-technology sector, an advanced sector, and an intermediate sector that produces an array of non-traded, i.e., domestic, goods, modelled as Dixit–Stiglitz commodities, which are inputs into the advanced sector. An expansion of the advanced sector increases the demand for non-traded inputs, and so lowers their average costs and increases the available variety. With a greater variety of intermediate inputs, production in the advanced sector is more efficient. It can thus be the case that, when many other firms enter the advanced sector, it pays the remaining firms in the traditional sector to do so; but, when all other firms remain in the traditional, low-technology sector, it pays the remaining firm to do so, too. A low-level equilibrium can therefore be sustained even when the economy is fully open to international trade.

**Breakdown of the Washington consensus.** The standard neoclassical model predicts that growth is inevitable in capital-poor market economies: over time, all economies will converge in per capita income. This model led a generation of economists to a simple set of policy prescriptions that would set the preconditions for growth: maintain macroeconomic stability (since high inflation interferes with the workings of the price system), limit government ownership of enterprise, and deregulate (‘stabilize, privatize, and liberalize’). This so-called Washington Consensus has broken down, in part because it has become clear that there are no sure-fire formulas for success, and in part because of the evolution of economic theory away from the perfect markets paradigm. The three central developments in economic theory have been the economics of information, game theory, and institutional economics. In the new economic theory, development is no longer seen primarily as a process of capital accumulation, but instead as a process of organizational change. Evidence of the breakdown of the Washington consensus is that a recent World Bank volume that reviews economic growth in developing countries in the 1990s states that ‘The central message of this volume is that there is no unique universal set of rules [to promote growth]…[W]e need to get away from formulae and the search for elusive “best practices”.’ (World Bank, 2005, p. xiii).

**Dysfunctional institutions.** In the past, many scholars have made the argument that institutions that emerge out of individual actions are necessarily optimal: they are there because their benefits outweigh the costs. Stiglitz’s work on sharecropping (Stiglitz 1974) exemplifies that approach. However, as Stiglitz has often remarked, that analysis is partial equilibrium. That analysis studies the optimal contract while holding fixed everything else in the economy.

In many cases, however, contracts that individuals enter into impose externalities on other agents. There may be no forces that ensure the Pareto efficiency of the set of contracts that individuals adopt. For instance, when insurance is provided through family and friends as well as through the market, the informal insurance will raise welfare because the additional insurance exacerbates moral hazard and so raises the cost of market insurance – an effect that no individual insurance analysis can capture. The analysis of the inefficiency of contracting choices generalizes widely, for example, to technological change...
One of the most important economic transformations in modern history began with the collapse of Communism in Eastern Europe and the former Soviet Union. The transition process in the 1990s entailed the creation of a new set of economic and political institutions and, in most countries, produced an unexpectedly deep and prolonged depression. In Russia and many other transition countries, the rapid transfer of state enterprises to private hands (‘Big Bang privatization’) did not lead to a political demand for institutional reforms needed to govern private property, as many economists had expected. Hoff and Stiglitz (2004; 2007) investigate the influence of economic policies on the demand for a rule of law. They show that Big Bang privatization can create powerful incentives to strip assets and to delay the establishment of a rule of law. This may result in a long period of economic decline. The cause is that no individual takes account of the effect of his economic choices on long-run institutional change.

Evaluation

The high level of idealization in much of Stiglitz's formal work, and the surprising (or at least counter-Walrasian) results often obtained, have led his harshest critics to see in his work a predilection for the intriguing exception rather than the general rule: granted that market failures occur, how much do they really matter? From a staunch admirer, Avinash Dixit, one hears the statement that a paper by Stiglitz begins with the phrase, ‘Assume there are two types’. However, the statement that ‘there are two types’ (or ‘two actions’) in Stiglitz's papers of the 1970s and 1980s marked a radical departure from the standard model, which implicitly assumes that in each market there is only one type (or one action); that is, that information in the market is symmetric. This modest relaxation of the perfect information assumption reveals that symmetric information is essential to the results of the standard neoclassical paradigm.

Stiglitz's work demonstrates that the standard theory misconstrues many of the virtues of the market. The standard theory exaggerates the role of prices in conveying information about scarcity, and fails to take account of the difficulties of making the price system work. At the same time, the standard theory fails to recognize some central virtues of the market – its ability to address problems of selection, incentives, information gathering, and innovation – because the standard paradigm is silent about all these problems. Compared to the state of economics in 1970, mainstream theory can now accommodate a far broader range of phenomena. But there is no unified single framework, as there was in the Walrasian paradigm. Instead, there is a fragmented collection of disparate models. Distinct models are capable of explaining the same phenomena but are difficult to distinguish empirically.

A further problem that remains for future work is that multiple forms of private information exist within any sector. With multiple incentive problems, it is necessary to consider the distortion among incentives that results when incentives for more easily observed actions are created at the expense of less easily observed actions. In these ways, Stiglitz's theoretical work has contributed to the resurgence of empirical work in economics. Kim, Morse and Zingales (2006) document a reversal in the previous 30 years in the importance of theoretical work, which dominated the profession in the 1970s and 1980s, and gave way to the primacy of empirical work in the early 1990s. Much of that empirical work is a response to a body of theory that established that neither markets nor governments work perfectly. Stiglitz's demonstration that imperfect information undermines the results of the standard neoclassical model has shifted not only models of thought in economics, but also the relative importance of different sources of knowledge about the economy.

Abstract

The many contemporary characterizations of stigma share the assumption that individuals have characteristics that devalue them in the eyes of others. The observer's response leads to status loss and discrimination. Stigmatized attributes, their linkage to a particular set of stereotypes and the general response to those stereotypes are shared within a particular ingroup, and thus are fundamental to social identity. Stigmatization affects the allocation of resources through direct discrimination, self-fulfilling beliefs, and identity threat.

Article

Contemporary research on stigma begins with Erving Goffman's (1963) essay, Stigma: Notes on the Management of a Spoiled Identity. He writes:

While the stranger is present before us, evidence can arise of his possessing an attribute that makes him different from others in the category of persons he is available to be, and of a less desirable kind…He is thus reduced in our minds from a whole and usual person into a tainted, discounted one. Such an attribute is a stigma, especially when its discrediting effect is very extensive; sometimes it is also called a failing, a shortcoming, a handicap. It constitutes a special discrepancy between virtual and real social identity. (Goffman, 1963, pp. 2–3)
Contemporary characterizations of stigma (and there are many) share the assumption that individuals have (or are assumed by others to have) characteristics that devalue them in the eyes of others. These characteristics trigger a stereotype response on the part of the observer which leads to status loss and discrimination against the status holder. Goffman observes that the essence of stigma is relational, the linking of attributes to stereotypes. Stigma is distinct from a simple stereotype response because of its social component. Stigmatized attributes, their linkage to a particular set of stereotypes and the general response to those stereotypes are shared within the ingroup, and thus are fundamental to the determination of social identity. The attributes tagged by the social process of stigmatization may have little or nothing to do with individual function, and little or nothing to do with the individual's self-perceived identity as opposed to their social identity (to the extent that these can be meaningfully separated). Triggers can be exogenous characteristics (types), such as gender or ethnicity, or behaviours, such as being a felon, or uneducated. They can be observed (race) or merely inferred (religion). They certainly vary across cultures, space and time (Crocker, Major and Steele, 1998).

### Stigma and resource allocation

Stigma is a profoundly important social process, with significant implications for individuals' ability to achieve desired social outcomes. There are at least three channels through which stigmatization affects the allocation of resources: (1) direct discrimination, (2) self-fulfilling beliefs, and (3) identity threat.

#### Discrimination

Direct discrimination in the United States was dramatically described in Gunnar Myrdal's seminal *An American Dilemma* (1944), and brought to the centre of economic research in Gary Becker's classic *The Economics of Discrimination* (1957). Becker's analysis emphasizes what has come to be known as taste-based discrimination, which can be understood as the assignment of negative attributes to an individual on the basis of their membership in an outgroup. Becker's notion of taste-based discrimination has been extended to that of stigma in work such as Price, Darity and Headen (2008), who explore how former slave status increased the probability that an individual would be lynched in the post-bellum South. These authors remark that ‘The consequences of racial stigma follow from a decision-making criterion by whites, who view blacks as stigmatized by slavery, which warrants standards of treatment in black–white social interactions that are lower than the standards warranted in typical human interactions (Price et al., p. 168). The empirical salience of this approach in understanding contemporaneously inequality is explored by Charles and Guryan (2007).

Goffman's notion of stigma is of course deeper that simply identifying a fixed effect associated with race or some other criterion for group membership, which is often how stigma is instantiated in empirical work. Besley and Coate (1992) undertake a theoretical analysis of welfare stigma which considers two sources of stigma. The first type corresponds to Goffman's notion of stigma as ascription. Individuals who are on welfare are stigmatized when participation in the programme is used to evaluate whether the individual is a shirker as opposed to disabled. A second notion of stigma developed by Besley and Coate focuses on taxpayer resentment, and is a function of the gap between what is regarded as an appropriate level of benefits and actual benefits. The two models differ in their conclusions concerning how stigma
varies with respect to the size and composition of the poor population. It is worthwhile observing that while economists have largely been concerned with the group implications of stigma, resource redirection resulting from stigma cuts across many group boundaries. A striking example is Crandall’s (1995) observation that the parents of heavy daughters are less likely to pay for their college education than are the parents of average-weight women.

Self-fulfilling beliefs

The problem of self-fulfilling beliefs was first and beautifully described not by an economist but by a sociologist. Robert Merton’s ‘The self-fulfilling prophecy’ (1947) not only coined a phrase, but carefully expressed the idea that beliefs give rise to decisions which confirm the beliefs, which would not otherwise be true. One of his leading examples addresses the stigmatization of black workers by pre-war union leaders as strikebreakers and scabs:

History creates its own test of the theory of self fulfilling prophecies. That Negroes were strike-breakers because they were excluded from unions (and from a large range of jobs) rather than excluded because they were strikebreakers can be seen from the virtual disappearance of Negroes as scabs in industries where they have gained admission to unions in the last decade.’ (Merton, 1947, p. 197)

Curiously, self-fulfilling prophecies are not unrelated to Myrdal’s (1944) principle of cumulation, or cumulative causation, or the vicious circle, wherein beliefs and institutional structures are self-reinforcing. Myrdal’s principle of cumulation, which appears earlier in his (1939) Monetary Equilibrium, is a multiplier effect. In An American Dilemma Myrdal identified a social multiplier effect. He argued that the degradation of daily life for the black community further reinforced the beliefs of the whites, whose collective political and social conditions instantiated the conditions at the outset.

The modern expression of Merton’s self-fulfilling prophecy is an expectations equilibrium, as in rational expectations models and in Nash equilibrium. This was expressed initially in Arrow’s (1972, 1973) models of statistical discrimination. In these labour market equilibrium models, employers believe the unobservable human capital investments of the outgroup to be low, and therefore do not hire them. Consequently, the return to human capital investment by outgroup members is low. They choose not to invest, and so the ingroup employers’ beliefs are correct. Social psychologists too have recognized self-fulfilling prophecies as a general phenomena. Their formulation has more to do with social process than the equilibrium formulations economists employ (Darley and Fazio, 1980).

The role of beliefs in the persistence of statistical discrimination has been a major source of theoretical developments. The contact hypothesis, due to Allport (1954), claims that stigmatic associations will be reduced if in- and outgroups come into closer contact. One justification for affirmative action programmes is that they do exactly this; they force otherwise separate groups to come into closer contact. Coate and Loury (1993) have described a theory of affirmative action in labour markets where statistical discrimination is prevalent. They find that affirmative action policies have ambiguous effects on employers’ beliefs. Affirmative action may fail because to implement an affirmative action policy, employers will have to lower standards for hiring outgroup employees. But if standards are lowered, the
Chaudhuri and Sethi (2008) offer an interesting variant of the contact hypothesis. The argument of the contact hypothesis is that groups in contact with each other will abandon stereotypes in favour of more refined and nuanced views of the meaning of group membership. That is, contact changes beliefs. Chaudhuri and Sethi suppose instead the existence of positive externalities in human capital acquisition. Integration lowers the cost of skill acquisition to the relatively unskilled group. Their model exhibits a discontinuity, a threshold of integration above which negative stereotypes cannot persist in equilibrium. Coate and Loury's analysis indicates how statistical discrimination models are of particular interest because of their ability to produce multiple equilibria such that in one equilibrium the outgroup is stigmatized, whereas in another employers discriminate against members of their own group, and in a third equilibrium no discrimination occurs at all. Whether some equilibria are more salient, more likely to arise, is a question similar to that addressed in the extensive literature on Nash equilibrium refinements. Blume (2005, 2006) develops learning models of statistical discrimination, in which payoff parameters of the model determine whether discrimination will persist in the long run and show how this persistence can in fact occur.

Identity threat

Identity threat, or stereotype threat, is a channel distinct from expectational equilibrium through which stigma affects individual outcomes. In situations where one's attributes or behaviours risk confirming the plausibility of negative stereotypes, for others or even for oneself, members of stigmatized groups may respond behaviourally.

Consider the stereotypes elicited by the terms *yuppie, feminist, liberal,* or *White male.* Their prevalence in society raises the possibility for potential targets that the stereotype is true of them, and also that other people will see them that way. When the allegations of the stereotype are importantly negative, this predicament may be self-threatening enough to have disruptive effects of its own. (Steele and Aronson, 1995, p. 797)

Steele and Aronson (1995) investigated the performance of black students in difficult verbal exams. Through different ways of varying the task description and of activating stereotypes about the academic performance of black students, they were able to conclude that the stereotypes led black students to underperform relative to whites when the test was presented as diagnostic of academic skills, but not when it was presented differently. Steele (1992) has argued that the pressure of negative stereotypes causes students to disidentify with school and school tasks, reduce motivation to succeed, and even creates black peer pressure to disidentify, all of which leads to bad schooling outcomes and all that follows. While economists' concern with stigma has mostly been focused on discrimination and statistical discrimination, most recent stigma research by social psychologists is concerned with identity threat (Major and O'Brien, 2005).

Relatively little work has been undertaken by economists on identity threat, although identity has become a topic of interest. Not surprisingly, a few experimentalists have replicated the findings of experimental social psychology, only using the economist's war horses: ultimatum games, and risky and
Benabou and Tirole (2006) build a cognitive model of belief management. The idea of their model is that individuals are uncertain and even forgetful of their deep motivations. They make inferences from their past choices, and so their past choices come to define their self-perception. Two of their key findings are that identity investments are largest in situations where self-information is scarce, and when one is most uncertain of one’s identity. They argue that the non-monotonicity of identity investment can explain a confirmatory response to identity threat, for instance by opting out of threatening situations such as academic achievement exams.

Implications of stigma

Stigma has been used to explain empirical phenomena that seem puzzling under narrow conceptualizations of rational choice theory. One well-studied example concerns stigma and participation in public assistance programmes. In a widely cited paper, Moffitt (1983) estimates welfare participation regressions which incorporate both fixed disutility to participation and a monetary cost that is proportional to the benefit. He argues that these explain why many eligible poor persons do not use available welfare programmes. In this context, the failure to pursue public assistance represents the puzzle; stigma associated with the receipt of welfare is argued to explain why some eligible individuals forgo assistance. The empirical analysis in this paper finds evidence of a fixed stigma cost. A limitation of this type of analysis is that it does not allow for other explanations of nonparticipation; for example, Daponte, Sanders and Taylor (1999) find that ignorance about public assistance programmes is a major source of nonparticipation; survey evidence is reported that suggests that stigma-type reasons are primary for about 6 per cent of those eligible but not participating in the US Food Stamps programme. Stigma has also been used to understand the dynamics of nonmarital fertility; here the fact to be understood is the rise of nonmarital fertility in light of the effects on the socioeconomic prospects of mother and child. Akerlof, Yellen and Katz (1996) argue that a large component of the observed increases in out-of-wedlock birth rates in the United States between the late 1960s and the late 1980s is a result of the decline in the rate with which an out-of-wedlock conception would end in a within-wedlock birth: that is, the rate of ‘shotgun marriage’. Their formal argument is that changes in the technology of contraception and the onset of legally available abortions are a technology shock which decreases the bargaining power of those unable to take advantage of them. Stigma, however, plays two roles in their analysis. One they explicitly mention is that an increase in the out-of-wedlock birth rate, by increasing the number of unwed mothers, destigmatizes the category, which lowers the cost of not terminating a pregnancy. The stigma reduction changes the parameters of the relevant model in a way that reinforces the decline in shotgun weddings and the increase of out-of-wedlock births.

A second role for stigma, not explicitly mentioned, is in male decision making. They quote a male in a pre-shock ethnographic study of shotgun marriage who says, ‘If a girl gets pregnant you married her. There wasn't no choice. So I married her.’ Why was there ‘no choice’? Men who refused to do the ‘right thing’ were stigmatized. Akerlof, Yellen and Katz (1996) quote an Internet (and therefore post-shock) contributor to a newsgroup who wrote, ‘Since the decision to have the child is solely up to the mother … I don't see how both parents have responsibility to that child.’ This is to say, turning a pre-nuptial pregnancy from a birth by necessity into a birth by woman’s choice led to the destigmatization of the male decision not to marry. Nechyba (2001) develops a dynamic model of nonmarital fertility based on
stigma, in which stigma is determined by a weighted average of the nonmarital fertility of past generations.

A third area where stigma has been invoked concerns crime. An early example of this type of argument is Rasmusen (1996). Rasmusen considers models in which conviction for a crime provides information to an employer either because of on-the-job misbehaviour (crime thus representing a moral hazard problem) or due to its informativeness concerning productivity-related unobservables (which represents an adverse selection problem). Rasmusen demonstrates that both models can have multiple, Pareto-ranked equilibria, and then nonetheless extols stigma manipulation as a deterrence strategy.

O'Flaherty and Sethi (2008) use racial stereotypes in a two-sided statistical discrimination model to explain black–white crime patterns in the United States. Blacks are more likely than either whites or Hispanics to be involved in crime, both as victims and as offenders. Furthermore, while crimes by whites against whites, by blacks against blacks and by blacks against whites are common, crimes by whites against blacks are rare. We might have expected white crimes against blacks to be abundant if it were thought that police were racist or that they devalued black safety, or that black witnesses were regarded by juries as less credible than whites. O'Flaherty and Sethi explain this pattern by constructing an incomplete information model of criminal/victim interaction. A potential criminal must decide whether or not to commit a crime, and a victim must decide whether or not to resist. If all victims believe that blacks are more likely to engage in violence during a crime, and if all criminals believe that whites are less likely to resist, then these beliefs can be sustained in equilibrium and the equilibrium has the black/white crime patterns described above.

Blume (2002) has built a dynamic game model of criminal behaviour wherein apprehended criminals pay both a direct penalty (fine or incarceration) and a stigma cost. For some time after conviction individuals are publicly labelled as criminals. The cost of being stigmatized is decreasing in the number of individuals similarly stigmatized – if everyone is a criminal, crime bears no stigma. The incentive effects of direct penalties are those of the standard Beckerian model. Similarly, shifting upward the stigma cost function decreases crime. Increasing the duration of stigmatization increases the cost of being a criminal, but it can nonetheless have a perverse incentive effect because it can lead to more people being stigmatized at any given time. The stream of stigma costs comes from farther down the cost curve. Consequently, labelling individuals as felons for their entire post-incarceration life may have a negative impact on crime deterrence.

Kendall and Tamura (2008) make a subtle argument about the impact of stigma on the relationship between out-of-wedlock births and crime. They observe that over the period from 1923 to 2002 in the United States, a rate of ten non-marital births per 1,000 live births is associated with increases of between 2.5 per cent and 5 per cent in murder and property crime rates. This relationship, however, is complicated by the match quality of the parents. In the 1940s and 1950s, when out-of-wedlock birth was stigmatized and termination was costly, only the lowest-quality matches, matches that would not have beneficial to the child, did not take place. From the 1970s, however, when the stigma pressure to marry declined, matches did not take place that would in all likelihood have benefited the child. Thus the positive relationship between out-of-wedlock fertility and future crime would have increased.

Finally, recent work by Glenn Loury (2002) has invoked racial stigma as an alternative to discrimination in understanding persistent inequality between blacks and whites. Loury defines racial stigma as ‘dishonorable meanings socially inscribed on arbitrary bodily marks, of “spoiled collective identities”’ (2002, p. 59), thus employing Goffman's language. While Loury's discussion of racial stigma
involves ideas that closely relate to statistical discrimination, he departs from this approach in his emphasis on the imprecision of the use of group identity to draw individual inferences. This is seen in Loury's discussion of racial profiling in policing. He argues that:

> [U]ncovering specification error in this example – learning that a group's average behavior is a poor predictor of what to expect from almost everyone in the group – requires a law enforcement agent to avoid constructing his subjects' social identities ‘from the outside’ But, and this is crucial, given his initial beliefs, he will expect it to be a waste of time and resources to retain idiosyncratic data. He perceives little gain from distinguishing individuals because he begins with the conviction that they are all alike. And yet unless he tracks individuals he cannot learn that he is dead wrong in this presumption. If he is not forced to track individuals then, short of a coincidental sequence of fortuitous occurrences, he is likely to persist in his erroneous belief and act accordingly. (Loury, 2002, pp. 63–4)

We believe that Loury's argument represents an important new way to understand stigma. Whereas statistical discrimination refers to self-confirmed beliefs, racial stigma in the Loury sense refers to unfalsified beliefs. Members of society face the problem that their experiences do not provide rich enough data to overrule prejudices. In our view, however, we need not equate prejudices with initial beliefs. Rather, we see prejudices as a way in which agents respond to information limitations. Given initial beliefs and experiences, racial stigma occurs, in our view, when an actor ascribes the least favourable set of characteristics to members of an outgroup that are consistent with the actor's experiences. From this vantage point, stigma is a form of ambiguity aversion, in which the history of racial oppression in the United States means that, in dealing with blacks, whites assume the worst. We recognize that Loury might not accept this interpretation of his views, but we believe that this interpretation is a useful way to understand and extend his thinking.

**Concluding comments**

While stigma is often invoked as an explanation, its use is often imprecise. In theoretical models, stigma is often conflated with a generic form of social interactions. For example, the stigma variable and associated assumed influence of the variable on preferences in Nechyba's (2001) analysis could just as easily have been labelled a conformity effect. Similar problems exist in empirical work. Pager's widely publicized (2003) field experiment to study the effects on black and white job applicants of a criminal background invokes stigma as a mechanism, but it is unclear whether her findings are due to direct discrimination, statistical discrimination, racial stigma as argued by Loury, or something else. Bertrand and Mullainathan's (2004) analysis, finding that resumés with black-sounding names receive fewer interview requests than those with white-sounding names, is admirable in its refusal to mechanically invoke stigma as an explanation.

In our view, the imprecision of much work on stigma can be addressed in two ways. First, it seems important to return to Goffman's ideas about ascription and spoiled identity in order to avoid conflating stigma with the presence of some ill-defined social interaction. Second, in empirical work, it is
important to avoid treating the presence of stigma as a primitive, and rather to model explicitly the mechanism by which stigma emerges, if we are serious about stigma as a structural determinant.

stochastic adaptive dynamics

H. Peyton Young
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Economic systems often involve large numbers of agents whose behaviour, and patterns of interaction, have stochastic components. The dynamic properties of such systems can be analysed using stochastic dynamical systems theory. A key feature of these processes is that their long-run behaviour often differs substantially from the behaviour of the deterministic process obtained by taking expectations of the random variables. Furthermore, unlike the deterministic dynamics, the theory yields sharp predictions about the probability of being in different equilibria independently of the initial conditions.

Article

Stochastic adaptive dynamics require analytical methods and solution concepts that differ in important ways from those used to study deterministic processes. Consider, for example, the notion of asymptotic stability: in a deterministic dynamical system, a state is locally asymptotically stable if any sufficiently small deviation from the original state is self-correcting. We can think of this as a first step toward analysing the effect of stochastic shocks; that is, a state is locally asymptotically stable if, after the impact of a small, one-time shock, the process evolves back to its original state.

This idea is not entirely satisfactory, however, because it treats shocks as if they were isolated events. Economic systems are usually composed of large numbers of interacting agents whose behaviour is constantly being buffeted by perturbations from various sources. These persistent shocks have substantially different effects from one-time shocks; in particular, persistent shocks can accumulate and tip the process out of the basin of attraction of an asymptotically stable state. Thus, in a stochastic setting, conventional notions of dynamic stability – including evolutionarily stable strategies – are inadequate to characterize the long-run behaviour of the process. Here we shall outline an alternative approach that is based on the theory of large deviations in Markov processes (Freidlin and Wentzell, 1984; Foster and Young, 1990; Young, 1993a).

Types of stochastic perturbations

Before introducing formal definitions, let us consider the various kinds of stochastic shocks to which a system of interacting agents may be exposed. First, there is the interaction process itself whereby agents randomly encounter other agents in the population. Second, the agents’ behaviour will be intentionally stochastic if they are employing mixed strategies. Third, their behaviour may be unintentionally stochastic if their payoffs are subject to unobserved utility shocks. Fourth, mutation processes may cause one type of agent to change spontaneously into another type. Fifth, in and out-migration can introduce new behaviours into the population or extinguish existing ones. Sixth, the system may be hit by aggregate shocks that change the distribution of behaviours. This list is by no means exhaustive, but it does convey some sense of the range of stochastic influences that arise quite naturally in economic (and biological) contexts.

Stochastic stability

The early literature on evolutionary game dynamics tended to sidestep stochastic issues by appealing to the law of large numbers. The reasoning is that, when a population is large, random influences at the individual level will tend to average out, and the aggregate state variables will evolve according to the expected (hence deterministic) direction of motion.
While this approximation may be reasonable in the short and medium run, however, it can be quite misleading when extrapolated over longer periods of time. The difficulty is that, even when the stochastic shocks have very small probability, their accumulation can have dramatic long-run effects that push the process far away from its deterministic trajectory.

The key to analyzing such processes is to observe that, when the aggregate stochastic effects are ‘small’ and the resulting process is ergodic, the long-run distribution will often be concentrated on a very small subset of states — possibly, in fact, on a single state. This leads to the idea of stochastic stability, a solution concept first proposed for general stochastic dynamical systems by Foster and Young (1990, p. 221): ‘the stochastically stable set (SSS) is the set of states S such that, in the long run, it is nearly certain that the system lies within every open set containing S as the noise tends slowly to zero.’ The analytical technique for computing these states relies on the theory of large deviations first developed for continuous-time processes by Freidlin and Wentzell (1984), and subsequently extended to general finite-state Markov chains by Young (1993a). It is in the latter form that the theory is usually applied in economic contexts.

An illustrative example

The following simple model illustrates the basic ideas. Consider a population of $n$ agents who are playing the ‘Stag Hunt’ game:

<table>
<thead>
<tr>
<th></th>
<th>$A$</th>
<th>$B$</th>
</tr>
</thead>
<tbody>
<tr>
<td>$A$</td>
<td>10, 10</td>
<td>0, 7</td>
</tr>
<tr>
<td>$B$</td>
<td>7, 0</td>
<td>7, 7</td>
</tr>
</tbody>
</table>

The state of the process at time $t$ is the current number of agents playing $A$, which we shall denote by $z_t \in Z = \{0, 1, 2, \ldots, n\}$. Time is discrete. At the start of period $t+1$, one agent is chosen at random. Strategy $A$ is a best response if $z_t \leq \frac{n}{2}$ and $B$ is a best response if $z_t > \frac{n}{2}$. (We assume that the player includes herself in assessing the current distribution, which simplifies the computations.) With high probability, say $1-\varepsilon$, the agent chooses a best response to the current distribution of strategies; while with probability $\varepsilon$ she chooses $A$ or $B$ at random (each with probability $\varepsilon/2$).

We can interpret such a departure from best response behaviour in various ways: it might be a form of experimentation, it might be a behavioural ‘mutation’, or it might simply be a form of ignorance – the agent may not know the current state. Whatever the explanation, the result is a perturbed best response process in which individuals choose (myopic) best responses to the current state with high probability and depart from best response behaviour with low probability.

This process is particularly easy to visualize because it is one-dimensional: the states can be viewed as points on a line, and in each period the process moves to the left by one step, to the right by one step, or stays put. Figure 1 illustrates the situation when the population consists of ten players.

Figure 1
Transitions for the perturbed best-response process in the Stag Hunt game and a population of ten agents. Note: Each vertex represents the number of agents playing action A at a given time. Solid arrows are transitions with high-probability, dotted arrows are transitions with low (order-$\varepsilon$) probability.

The transitions indicated by solid arrows have high probability and represent the direction of best response, that is, the main flow of the process. The dashed arrows go against the flow and have low probability, which is the same order of magnitude as $\varepsilon$. (The process can also loop by staying in a given state with positive probability; these loops are omitted from the figure to avoid clutter.)

In this example the transition probabilities are easy to compute. Consider any state $z$ to the left of the critical value $z^* = 7$. The process moves right if and only if one more agent plays A. This occurs if and only if an agent currently playing B is drawn (an event with probability $1 - z/10$) and this agent mistakenly chooses A (an event with probability $\varepsilon/2$). In other words, if $z < 7$ the probability of moving right is $R_z = (1 - z/10)(\varepsilon/2)$. Similarly, the probability of moving left is $L_z = (z/10)(1 - \varepsilon/2)$. The key point is that the right transitions have much smaller probability than the left transitions when $\varepsilon$ is small. Exactly the reverse is true for those states $z > 7$. In this case the probability of moving right is $R_z = (1 - z/10)(1 - \varepsilon/2)$, whereas the probability of moving left is $L_z = (z/10)(\varepsilon/2)$. (At $z = 7$ the process moves left with probability .15, moves right with probability .35, and stays put with probability .50.)

Computing the long-run distribution

Since this finite-state Markov chain is irreducible (each state is reachable from every other via a finite number of transitions), the process has a unique long-run distribution. That is, with probability 1, the relative frequency of being in any given state $z$ equals some number $\mu_z$ independently of the initial state. Since the process is one-dimensional, the equations defining $\mu_z$ are particularly transparent, namely, it can be shown that for every $z < n$, $\mu_z R_z = \mu_z + 1 L_z + 1$. This is known as the detailed balance condition. It has a simple interpretation: in the long run, the process transits from $z+1$ to $z$ as often as it transits from $z$ to $z+1$.

The solution in this case is very simple. Given any state $z$, consider the directed tree $T_z$ consisting of all right transitions from states to the left of $z$ and all left transitions from states to the right of $z$. This is called a $z$-tree (see Figure 2).

Figure 2
The unique 3-tree

An elementary result in Markov chain theory says that, for one-dimensional chains, the long-run probability of being in state $z$ is proportional to the product of the probabilities on the edges of $T_z$:

$$\mu_z \propto \prod_{y < z} R_y \prod_{y > z} L_y.$$  \hspace{1cm} (1)$$

This is a special case of the Markov chain tree theorem, which expresses the stationary distribution of any finite chain in terms of the probabilities of its $z$-trees. (Versions of this result go back at least to Kirchhoff's work in the 1840s; see Haken, 1978, s. 4.8. Freidlin and Wentzell, 1984, use it to study large deviations in continuous-time Wiener processes.)
Stochastic stability and equilibrium selection

This example illustrates a general property of adaptive processes with small persistent shocks. That is, the persistent shocks act as a selection mechanism, and the selection strength increases the less likely the shocks are. The reason is that the long-run distribution depends on the probability of escaping from various states, and the critical escape probabilities are exponential in ε. Figure 1 shows, for example, that the probability of all-B (the left endpoint) is larger by a factor of 1/ε than the probability of any other state, and it is larger by a factor of 1/ε 4 than the probability of all-A (the right endpoint). It follows that, as ε approaches zero, the long-run distribution of the process is concentrated entirely on the all-B state. It is the unique stochastically stable state.

While stochastic stability is defined in terms of the limit as the perturbation probabilities go to zero, sharp selection can in fact occur when the probabilities are quite large. To illustrate, suppose that we take ε =.20 in the above example. This defines a very noisy adjustment process, but in fact the long-run distribution is still strongly biased in favour of the all-B state. It can be shown, in fact, that the all-B state is nearly 50 times as probable as the all-A state. (See Young, 1998b, ch. 4, for a general analysis of stochastic selection bias in one-dimensional evolutionary models.)

A noteworthy feature of this example is that the stochastically stable state (all-B) does not correspond to the Pareto optimal equilibrium of the game, but rather to the risk dominant equilibrium (Harsanyi and Selten, 1988). The connection between stochastic stability and risk dominance was first pointed out by Kandori, Mailath and Rob (1993). Essentially their result says that, in any symmetric 2x2 game with a uniform mutation process, the risk dominant equilibrium is stochastically stable provided the population is sufficiently large. The logic of this connection can be seen in the above example. In the pure best response process (ε =0) there are two absorbing states: all-B and all-A. The basin of attraction of all-B is the set of states to the right of the critical point, while the basin of attraction of all-A is the set of states to the right of the critical point. The left basin is bigger than the right basin. To go from the left endpoint into the opposite basin therefore requires more ‘uphill’ motion than to go the other way around. In any symmetric 2x2 coordination game the risk dominant equilibrium is the one with the widest basin, hence it is stochastically stable under uniform stochastic shocks of the above type.

How general is this result? It depends in part on the nature of the shocks. On the one hand, if we change the probabilities of left and right transitions in an arbitrary way, then we can force any given state – including non-equilibrium states – to have the highest long-run probability; indeed this follows readily from formula (1). (See Bergin and Lipman, 1996.) On the other hand, there are many natural perturbations that do lead to the risk dominant equilibrium in 2x2 games. Consider the following class of perturbed best response dynamics. In state z, let Δ(z) be the expected payoff from playing A against the population minus the payoff from playing B against the population. Assume that in state z the probability of choosing A divided by the probability of choosing B is well-approximated by a function of form $e^{h(\Delta(z))/\epsilon}$ where h(Δ) is non-decreasing in Δ, strictly increasing at Δ =0, and skew-symmetric (h(Δ) =−h(−Δ)). The positive scalar $\epsilon$ is a measure of the noise level. In this set-up, a state is stochastically stable if its long-run probability is bounded away from zero as $\epsilon \to 0$. Subject to some minor additional regularity assumptions, it can be shown that, in any symmetric 2x2 coordination game, if the population is large enough, the unique stochastically stable state is the one in which everyone plays the risk-dominant equilibrium (Blume, 2003).

Unfortunately, the connection between risk dominance and stochastic stability breaks down – even for uniform mutation rates – in games with more than two strategies per player (Young, 1993a). The difficulty stems from the fact that comparing ‘basin sizes’ works only in special situations. To determine the stochastically stable states in more general settings requires finding the path of least resistance – the path of greatest probability – from every absorbing set to every other absorbing set, and then constructing a rooted tree from these critical paths (Young, 1993a). (An absorbing set is a minimal set of states from which the unperturbed process cannot escape.) What makes the one-dimensional situation so special is that there are only two absorbing sets – the left endpoint and the right endpoint – and there is a unique directed path going from left to right and another unique path going from right to left. (For other situations in which the analysis can be simplified, see Ellison, 2000; Kandori and Rob, 1995.)

There are many games of economic importance in which this theory has powerful implications for equilibrium selection. In the non-cooperative Nash bargaining model, for example, the Nash bargaining solution is essentially the unique stochastically stable outcome (Young, 1993b). Different assumptions about the one-shot bargaining process lead instead to the selection of the Kalai–Smorodinsky solution (Young, 1998a; for further variations see Binmore, Samuelson and Young, 2003). In a standard oligopoly framework, marginal cost pricing turns out to be the stochastically stable solution (Vega-Redondo, 1997).

Speed of adjustment

One criticism that has been levelled at this approach is that it may take an exceedingly long time for the evolutionary process to reach the stochastically stable states when it starts.
from somewhere else. The difficulty is that, when the shocks have very small probability, it takes a long time (in expectation) before enough of them accumulate to tip the process into the stochastically stable state(s). While this is correct in principle, the waiting time can be very sensitive to various modelling details. First, it depends on the size and probability of the shocks themselves. As we have already noted, the shocks need not be small for sharp selection to occur, in which case the waiting time need not be long either. (In the above example we found that an error rate of 20 per cent still selects the all-B state with high probability.) Second, the expected waiting time depends crucially on the topology of interaction. In the above example we assumed that each agent reacts to the distribution of actions in the whole population. If instead we suppose that people respond only to actions of those in their immediate geographic (or social) neighbourhood, the time to reach the stochastically stable state is greatly reduced (Ellison, 1993; Young, 1998b, ch. 6). Third, the waiting time is reduced if the stochastic perturbations are not independent, either because the agents act in a coordinated fashion, or because the utility shocks among agents are statistically correlated (Young, 1998b, ch. 9; Bowles, 2004).

Path dependence

The results discussed above rely on the assumption that the adaptive process is ergodic, that is, its long-run behaviour is almost surely independent of the initial state. Ergodicity holds if, for example, the number of states is finite, the transition probabilities are time-homogeneous, and there is a positive probability of transiting from any state to any other state within a finite number of periods. One way in which these conditions may fail is that the weight of history grows indefinitely. Consider, for example, a two-person game G together with a population of potential row players and another population of potential column players. Assume that an initial history of plays is given. In each period, one row player and one column player are drawn at random, and each of them chooses an ε-trembled best reply to the opposite population’s previous actions (alternatively, to a random sample of fixed size drawn from the opponent’s previous actions). This is a stochastic form of fictitious play (Fudenberg and Kreps, 1993; Kaniowski and Young, 1995). The proportion of agents playing each action evolves according to a stochastic difference equation in which the magnitude of the stochastic term decreases over time; in particular it decreases at the rate 1/t. This type of process is not ergodic. It can be shown, in fact, that the long-run proportions converge almost surely either to a neighbourhood of all-A or to a neighbourhood of all-B, where the relative probabilities of these two events depend on the initial state (Kaniowski and Young, 1995). Processes of this type require substantially different techniques of analysis from the ergodic processes discussed earlier; see in particular Arthur, Ermoliev and Kaniowski (1987), Benaim and Hirsch (1999) and Hofbauer and Sandholm (2002).

Summary

The introduction of persistent random shocks into models with large numbers of interacting agents can be handled using methods from stochastic dynamical systems theory; moreover, there is virtually no limit on the dimensionality of the systems that can be analysed using these techniques. Such processes can exhibit path dependence if the weight of history is allowed to grow indefinitely. If instead past actions fade away or are forgotten, the presence of persistent random shocks makes the process ergodic and its long-run behaviour is often easier to analyse. An important feature of such ergodic models is that some equilibrium states are much more likely to occur in the long run than others, and this holds independently of the initial state. The length of time that it takes to reach such states from out-of-equilibrium conditions depends on key structural properties of the model, including the size and frequency of the stochastic shocks, the extent to which they are correlated among agents, and the network topology governing agents’ interactions with one another.

Stochastic dominance is a term which refers to a set of relations that may hold between a pair of distributions. A very common application of stochastic dominance is to the analysis of income distributions and income inequality, the main focus in this article. The concept can, however, be applied in many other domains, in particular financial economics, where the distributions considered are usually those of the random returns to various financial assets. In what follows, there are often clear analogies between things expressed in terms of income distributions and financial counterparts.

In order to determine whether a relation of stochastic dominance holds between two distributions, the distributions are first characterized by their cumulative distribution functions (CDFs). For a given set of incomes, the value of the CDF at income \( y \) is the proportion of incomes in the set that are no greater than \( y \). In the context of a random variable \( Y \), the value of the CDF of the distribution of \( Y \) at \( y \) is the probability that \( Y \) should be no greater than \( y \).

Suppose that we consider two distributions \( A \) and \( B \), characterized respectively by CDFs \( F_A \) and \( F_B \). Then distribution \( B \) dominates distribution \( A \) stochastically at first order if, for any argument \( y \), \( F_A(y) \geq F_B(y) \). This definition often looks as though it is the wrong way round, but a moment’s reflection shows that it is correct as stated. If \( y \) denotes an income level, then the inequality in the definition means that the proportion of individuals in distribution \( A \) with incomes no greater than \( y \) is no smaller than the proportion of such individuals in \( B \). In other words, there is at least as high a proportion of poor people in \( A \) as in \( B \), if poverty means an income smaller than \( y \). If \( B \) dominates \( A \) at first order, then, whatever poverty line we may choose, there is always more poverty in \( A \) than in \( B \), which is why we say that \( A \) is the dominated distribution.

Higher orders of stochastic dominance can also be defined. To this end, we define repeated integrals of the CDF of each distribution. Formally, we define a sequence of functions by the recursive definition

\[
D^1(y) = F(y), \quad D^{s+1}(y) = \int_0^y D^s(z) \, dz, \quad \text{for } s = 1, 2, 3, \ldots
\]

Thus the function \( D^1 \) is the CDF of the distribution under study, \( D^2(y) \) is the integral of \( D^1 \) from 0 to \( y \), \( D^3(y) \) is the integral of \( D^2 \) from 0 to \( y \), and so on. By definition, distribution \( B \)
stochastic dominance: The New Palgrave Dictionary of Economics

dominates A at order $s$ if $D^s_A(y) > D^s_B(y)$ for all arguments $y$. The lower limit of 0 is used for clarity of exposition; in general it is the lowest income in the pooled distributions. The definition makes it clear that first-order dominance implies dominance at all higher orders, and more generally that dominance at order $s$ implies dominance at all orders higher than $s$. Since the implications go in only one direction, it follows that higher-order dominance is a weaker condition than lower-order dominance. I will give a more detailed interpretation of the functions $D^s$ shortly in the context of poverty indices.

In theoretical arguments, it is sometimes desirable to distinguish weak from strong stochastic dominance. The above definitions are of weak dominance. For strong dominance, it is required that the inequality should be strict for at least one value of the argument $y$. In empirical investigations, the distinction is of no interest, since no statistical test can detect a significant difference between weak and strong inequalities.

Some applications make use of the concept of restricted stochastic dominance. This means that the relevant inequality is required to hold over some restricted range of the argument $y$ rather than for all possible values. In empirical work, it is often only restricted dominance that can usefully be studied, since with continuous distributions there are usually too few data in the tails of the distributions for statistically significant conclusions to be drawn. Again, for measures of poverty, it is only dominance over the range of incomes up to the poverty line that is of interest.

Relation between stochastic dominance and welfare

When studying either income inequality or poverty, one is automatically in a normative context. Most modern studies make explicit or implicit use of a social welfare function (SWF). In a paper by Blackorby and Donaldson (1980) (henceforth BD), various ethically desirable criteria are developed and the sorts of SWF that respect these criteria are characterized.

One of these criteria is the anonymity of individuals. If we take all the worldly goods of a rich man and give them to a poor man, and then give the few worldly goods of the poor man to the rich man, then social welfare should be unchanged. Formally, a SWF that respects this requirement is symmetric with respect to its arguments, which are the incomes of the members of society.

Another requirement is the Pareto principle. According to it, we should rank situation $B$ better than situation $A$ if at least one individual is better off in $B$ than in $A$, and no one is worse off. In order for a SWF to respect the Pareto principle, it must be increasing in all its arguments.

Another requirement, for measures of poverty only, is that a poverty index should not depend at all on the incomes of the non-poor. BD show that this implies a separability condition on the SWF. If in addition we require that the poverty index should be defined for arbitrary poverty lines, then the separability condition becomes a requirement of additive separability. The SWF can therefore be written as

$$W(y_1, \ldots, y_N) = \sum_{i=1}^{N} u(y_i),$$

(1)

where the ‘utility’ function $u$ is increasing in its argument. Alternatively, the SWF can be any increasing transform of the function $W$. In all cases, the SWF is symmetric and increasing in its arguments, and so satisfies BD’s ethical criteria.

It can be seen that first-order stochastic dominance of $A$ by $B$ means that $B$ has higher social welfare than $A$ for all SWFs of the form (1). This can be shown by a simple integration by parts, under the assumption that the function $u$ is differentiable. In fact, this dominance is also a necessary condition for $B$ to have higher welfare than $A$ for all SWFs of the form (1). It follows from the above argument that, if we use first-order stochastic dominance as a criterion for ranking distributions, then we need not restrict attention to a specific SWF, since any SWF of the form (1) gives the same ranking if one distribution dominates the other at first order.

A more restricted class of SWFs is given by functions of the form (1) where we impose the additional restriction that the second derivative of $u$ is negative. It turns out that all the SWFs of this more restricted class give a unanimous ranking of two distributions if one dominates the other at second order. This sort of result can be extended to higher orders of dominance. As the dominance condition becomes progressively weaker, the class of SWFs that give unanimous rankings becomes progressively smaller, subject to more and more restrictive conditions on the function $u$ and its derivatives.

Relation between stochastic dominance and poverty

The so-called headcount ratio is sometimes used as a measure of the amount of poverty in a given income distribution. This ratio is the proportion of individuals in the distribution with incomes below, or equal to, the poverty line. If this line is denoted by \( z \), then the headcount ratio is the value of the CDF at \( z \). If we have two populations, \( A \) and \( B \), characterized by two CDFs, \( F_A \) and \( F_B \), then, for poverty line \( z \), the headcount ratio is higher in \( A \) than in \( B \) if and only if \( F_A(z) > F_B(z) \). If the inequality \( F_A(y) > F_B(y) \) holds for all values of \( y \) up to \( z \), then we have restricted first-order stochastic dominance up to \( z \).

Corresponding to any income \( y \) less than \( z \), we define the poverty gap as \( z - y \). When we restrict attention to the welfare of people with incomes less than \( z \), it is convenient to use a function \( \pi \) that measures the disutility of the poverty gap, rather than a function \( u \) of the sort used in a SWF. Thus we have a class of poverty indices, defined as follows:

\[
\pi(z) = \int_0^z \pi(z - y) \, dF(y),
\]

If \( \pi' > 0 \), which means that the disutility of poverty increases with the poverty gap, it can be shown that, for all poverty indices of the above form, there is more poverty in \( A \) than in \( B \) if \( B \) dominates \( A \) at first order over the range of incomes less than or equal to \( z \).

Earlier, a sequence of functions \( D^s \) was introduced, these functions being repeated integrals of the CDF. A useful explicit representation of these functions is given by the formula

\[
D^s(z) = \frac{1}{(s-1)!} \int_0^z (z - y)^{s-1} \, dF(y).
\]

The formula clearly holds for \( s = 1 \), if we remember that \( 0! = 1 \). It is not hard to show by induction that it also holds for integers greater than 1.

For \( s = 2 \), the formula becomes

\[
D^2(z) = \int_0^z (z - y) \, dF(y),
\]

from which we see that, for given \( z \), \( D^2(z) \) is the average poverty gap for poverty line \( z \). If, for all \( z \in [z_-, z_+] \), \( D^2_A(z) > D^2_B(z) \), then it follows that the average poverty gap is greater in \( A \) than in \( B \) for all poverty lines in the interval \([z_-, z_+]\). But this condition is just restricted second-order stochastic dominance of \( A \) by \( B \) over that interval.

As with welfare functions, this result can be extended. By progressively restricting the admissible class of poverty indices, in particular by imposing signs on the derivatives of \( \pi \), it can be seen that all poverty indices in these more restricted classes unanimously see more poverty in \( A \) than in \( B \) if there is a progressively higher order of stochastic dominance; see Davidson and Duclos (2000) for more details. An essential reference on poverty measurement is Atkinson (1987), in which the axiomatic approach of BD is extended to poverty measurement. See also three papers by Foster and Shorrocks (1988a; 1988b; 1988c).

**Relation between stochastic dominance and inequality**

If a richer person in distribution \( A \) transfers some income to a poorer person in such a way that the richer person stays richer after the transfer, the post-transfer distribution \( B \) stochastically dominates \( A \) at second order. The Pigou–Dalton principle of transfers says that ‘Robin-Hood’ transfers of the sort described should improve welfare. But it is easy to see that distribution \( B \) does not dominate \( A \) at first order, and indeed this is right and proper according to the Pareto principle, since the richer person is worse off after the transfer.
This example shows that, when we discuss inequality, we are not talking about the same thing as welfare. Any reasonable measure of inequality must declare that there is no inequality if everyone has the same income, even if everyone is in abject poverty.

The classical tool for studying inequality is the **Lorenz curve**. For any proportion \( p \) between zero and one, the ordinate of the corresponding point on the Lorenz curve for a given income distribution is the proportion of total income that accrues to the first 100\( p \) per cent of people when they are sorted in order of increasing income. By construction, the Lorenz curve fits into the unit square, lies below the 45-degree line that is the diagonal of that square, and is (weakly) convex. Figure 1 displays a typical Lorenz curve.

![A typical Lorenz curve](https://0-www.dictionaryofeconomics.com.library.lemoyne.edu/article?id=pde2008_S000266&goto=S&result_number=1653)
A distribution $B$ is said to \textit{Lorenz dominate} another distribution $A$ if the Lorenz curve of $B$ lies everywhere above that of $A$. We then say that there is less inequality in $B$ than in $A$. But this comparison of $A$ and $B$ is not a welfare comparison, and, in particular, does not allow a comparison of poverty. This defect is remedied by the concept of \textit{generalized Lorenz dominance}, based on the generalized Lorenz curve introduced by Shorrocks (1983). The ordinates of this curve are the Lorenz ordinates multiplied by the average income of the distribution. It turns out that generalized Lorenz dominance is the same thing as second-order stochastic dominance. Either one of these concepts implicitly mixes notions of welfare and inequality, as shown by the fact that the function $u$ in a SWF of form (1) that respects second-order dominance has a negative second derivative, which implies diminishing marginal (social) utility of income. The discussion of the previous section shows that higher-order dominance criteria put more and more weight on the welfare of the poorest members of society.

\textbf{Graphical representation and quantiles}

Consider the setup in Figure 2, where the CDFs of two distributions $A$ and $B$ are plotted. The functions $D^2$ used for second-order dominance comparisons can be evaluated for a given argument, like $z_1$ in the figure, as the areas beneath the CDFs, by the usual geometric interpretation of the Riemann integral. We see that distribution $B$ dominates $A$ at second order because, although the CDFs cross, the areas between them are such that the condition for second-order dominance is always satisfied. Thus the vertical line $MN$ marks off a large positive area between the graphs of the two CDFs up to the point at which they cross, and thereafter a small negative area bounded on the right by $MN$.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{Lorenz_curve.png}
\caption{Generalized Lorenz and second-order dominance}
\end{figure}
For generalized Lorenz dominance, it can be shown that what must be non-negative everywhere is the area between the two curves, bounded not by a vertical line like MN but rather by a horizontal line like KL. This area is the difference between the areas under two quantile functions, a quantile function being by definition the inverse of the CDF. Although it is tedious to demonstrate it algebraically, it is intuitively clear that, if the areas bounded on the right by vertical lines like MN are always positive, then so are the areas bounded above by horizontal lines like KL. This is why generalized Lorenz dominance and second-order stochastic dominance are equivalent conditions. The whole theory of stochastic dominance can be developed using quantiles rather than incomes; this is called a \textit{p-approach}. Such approaches are used to advantage in Jenkins and Lambert (1997; 1998), Shorrocks (1998), and...
Another thing that emerges clearly from Figure 2 is that the threshold income $z_1$ up to which first-order stochastic dominance holds is always smaller than the threshold $z_2$ up to which we have second-order dominance. In the figure, we have second-order dominance everywhere, and so we can set $z_2$ equal to the highest income in either distribution. More generally, we can define a threshold $z_s$ as the greatest income up to which we have dominance at order $s$. The $z_s$ constitute an increasing sequence.

A result shown in Davidson and Duclos (2000) is that, if the distribution $B$ dominates $A$ at first-order over a range $[0, z]$, with $z > 0$, then, no matter what happens for incomes above $z$, there is always some order $s$ such that $B$ dominates $A$ at order $s$ over the full range of the two distributions, provided only that that range is finite.

**Estimation and inference**

Suppose that we have a random sample of $N$ independent observations $y_i, i = 1, \ldots, N,$ from a population. Then it follows from (2) that a natural estimator of $D^s(z)$ (for a non-stochastic $z$) is

$$
\hat{D}^s(z) = \frac{1}{(s-1)!} \sum_{i=1}^{N} \left( z - y_i \right)^{s-1} I(y_i \leq z),
$$

where $\hat{F}$ denotes the empirical distribution function of the sample and $I(.)$ is an indicator function equal to 1 when its argument is true and 0 otherwise. For $s=1$, the formula (3) estimates the population CDF by the empirical distribution function. For arbitrary $s$, it has the convenient property of being a sum of independent and identically distributed (IID) variables, which makes it easy to show that (3) is consistent and asymptotically normal. The asymptotic variance is also easy to estimate in a distribution-free manner, by which is meant that no parametric assumptions need be made about the distributions under study.

When two distributions are compared for stochastic dominance, two kinds of situations typically arise. The first is when there are two independent populations, with random samples from each. The other arises when we have independent paired drawings from the same population. For instance, one variable could be before-tax income, and the other after-tax income for the same individual. Explicit expressions for the asymptotic variance of the difference between the estimates of $D^s(z)$ for the case of independent samples were given as early as 1989 in an unpublished thesis (Chow, 1989). The sampling distribution of a related estimator for poverty indices and independent samples is found in Kakwani (1993), Bishop, Chow and Zheng (1995) and Rongve (1997). For a different approach to inference on stochastic dominance, see Anderson (1996). A comprehensive approach to inference on stochastic dominance is found in Davidson and Duclos (2000).

The approach proposed by McFadden (1989) is based on the supremum of the difference between the estimates (3) for two independent populations. For $s = 1$, this turns out to be a variant of the Kolmogorov–Smirnov test, with known properties. For higher values of $s$, although it is easy to compute the statistic, its asymptotic properties under the null are not analytically tractable. However, simulation-based methods can surmount this difficulty; see Barrett and Donald (2003).

A somewhat vexed question in testing for dominance is whether to test the null hypothesis of dominance or that of non-dominance. The latter has the advantage that, if the null is rejected, all that remains is dominance. More generally, the former approach rejects the null of dominance only when there is clear evidence against it, and the latter accepts the alternative of dominance only when there is clear evidence in its favour. The former approach is more common in the literature; see for instance Richmond (1982), Beach and Richmond (1985), Wolak (1989), and Bishop, Formby and Thistle (1992). The latter is discussed in an unpublished paper (Howes, 1993) and in Kaur, Prakasa Rao and Singh (1994).

The stochastic frontier model was first proposed by Aigner, Lovell and Schmidt (1977) and Meeusen and van den Broeck (1977) in the context of production function estimation. The model extends the classical production function estimation by allowing for the presence of technical inefficiency. The idea is that, although the production technology is common knowledge to a group of producers, efficiency in using that technology in the production process may vary by producers, with the degree of efficiency depending possibly on factors such as experience, management skills, and so on. Given the technology, fully efficient producers may realize the full potential of the technology and obtain the maximum possible output for given inputs, while less efficient producers see their output fall short of the maximum
stochastic frontier models: The New Palgrave Dictionary of Economics

possible level. Therefore, the underlying technology defines a frontier of production, and actual outputs observed in the data may fall below the frontier because of the presence of technical inefficiency. A stochastic production frontier model can be specified as

\[
\ln y_i = \ln y_i^* - u_i, \quad u_i \geq 0,
\]

(1)

\[
\ln y_i^* = f(x_i; \beta) + \nu_i
\]

(2)

where \(y_i\) is the observed output of producer \(i\), \(y_i^*\) is the potential output which is subject to a zero-mean random error \(\nu_i\), \(x_i\) and \(\beta\) are vectors of inputs and the corresponding coefficients, respectively, and \(u_i \geq 0\) is the effect of technical inefficiency. Equation (2) defines the stochastic frontier of the production function; it is stochastic because of \(\nu_i\). Given that \(u_i \geq 0\), observed log of output (\(\ln y_i\)) is bounded below the frontier. The value of \(100\% u_i\) is the percentage by which output can be increased using the same inputs if production is fully efficient. The model without \(u_i\) reduces to the classical specification of a production function.

A popular empirical strategy in estimating the above model is to impose distributional assumptions on \(u_i\) and \(\nu_i\), from which a likelihood function can be derived and estimated. For instance, one may assume that

\[
\nu_i \sim N(0, \sigma^2),
\]

(3)

\[
u_i \sim N^+(\mu, \sigma_{\nu_i}^2), \]

(4)
where $N^+(\cdot)$ indicates the positive truncation of a normal distribution. The positive truncation gives non-negative values of $u_i$ and hence ensures that firms are constrained by the technology frontier. By making $\mu$ and/or $\sigma^2_u$ functions of observables (such as ages and years of schooling), one can model the determinants of inefficiency.

The distribution assumption of (4) encompasses many of the models in the literature as special cases. For instance, the half-normal distribution of $u_i$ proposed by Aigner, Lovell and Schmidt (1977) is obtained by restricting $\mu=0$ and $\sigma^2_u$ to be a constant. The half-normal density has a mode at 0 which implies that the majority of the producers are clustered near full efficiency level. The assumption may be unnecessarily restrictive, in particular for industries in which certain degree of inefficiency is expected for the producers. The assumption is relaxed by having $\mu \neq 0$ to allow the mode to depart from 0.

Since limited theory is available in guiding the choice of $u_i$'s distribution, various distribution assumptions are explored in the literature for their flexibility in shaping the distribution (for example, the Gamma distribution of Greene, 1980) and/or for checking the robustness of estimation results.

It is often of great empirical interest to estimate the degree of inefficiency ($u_i$) for each producer (observation). The observation-level estimates are obtained using the estimator $E(u_i|v_i - u_i)$ proposed by Jondrow et al. (1982). The value of $100 \times E(u_i|v_i - u_i)$ gives the percentage by which output is increased if production is fully efficient. Similarly, an efficiency index is estimated using $E(\exp(-u_i|v_i - u_i))$ (Battese and Coelli, 1988). The estimated value gives the actual output as a share of potential output, and the value is bounded between 0 and 1. A likelihood ratio test of the null hypothesis that $u_i$ equals 0 can be performed to test for the presence of inefficiency. It amounts to testing the model against its OLS counterpart (the model without $u_i$). The distribution of the test statistic, however, is non-standard, because the value of 0 is on the boundary of $u_i$'s support. Alternatively, given that an obvious difference between $v_i$ and $v_i - u_i$ is the skewness of the latter, Schmidt and Lin (1984) suggest a simple test based on the sample skewness of the OLS residuals. If $v_i - u_i$ is the correct specification, the residuals would skew to the left and the null hypothesis of a normal error would be rejected.

If panel data is available, the model may be written as (for the ease of illustration, assume that the deterministic part of the frontier function is linear):

$$\ln y_{it} = \alpha + x_{it}' \theta + v_{it} - u_i, \quad u_i \geq 0,$$

(5)

where $\alpha$ is a constant. One may impose distributional assumptions on $v_{it}$ and $u_i$ to derive the likelihood function of the model. Alternatively, a distribution-free approach suggested by Schmidt and Sickles (1984) is available. In this approach, one defines $\alpha_i = \alpha - u_i$ and assumes that the $u_i$ is an individual-specific parameter. With the definition of $\alpha_i$ substituted into (5), the model is estimated by standard
fixed-effect panel estimators which yield consistent estimates of $\alpha_i$ for a large $T$. Since $\alpha_i = \alpha - u_i$ and $u_i \geq 0$, one then recovers the estimated values of $\alpha$ and $u_i$ using the normalization equations of 

$$\hat{\alpha} = \max \{ \hat{\alpha}_i \}$$

and

$$\hat{u}_i = \hat{\alpha} - \hat{\alpha}_i.$$  

This normalization procedure amounts to counting the most efficient firm in the sample as 100 per cent efficient. 

By duality, technical inefficiency in the production also leads to a higher cost of production. The estimated cost of technical inefficiency often has important policy implications, and estimation can be done using a stochastic cost frontier model in a cost minimization framework. The model specification is:

$$\ln C_i = \ln \widehat{C}_i + u'_i, \quad u'_i \geq 0,$$

(6)

$$\ln \widehat{C}_i = g(w_i, \gamma) + v'_i,$$

(7)

where $C_i$ is the observed cost of producer $i$, $\widehat{C}_i$ is the efficient level of cost which is subject to a zero-mean random error $v'_i$, $w_i$ is the vector of input prices, $\gamma$ is the vector of coefficients, and $u'_i \geq 0$ is the effect of inefficiency on the cost of production. Equation (7) defines the stochastic cost frontier, and the observed cost lies above the frontier. The value of $100 \times u'_i$ measures the extra cost as a percentage of the minimum cost. Econometric analysis of (6) and (7) is similar to that of the production function model. A notable difference is that the cost model’s OLS residuals skew to the right if inefficiency presents in the data.

An advantage of a cost function approach over a production function approach is that the issue of allocative inefficiency can be addressed in addition to the technical inefficiency. Allocative inefficiency refers to the use of improper input combinations, that is, the marginal rate of technical substitution between inputs departs from the input price ratio. The improper input mix increases the cost of production, and the effect is not the same as technical inefficiency. Because the analysis of allocative inefficiency requires information of input prices, it is usually carried out in a cost minimization framework. To jointly estimate both technical and allocative inefficiency, Schmidt and Lovell (1979) provide the solution technique for a cost system in which the production technology is Cobb-Douglas. Kumbhakar (1997) presents a theoretical solution for a model with a translog cost function, and the difficulty in the empirical implementation of this model is discussed and resolved in Kumbhakar and
Although the stochastic frontier model is most often applied to the estimation of production and cost functions, an increasing body of research has adopted the methodology to other fields of study. Hofler and Murphy (1992) apply this estimation approach to labour market search models. Due to the costs of search, observed wages tend to fall below the maximum offers that are available in the market; this shortfall is analogous to a technical inefficiency. Another application is found in the study of financing constraints on investment, where Wang (2003) models the frictionless level of investment as the frontier, and actual investment falls below the frontier because of financing constraints. This approach allows Wang to quantify the effect of financing constraints on investment (represent by $u_i$), which is infeasible with the conventional linear-regression approach. In an application to economic growth, Kumbhakar and Wang (2005) employ the stochastic frontier approach and model growth convergence as countries’ movements towards the world production frontier. A country may fall short of producing the maximum possible output because of technical inefficiency, and the phenomenon of technological catch-up is observed if the country moves towards the world production frontier over time. By making $u_i$ a function of time and other macro variables, Kumbhakar and Wang test and confirm the convergence hypothesis.

The stochastic frontier model also finds applications in finance. For example, a long-standing issue in the finance literature is whether the initial public offering (IPO) underpricing – the phenomenon whereby the initial offer price of an IPO is below the closing day’s bid price – is deliberate on the firm’s part or not. Hunt-McCool, Koh and Francis (1996) adopt the stochastic frontier model to investigate the issue, in which $u_i$ measures the difference between the maximum predicted offer price and the actual offer price. The advantage of the stochastic frontier model in this application is that it can be used to measure the level of deliberate underpricing in the pre-market without using aftermarket information. Kumbhakar and Lovell (2000) offer an excellent review of the existing models in the stochastic frontier literature. The more recent developments in the literature aim to make the model more flexible. For instance, correlations between $v_i$ and $u_i$ are made possible through copula functions. If time series or panel data are available, then it is possible to make $u_t$ or $u_{it}$ serially correlated. Semiparametric and nonparametric estimation methods are also adopted to estimate the frontier of the production function (for example, $f(x_i; \boldsymbol{\beta})$) and the frontier of the cost function (for example, $g(w_i; \lambda_i; \gamma)$) so that they are not restricted to specific functional forms.

stochastic optimal control

Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

The purpose of this article is, first, to state the stochastic optimal control problem and, second, to explain how it differs from deterministic optimal control and why that difference is crucial in economic problems. The article presents intuitively the methodology of optimal stochastic control and provides an illustration from optimal stochastic economic growth as an application of this mathematical technique in economics.

Article

In the long history of mathematics, stochastic optimal control is a rather recent development. Using Bellman's principle of optimality along with measure-theoretic and functional-analytic methods, several mathematicians such as H. Kushner, W. Fleming, R. Rishel, W.M. Wonham and J.M. Bismut, among many others, made important contributions to this new area of mathematical research during the 1960s and early 1970s. For a complete mathematical exposition of the continuous time case, see Fleming and Rishel (1975), and for the discrete time case, see Bertsekas and Shreve (1978).

The assimilation of the mathematical methods of stochastic optimal control by economists was very rapid. Several economic papers started to appear in the early 1970s, among which we mention Merton (1971) on consumption and portfolio rules using continuous time methodology and Brock and Mirman (1972) on optimal economic growth under uncertainty using discrete time techniques. Since then, stochastic optimal control methods have been applied in most major areas of economics such as price theory, macroeconomics, monetary economics and financial economics. Chang (2004) offers a rigorous mathematical exposition of stochastic control methods and numerous examples from economics.

In this article we (a) state the stochastic optimal control problem, (b) explain how it differs from deterministic optimal control and why that difference is crucial in economic problems, (c) present intuitively the methodology of optimal stochastic control and, finally, (d) give an illustration from optimal stochastic economic growth.

Consider the problem:
subject to the conditions

\[ d\kappa(t) = T[\kappa(t), \nu(t)]dt + \sigma[\kappa(t), \nu(t)]dZ(t), \kappa(t) \text{given}. \]  

(2)

Here \( \nu = \nu(t) = \nu(t, \omega) \) is the control random variable, \( k = k(t) = k(t, \omega) \) is the state random variable, \( \rho \geq 0 \) is the discount on future utility, \( \mu \) denotes a utility function, \( T \) is the drift component of technology, \( \sigma \) is the diffusion component, \( dZ \) is a Wiener process and \( E_t \) denotes expectation conditioned on \( \kappa(t) \) and \( \nu(t) \).

We note immediately that (1) and (2) generalize the deterministic optimal control by incorporating uncertainty. The modelling of economic uncertainty is achieved by allowing both the control and state variables to be random and more importantly by postulating that condition (2) is described by a stochastic differential equation of the Itô type.

In the problem described by (1) and (2), if \( \sigma(k, \nu) = 0 \) and if \( k \) and \( \nu \) are assumed to be real variables instead of random, then (1) and (2) reduce to the special case of deterministic optimal control. Thus, the stochastic optimal control problem differs from the deterministic optimal control in the sense that the former generalizes the latter, or equivalently, in the sense that the latter is a special case of the former. This is crucial mathematical difference.

For the economist, the generalization achieved from stochastic optimal control means that the analysis of dynamic economic models becomes more realistic. The economic theorist who uses stochastic optimal control in positive or in welfare economics, in free market or centrally planned economies allows for randomness. Measurement errors, omission of important variables, non-exact relationships, incomplete theories and other methodological complexities are modelled in stochastic optimal control by allowing the control and state variables to be random, and also, by incorporating pure randomness through the white noise factor \( dZ(t) \). The random variable \( dZ(t) \) describes increments in the Wiener process \( Z(t), t \geq 0 \) that are independent and normally distributed with mean, \( E[dZ(t)] = 0 \) and variance \( \text{Var}[dZ(t)] = dt \).

In particular, eq. (2) is a significant economic generalization of the analogous equation in deterministic control. The reader may recall that in deterministic control the constraint is given by \( \kappa = \frac{dk(t)}{dt} = T[k(t), \nu(t)] \). Because \( dk(t) \) in (2) is a random variable we can compute its mean and variance. They are given by

\[ E[dk(t)] = T[k(t), \nu(t)]; \text{Var}[dk(t)] = \sigma^2[k(t), \nu(t)]. \]

Thus (2) is a meaningful generalization of its counterpart in deterministic control because it involves means, standard deviations and pure randomness in capturing the complexities of economic reality. A comprehensive analysis of Itô equations, such as (2), is given in Malliaris and Brock (1982).

The problem in (1) and (2) is a stochastic analogue of the deterministic one studied in Arrow and Kurz (1970, pp. 27–51). A standard technique for our problem, as in the case of Arrow and Kurz, is Bellman's (1957, p. 83) 'Principle of Optimality' according to which 'an optimal policy has the property that, whatever the initial state and control are, the remaining decisions must constitute an optimal policy with
regard to the state resulting from the first decision’. The problem in eqs (1) and (2) is studied here for
the undiscounted, finite horizon case, that is, for \( \varphi = 0 \) and \( N < \infty \).
Using Bellman's technique for dynamic programming, eqs (1) and (2) can be analysed as follows:

\[
J[k(t), t, N] = \max E_t \int_t^N u(k, \nu) \, ds = \max E_t \int_t^{t+\Delta t} u(k, \nu) \, ds + \max E_t \Delta t \int_{t+\Delta t}^N u(k, \nu) \, ds = \max E_t \int_t^{t+\Delta t} u(k, \nu) \, ds \tag{3}
\]

Observe that Taylor's theorem is used to obtain (3) and therefore it is assumed that \( J \) has continuous
partial derivatives of all orders less than three in some open set containing the line segment connecting
the two points \( [k(t), t] \) and \( [k(t + \Delta t), t + \Delta t] \). Let (2) be approximated and write

\[
\Delta k = \mathcal{T}(k, \nu) \Delta t + \mathcal{S}(k, \nu) \Delta \mathbf{Z} + \phi(\Delta t). \tag{4}
\]

Insert (4) into (3) and use the multiplication rules

\[
(\Delta \mathbf{Z}) \times (\Delta t) = 0, (\Delta t) \times (\Delta t) = 0 \text{ and } (\Delta \mathbf{Z}) \times (\Delta \mathbf{Z}) = \Delta 
\]

to get

\[
0 = \max E_t \left[ u(k, \nu) \Delta t + \left( J_t + J_t + \frac{1}{2} J_{kk} \sigma^2 \right) \Delta t + J_t \sigma \Delta \mathbf{Z} + \phi(\Delta t) \right]. \tag{5}
\]

For notational convenience let

\[
\Delta J = \left[ J_t + J_t + \frac{1}{2} J_{kk} \sigma^2 \right] \Delta t + J_t \sigma \Delta \mathbf{Z}. \tag{6}
\]

Using (6), eq. (5) becomes

\[
0 = \max E_t \left[ u(k, \nu) \Delta t + \Delta J + \phi(\Delta t) \right]. \tag{7}
\]

This is a partial differential equation with boundary condition \( \left[ \frac{\partial J}{\partial K} \right] [k(N), N, N] = 0 \). Pass \( E_t \)
through the parentheses of (7) and, after dividing both sides by $\Delta t$, let $\Delta t \to 0$ to conclude

$$0 = \max \left[ u(k, \nu) + J_T + \int_{k} \frac{1}{2} k_k \sigma^2(k, \nu) \right].$$

(8)

This last equation is usually written as

$$-J_T = \max \left[ u(k, \nu) + J_T + \int_{k} \frac{1}{2} k_k \sigma^2(k, \nu) \right].$$

(9)

and is known as the Hamilton–Jacobi–Bellman equation of stochastic control theory.

Next, we define the costate variable $p(t)$ as

$$p(t) = J_{k}[k(t), t, N]$$

from which it follows that its partial derivative with respect to $k$ is

$$p_{k} = \partial p / \partial k = J_{kk}.$$  

(10)

Therefore, we may rewrite (9) as

$$-J_T = \max H(k, \nu, p, \partial p / \partial k).$$

(11)

where $H$ is the functional notation of the expression inside the brackets of (9). Assume next that a function $v$ exists that solves the maximization problem of (11) and denote such a function by

$$v^0 = v^0(k, \nu, \partial p / \partial k).$$

(12)

Note that $v^0$ is a function of $k(t)$ and $t$ alone, along the optimum path, because $J_{k}$ is a function of $k(t)$ and $t$ alone. In the applied control literature, and more specifically in economic applications, $v^0$ is called a policy function. Assuming then that a policy function $v^0$ exists, (11) may be rewritten as
This last equation is again a functional notation of the right-hand side expression of (9) under the assumption of the existence of an optimum control \( v^0 \), that is,
\[
H^0(k, p, \partial p / \partial k) = \mathcal{H}[k, v^0(k, p, \partial p / \partial k), p, \partial p / \partial k] = H^0(k, p, \partial p / \partial k).
\]
(13)

Equipped with the above analysis we can now state

**Proposition 1:** (Pontryagin stochastic maximum principle). Suppose that \( k(t) \) and \( v^0(t) \) solve for \( t \in [0, N] \) the problem:

\[
\max E_0 \int_0^N u(k, v) \, dt;
\]

subject to the conditions

\[
dk = T(k, v) dt + \sigma(k, v) d\zeta, \quad k(t) \text{ given}. \]

Then, there exists a costate variable \( p(t) \) such that for each \( t, t \in [0, N] \):

1. \( v^0 \) maximizes \( H(k, v, p, \partial p / \partial k) \) where
\[
H(k, v, p, \partial p / \partial k) = u(k, v) + pT(k, v) + \frac{1}{2} \frac{\partial p}{\partial k} \sigma^2(k, v),
\]
2. the costate function \( p(t) \) satisfies the stochastic differential equation
\[
dp = - H^0(k) dt + \sigma(k, v^0) d\zeta; \quad \text{and}
\]
3. the transversality condition holds
Finally, we briefly illustrate the stochastic optimal control technique to the stochastic Ramsey problem studied in Merton (1975). The problem is to find an optimal saving policy $s^0$ to

$$\max E_0 \int_0^T u(c) dt,$$

subject to

$$\dot{k} = \left[ sf(k) - (n - \sigma^2)k \right] dt - \sigma kd \lambda$$

and $k(t) \geq 0$ for each $t$. Here, $u$ is a strictly concave, von Neumann–Morgenstern utility function of per capita consumption $c$ for the representative consumer and $f(k)$ is a well-behaved production function. Note that $c = (1 - s)f(k)$ and that eq. (16) generalizes Solow’s equation of neoclassical economic growth. Uncertainty enters (16) via randomness in the rate of growth of the labour force. Let

$$J[k(t), t, T] = \max_s E_t \int_t^T u[(1 - s)f(k)] dt.$$

The Hamilton–Jacobi–Bellman equation is given by

$$0 = \max \{ u[(1 - s)f(k)] + J_t + J_k \left[ sf(k) - (n - \sigma^2)k \right] + \frac{1}{2} J_{kk} \sigma^2 k^2 \},$$

which yields

$$\frac{du}{dt} \left[(1 - s^0)f(k)\right] = J_k.$$
To solve for $s^0$, in principle, one solves (18) for $s^0$ as a function of $k$, $T - t$ and $J_k$, and then substitutes this solution into (17) which becomes a partial differential equation for $J$. Once (17) is solved, then its solution is substituted back into (18) to determine $s^0$ as a function of $k$ and $T - t$. The nonlinearity of the Hamilton–Jacobi–Bellman equation causes difficulties in finding a closed form solution for the optimal saving function. However, if we let $\sigma=0$ in (17), one obtains the classical Ramsey rule of the certainty case.

From the fact that numerous economic qsts involve uncertainty and can be formulated as stochastic optimal control problems, one may conclude that economic interest is likely to be lively in this area for some time to come.

stochastic volatility models

Neil Shephard
Edited by Steven N. Durlauf and Lawrence E. Blume

Abstract

Stochastic volatility (SV) is the main concept used in the fields of financial economics and mathematical finance to deal with the endemic time-varying volatility and codependence found in financial markets. Here I trace the origins of SV and provide links with the basic models used today in the literature. I briefly discuss some of the innovations in the second generation of SV models and discuss the literature on conducting inference for SV models. I talk about the use of SV to price options, and consider the connection of SV with realized volatility.
